In reflecting upon these things one cannot help but be amazed at how short are the memories of many engineers and engineering faculties, and how often the battle to achieve these objectives needs to be refought. At the beginning of World War II, when engineers were presented the problem of developing radar, they were (except in very few cases) found woefully lacking in an ability to cope with such an unconventional situation; and physicists, both theoretical and experimental, had to be called in to do what essentially was an engineering job.[1] After the war was over, engineering educators told

[1] "Longhairs and short waves," *Fortune*, vol. 32, pp. 163–169, 206, 208; November, 1945.

themselves that never again should engineers be found wanting in the ability to solve problems for which no set pattern or method of solution exists; and thus was born the present-day clamor for more basic science in the engineering curriculum.

This move was in the right direction, but, unfortunately, clothes do not make the man, or rather, subject matter alone does not make a curriculum; and now after fifteen post-war years, many of our younger engineering teachers who professionally did not live through the pre- and post-war periods, are in favor of making all the old mistakes over again. The industry, with some notable exceptions, appears to be back to all of its old attitudes, and favors the kind of curriculum that makes men more immediately useful but leaves them essentially uneducated. This is why we need to be reminded constantly of the things that constitute an education in the true sense of the word.

Subject Matter and Subject Order

If, for the moment, we limit ourselves to content, it should be rather clear that the fundamentals of circuit theory are first of all concerned only with situations in which the behavior is essentially linear, and we may as well add the adjectives *passive* and *bilateral*. We can take it for granted that finiteness in element numbers or physical dimensions is an implicit restriction and that nothing essentially is lost by considering only lumped elements, since the transcendental functions characterizing so-called "distributed-parameter" systems such as lines and wave guides are conceptually rather effectively thought of as limiting forms of rational functions. In fact, if we present the subject of circuit theory as an approximation to field theory, then the so-called "lumped" network and its characterization in terms of rational functions is already playing the role of a discrete approximant to a distributed system, and any further distinction between general properties of these two embodiments is not only trivial but redundant as well.

Any first course or introductory treatment of circuit theory should limit its considerations to lumped, linear, passive and bilateral elements, for the methods of analysis applicable to this restricted class of circuits and a knowledge of their properties forms an indispensable basis for the clear understanding of methods designed to deal with problems involving more general types of circuit elements. For example, properties injected by the presence of active elements cannot be clearly understood without a background provided by properties of passive circuits. Circuits whose behavior patterns do not conform with the reciprocity theorem because they contain nonbilateral elements are presented preferably as a departure from the normal situation; and the existing methods of dealing with nonlinear circuits, such as the incrementally-linear method for small signal applications and the piecewise linear method for the determination of large-signal behavior, tacitly assume familiarity with methods of linear system analysis and, consequently, cannot be properly discussed without a solid foundation in the linear theory.

Linear circuit theory is linear system theory regardless of whether that system is electrical, mechanical, acoustic or a combination of these. Even problems in economics and business procedures, or any others in which the controlling relations are linear, may be included in this broad class. All of the theory of classical dynamics is applicable here, as is the theory of linear algebra and of functions of a complex variable with its collateral overlap in potential theory and conformal mapping. Last, but not least, is the pertinence of combinatorial topology through which the properties of circuits dealing with invariance to changes in geometrical form or topological structure, as well as questions relating to the introduction and transformation of variables, can be studied effectively. Linear system theory and the collateral branches of physics and mathematics upon which it rests is indeed the essential foundation. Without it, no engineer can get beyond the conventional things he has learned to do by rote; with it, his horizon is practically unlimited, for he can adapt and devise and, thus, create methods of solution where none have existed before.

The sequence in which various topics in circuit theory are presented is extremely important in providing a proper perspective and an understanding of the basic definitions of various pertinent quantities, especially those whose existence is solely mathematical in character. The most important of these is the so-called impedance function. It has no physical significance. It is merely a mathematical convenience. Nevertheless, its role is an important one and its usefulness can be moderate or great depending upon one's awareness of all the implications that stem from the way in which it is derived or defined.

The ideal arrangement of topic order would be to have the students equipped with the essential physics and mathematics background before presenting them with any circuit theory principles. Unfortunately, other curriculum constraints force us to begin our circuit theory discussions before the above mentioned mathematical topics can be introduced and even before, or simultaneously with, a presentation of the physics of electricity and magnetism. The difficulty presented by these circumstances can be met by beginning with the purely topological aspects of circuit theory concerning the proper introduction of sets of independent variables. This discussion requires as yet no background in the physics of electricity (beyond the concepts of voltage and current with which most students are familiar anyway) and settles an issue which is logically, at least, Number 1 on the agenda anyway. By the time the discussion gets around to inductance and capacitance elements, these have been introduced by the contemporary physics subject.

The point at issue here is not crucial. One can introduce these elements in the circuit theory discussions before students have become acquainted with the pertinent physics background by tentatively defining them in terms of their volt-ampere relations in the same way that Ohm's law defines a resistance. This expedient is a compromise, of course, but the many constraints which present themselves in the construction of a curriculum leave us little choice.

Although, as mentioned above, a discussion of network topology logically belongs at the beginning, there are those who feel it is better to postpone this topic of topology until some circuit theory motivation for it has been provided. In this arrangement there is, however, the danger that it will be postponed indefinitely and thus be crowded out entirely. Considering its growing importance and usefulness in various branches of electrical engineering as well as its indispensability in a thorough consideration of basic circuit theory, this possible end result should not be considered too lightly.

A second item of prime importance is the early consideration of transient response or the natural behavior of circuits. There was a time, not too long ago, when this topic was considered as the "frosting on the cake," a dispensable item that could be added as a final flourish if one wanted to dress things up. The sinusoidal steady-state behavior of circuits in terms of a very restricted interpretation of the impedance function encompassed what was then considered to be the essential aspects of circuit theory for electrical engineers.

The increase in importance of the communication and control art put an entirely different light upon this state of things. Transient response became of primary importance; the impedance concept took on a much more general aspect, and the sinusoidal steady state became a very minor part of the total picture.

Classical dynamics correctly places great emphasis upon the natural behavior of a system. Natural frequencies or natural modes and normal coordinates play a dominant role here; and so they should in the teaching of circuit theory, especially if one wants the student to acquire an understanding of the physical picture that accompanies network response. Although the concept of normal coordinates is a mathematical fiction, it provides a tremendously useful interpretation for the mechanism whereby an excitation spreads its influence throughout a network, and how the subtle results peculiar to various degeneracies come about. In fact, one may go so far as to say that a clear understanding of such peculiarities cannot be had without these concepts. Even the sinusoidal steady-state behavior is more effectively portrayed in terms of this same mechanism which provides an insight into the current or voltage distribution pattern throughout a network and shows how this pattern becomes frozen in the vicinity of resonance.

From this point of view, it is impossible to discuss steady-state response without first presenting the story about natural behavior. Transient theory must precede steady-state theory. The concept of complex frequency, so indispensable to the interpretation of the impedance function and to network response generally, is thus logically introduced by pointing out that natural frequencies have this character. The impedance concept is most effectively introduced by forming the total solution as a sum of forced and force-free components which mathematically are, respectively, the particular integral and the complementary function.

For a suddenly applied sinusoid, this approach introduces the impedance function as characterizing the particular integral or steady-state response and yields it in the form of a rational function of the complex-frequency variable. In the case of a driving-point impedance, its zeros and poles are revealed as the natural frequencies on short- and open-circuit, and thus the fact that the impedance function characterizes the transient as well as the steady-state response becomes obvious. In simple cases where the open- and short-circuit natural frequencies are determined by inspection, one can write down the pertinent impedance at once.

In terms of pole-zero plots in the complex frequency plane, and with the help of some principles of conformal mapping, one can readily study the properties of impedance or more general response functions; and one can classify these functions and the pertinent networks according to particular pole-zero patterns.

The advantages that flow from this approach to linear circuit theory are admittedly so great that any objections that may be raised against its adoption quickly vanish once the results are recognized. Although some missionary work still remains to be done, the teaching of linear circuit theory from this point of view is now quite generally established in our engineering schools.

A Remaining Difficulty

There is, however, an important item on which much confusion remains and where the tendency to crowd too much into too little time and, hence, jeopardize clear thinking and understanding still holds sway. This item concerns the introduction of Fourier (and Laplace) theory into the circuit-theory picture. It is a mistake to inject Fourier methods into the presentation of circuit theory at too early a stage. The purely mathematical subtleties of Fourier representation offer a challenge in themselves; superimposing them upon the problem of formulating network response at a time when that process is still only moderately clear, produces a state of confusion in the student's mind that precludes the possibility that he will gain a proper understanding of either topic. Moreover, the tendency is to keep the presentation so shallow that subtleties or difficulties of any kind are avoided, in which case the student is duped, for he is given a tool without proper instructions regarding its use. He is given a set of inadequate rules with little or no explanatory justification.

Fourier representation is a mathematical trick. It deals with the subject of how one constructs arbitrary functions out of sinusoids. The given function emerges as the result of an interference of sinusoidal components and, hence, is also referred to as an interference pattern. One can build the same interference pattern out of sinusoids with steady amplitudes or out of sinusoids with exponentially growing or decaying amplitudes, or out of endless mixtures of these; and there are all sorts of rules as to what can or cannot be built in this way and what restrictions must be placed upon the mixtures, and so forth. This is Fourier theory. It has nothing whatever to do with circuit theory, but when we apply Fourier theory to the problem of computing network response, some additional restrictions and rules enter the picture. It is important to be able to distinguish between conditions imposed by Fourier theory and those imposed by circuit theory. In the usual presentation of this topic, especially in the watered-down variety that is injected into an introductory circuits subject, these restrictions become gloriously mixed up. The poor student is either hopelessly confused or not even aware of the fact that he should be confused.

This state of confusion is not restricted to students. There is, for example, a general misunderstanding about what is Fourier theory and what is Laplace transform theory and how the two are related. Since many books on Laplace transform theory introduce the unit-step and unit-impulse functions, the mere use of these is sometimes mistaken for Laplace transform methods. Expanding a transfer impedance in partial fractions and writing down the time-domain equivalent of each term as a means for finding the impulse response of a given network has nothing whatever to do with either Fourier or Laplace theory, yet there is a general impression among engineers and engineering teachers that the use of this process is synonymous with the use of Laplace transform methods.

It is important to be aware of the fact that the same compact form of solution usually gotten by Fourier or Laplace transform methods is also obtainable by the differential equation approach with far less mathematical fanfare since the convergence of infinite integrals and the evaluation of complex integrals is not involved. From the point of view of computing network response for an applied impulse, step, or sinusoid, nothing whatever is gained by the use of Laplace transform theory, and much time is consumed by its introduction if a worthwhile understanding is to be achieved.

This statement does not imply that Fourier theory is not an essential part of the electrical engineering curriculum, especially for students interested in communications and automatic control systems. However, its introduction into the curriculum should be postponed until a fairly complete and thorough understanding of basic circuit theory principles has been achieved, so that the student does not confuse these with the principles of Fourier theory and can distinguish clearly the part played by each with reference to their practical application. Thoroughness and depth of understanding are here more than ever essential.

On this point, there seems to be a wide divergence of opinion and the confusion and misconceptions caused thereby are not inconsiderable. First of all, the early introduction of Laplace transform methods is pedagogically bad because it provides the student with a batch of rules and a procedure which he can learn to apply by rote. Many students like this sort of thing; it saves them from having to think, a painful process which they are eager to avoid. It is essentially an answer-getting process of fairly general capabilities. Once this crank-turning process is learned, circuit theory for them is "in the bag." This attitude might even be tolerated if it meant that a real depth of understanding of Fourier and Laplace theory lay behind it, but such is seldom the case.

The introduction of Fourier and Laplace methods early in the curriculum has even more fundamentally undesirable consequences. These stem from a tendency to make Fourier and Laplace methods, instead of classical dynamics, the basis for circuit theory or linear system theory. According to this attitude, the frequency-domain response function of a network (for example, the impedance function) is defined as the transform of the unit impulse response in the time domain. The difficulty with this definition is that, in calculating network response, the Fourier or Laplace integral yields only the forced part of the total solution and, hence, represents that solution only if conditions are such that the force-free part is zero. However, since this approach to circuit theory is intended to be independent of any classical background, other ways must be sought in which to express this condition. It turns out in some cases that the specification of a particular path of integration is a mathematically equivalent condition, and the pertinent response function (impedance) is then said to "exist" only in corresponding regions of the s plane. This makeshift method of dealing with the difficulty not only substitutes a false reason for the correct one and, hence, misleads the student, but it puts restrictions upon the impedance function which, from a fundamental point of view, do not belong there and make no sense at all.

This method of defining a response function implies by dictum that the total response is given by the forced part alone. It even goes so far as to deny the existence of a force-free behavior; it denies the existence of natural frequencies; it even denies that the system have an equilibrium condition of any kind. For all this it substitutes an infinite integral definition and a set of rules ostensibly based only upon a convergence argument for the integral, which is not always valid. The student who does not have a classical background in circuit theory cannot possibly salvage anything useful from such a presentation.

Summary

Although topic-wise the teaching of circuit theory has pretty well kept pace with that rapidly developing subject during the past 35 years, the struggle to see that students get the right kind of training in basic principles is never ending. To understand the problem of teaching circuit theory fully, requires a continued long-lasting interest that, alone, enables one to see clearly the whole picture and the relative aspects of its various parts. It takes an interest that absorbs one's entire time and energy on the single topic of network theory.

The young teacher of today, with very few exceptions, does not devote such wholehearted effort to a single subject, especially to its teaching aspects. As a result, his attitudes are usually based upon a very limited appreciation of the total picture and, moreover, are biased by those applications which his particular research interest finds useful. This situation has been aggravated in recent years by a strong trend in academic circles to emphasize research and minimize the importance of teaching effort as regards staff promotions.

One hears much comment to the effect that more weight is laid these days upon excellence in teaching. Yet, contrary to the statement that we encourage only those who have demonstrated both teaching and research ability, there are numerous instances where excellent research ability alone has sufficed to assure promotion, but never one in which excellent teaching ability alone was regarded as sufficient. Until this attitude among academic administrators changes, we shall have the curriculum and teaching difficulties pointed out above.

There is a growing tendency to regard as undesirable a continued interest on the part of a staff member in teaching the same subject year after year. It is tacitly assumed that this situation must lead to stagnation. Toward a teacher who is really interested in his subject, this is an unfair attitude. Excellence in teaching implies a continued freshness of viewpoint and a perpetual change that keeps pace with and participates in the growth of the subject. Frequent rotation of staff, on the other hand, tends toward a repetition of mistakes and offers little opportunity to benefit from past experiences.

Without bias, it may be said that the growth and development of modern network theory throughout the past 35 years had a marked influence upon the upgrading of teaching methods and attitudes in other subjects in the electrical engineering curriculum, especially those in which circuit theory or the principles of linear system theory are essential tools. This upgrading, although stimulated primarily by the war and significantly evident since then, had its roots definitely established for at least a decade before this period.

The modern approach to network theory and, in particular, the methods relevant to its synthesis aspects, with their strong tendency toward rigor and generality, establish a habit of thought for the engineer that cannot help but spill over into his other areas of interest and there awaken the desire to achieve a similar degree of formulative compactness and mathematical elegance. In the engineering curriculum revision process, circuit theory has a 35-year head start over the other subjects. Eventually these will surely face all of the trials and struggles that it has been our pleasure to cope with and to write about here.

COMMUNICATIONS SYSTEMS

Organized with the assistance of the IRE Professional Group on Communications Systems

Antennas and Transmission Lines*

HAROLD H. BEVERAGE†, FELLOW, IRE

Summary—**Antennas and transmission lines used in long-distance point-to-point radio communication are described. Long wavelengths (3000 to 23,000 meters) were used exclusively in the early days of transoceanic communication, and are still used for specific services. The design parameters of long-wave transmitting antennas are briefly mentioned. This is followed by a description of some of the directive antennas used for reception of long waves to reduce the effects of atmospherics and interference.**

The discovery in 1924 that portions of the short-wave spectrum (10 to 100 meters) could be used for long-distance transmission during daylight as well as at night, completely revolutionized long-distance radio communication. The development of arrays and long wire types of antennas for short-wave transmission and reception are described. The radiation of undesired sidelobes from long wire types of antennas is discussed and means which have been used to reduce these side lobes are described.

The parameters which enter into the design of open-wire and coaxial transmission lines are briefly presented. Finally, trends which may tend to reduce the extreme congestion of the short-wave spectrum are mentioned.

THIS paper is limited to a discussion of antennas and transmission-line developments used for long-distance radio communication. The early experiments of Hertz, Marconi, and others were performed with short-wave dipole antennas, including cylindrical reflectors in some cases. Marconi found that as he increased the height and capacity of his antenna, he was able to increase the distance to which he could communicate. Hence, the wavelengths used for long-distance communication gradually increased until by 1914, wavelengths of 10,000 meters (30 kc) or more were in use with large top-loaded antennas of various types [1]. During and after the war, the wavelengths used continued to increase to upwards of 23,000 meters (13 kc).

Long-Wave Transmitting Antennas

In the design of long-wave transmitting antennas, it is of paramount importance to reduce the losses to the greatest extent economically feasible [2], [35].

Blondel pointed out in 1898 that the effect of the earth on a vertical antenna was to produce an image of the antenna, an approximation that was good for the long waves [3]. It can be shown that the radiation resistance R_r of a short vertical antenna is as follows [4], [5], [35]:

$$R_r = 160\pi^2\left(\frac{\alpha h}{\lambda}\right)^2 = 1576\left(\frac{H_{\text{eff.}}}{\lambda}\right)^2.$$

Where α is the form factor which takes into account the distribution of the current in the antenna,

h = height of the antenna in meters,
λ = wavelength in meters,
$H_{\text{eff.}}$ = effective height in meters $=\alpha h$.

$H_{\text{eff.}}$ is on the order of 0.60 to 0.80 of the antenna height h for long-wave top-loaded antennas. It is obvious that the ratio of effective height to wavelength for the long

* Received by the IRE, August 16, 1961.
† RCA Labs., Stony Brook, N. Y.

waves is a very small number, so the radiation resistance is also very small.

In 1917, the General Electric Company in cooperation with the U. S. Navy, installed Alexanderson alternators at the Marconi station at New Brunswick, N. J.; one of the outstanding features of this installation was the great improvement in the radiation efficiency of the antenna by the application of multiple tuning [6]. The Marconi antenna was a flat-top 5000 ft (1530 meters) long, 600 ft (183 meters) wide, supported by 13 guyed tubular masts 400 ft (122 meters) high. At the operating wavelength of 13,600 meters (22 kc) the effective height of the antenna was about 90 meters (295 ft) making the radiation resistance 0.07 ohm. Originally the antenna was tuned at the transmitter end only, and the total resistance was 3.8 ohms, making the radiation efficiency about 1.85 per cent. By multiple tuning the antenna at six points along its length, the ground resistance was reduced to such an extent that the total resistance of the antenna was 0.5 ohm, thereby increasing the efficiency from 1.85 per cent to 14 per cent. With multiple tuning, the total antenna resistance was made up of the following components [6]:

Radiation resistance	0.07 ohm
Tuning coils and insulation	0.10 ohm
Ground resistance	0.33 ohm
Total Resistance	0.50 ohm.

At Rocky Point, N. Y., two multiple-tuned antennas were erected in 1921. Each antenna consisted of twelve wires about 1.25 miles (2 km) long, hung from cross-arms 150 ft (46 meters) long at the top of six self-supporting towers 400 ft (122 meters) high. Because of the low conductivity of the soil at Rocky Point, a very extensive ground system was required. The total length of the buried ground wires was 284 miles (460 km) [7]. It is obvious that to obtain high radiation efficiency, it is necessary to reduce the ground resistance to the greatest extent possible. VLF antennas have been constructed with radiation efficiencies in excess of 50 per cent at 15 kc.

Receiving Antennas for Long Waves

In the early days of wireless communication, the same antenna was usually used alternately for both transmitting and receiving. Later, for duplex operation, a separate receiving antenna was used at a location several miles distance from the transmitting station.

For bidirectional reception, loops were sometimes used. Pickard combined a loop with an open antenna to obtain a unidirectional cardioid pattern. He applied for a patent on this combination on June 10, 1907 [8]. During World War I, several of Pickard's unidirectional antennas were used for transatlantic reception at the Naval Receiving Station, Otter Cliffs, Me. [8].

Ground wires were also used during World War I for directive reception by Taylor, Rogers, and others. Taylor utilized a balancing arrangement between loops and ground wires [9].

Weagant developed a receiving system utilizing large loops spaced several thousand feet apart along the great circle path to the desired transmitting station. His system was based on the theory that certain types of atmospheric disturbances originated from directly overhead. He stated that, "These results showed that static disturbances of the grinders type behaved as though due to heterogeneously polarized, electromagnetic, highly damped waves propagated in a direction perpendicular to the earth's surface" [10].

In an effort to solve a wartime interference problem, Alexanderson devised a receiving system which consisted of insulated wires laid on the ground, extending two miles in each direction from the receiver along the great circle bearing to the desired transmitting station. Means were provided for adjusting the phase and intensity from each wire to produce nulls in the antenna pattern in a direction more or less opposite to the direction of the desired signal. This arrangement was termed the "Barrage Receiver" [11].

The barrage receiver was found to be very effective in reducing atmospheric disturbances coming from the southwest while receiving European signals from the northeast. A barrage receiver was installed at the Naval Radio Station, Otter Cliffs, Me. in 1918. Experience with the long ground wires there indicated that each wire had a unidirectional characteristic, receiving best from the direction in which it was pointing. In the fall of 1919, ground wires several miles long were laid out on Long Island and it was confirmed that the unidirectional characteristic was due to the high attenuation of the ground wire which absorbed reflections from the distant end. This led to the development of the "Wave Antenna" [12]. In the spring of 1920, a two-wire wave antenna was erected on poles with a damping resistance equal to the surge resistance installed at the northeast end. Since the wave antenna was aperiodic, it was usable over a wide band of frequencies without adjustment of any kind. The receiving station at Riverhead, N. Y., was equipped with nine receivers and all long-wave reception was concentrated there.

The wave antenna depends for its operation upon the wave tilt produced by losses in the ground. This produces a horizontal component of the wave passing along the antenna, which induces a voltage in the horizontal wire. The ground parameters are the dielectric constant and the conductance. The wave antenna works best over poorly conducting ground, and will not work at all over a perfect conductor. For poorly conducting ground, the dielectric constant will range from about 6 to 15, which may be neglected in comparison with the conductance term. The wave tilt equation then reduces to the following simple relation [13], [14]:

$$T = 0.235 \times 10^{-10} \sqrt{\frac{f}{\sigma}}$$

where T is the wave tilt, or the ratio between the horizontal and the vertical component of the wave passing over the ground, and

f = frequency in cps,
σ = conductance in emu.

As an example the ground conductance at Riverhead is about 10^{-14} emu, at 20,000 cycles the wave tilt $T=0.033$. Hence, for the 9 mile (14,600 meters) long antenna, the "effective length" is approximately 1580 ft (428 meters).

The wave antenna has also been used as a transmitting antenna at locations where the ground is a poor conductor, which is a handicap to a conventional antenna. While the losses with the wave antenna are high, the directional gain more than makes up for these losses in situations where directional transmission is desired or can be tolerated.

Antennas for Short Waves—10 to 100 Meters

In 1924 Marconi reduced the wavelength of the Poldhu, Cornwall Station to 32 meters and made the important discovery that signals at this wavelength could be transmitted over distances of thousands of miles during daylight [15]. This opened the way for transmitting over great distances with equipment costing a fraction of the cost of the long-wave facilities required for a comparative grade of service. However, the atmospheric noise problem on the long waves was exchanged for deep fading on the short waves. One obvious approach to the fading problem was to transmit a signal of sufficient intensity such that at the receiver, the signal would seldom fade below the noise level.

On the short waves, it is possible to utilize antennas with gains of 20 db or more as compared with a single omnidirectional vertical antenna. As early as 1899, Brown [16] proposed the use of two vertical antennas, separated in space by an appreciable portion of a wavelength and excited at a half-period phase difference, as a means of directional transmission and reception. Foster calculated and plotted the directive pattern for 90 combinations of two antennas with spacings varying from zero to four wavelengths with phase differences varying from zero to 180 degrees. He also plotted 612 patterns for an array of 16 antennas with spacing and phase relations as the parameters [17], [35].

The early highly-directive short-wave antennas generally consisted of arrays of a number of half-wave radiators combined in proper phase for maximum directivity. The first extensive array was the Marconi beam antenna developed by C. S. Franklin. A typical Marconi beam array was supported from crossarms on towers 300 ft (92 meters) high spaced 650 ft (198 meters) apart. Vertical radiators consisting of several stacked vertical half-wave elements were suspended from the cross-arms with an arrangement of vertical wires functioning as a reflector located a multiple of a quarter wavelength behind the radiating elements. The radiators consisted of two or more half-wave elements stacked vertically, separated by nonradiating coils which reversed the phase 180 degrees, thereby causing the antenna elements to radiate in phase. A typical array designed for 22 meters utilized 16 vertical wires consisting of three half-wave elements stacked vertically. The reflector consisted of 53 wires spaced three-fourths of a wavelength behind the radiating array [18].

Several other arrays were developed using similar techniques. Sterba used half-wave balanced nonradiating horizontal sections to reverse the phase for the stacked vertical radiators [19]. Other arrays utilizing wires excited as half-wave or multiple half-wave antennas were developed by Koomans (Dutch), Chireix-Mesny (French), Tannenbaum antenna (Germany), and others. In some cases the radiators were vertical, and, in other cases, the radiators were horizontal [20], [35].

These arrays provided excellent performance, but were relatively expensive and were difficult to maintain in areas having severe icing conditions.

Some experiments were performed using the wave antenna [12] for short-wave reception. The simple horizontal wire was too short to be effective in comparison with the vertical antenna effect. Dr. Peterson overcame this difficulty by coupling horizontal doublets to a balanced transmission line through small capacitors in order to maintain the velocity in the transmission line near the velocity of light. This array was in the form of a fishbone and is often referred to as the "Fishbone Antenna." The fishbone antenna was useful over an extended range of frequencies, and since it was symmetrical with respect to the ground it could conveniently be used with long balanced open-wire transmission lines. These long transmission lines were required for the space diversity system where the antennas were located approximately 1000 ft (300 meters) apart [21].

In England, an array was developed which is similar in appearance to the fishbone antenna, but the antenna elements are approximately a half-wave long on each side of the balanced transmission line. This antenna is known as the HAD antenna (Horizontal Array of Dipoles) [22].

Carter, Hansell and Lindenblad attempted to devise an antenna similar to the fishbone antenna for transmission. They had difficulty in obtaining the proper phase relations for an end-on array, so it ended up as a broadside array, known as the "Type A" antenna [23]. This group then pioneered in the development of antennas utilizing simple long wires as radiators. Several different arrangements were developed, termed "Type B," "Type C," and "Type D" antennas [23].

A long wire in free space has a radiation pattern in the form of two hollow cones 180 degrees apart. The angle which the cones make with respect to the wire depends upon the length of the wire in wavelengths. For example, if the wire is 8 wavelengths long, the maximum radiation in the cones occurs at an angle of 17.5 degrees with respect to the wire. In the Model D antenna, two horizontal wires are utilized in the form of a "V" having an included angle of 35 degrees. The radiated energy in the two cones add along the bisector of the V in the forward and rear sectors, and tend to cancel elsewhere. By erecting another "V" antenna spaced an odd multiple of a quarter wavelength, the radiation in the rearward direction is canceled. Reflection from the ground tends to add the energy from the lower portion of the forward cone to the desired maximum main lobe. The angle which the main lobe makes with respect to the ground depends mainly on the height of the wires above ground. The long-wire type of antenna can be constructed at a small fraction of the cost of an array having similar gain.

Lindenblad proposed constructing a long-wire type of antenna in the shape of a diamond or rhombic. However, it remained for Bruce to propose the use of a damping resistance at the far end of the rhombic, thereby absorbing the energy which would otherwise be reflected to produce standing waves [24], [26]. In effect, the rhombic antenna with the damping resistor becomes a substantially aperiodic traveling-wave antenna readily matched to a transmission line over a relatively wide range of frequencies. Thus the terminated rhombic antenna has become the most widely used short-wave antenna all over the world because of its simplicity, wide bandwidth, and low cost.

An appreciable portion of the power is lost in the terminating resistance. This loss can be minimized by feeding energy back to the input end of the rhombic in the proper phase. However, when this is done, the rhombic is no longer aperiodic and can be operated only at a fixed frequency.

In spite of its many advantages, the rhombic antenna, or any simple long wire antenna, has some disadvantages which become increasingly important as the radio spectrum becomes more and more crowded. Dr. Brueckmann points out that rhombic antennas poorly reject interfering signals from the forward sector over the entire frequency range. At all frequencies, some side lobes exist which are only 6 to 10 db down from the main lobe. The back lobe varies between -6 and -20 db, decreasing gradually in strength with increasing frequency, as do the other side lobes in the rear sector. Brueckmann has described methods for suppressing the side lobes, finally resulting in the TAHA Antenna (Tapered Aperture Horn Antenna). From model measurements, the sidelobe level is -20 db or less over the entire frequency range; the bandwidth is equal to or better than the rhombic, and the sidelobe suppression is superior by a factor of 10 to 15 db. A full scale TAHA horn antenna has an over-all length of approximately 850 ft (259 meters), height 250 ft (75 meters), and width 560 ft (170 meters) [25].

The corner reflector antenna, developed primarily for ionospheric forward scatter, is another effective method for reducing the side lobes on the order of 40 db or more below the main lobe. For this service, which requires relatively high power, it is necessary to reduce the side lobes to prevent interference from back scatter and to or from other VHF services. This is particularly important during periods of high sunspot numbers, since there is occasional long distance VHF transmission due to *F*-layer propagation. The corner reflector antenna main beam can also be slewed to either side by grading the phases of the energy fed to the beam elements. Off-path transmission is sometimes advantageous with VHF ionospheric scatter [27].

In general, the side lobes in any type of multiple-element broadside array can be reduced by radiating the major portion of the energy from the central elements and tapering the energy radiated from the end elements [28], [29].

A method for reducing the undesired side lobes radiated from a rhombic antenna has been described by Christianson. In his arrangement, two or more rhombics are overlapped with the proper spacing and phase relations to reduce the side lobes [30].

Laport and Veldhuis have developed antennas that provide greater sidelobe suppression than conventional rhombic antennas, yet retain the desirable features of the rhombic. Their arrangement consists of two or more rhomboid antennas with a common apex wherein the length of the sides and the apex angles are adjusted to produce zeros in the array pattern to inhibit the growth of the side lobes [31].

Friis and Feldman devised a steerable antenna system consisting of six rhombics spaced end-on. This array had sufficient resolution to separate signals arriving at different vertical angles. Two or more discrete waves, or bundles of waves, may be separated and added in phase, thereby providing a system that might be considered "Vertical Angle Diversity." This arrangement not only increases the SNR, but, more importantly, it simultaneously reduces the distortion due to selective fading [32].

Ehrenspeck and Kearns have investigated another method for reducing the side lobes. Their Type II arrangement consists of a Yagi type array, six wavelengths long, designed to reduce the side lobes to a maximum level of 30 db. This is accomplished by utilizing parasitic elements spaced 0.66 wavelength each side of the main array. The gain of the Type II antenna was 30 per cent above that of a single Yagi of the same length [33].

Isbell has described dipole arrays which make use of the principles of the log periodic antenna design. Antennas are described which provide unidirectional radiation patterns of constant beamwidth and nearly constant input inpedances over any desired bandwidth [34], [35].

Transmission Lines

Standard two-conductor copper telephone lines, several miles long, with special transpositions, were used in connection with broadside VLF wave antennas [12].

Four-wire balanced lines were used with space-diversity antennas [21]. Both applications were for reception.

The writer's earliest knowledge of the application of balanced transmission lines for transmitters was based on a suggestion by Lindenblad about 1921. Lindenblad and the writer used a two-wire transmission line 1400 ft (427 meters) in length to energize a vertical antenna tuned to the amateur wavelength of 200 meters (1500 kc) at Belmar, N. J.

In 1924, two marine transmitters at Marion, Mass., were equipped with open-wire transmission lines to energize antennas which were respectively 300 ft (92 meters) and 600 ft (184 meters) from the transmitting building [36].

When the short waves became widely used, starting about 1925, transmission lines came into universal use for energizing antennas hundreds or even thousands of feet distant from the transmitter. Both balanced open-wire transmission lines and unbalanced coaxial transmission lines have been used extensively. Coaxial transmission lines have been used more widely in Europe than in the United States [20]. Open-wire transmission lines of the balanced type continue to be used extensively in the United States with high-frequency transmitters. Coaxial cable is used in the majority of receiving installations, although carefully balanced four-wire lines continue to be used in some large receiving centers [21].

Great care is required in the installation and maintenance of open-wire transmission lines for transmitters, since relatively slight unbalance may make the transmission line act like a wave antenna, causing it to radiate considerable energy in the direction in which it is pointed. Furthermore, unbalanced excitation of an open-wire line can occur through coupling to an adjacent perfectly balanced line, particularly at the transmitter building where the transmission lines are close together. In cases where special arrangements are made to reduce the intensity of the antenna side lobes, the improvement may be nullified by radiation from an unbalance in the transmission line [25].

In many respects, it is convenient to use open-wire transmission lines. For example, a rhombic or fishbone antenna is inherently balanced with respect to ground. The use of a transformer can be avoided by means of a tapered section to match the impedance of the antenna to a balanced transmission line [37]. Alternatively, broadside antennas have low enough impedance to enable matching the antenna directly to the transmission line [21]. The impedance of an open-wire transmission line is primarily a function of the ratio between the diameter of the conductors and the spacing of the conductors. Likewise, the impedance of a coaxial transmission line depends upon the relative sizes of the inner and outer conductors, and the dielectric constant of the insulation. Accordingly, the impedance of transmission lines can be varied over rather wide limits by design [35], [38].

Future Trends

For many years, the high-frequency spectrum has been close to saturation. Increases in traffic-handling capacity have been made through improved frequency stability, receivers with superior selectivity, multiplex printer operation, etc., but any improvement in spectrum utilization has quickly resulted in additional stations coming on the air, thus continuing the saturation of available channels. The congestion becomes particularly acute during periods of sunspot minimum when the band of frequencies suitable for long-distance high-frequency communication is sometimes squeezed down to a few megacycles by propagation conditions. Obviously, the high-frequency spectrum should be reserved for services that cannot be provided in any other manner [39].

There is great promise for the future in the use of satellites to provide wide bands of frequencies suitable for relaying television and hundreds of channels for telephony and telegraphy. Due to the high initial costs of wide-band relays by means of satellites, it seems apparent that such relays will be used initially only between cities having very large potential traffic requirements. The assignments in the high-frequency spectrum eventually released by satellite relays will be needed by aviation and other mobile services, as well as by recently independent countries which will need frequencies for international communication and broadcasting.

The antennas for use with satellite relays will probably be large parabolic or horn antennas on the ground cooperating with antennas on the satellite having relatively little gain. It will be essential to use antennas on the ground with minimum sidelobes to avoid mutual interference with terrestrial radio services. Most of the methods for suppressing the sidelobes described in this paper are applicable to the higher frequencies, plus other arrangements which are practical for microwave but not for the high-frequency spectrum. The characteristics of antennas for radio relays are covered elsewhere [40].

Radio Receivers—Past and Present*

CHRISTOPHER BUFF†, SENIOR MEMBER, IRE

***Summary*—This paper reviews the origin and evolution of some of the more important techniques and instrumentalities of radio receiver development. A completely comprehensive story would require many more pages than are available in this anniversary issue. Highlights of development between the early era of the magnetic detector, or coherer, and the present time are discussed.**

INTRODUCTION

THE fundamental laws governing electromagnetic radiation were first stated by James Clerk Maxwell in 1865. Twenty years later, Heinrich Hertz first detected the presence of electromagnetic radiation from his spark-gap oscillator. His receiver was simply a piece of wire bent into a circle with a ball on one end and a sharp point on the other. When the circle of wire was tuned to the same frequency as the oscillator by adjustment of its circumference, the oscillator spark-gap discharge caused a spark across the air-gap of the receiving circuit.

Subsequent experimenters tried to improve receiver sensitivity by depending on luminous discharges through rarified gas, heat produced by HF currents, contraction of frogs' legs, explosion of oxygen and hydrogen by passage of sparks, mechanical attraction between oppositely charged conductors, demagnetization of iron, and depolarization of electrolytic cells. None of these schemes achieved significant results.

The first real advance in detection was the magnetic detector, or coherer, invented by Prof. Edward Branly. He did not, however, conceive its use for radio reception. The coherer operates on the principle that, while most powdered metals are poor dc conductors, metallic powder becomes conductive when HF current is applied. Shades of semiconductors! The iron filings that were used were continually vibrated to recondition them to their sensitive condition. The evolution of coherers resolved itself mainly into a study of the most sensitive metals and best mechanical tapping device permitting continuous use. Oliver Lodge coined the name coherer and first used the device for detecting

* Received by the IRE, June 6, 1961.

radiotelegraph signals. Further improvements were made by Prof. A. S. Popoff and Guglielmo Marconi. For about 10 years, the coherer was the receiving detector used in the Marconi radio stations.

The mechanically unstable coherer gave way to the crystal detector using the semiconductors silicon or galena with a cat's-whisker contact, as invented by Pickard and Dunwoody.

At about the same time as the crystal detector, there appeared the first vacuum-tube-diode detector. Using the Edison Effect as a basis, Prof. Ambrose Fleming patented the Fleming valve in 1904. In its original form, the vacuum-tube diode was not as good a detector as the crystal and was therefore never used in practical radiotelegraph reception. Historically, however, the Fleming valve was greatly important as a forerunner of things to come. De Forest added the grid control, endowing what was previously a simple rectifier with the magical property of amplification. Arnold and Langmuir showed the necessity of a very high vacuum, which, in turn, was made possible by Wolfgang Gaede's molecular pump in 1913. The electron tube thus became the keystone of modern radio communications.

The early history of radio is an international one and it so continues today. Fascinating accounts of the early days were given by Espenschied, Hammond, and others.[1,2] Six decades of radio-receiver art have taken us from the iron-filing coherer to the ruby maser, from mile to multimillion-mile reception, from bandwidths of cycles to megacycles. That a few watts of man-made signals from millions-of-miles in outer space could be picked up on earth testifies to the great improvements embodied in the modern radio receiver. This is a startling example of the homily that a decibel is a decibel, whether costfully gained through more power at the transmitter or by reducing noise bandwidth at the receiver.

The basic obstructions to perfect reception are in the propagation medium, interference, and the receiver itself. Experiments conducted from the depths of the ocean into the cosmos are now revealing the origins of natural noise in relation to the frequencies employed. The International Radio Consultative Committee (CCIR) is contributing greatly in organizing and coordinating the impressive mass of data already obtained.[3]

A common and insidious source of noise is the receiver itself. Receiver noise is explained as originating in the unorganized motion of electrons in the early receiver stages. In vacuum-tube receivers, notable improvement has been achieved with traveling-wave tubes where the noise factor has been reduced from 10 or 12 to 5 db or less at about 3000 Mc. We are now witnessing staggering developments in parametric-amplifier, low-temperature, and atomic-excitation techniques that will extend the range and reliability of electromagnetic-wave reception from the VLF bands through bands probably far above those of visible radiation.

At a time when truly reliable earthbound communications are becoming achieved by improved types of ocean cable, it is apparent that these new developments will pay off in future space communications via orbiting satellites. At the very least, it seems safe to say that radio is here to stay when it comes to interplanetary communications; cable to the moon would be awkward indeed!

What is a radio receiver? A radio receiver might be defined as a device converting to useful form the information contained in the radio waves applied to its input. Basically it is a frequency converter with tuned circuits and amplifiers that specifically adapt it to a particular type of signal reception. In the early days, long-wave transoceanic telegraph signals were transmitted by very-high-powered alternators in the range 10 to 20 kc. Radio folklore tells us that a man on Long Island could simply connect his headphones to a good-sized antenna and read directly the telegraphic messages originating in Europe. This was about as simple a receiver of electromagnetic waves as has ever been achieved, comparing favorably with the first Hertzian detector.

Basic Receiver Circuits

Broadly speaking, all radio receivers might be classified by operating principle as follows:

1) tuned radiofrequency,
2) regnerative,
3) superregenerative, and
4) superheterodyne.

1) Tuned Radio-Frequency (TRF) Receivers

TRF receivers obtain selectivity through circuits tuned to the incoming signal frequency. Through hindsight, it might seem that receiver evolution could have progressed better from the TRF circuit to the superheterodyne, but this was not the case. Although Prof. Reginald Fessenden touched on a basic element by invention of the heterodyne oscillator in 1912, the contemporary invention of the self-oscillating detector, or Ultrauidon, by De Forest immediately focussed attention on this simpler means of increasing sensitivity.

Although the superheterodyne was invented by 1920, many TRF receivers were used in the following decade. This was in great part due to the invention and successful commercial development of the Neutrodyne circuit by Prof. L. A. Hazeltine. The Neutrodyne provided control of the regenerative feedback used by De Forest and others. Prior to this, the regenerative receivers used were unstable; the difficulty of tuning, their squeals,

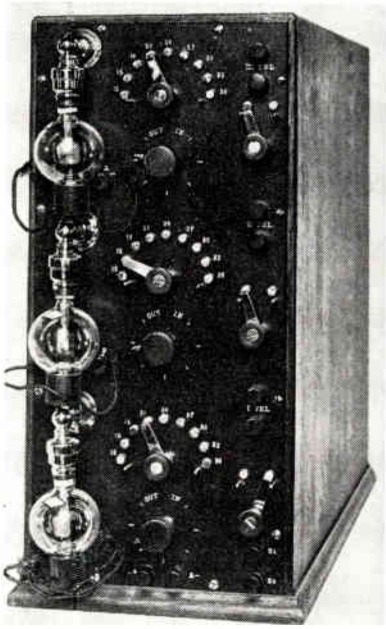

Fig. 2—Three-stage De Forest audion amplifier of the type first built in 1912 by the Federal Telegraph Company. This is the earliest known cascade AF amplifier. Tests made at that time indicated that the amplifier increased the received signal intensity by 120 times. (*Courtesy of ITT.*)

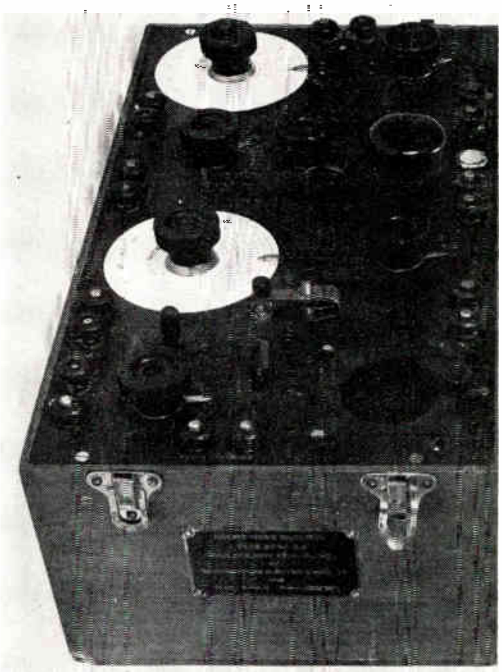

Fig. 3—Front view of the SE-1012A receiver manufactured for the Navy Dept., Bureau of Steam Engineering, by the Westinghouse Electric and Manufacturing Co., in the year 1918. It followed a design originally made by the Radio Test Shop, U. S. Navy Yard, Washington, D. C., and designated as type SE-1012. Signals could be received over wavelengths from 50 to 1100 m. The design included both a crystal-diode and a vacuum-tube detector, either of which could be used as desired. With the vacuum tube in use, the receiver could be operated with either a regenerative or an oscillating detector, and was usable with either damped or undamped signals, to use the terminology of that day. Either a Navy "G" or a Navy "J" tube could be used. (*Courtesy of USNRL.*)

howls, and the interference they caused were soul-racking. But now several stages of RF amplification could be used for isolation and for greater sensitivity; stations always came in at the same dial reading. Two factors contributed greatly to the demise of the TRF receiver during this period. These were the increasing signal congestion in the broadcast band caused by the ever-larger number of stations and the increasing use of what were then termed the short waves; those frequencies lying above 1.5 Mc (200 m) where the amplification and selectivity of the superheterodyne became manifest. By the early 1930's the superheterodyne gained dominance at all frequencies above 500 kc and TRF receivers were on the way out.

2) Regenerative Receivers

In a regenerative receiver, the received voltage is applied to the input of an amplifying stage and a portion of the amplified output of that stage is fed back to the input circuit in the phase that causes an increase in the input. This reduces the effective resistance (raises the q) of the input resonant circuit and thereby provides greater amplification of the signal. If the feedback is increased beyond a certain point sustained oscillations occur. The regenerative receiver is quite sensitive with even a single stage. Four inventors (De Forest, Armstrong, and Langmuir in the United States, and Meissner in Germany) independently discovered the increased receiver sensitivity produced by regenerative feedback around a triode. This feedback circuit made possible, in the heart of a city, the reception of transatlantic signals with comparatively small antennas, a theretofore impossible feat. It was then quickly recognized that the feedback circuit was to be of great commercial importance.

The patent litigation that followed was the most controversial in the annals of electronics. The case dragged on for 20 years. It was finally settled in De Forest's favor by the Supreme Court in 1934. By this time legal expenses had reached huge totals and improved receiver techniques had by then made the regenerative receiver obsolete except for some amateur and marine work.

Regeneration is still used occasionally in q-multiplier circuits for improving tuned-circuit selectivity.

3) Superregenerative Receivers

Superregeneration was discovered by E. H. Armstrong during the defense of his patent case for the regenerative receiver. In a superregenerative receiver, sustained oscillations are squelched by periodic variation of the effective resistance of the input resonant circuit. Oscillations periodically build up in a circuit resonant at the signal frequency. Sustained oscillations are prevented by periodic application to the grid of the superregenerative tube of a signal that damps the oscillations. The quenching frequency is usually between 20,000 and 100,000 cps. The superregenerative detector, because of its broad tuning and considerable sensitivity, was practical and popular earlier when unstable modulated oscillators were used as transmitters at frequencies above 30 Mc.

More recently, superregeneration has been applied to parametric amplifier detectors. Their relatively broad bandwidth with stable and high gain are desirable attributes in S-band experiments. The theory of superregeneration has generally not been well understood in the past and is only now being clarified.

4) Superheterodyne Receivers

In superheterodyne receivers, the incoming signal is combined with a local oscillator voltage to derive an IF signal, marked by the information-bearing modulation, which is then amplified and detected to reproduce the information. Underlying the superheterodyne principle is the basic modulation or mixing process that generates the sum-and-difference sideband pairs that make frequency translation possible.

Prof. Fessenden, in his search for an improved receiver, invented the heterodyne system in 1912. Previous receivers had merely acted as valves, detecting by turning a direct current on and off in amounts proportional to the received signal. In contrast, the heterodyne system operated through the joint action of the received signal and a local wave generated at the receiving station. Combination of these two alternating currents resulted in an audio beat-note, the difference frequency between the two waves. Although Fessenden's local oscillator was an arc source, very bulky and troublesome, it was nevertheless the forerunner of superheterodyne and single-sideband reception.

The next advance in double-detection technique involved amplification of the beat-note or intermediate frequency. Several parallel developments took place in the United States and in Europe. It is difficult to name an inventor since the superheterodyne system as a basic idea seemed to appear from several sources at about the same time. The works of J. H. Hammond, A. Meissner, Lucian Levy, E. F. Alexanderson, and E. H. Armstrong stand out. Armstrong fully appreciated the problem and obtained a patent in 1920 that was of major importance in the practical application of the superheterodyne system. Superheterodyne technique today has universal application in transmission as well as reception.

Superheterodyne receiver technique derives its main advantage in that almost all the receiver selectivity and most of the receiver gain can be obtained in stable IF-amplifier stages. Recently, extremely small and efficient megacycle-range quartz-crystal IF band-pass filters have been developed. These improved selective elements greatly reduce the number of conventional tuned circuits required in IF amplifiers. Where triple IF conversion was sometimes formerly required, it is now feasible to use a single conversion. Indeed, the carrier frequencies of yesterday have become the intermediate frequencies of today.

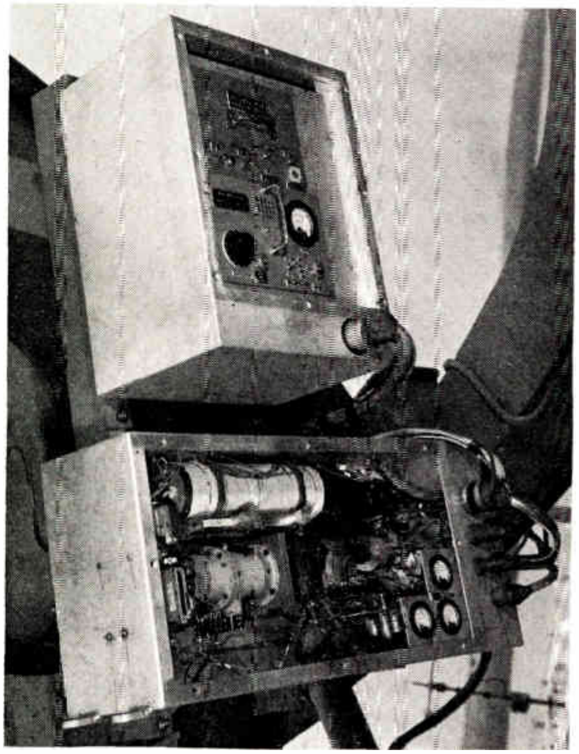

Fig. 6—35-kMc radio receiver for mounting on back of 10-foot radiotelescope at the USNRL. The waveguide from the focal point of the reflector can be seen entering the receiver on the left of the assembly. (*Courtesy of USNRL.*)

In communications receivers there is still, however, a serious fault. This is the wide-open door at the input to a noise bandwidth that is usually many times greater than that actually required to accommodate the desired information. What we must develop is an adjustable "window" between the antenna and the first RF stage that can be tuned over a wide frequency range and widened or narrowed as required to accept only the information content represented by the signal bandwidth.

Although present receivers have narrow IF bandwidth, much unnecessary noise and cross-modulation can result from the wide-open front end.

It is suggested that development of sharp, tunable receiver-input filters would hold great possibilities for improving radio-receiver performance.

Diversity Reception

As a result of some elegant experimental work by radio amateurs in this country and in Europe, the short-wave band was opened for all in the early 1920's. The variable nature of HF propagation was quickly recognized and led to many ingenious innovations in receiving technique. On the lower frequencies, below 500 kc, improved communications were attained through use of higher transmitter power and larger antennas. Because of the turbulence and abrupt changes encountered in the HF medium, special attention had to be given to improved means of reception as it became apparent that transmitter power increases were not alone sufficient.

Among the significant techniques developed, one of the most important is diversity reception, wherein a considerable improvement is obtained due to the statistical independence in the fading characteristics of two or more paths. Diversity reception is basic, improving the reception of any type of modulation at any frequency. H. H. Beverage, H. O. Peterson, and J. B. Moore described and developed a triple-space-diversity system for on-off telegraph reception around 1928.[4] This employed three antennas spaced about 1000 feet apart. The rectified outputs of three separate receivers were combined across a common load resistor and the voltage across the resistor keyed a local tone generator. As long as the voltage was above a certain minimum from any receiver, a properly keyed tone signal was reproduced. Prior to this, separate "raw" signals from two receivers were connected to separate earphones on the operator's head. Through his mental processes a diversity improvement resulted. This method was dubbed by some, "Scotch Diversity." Statistics on the improvement obtained or on the longevity of the operators do not seem to be available.

Also about 1927 or 1928, A. de Haas of the Netherlands Post, Telephones, and Telegraphs Administration described a complete diversity system used in the

[4] H. H. Beverage and H. O. Peterson, "Diversity receiving system of R.C.A. Communications Inc., for radiotelegraphy," Proc. IRE, vol. 19, pp. 531–561; April, 1931.

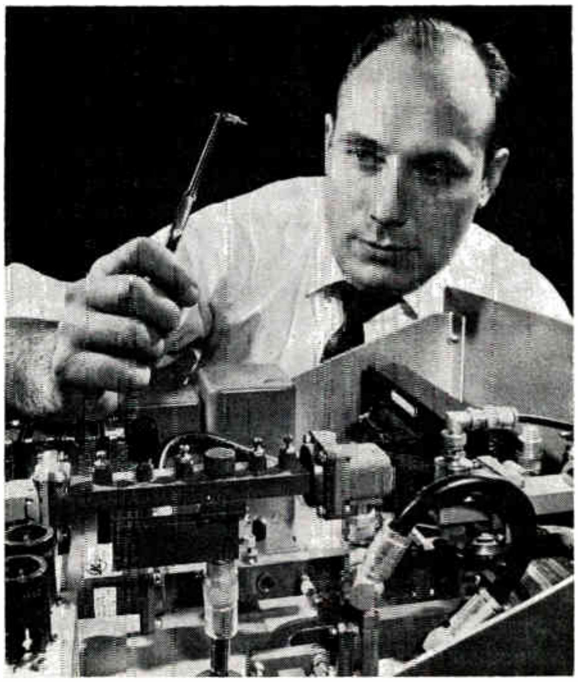

Fig. 7—Front end of a Tacan ground-beacon receiver employing a parametric amplifier. The parametric diode held in the tweezers is the heart of the amplifier. Lower-sideband up-converter is used to receive signals in the 1025–1150-Mc range. The pump frequency is 10 kMc. Another oscillator beats the lower sideband down to the 63-Mc IF. Noise figure of the amplifier is 2.5 db. (*Courtesy of ITT.*)

Dutch East Indies to improve reception of the Kootwijk, Holland, transmitters.[5] De Haas had all the essentials of an equal-gain postdetection combiner. This is another instance where a basic idea germinated at two sources at the same time. Confronted by similar problems, different people sometimes arrive at the same solution!

In recent years more has probably been written about space, frequency, and polarization diversity and combining methods than about any other receiving technique. With notable exceptions, much of this concerns refinement rather than true innovation, plus mathematical studies of the statistical performance of the various combining methods. The excellent analysis of D. G. Brennan is an example of this work.[6]

L. R. Kahn's important analysis showed that the optimum diversity advantage for frequency-modulation and frequency-shift reception could be obtained only by prelimiter evaluation of the signals.[7] Individual diversity channel contribution is then made proportional to the square of the signal level at the limiter input. Actual postdetector combining is by suitable discriminator cross-connections. This method is widely used on HF for individual telegraph channel combining and also at VHF and higher where the principle is used in baseband combining systems.

Another and more elegant solution of the diversity problem is that provided by F. J. Altman and W. Sichak in their predetector IF phase combiner.[8] Essentially, this system phases the signals in two diversity channels by phase control of one of the receiver local oscillators. This predetector combining system provides simplified circuits and improved distortion ratio as compared to baseband postdetector combiners using out-of-band noise as a criterion. This scheme has been mainly used in over-the-horizon scatter systems.

Assuming proper design, there seems to be very little practical difference in performance of the several basic diversity combining systems. However, an adequate diversity arrangement of some type is considered a necessity for reliability in any radio system involving even a minor degree of multipath propagation. This is especially true for telegraph and data transmission which inherently can tolerate less signal mutilation than voice transmission.

Frequency-Shift Telegraph Reception

By increasing the reliability of HF radio circuits in the international record traffic services, frequency-shift telegraphy has certainly become a classic receiving method deserving some mention. Its origin is somewhat nebulous although credit for the underlying modulation principles properly belong to E. H. Armstrong, the father of FM.

As modulation technique, frequency-shift keying (FSK) dated back to the Poulsen-arc days of the old Federal Telegraph Company in Palo Alto, Calif., circa 1915. Because their high-power arcs could not be on-off keyed, the transmitted frequency was instead shifted a few hundred cycles by means of resonant circuits switched in and out by the telegraph key. At the receiver, the key-up or spacing frequency was disregarded in the detection process. Obviously, there was no improvement obtained as far as reception was concerned.

In 1927 Armstrong is reported to have proposed an FSK system for VLF telegraph circuits to combat atmospherics. After this there seems to have been a lapse of several years. The early 1930's saw the utilization of subcarrier FM (SCFM) methods by Press Wireless, Inc., for receiving radiophotos from the Byrd south-polar expedition. The improvements in picture quality as compared to the former AM method were immediately apparent. By the late 1930's the significance of frequency-shift technique for teleprinter as well as facsimile purposes was widely recognized. The work of J. A. Smale in England on two-tone keying around this time is worthy of note. With the continuing improvement in transmitter and receiver oscillator stability,

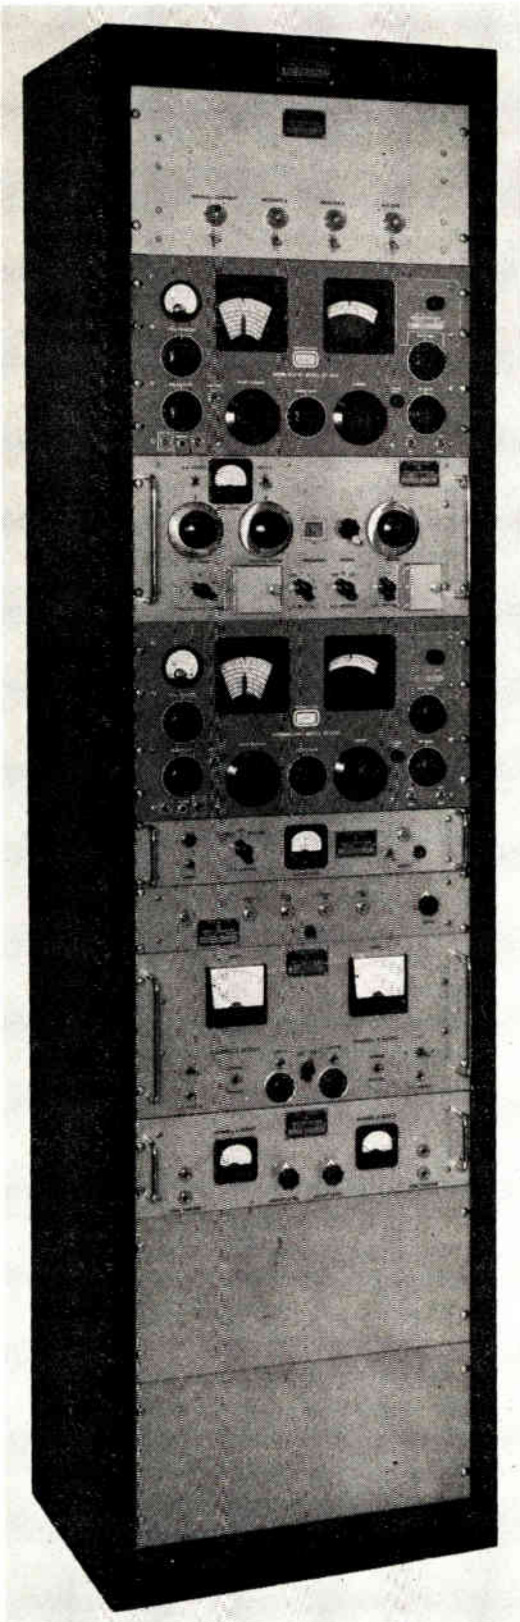

Fig. 8—Dual-diversity FSK Twinplex radio receiving terminal, as used in international point-to-point HF communications, features automatic frequency control and narrow-band Twinplex reception using 200-cps shift intervals. Eight 50-baud channels can be received with a total frequency-shift spread of 600 c through the combination of synchronized time-division multiplex and narrow-band twinplex techniques. (*Courtesy of Mackay Radio and Telegraph Company.*)

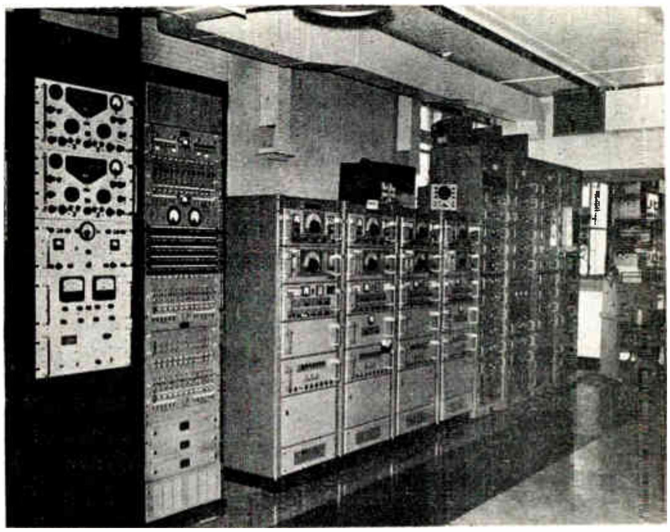

Fig. 9—Two types of ISB radiotelegraph receivers for HF are shown. At the left is a new type of dual diversity ISB receiver working into a twelve-channel transistorized FM voice-frequency-telegraph terminal directly adjacent. The lower bays in the center are older types of ISB receivers, two bays for dual-diversity, operating into tube-type FM voice-frequency-telegraph terminals at the far right. The differences in floor space requirements are readily apparent. (*Courtesy of Mackay Radio and Telegraph Company.*)

direct RF-carrier shift became a practical reality around 1941. As is well known, the ensuing war gave great impetus to FSK because of the wide application of teleprinters to radio circuits, which, in turn, was partly caused by the shortage of skilled Morse-code operators.

Essentially, the greatest single improvement produced in FSK reception is obtained by the action of a high-speed transient-free amplitude limiter inserted between the radio receiver proper and the telegraph-signal detector. The radio signals can then assume a very wide range of fading levels without altering the mark-to-space ratio of the telegraph signal. It is this effect more than the noise-reducing properties of FM that has made automatic (teleprinter) reception a practicality.

Over-all performance during fades is impaired by circuit elements, including band-pass filters, that have a poor transient response. These elements may, of necessity, precede the limiter for selectivity purposes or may, through poor design, be unintentionally incorporated in the limiter. Because narrow-band filters inherently have poorer transient response, systems using such filters, for example those for 85-cps shift, must place greater reliance on optimum diversity-path combination than those using relatively wide prelimiter band-pass filters. H. B. Law in England and others have developed FSK receivers that dispense with predetection limiting and through an "assessor" circuit evaluate both mark and space frequencies to obtain a frequency diversity effect.[9] Improvements are claimed, but it can probably be shown that a narrow-band independent-

[9] "Six papers on radiotelegraphy and fading," reprint from the *Proc. IEE*, vol. 104, pt. B, no. 14; March, 1957

sideband (ISB) multitone system with conventional limiting and optimally executed ratio-squared diversity combination performs at least as well and with better bandwidth utilization.

The entire subject of frequency-shift telegraphy, particularly reception, has been rather continuously reexamined during the past fifteen years; the practicing communications engineer may now feel the need for a really basic evaluation of the various FSK systems. Until now, there have been under study phase-shift, multiple-frequency-shift, four-frequency diplex (Twinplex), and coherent detection systems. Probably the most widely used variations of FSK are the Twinplex and ISB multitone methods. Significant reductions in transmitted bandwidth have been achieved through improved detection schemes at the receiver. Frequency-shift deviation at HF has been reduced from 850 to as low as 60 cps in ISB multitone systems. Twinplex bandwidth, by frequency-multiplication techniques at the receiver, has been reduced from 1200 to 600 cps while retaining its speed of 200 bauds per channel. Kineplex, which may be thought of as a phase-shifted Twinplex system, reduces the deviation to but a fraction of a cycle.

After much backing-and-filling, it has been established that the actual frequency deviation is not as all-important as it was once thought to be. The bandwidth employed can mainly be considered to be a function of the signaling speed and the deviation adjusted accordingly within this prescribed bandwidth. Through the use of extremely stable oscillators coupled with automatic frequency control and optimum diversity combination at the receivers, a 50-baud HF teleprinter circuit need occupy only one-tenth the bandwidth required for early FSK circuits.

Conclusion

The advent of space-probing efforts has overtaxed radio-receiving techniques once again. Until that day when high-powered ground transmitters become a reality and higher-gain antennas are available at the distant end, be it a spaceship or another planet, improvements must seem to come mainly from improved receivers. We find used in these receivers most of the basic developments of the past 50 years, such as the superheterodyne, sharp IF filtering, diversity reception, automatic gain control, FSK, and automatic frequency control. The major innovations in space-age receivers are mainly those relating to improvement of the front-end noise figure: the traveling-wave tubes, parametric amplifiers, and masers.

In earth-bound communications, receiver front-end technique has, it seems, always lagged behind. Now a supreme effort must be made to eliminate internal receiver noise, for we seek to use signals that are but flickering ghosts. No matter how low the noise figure of the input amplifier, however, the accepted bandwidths, being extremely wide compared with the desired signal, leave something to be desired. Interference from other signal sources, for example, cannot be wholly negated by IF filtering. What can be hoped for from our filter network discipline toward developing tunable filters that will eliminate everything but a desired signal right at the front end of the receiver? Radio astronomy is purely a receiving technique. The signal sources are not man-made. We have to do the best we can with these cosmic "noises." The pioneering work of Karl Jansky led the way to the exploration of space. He was followed by many others, including Grote Reber and John Kraus. At present, major efforts in radio astronomy are being carried forward in many countries. The magnitude and world-wide scope of the work being done on masers and parametric amplifiers can best be evaluated by referring to the literature.[10]

It has been half-seriously observed by some practical earth communicators that had it not been for the untimely intervention of HF radio, we would have been blessed by a highly-developed intercontinental cable network much sooner. Before the advent of space technology, this attitude may have had a degree of validity, albeit small. We realize now, however, the neatness with which the lower-frequency techniques are assuming their place in the pattern of requirements for space communications. Because of the past research into the vagaries of radio propagation and development of means to combat these, the new problems before us become much more tractable. The basic tools are available; still further refinement is needed.

The Compatible Technologies of Wire and Radio*

IVAN S. COGGESHALL†, FELLOW, IRE

Summary—**During the 50-year history of the Institute of Radio Engineers the respective technologies of wire and submarine cable telegraphy and telephony, on the one hand, and mobile and point-to-point radio, broadcasting, and television, on the other, have been commingled in an ever increasing degree. Initial contributions leading to the mutuality of the wire and radio branches of applied science came from pioneers who worked in both media. Subsequent discoveries were eagerly put to work in both, prompted by users' requirements for direct, end-to-end service. Opportunities for interchange of general communication engineering ideas and experience through the IRE were purposely fostered by its directorate from 1912 to 1962. An impressive list of exchanged benefits is attributable in part to the Institute's hospitable climate. An Appendix lists sources of information on the present status of wire communication, technical and organizational.**

Introduction

THROUGHOUT its 50-year history, the IRE has provided the men, terrain, and climate for ideas to undergo cross-pollination between the fields of wire and radio communication. Fenced-in frequencies protected the purity of their separate strains when the Institute was founded in 1912. But in the ensuing years, through the IRE's meetings, its adaptive organization, and the pages of its PROCEEDINGS, engineers, busy as bees in their deep probings of a flowering science, not only have caused the distinctions to be erased which classified the early genera of wire and wireless, but within the genera have transmutted their species: telegraphy, telephony, television, and data processing and control.

In 1962, raw bandwidth is being sold for end-use; and end-users, beholden to the miracle of their modulations only by the buttons they push, know not the successive channeling of their signals through courses of wire and space nor the modes nor the ducts whereof.

In 1912, telegraphy and telephony were clearly differentiated. In the 1920's and 1930's a first integration was occasioned by the vacuum tube; the two arts adopted identical techniques of ac modulating higher frequencies, in the form of code, voice, and photographs. A second integration followed World War II. The miniscular subdivision of time brought about by multiplexing and television scanning, the entry of binary dc computers into the field of megacycle communication, the time refinements of pulsed radar, and the realization that even speech and music could be converted into yes-no code by a sampling process, all conspired to reveal the digital pulse as the ultimate communication building block of Nature. Once the informational bit began to preoccupy engineering thought, telegraphy, telephony, and television could never again appear otherwise than as separate mutations of a single species.

So, after 50 years of the IRE, sight and sound, ideas and images, languages of men and stimuli of machines, together ride the carriers, stack upon stack, and are transferred willy-nilly between copper and air. Collectively they may find themselves poured through the same sieve and transmitted 0,1.

A Pioneering Spirit

Contemporaneously with and even antedating Marconi, there were a few physicists, acquainted with the mathematical findings of Faraday and Maxwell, the radiation experiments of Hertz, and the demonstrations of sound-resonance by Helmholtz, who conceived a pattern of unity in R, L, and C bridging the great gulf fixed between the frequencies of wire and wireless transmission.

Three of them—Stone, Kennelly, and Pupin—became the fourth, fifth, and sixth Presidents of the IRE. To their mathematical minds the wide separation in frequencies between radio and audio (using the terminology of today) offered no obstacles to a unified approach and solutions before the turn of the century; regardless of the fact that, at that time, radio was strictly a laboratory experiment holding great interest, while audio was a matter of field importance involving cross-country configurations.

Stone worked in the research laboratory of the American Bell Telephone Company, Boston, from 1890 to 1900. His early work on circuit resonance was with voice-frequencies on tone channels. His inductive and capacitative components in resonant circuits were substituted for the vibrating reeds unsuccessfully used by Bell in his search for a harmonic telegraph, out of which emerged the telephone. In 1894, Stone was using a voice-diaphragm-operated mechanical modulation of a high-frequency dc arc to generate a voice-bearing composite transmission signal over wires.

Pupin was adjunct Professor of Mathematical Physics at Columbia University, where he assembled units of L and C in circuits resonant to the harmonics of ac power. With them he demonstrated in 1893 what he named "electrical tuning" to his former professor, Helmholtz. When he applied for a patent that year, he found himself in interference with Stone.

* Received by the IRE, June 19, 1961.
† 670 Maywood Ave., Maywood, N. J.

Stone and Pupin were now working so close to the radio borderland that when the news broke in 1895 that Marconi was sending Morse messages by wireless over field distances, both were swept up in an endeavor to make additional contributions to the success of the new mode. Stone's researches led him to his loose-coupled "4-circuits" patent of 1900, which went into litigation against claims of Marconi, to whose American company Pupin sold all his wireless inventions outright in 1903.

In 1896, Pupin set about solving the problems of loading telephone lines inductively to decrease transmission losses. He deduced, from a shot-loaded, weightless, stretched-string mathematical model after La Grange, that on telephone spaced pairs on pole-lines and in multipair cable, the optimum relationship should be: $L>C>R$; hence that several lumped loadings should appear in each wavelength representing a frequency of interest in transmission. By attention to this detail he succeeded where predecessors had failed.

The 5th IRE President-to-be, A. E. Kennelly, worked as a submarine cable operator and ship's electrician with the Eastern Telegraph Company, London, before he came to the United States and became principal electrical assistant to Edison. From 1902 on, he was Professor of Electrical Engineering at Harvard and Massachusetts Institute of Technology. His nonradio specialties of value to radio included the mathematical treatment of oscillatory phenomena, acoustics, and the introduction of hyperbolic functions applied to ac.

Of such wide-ranging pioneers, was the IRE in its formative years.

A Benign Climate

From its beginnings, the Institute's terrain was what its members would have it. They expanded its field of influence year by year as accumulating knowledge made it expedient to cultivate new territories. But the unvarying, benign, hospitable climate with which it surrounded those engaged in "arts allied with radio," was purposefully created by the men who firmly directed its continuing policies and operations.

The founding fathers were radio men of broadest gauge. That they did not look askance at engineers in allied fields is witnessed from Volume 1, Part 1, paper No. 1 in the 1913 Proceedings; discussion:

> Pupin: I regard the one hundred thousand cycle alternators which General Electric Company produced for Mr. Fessenden, to deliver two kilowatts, as a triumph of mechanical and engineering skill.
>
> Goldsmith (*Editor*): . . . an excellent illustration of the courage needed to transfer ideas from one field of research to allied fields.

After the first three IRE Presidents had been drawn from eminently highly-placed wireless men, the next three, as related above, were chosen with full knowledge that before their conversion they had offered sacrifices to Moloch. Wire communication could not have been more highly honored. On the other hand, the versatility of such leaders to shift readily from laboratory to radio to open-wire and cable lines, and to find their way by the light of mathematical physics, cannot but have had an intellectually buoyant effect in a new organization which more than anything else wished to demonstrate engineering maturity.

Goldsmith led the Proceedings to unassailably high standards. They were read and the IRE meetings were regularly attended by many wire engineers who joined because of the "pull" of radio; or because of the stimulation, or direct usefulness in their work, of what they picked up; or because they liked the other people who were at the Institute or Section meetings or running the show.

The IRE poured the honor of scores of Fellowships upon men whose technical achievements spanned the wire and radio arts, bestowed upon 21 of them its most preciously held medals, entrusted 20 of them to help guide the Institute as Managers and Directors, and elected 9 of them Presidents. In the IRE's 50-year history, there was no period of five years when either the Medal of Honor or the Morris Liebman Memorial Prize, or both, or a number of these awards, did not go to recipients the value of whose achievements was shared by wire and radio communication. There were only four years in the 50 when the Board of Managers or Directors did not have in its membership at least one engineer whose reputation was established in both arts; and in 24 of the 50 years there were from three to five such men on the Board.

The mid-century Professional Group movement within the IRE supplied the finishing touches of radio's hospitality to its allied arts. Wire-oriented members were quick to avail themselves of alliance with radio men in groupings that both helped to create. At this writing the process of mutation goes on in the fields of microwave theory and techniques, vehicular communication, information and circuit theory, communication systems, and as many more areas of Professional Group interest.

A Lush Terrain

Radiocommunication had no need to invent either telegraphy or telephony. Marconi received from Morse a heritage which needed only adaptations, some of them difficult. By the same token, to Fessenden, Poulsen, De Forest, and other pioneers of radiotelephony around 1900–1907, Bell's invention had sprung full-blown from the head of Zeus.

By 1912, radiotelegraphy was well established as a maritime adjunct and was making valiant but feeble inroads on the traffic of wire telegraphs and the submarine cable. De Forest had invented, merchandised, but not tamed the vacuum tube. Within the realm of technology in the life of the people, his invention was to vie with the internal combustion engine as the most important socio-cultural, civilizing influence of the 20th Century. In expanding its utility, the IRE was to play a vital part. But before 1912 it had not come into its own.

In 1912, radio was suffering from want of amplification. Only the Rutherford-Marconi magnetic detector and Fessenden's arc-oscillated heterodyne receiver had received any at all, and in the latter, most favorable, case only the beat-energy to which a weak signal could contribute a component. Wire telegraphy was more fortunate, in dealing with frequencies so low that steady-state transmissions could provide enough received power to actuate relays; as a result the repeater art was well established. Submarine telegraphy had an amplifier of sorts in the hot-wire relay, but its gain was small and the technique applicable only to slow, galvanometer frequencies. But in long-distance telephony, power increments at repeaters were limited to those produced by microphones in battery circuits. Bell's harmonic telegraph had failed and Stone's carrier telephone channels had languished—either the received currents were too weak to vibrate the reeds or to survive the attenuation of tuned circuits.

Nineteen-twelve, the year of the IRE's birth, was in at least four other respects a significant wire-radio landmark. Arnold of Bell and Langmuir of General Electric pumped life into De Forest's vacuum tube. De Forest sold his wire rights in it to the telephone company and he began using tube circuits in cascade. He and others learned how to control them as oscillators and with feedback or regeneration.

In retrospect, it was "the year the dam broke." Released were the pent-up frustrations which hitherto had limited radio to the trickle of energy rectified from its antennas, and wires and cables to bandwidths and distances achievable within the strictures of signal attenuation. New found flood waters of local power distantly valved would thereafter course through prepared channels, bringing fresh life to a lush terrain.

By the time of the broadcasting and shortwave achievements of the 1920's, remote pick-ups and end-to-end sequences of wire and radio preoccupied their engineers domestically and internationally in shared problems and shared triumphs of quality improvements, traffic bandwidth stretching, and distance records. It was like the confluence of two streams of technology, both fed from headwaters in Europe and North America, mingling before being joined downstream by electronic tributaries rising in noncommunication sources. This figure of speech can be documented:

Wire Telegraphy's Assistance to Radio

Basic were the audible Morse and Continental code systems. Siphon recorders and undulators were adopted by radio from landline ocean cable arts. High-speed telegraphy, much favored in radio, stemmed from wire Wheatstone.

Wire telegraphy furnished the high-speed mechanical relay. Thyratrons, as substitutes for relays, were first used on telegraph cables. Repeaters, both telegraph and telephone, were developed for wire use. Wire rotary repeaters first utilized the principle of regeneration of unit signal pulses.

The uniform 5-unit printer code and its 7-unit start-stop version came from the wires, as indeed did machine telegraphy generally with its perforators, tape transmitters, page and tape printers and reperforators. Storage of signals, now universal in radio and computers, originally was employed on wires in holes-in-tape embodiment; so were machine encryption, multiple-storage, sequential, flip-flop, and programmed release, and demand read-out. The idea of interrupting and holding the flow of transmission enroute for the interpolation of pulses, characters, printer-control and switching functions, and stored information, came from wire telegraph and cable arts.

Simultaneous two-way operation, synchronism and isochronism of sending and receiving apparatus, and facsimile transmission and telephotography were worked out on landlines, together with the Nipkow-disk application of scanning as an unfolder of time-spatial relationships utilized in television. Time-division multiplexing by the interlacing of channels was a wire-art extension of synchronism. The Varioplex and Tasi systems of switching, making available to other users the line capacity of temporarily idle channels, were contributions of landline telegraphy and cable telephony, respectively.

Telegraph wire systems produced teletypewriter exchanges, reperforator-switching offices, automatically switched telex exchanges (from Europe), and customers' private wire systems.

From the telegraph wires and cables came initial steps in circuit network theory, in their artificial lines and employment of sending-end curbing and receiving-end shaping of signals; and the selenium cell, forerunner of the phototube.

Wire-Telephony's Assistance to Radio

Basic were the microphone, the telephone receiver, and amplitude modulation. Plug-and-jack circuits and multicontact Craft relays provided the essentials of manual and remote switching. Wire telephony also furnished the essentials of machine switching, dial controlled.

The wire-telephone art pioneered the frequency fundamentals of speech analysis, stereophonic sound, the theory of sidebands, a succession of "laws" in information theory, and the decibel system of measurement.

Out of telephone carrier technics came filtering, suppressed-carrier, and single-sideband practices; also speech inversion, compression, and scrambling; a number of types of pulse modulation, and practical negative-feedback amplifiers.

Wire telephony is credited with pioneer use of the "hard" vacuum tube. From telephone sources came nonlinear circuit elements: the varistor, thermistor, and transistor—the latter, in its versatility, constituting something of a writing off of indebtedness to radio for the vacuum tube and its circuitry.

The telephone system was first in communication to adapt the relay and vacuum tube to digital arithmetic of radix 2, and to the logic processes of Boolean algebra. Coaxial cables and waveguides, useful in radio installations, also came from wire telephone art.

Radio's Assistance to the Wire Arts

By far the most valuable single gift in the entire two-way exchange was De Forest's vacuum tube with control-grid and B-battery. Radio also contributed C-battery grid bias, tubes in cascade, the stabilizing screen-grid and other multielement tubes. The older and less spectacular radio crystal- and VT-diodes also served the wire arts.

Radio adopted, improved upon, and handed back to the wires better components like microphones and loudspeakers; or speeded them up, as in the case of telegraph recorders. Public demand, created by the wide acceptance of higher-fidelity radio broadcasting, caused the broadening of the commercially acceptable speech band; and radio produced frequency modulation. The radio public also brought into being the ac-dc power pack and the ac heated cathode. Automatic gain controls evolved from radio's meeting its AM transmission problems; piezoelectric frequency stabilizers were originally used to prevent radio transmitter drift. Error detection and correction in radiotelegraphy also were inventions to overcome transmission vagaries. All have been adopted to advantage by the wire companies.

The heterodyne reached perfection in radio; the earliest form of magnetic amplifier appeared there. Proximity fuses, rockets and satellites spurred radio to initial supremacy in printed circuits, modular construction, and microminiaturization.

It is not far-fetched to classify the IRE as one of radio's gifts to wire communication. Certainly the list under this subheading would be much longer had the fraternizing of engineers under the IRE not been so complete that inventions were adopted as hybrids on wire lines and in radio simultaneously and thus lost their identity as "gifts" of one to the other. American innovations were the more quickly put to use in tandem wire and radio circuit sections because wire, radio, and, later, submarine cables came together in one principal corporate organization. British inventions, particularly in globe-girdling shortwave telegraphy, had an advantage over American developments by virtue of corporate unity of cables and wireless, to which the Post Office landlines later were added.

Under such consolidations, determination of the realm of first application is of secondary interest and leads to omitting in the listing certain major items, like television and color TV, where landline demonstrations may have preceded first use on radio (or vice versa) but where neither branch of the art could thereby be held to be in obligation to the other.

Conclusion

It would be trite to say the trend outlined in the foregoing will continue. The thing has been done. More indicative of the future is the close involvement of communication *in toto*, as a transmitter of electrical intelligence, with electronic, nonlanguage, thought simulators like computers and servomechanisms, applied to machine sensing, memory, logic, and control.

This narrative perforce has had nothing to say about communication's pioneering spirit in the discovery of electronic bypaths. Discoveries there have been many and constant, but none more significant to the future than the route uncovered, by way of radar and video, to the speechless realm which lies between engineering and psychology. Here, where the techniques of mark-space find analogies in the yes-no elemental reactions of brain and nervous system, electricity bids fair to take over the repetitive tasks of man's mind and his directing hand much as in the past electric power helped emancipate him from muscular drudgery. For telecommunication engineers happy to accept challenges, what a wonderful approach to tomorrow's far horizons!

Appendix

The space allotted to this article featuring wire communication precluded adequate survey of the present state of the wire art or estimates of its future—both of which are desirable in a commemorative issue likely to be referred to, say, 25 and 50 years hence. Fortunately, reference may be made to several recent articles written expressly for those purposes, and the author's responsibility discharged in that way.

1) *Present technical status.* Two new chapters were added by Keith Henney, Editor, in the 5th edition of his handbook:

I. S. Coggeshall, "Wire telegraphy," ch. 27 (66 pp);
H. A. Affel, "Telephony," in "Radio Engineering Handbook," McGraw-Hill Book Co., New York, N. Y., ch. 28 (51 pp.); 1959. (Bibliographies.)

2) *Looking 25 years ahead.* To celebrate its 75th anniversary, the American Institute of Electrical Engineers had four articles prepared:

E. I. Green, "The evolving technology of communication," "*Elec. Engrg.*," vol. 78, pp. 470–480; May, 1959.
H. I. Romnes, "Advances in communication," *Elect. Engrg.*, vol. 78, pp. 481–492; May, 1959.
I. S. Coggeshall, "Telegraphy's next 25 years," *Elect. Engrg.*, vol. 78, pp. 493–499; May, 1959.
W. P. Marshall, "Electrical intelligence and power—A trusteeship," *Elect. Engrg.*, vol. 78, pp. 808–810; August, 1959.

3) *Encyclopedic-type articles.* The article by Green was prepared for "Encyclopaedia Britannica;" the other reference contains many short articles on facets of wire communication:

E. I. Green, "Telephone," *Bell Sys. Tech. J.*, vol. 37, pp. 289–338; March, 1958.

Modulation Methods*

RAYMOND A. HEISING†, FELLOW, IRE

***Summary*—This paper covers briefly the early radio telephone experiments with efforts by the various inventors to modulate spark, arc and alternator outputs with microphones of various kinds, and also with variable reactances controlled by voice signals. The development of the high-vacuum triode provided a basis for a completely new art, both in sustained wave generation, and in modulation. A few of the methods of modulation by the triode, as well as the development of the first practical radio telephone which led the way to early broadcast transmitters, are outlined. The discovery of sidebands with its early influence on transmitter circuits, which led to channel spacing, and also to single sideband use for ether space conservation, is mentioned. The early fumbling with frequency modulation and then the eventual discovery of how it could be used to advantage is outlined. Pulse-modulation systems, which have not yet reached their full development, are covered briefly. Nothing is given about modulation methods for the infrared optical waves for which methods of generation have lately been discovered, but for which modulation methods have not yet been published.**

Introduction

THE word "modulate" did not originate in the radio field. Like many other words, it was adopted in radio because its prior meaning appeared to be expressive of a certain action that was a necessary part of radio. Basically it means: "to proportion; to adjust; to vary; to alter; to deviate; to diverge; or to change." In speech it meant to vary or inflect the sound in such a manner as to give expression to what is uttered, or to vary (the voice) in tone. In music it meant to change the key or mode of, in the course of composition.

When adapted to radio, it originally meant to vary in some suitable manner the character of a radio wave so as to cause the latter to act as a carrier of speech or music. Shortly after radio and carrier systems came into extensive use, some engineers began to use the word to mean the interaction in a circuit of one wave upon another without regard to communication. In the early standardization by the Institute, the definition restricted its use to signalling. However, some engineers continued to use it in the broader circuital sense, and so the definition has been broadened.

The earliest use of the word in radio was found by the author in an article by Fessenden in *The Electrical Review*, February 15, 1907. It next appears in books by J. A. Fleming and Prof. G. W. Pierce, both in 1910. Prior to 1910, most radio experimenters used *modify*, *control*, *vary*, *mould*, with *control* used in the majority of cases. In Telegraphy, *keying* was used.

Early History

The early experimenters appeared interested only in AM. Fessenden, in 1902, proposed using a condenser type of microphone in circuits that appear to produce FM, but in his published remarks about tests he seemed interested in using the frequency variation to produce amplitude variation by throwing the frequency in and

* Received by the IRE, June 6, 1961.
† 232 Oak Ridge Ave., Summit, N. J.

out of resonance with the antenna or other tuned circuit to modulate the amplitude. Fessenden used the Elihu Thomson (Duddell) arc in the early 1900's and keyed the waves by shunting part of the inductance, thus using FM in telegraphy. There is no clear idea that he was interested in, or tested, FM telephony as such. The earliest discussion on FM in telephony is a short item in a book by Dr. A. N. Goldsmith in 1918.

It is interesting to note that none of the early experimenters discovered sidebands. Several of them have mentioned a phenomenon they called the "fly-wheel effect" in that they were aware that a tuned circuit or antenna might not permit the radio wave to build up, or die down fast enough to handle the higher rates of variation required by the higher frequencies in the voice. Solutions were not provided, but the discussions appear to put the blame on the inductance in the circuit, and it was thought that careful design would overcome the trouble. However, no suggestions were made as to just how to do this. Others believed that the only limit to the number of channels to be secured depended upon how low the resistance of the antenna circuit could be made. No equation for a modulated wave is found in the literature prior to World War I. So far as the author has any direct knowledge, the equation was first set up and side frequencies discovered by Carl Englund in 1914. The disclosure to the armed forces during World War I and to the public afterward stemmed from Englund's discovery. It is true that some engineers of the American Telephone and Telegraph Company seem to have had earlier knowledge of the sidebands from their study of carrier-system theory for wire lines, but the perusal of their memoranda and other company writings has not turned up a prior discoverer. Dr. G. A. Campbell (AT&T Company) believed their knowledge was derived from mathematical expressions in Rayleigh's *Theory of Sound* involving periodically interrupted sound tones.

Knowledge of sidebands led to departures in antenna adjustments from the practices in radio telegraphy. In the AT&T Company tests of 1915, closer coupling of the antenna circuit to the power tubes than the adjustment for maximum power was resorted to in order to bring up the side frequencies. In the General Electric Company work of early 1919 providing a ship-shore circuit for President Wilson while traveling to Europe, the shore antenna was tuned to one sideband with an arrangement to accentuate the carrier.

The early radio telephone tests were made using spark systems, where the spark rate was pushed up as high as 10,000 cps. The noise convinced the experimenters that sustained waves were preferable, and efforts were made to devise sustained wave generators. Fessenden used arcs in 1902, as did others about that time, while Alexanderson and associates developed HF generators, one of which was used by Fessenden in 1904. Fessenden appears to have dropped his spark and arc work with the appearance of generators, but the development of these devices was continued both here and in Europe for a decade. Poulsen had developed a usable arc by 1904, and various forms of arcs were used by a large number of experimenters in Europe, and a few in the United States. Attempts were made on both continents to devise usable spark systems and some were put on the market with little success.

As generators of suitable HF waves were developed, circuits and devices were invented for modulating the waves. The carbon button microphone would not handle sufficient power to modulate the RF power that was to be used. There began, then, efforts to try to find circuits that would utilize the microphone more efficiently. The microphone was tried in the antenna circuit, then in shunt to the antenna coil, or with part of the coil, in a circuit coupled to the antenna and in numerous other positions. It was evident that a new problem had arisen.

In 1907 Fessenden said, "The difficult problem in wireless telephone is, of course, the modulation of the large amount of energy used for transmission." In 1910 J. A. Fleming said in, *The Principles of Electric Wave Telegraphy and Telephony*, "The difficulties still outstanding in radio telephone are largely those of modulating large high-frequency currents by means of some form of speaking microphone . . . " and again "The chief difficulty which presents itself in connection with radio telephony is that of modulating the oscillations of sufficient intensity in the sending antenna by means of some suitable form of microphone."

All experimenters, most of whom were European, began by using a single simple microphone. After overheating appeared, they began making efforts to surmount or avoid that trouble. It is interesting to see the extent to which they went to devise suitable modulators of the variable resistance type.

Poulsen used six microphones in series connected to one mouthpiece. Colin and Jeance used two microphones, switching from one to the other when one heated. Ditcham used two microphones at a time with several pairs of microphones on a turntable so he could quickly rotate it and switch from one set to the next. Lorenz used 25 microphones in parallel connected to one mouthpiece. De Forest used a microphone shaker that was periodically operated. Goldschmidt used several microphones at a time in parallel, with transformers arranged to divide the load between them and prevent one from taking all the load upon its resistance dropping with heating. Fessenden devised a special microphone that was water jacketed as well as having other advantages of design. Dubilier devised a form of wire-to-radio modulating relay using water cooled carbon-containing elements. Jahnke and Tate passed alcohol through their granulated carbon in their microphone to keep it cool. Berliner devised a heavy-current microphone with fan cooling. Egner-Holmstrom used 16 small carbon buttons, oil cooled, and connected to a single diaphragm. Marzi devised a microphone as part of a telephone relay in which powdered carbon passed from a hopper through a specially shaped carbon button, during operation. Majorana devised a liquid microphone in which he vibrated one side of an opening from which a fine even stream of acidulated water issued so as to transfer the speech wave form to the falling stream of water, and the stream passed onto two electrodes in the RF circuit. Good results were secured. Chambers devised a liquid microphone in which an electrolyte emerged vertically from a flat ended nozzle against the vibrating diaphragm and the thickness of the film of water was varied by the speech sounds so as to provide the modulating resistance. Vanni devised a liquid microphone in which a stream of acidulated water fell between two specially shaped electrodes, one of which was vibrated by a connection to a diaphragm.

Fessenden tried variable reactances. He made the tests mentioned earlier with a condenser microphone. He also planned to secure modulation by means of a variable inductance in which the inductance contained iron, and its permeability was varied by means of a variable current from a microphone. This appears to be the first "magnetic amplifier," but it is not known if he made use of it or not.[1]

Alexanderson and Nixdorff in 1916 published their paper describing their magnetic amplifier and its use in wireless telephony. They used it for modulating the output of Alexanderson's HF alternators.

During 1911 and 1912, Fritz Lowenstein, Lee De Forest, E. H. Armstrong, and Alexander Meissner (with gas tube) observed that the thermionic triode could generate oscillations. The last three filed patent applications in the United States and the litigation following was not ended until 1930. Though De Forest prevailed in the litigation, it was Armstrong who educated the engineering profession in the audion's possibilities. With the development of high-power vacuum tubes a few years later, the efforts of using arcs or alternating current generators of high frequency for radio telephony came to an end, though both devices continued in use in telegraphy until recently.

In 1912 De Forest's audion was called to the attention of both I. Langmuir of the General Electric Company and H. D. Arnold of the Western Electric Company. They both conceived of improving the vacuum and securing more power than De Forest's original tubes would give. With the respective assistance of W. C. White and H. J. van der Bijl, they converted the audion into a modulation device as well as a good amplifier. Langmuir and Arnold both filed patent applications on the improvement, and the litigation that followed went to the Supreme Court before being settled.

Alexanderson appears to have been the first to conceive of using the audion as a variable resistance to use as a modulator in modulating the output of his alternators. In the Western Electric Company, Colpitts conceived of using it as an oscillator that could be modulated by impressing a signal voltage upon the grid. Colpitts knew from telephone experience with mechanical audio amplifiers that oscillations could be generated in an amplifier if some of the output energy got back into the input. Apparently he didn't know just how to secure this action with the vacuum tube so he devised a circuit with many elements whose actual mode of operation is uncertain, and secured a patent.[2] Logwood, working with De Forest, devised a simpler oscillator circuit with means for impressing the audio signal upon the grid, and this circuit was used in 1916 by De Forest in broadcasting around New York.

H. J. Round in England devised a circuit in 1914 with a vacuum tube oscillator, but he used an ordinary microphone for modulating the output. In the earlier form, the output was fed to an antenna and the microphone was inserted in the antenna. In a later form, the output was modulated by a microphone and fed to a second tube which acted as amplifier and delivered its output to the antenna. The author does not know to what extent these sets might have gone into actual use.

Practical Applications

In the Western Electric Company, van der Bijl in 1913 observed that the improved triode had a square law characteristic curve. He conceived the idea of utilizing the variable slope of the curve to produce a modulated wave, such wave to be amplified to a desired power in a later stage. A small HF voltage, and a larger signal voltage were to be applied to the grid of the tube, and the HF output was to be amplified as much as needed. This system of modulation was used in the Bell System tests of 1915 in which speech was transmitted various distances, eventually reaching San Francisco, Panama, Hawaii and Paris, with the transmitter located at the U. S. Naval Radio Station in Washington, D. C. (June to October, 1915).

The author, then in the Research Department of the Western Electric Company (which later became part of the Bell Telephone Laboratories), devised several transmitter circuits using a vacuum tube as an oscillator and a second one as a modulator arranged in various ways. Two of the systems were plate-modulating systems, and two were grid-modulating systems. In the plate-modulating systems, the oscillator and modulator were in series in one system with a constant potential power supply, and in the second were in parallel on a constant current supply. In the grid-modulating systems, one utilized a large RF voltage, and a medium signal voltage on the grid, and the second system utilized a modulator tube with two grids, on one of which the HF voltage was impressed and on the other the signal voltage

[1] Fuller descriptions of these devices may be found in J. Zanneck, "Wireless Telegraphy," Dr. A. Enke, Stuttgart, 1912. (In German.) Translated by A. E. Seelig in 1915, McGraw-Hill Book Co., Inc., New York, N. Y. Also see A. N. Goldsmith, "Radio Telephony," Wireless Press, New York, N. Y.; 1918.

[2] Not to be confused with the simple oscillator circuit known as the "Colpitts oscillator."

was impressed. The HF output was amplified to the desired power. Also a circuit was devised using a rectifier as a modulator, where both the HF and the signal waves were impressed in series with the rectifier and its output circuit. The output was amplified when necessary. It might be noted that the first wire carrier systems used van der Bijl's modulating system, with a single sideband as proposed by Carson. Later, the triode modulators were replaced by rectifiers as modulators.

During this period, W. C. White of the General Electric Company came up with some modulating systems resulting in a complicated patent situation on radio transmitters such that no one could build equipment for commercial use until arrangements were made to exchange licenses.

In 1917, upon our entry into the war, the author was appointed a member of the subcommittee on Wireless Communication between Aircraft, of the National Research Council, and was called upon to develop a radio telephone transmitter for aircraft use. He chose one of his own inventions, a circuit that was simple and easy to adjust, and which is known as the "constant current modulating system." The radio sets known as the SCR 67 and 68 were the first ones developed for the Army, and the CW 936 for the Navy. Thousands of these sets were manufactured for the government before the war was over. Some of the CW 936 sets were used as transmitters in the early days of broadcasting. These two developments were probably the first successful practical radio telephone sets made.

The use of double modulation in radio telephony, involving a frequency intermediate between the carrier and signal frequencies, was conceived by Hammond as evidenced by a patent[3] filed in 1912. The author independently devised an operable double-modulation system in 1915[4] in which one or more speech signals individually modulated one of a series of spaced superaudible intermediate carriers, and all of the latter, then modulated a higher radio carrier. Experimental equipment utilizing the system was lent the Navy in January 1917. A modified form involving single sideband[5] was employed in the transoceanic long-wave system, demonstrated for one channel, one way to England on January 5, 1923, and it has been employed in multiplex form[6] on wire carrier and UHF radio systems since to shift an entire group of single-sideband channels from a frequency region where the single sideband is easily separable, to much higher regions in the frequency spectrum. Double detection is employed in reception.

A closely similar type of modulation is that devised by Kendall[7] for use at a radio repeater station in which a radio signal coming in on one frequency is shifted to a different outgoing frequency in a single step similar to the converter step in the superheterodyne receiver. It is widely used in radio relay stations.

HF carrier systems on wire lines were proposed before radio appeared on the scene. They began as "harmonic telegraph" systems, and are associated with the names of Gray, Bell, Edison, Mercadier and others. In the telephone field they appeared with Pupin, and Hutin and Leblanc in 1892, and with others following, such as Gibboney, J. Stone Stone, and Ruhmer. Arcs and high-frequency alternators were proposed as generators. Stone mechanically moved one electrode of the arc in modulation while the others were used microphones. None of the systems showed much promise because of the arc and high-frequency alternator required, together with modulation difficulties. About 1910 General Squier began tests in this field. Bell System work with an all-audion system, and the van der Bijl modulation system began in 1914, utilized Carson's idea of single sideband without carrier. In 1916 the first equipment was installed on wire lines between South Bend, Ind., and Toledo, Ohio. Since that time numerous advances have been made, one of which, from the modulating standpoint, was the use of rectifiers instead of vacuum tubes as modulators.

The carrier systems on wire are almost all of the single-sideband type without carrier. A device necessary for their original success was the band-pass filter. About 1909, G. A. Campbell discovered how to construct networks with substantially flat transmission characteristics over a band of frequencies and rapid attenuation outside. Their use enabled one sideband to be selected and the other sideband rejected with a carrier as high as 30 kc in the early installations (1916). As better magnetic materials became available in later years, higher carriers could be employed. With piezoelectric resonators used in the filters, carriers in the hundreds of kilocycles are possible. In all these systems, the carrier, if eliminated, is eliminated by a balanced modulating circuit, either of triodes or rectifiers.

Frequency Modulation

Radio telephone devices and tests so far discussed were all for AM, FM or "wavelength" modulation is occasionally mentioned in the early literature, but not favorably. The establishment of broadcasting and the spacing of channels 10 kc apart caused many engineers to give thought to how to narrow the band. FM was proposed. In 1922 J. R. Carson published his famous paper pointing out that FM would not provide a narrower band than AM, but might actually require a wider band. His analysis, however, led him to believe that FM inherently produced distortion in the signal and this he stated in his paper. For a time this subject seemed to have been disposed of. However, a few years later others who must not have noticed Carson's paper began working on the subject again under the impression "that the necessary frequency band for each transmitter may be reduced to any desired minimum." The

[3] J. H. Hammond, U. S. Patent No. 1,491,774; 1912.
[4] R. A. Heising, U. S. Patent No. 1,633,100; 1927.
[5] R. A. Heising, U. S. Patent No. 1,675,888; 1928.
[6] R. A. Heising, U. S. Patent No. 1,690,227; 1928.
[7] B. W. Kendall, U. S. Patent No. 1,734,132; 1929.

expected results did not materialize upon making tests, and published analyses by others supported most of what Carson had said. However, E. H. Armstrong who had been trying to circumvent static for many years discovered that if one widened the swing in FM much beyond the bandwidth used in AM, and used an effective limiter in the receiver, noise lower than the carrier could be substantially eliminated. This was an unexpected discovery, because it had been previously shown in connection with AM systems that once the noise got into the circuit nothing could be done to eliminate it without eliminating part or all of the signal. This property in a FM system, together with the "capture effect" and other advantages have resulted in the wide use of FM.

Any analysis of FM brings forth the subject of "phase modulation" as frequency shift and phase shift go hand in hand. Frequency and phase modulation transmitters may be used interchangeably by proper predistortion of the signal wave.

FM of a master oscillator may be produced in small amounts by variation in plate voltage, in larger amounts by a variable resistance (a triode with the signal on its grid) across the inductance or capacitance of the oscillator circuit, by variably introducing a 90° component, by core saturation of the inductance, as well as by numerous other arrangements. To insure that the carrier has suitable frequency stability, phase modulators excited by piezoelectric oscillators are often used. A phase-modulated wave of less than ±30° phase swing is the equivalent of an AM wave with the carrier shifted 90° from its amplitude position. By using a balanced modulator to produce the two sidebands without the carrier, and then adding the carrier shifted 90°, the phase-modulated wave can be originated using a crystal master oscillator. The correction circuit mentioned above must be used when FM is desired. Harmonic step-up increases the frequency and the frequency swing up to any desired amount.

Pulse Modulation

Modulation methods and devices are designed to go with the type of HF generator used and fit into the communication system involved. The systems discussed so far are for AM and FM and involve frequency selection to separate channels. Before the frequency selection systems were in commercial use in telephony, time-division systems were in use in wire telegraphy. Such systems arrange to synchronously switch a wire channel between sets of transmitting and receiving telegraph devices. These systems came into wide use with the printing telegraph. In a common system, a 5 dot code, called the Baudot code, formed the basis, where the various combinations of the 5 dots in their positions were transmitted or omitted, and the 32 combinations possible permitted covering the 26 letters of the alphabet, space between words, punctuations, shifting to figures, etc. In the synchronous printing telegraph, a full set of 5 "bits" or pulses were transmitted while one pair of instruments had the line, and the character was printed while the line was in use by others. Such a system had one advantage over frequency selection systems in that all pulses were of the same amplitude, and when repeated at a repeater station by relay-type devices, constant amplitude pulses were regenerated and sent out so no accumulation of noise is built up by successive repeatings. This, together with the difficulties of frequency selections at very high frequencies, led to the study of using pulse modulation and transmission systems in telephony. The principal systems are called:

pulse amplitude modulation	PAM
pulse duration modulation	PDM
pulse position modulation	PPM
pulse code modulation	PCM.

In the printing telegraph, the switching rate of the channel between users is slower than the rate of transmission of pulses. In telephony, that is not possible. In practice, the speech signal is sampled—say 6000 times a second if 3000 c is the highest frequency to be transmitted. One of the pulse-modulation systems is then utilized to convey to the receiving end information as to the magnitude of each and every pulse in succession. In pulse amplitude modulation, each pulse is of suitable short duration, and could be unidirectional in character in the apparatus at the ends, but is transmitted as a short burst of high frequency. The PAM pulses are transmitted, as generated, in time and amplitude. The length of each pulse will depend upon how many channels are planned, as pulses for the several channels will be interspersed.

In PAM the pulses may be produced in a variety of ways such as by a flip-flop circuit stable on one side, which remains on the other side for a suitably short time. The short pulses are then amplitude controlled in any of numerous ways used in AM that do not destroy their length. At the receiving location, after detection, a low-pass filter of 3000 c will average out the pulses into the original complex signal. Multiplexing will require synchronous switching of the channel between pulses to other users. This system is not free of noise accumulation problems on passing through a repeater as the pulses repeated must be proportioned to the amplitude of the incoming pulses.

In PDM the pulses can be produced in numerous ways. A simple manner is to apply the signal directly to the flip-flop circuit so as to control or modulate the duration of the "flip." This system, because of variation of pulse lengths, will not permit of as many channels upon multiplexing as PAM for the same average pulse length. However, all pulses are of the same amplitude, and suitable constant amplitude repeaters can avoid much noise accumulation. Reception, after detection, requires only a low-pass filter to smooth out the pulses.

Pulse position modulation depends upon the movement of pulses away from and toward a mean position, or back and forth across it to represent the amplitude being conveyed. It resembles in a way phase modulation. An early way of generating these pulses is to first generate pulses by PDM and then differentiate them, utilizing a uniconducting arrangement to pass pulses of one sign only.

Pulse code modulation utilizes a code to represent the amplitude of the sampling pulses. A common one is to use the code for the Baudot telegraph system in which a group of pulses 5 in number identify certain amplitudes instead of alphabetical characters. The code does not necessarily have to use 5 pulses, but can start with 2, and extend upward. The codes will not represent each and every gradation in a signal wave, but only a certain number of discrete amplitudes. A sine wave signal will be represented by a wave that possesses only horizontal and vertical components and will zig-zag back and forth across the sine wave trace. The wave will be approximated, or "quantized." The wave will approach the sine wave more and more as the number of pulses in a character is increased.

In PCM the pulses in a group represent different components of magnitude of the sample in geometrical relation 1, 2, 4, 8, etc., and in the receiver must each contribute its component to the resultant pulse. The circuits and devices for generating the code and reproducing the original sampling pulse are too numerous to describe in this article.[8]

Miscellaneous

With the invention of new devices for generating the extra high frequencies coming into general use, new methods and circuits for modulation have been devised. The reflex klystron, generating frequencies in the thousands of kilocycles, is used for pulse systems, and also for FM sustained wave telephony. The frequency varies with applied voltage and so it provides a convenient generator and modulator combined for FM. The two-cavity klystron is used largely as an amplifier, but can be used for generating oscillations. The traveling-wave tube, which operates at higher frequencies than the klystrons, is largely used as an amplifier. The magnetron can be made for operation in most parts of the radio spectrum and can deliver large amounts of power. It is used in pulse systems, especially radar systems. Electro-optical devices have been devised that will generate radiations in the infrared region and have been tested for telephony. The methods of modulating them have not been publicized.

Transmitters*

JAMES O. WELDON†, FELLOW, IRE

Summary—**The evolution of the type, form and scope of radio transmitters is traceable from the nascent technology of not yet a century ago to today's elaborately sophisticated systems, among which are included radar, multichannel microwave, aircraft and marine communications and navigation and commercial broadcast. Apparatus and techniques progressed from the early spark and arc transmitters to alternators of various designs and powers, through the era of the first vacuum-tube transmitters to the later highly efficient vacuum-tube types. More recently, transmitter design has utilized high-power tetrode and klystron amplifiers. Although code signaling was the first practical method of communicating intelligence, interest in voice transmission resulted in concurrent efforts to adapt the then existing transmitters to this purpose. The discovery of ionospheric phenomena permitted advances into areas of transmitter development previously considered impractical for other than short-distance communications. Regulations governing transmitter power, frequency and use were established by government agency as the need became apparent. The regulations have been adjusted to keep pace with the increase in power capabilities and the use of the frequency spectrum as the trend continues toward higher-power transmitters.**

* Received by the IRE, August 2, 1961.

IT is interesting to note the progress of the entire field of electromagnetic phenomena which has taken place since the inspired mathematical formulation of the electromagnetic theory by James C. Maxwell in 1864. Twenty-two years later, in 1886, Heinrich Hertz successfully demonstrated the truth of Maxwell's equations, and thirty-seven years later radio communications first became a reality with the transmission and reception of the first feeble code signals across the Atlantic by Marconi in 1901.

All the progress from Maxwell to the present has taken place during the lifetime of some older people, and almost all the progress has taken place during the last thirty years, within the life-span of our younger engineers.

The first emphasis was naturally upon communications for ships at sea, and the first interest in transmitter development was for ship-to-shore and ship-to-ship use. The spark transmitter, the only known system at that time, became the subject of intensive development. Considering the existing state of the art and the fundamental limitations of the spark transmitter itself, the development which followed was amazing.

From the open-spark direct-excitation method, with antenna selectivity only, elaborate circuitry evolved to reduce the bandwidth. The energy source, initially a battery and induction coil with a vibrating interrupter, developed into the alternator and step-up power transformer. The spark-gap underwent several stages of development from the simple 2-electrode gap to the non-synchronous and synchronous rotary gap, the quenched gap and other variations. The power of such transmitters was continuously increased until shore stations rated at 100 kw were common. Spark transmitters emitting damped waves for telegraph communications continued to be popular and were extensively used, on wavelengths between 600 and 800 m, as late as 1930.

In about 1912, the dominance of the spark transmitter was challenged by the arc transmitter. The Danish scientist, Valdemar Poulsen, invented the Poulsen arc in 1903, following original work by Elihu Thomson in 1892. Fig. 1 is a photograph of the first Poulsen arc brought to the United States. As early as 1912, 30-kw arc transmitters used by the Navy established communication between Arlington, Va., and Mare Island, Calif., and later from Arlington to Honolulu, Hawaii. Before vacuum-tube transmitters began replacing the older systems, arc transmitters rated as high as 1000 kw had been developed. The transmitter at the U. S. Navy LaFayette Station in Bordeaux, France, shown in Fig. 2, is an example. The arc transmitter represented the first introduction of continuous-wave telegraph systems.

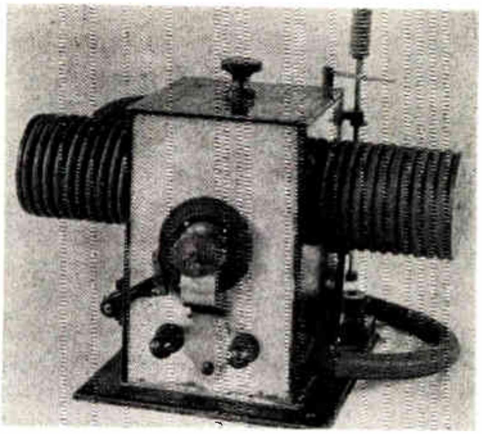

Fig. 1—First Poulsen arc brought to the U.S.A. from Denmark in 1909. Rated at 100 watts, it actually delivered about 50 w of RF power. With it, radio-telephone signals were sent from North Palo Alto to South Palo Alto, thereby demonstrating the efficacy of the Poulsen arc for radiotelephony. (Courtesy of *Electrical Communication*.)

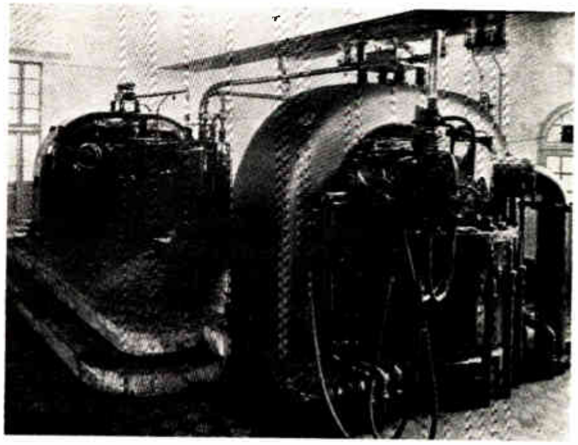

Fig. 2—Historic Lafayette radio transmitter station built by the Federal Telegraph Co. for the U. S. Navy near Bordeaux, France, during World War I. It was the largest transmitter ever built up to that time. (Courtesy of *Electrical Communication*.)

Another early system extensively used was the Alexanderson alternator, a high-speed, ac generator by which the high frequency was directly produced. Frequencies as high as 200 kc were generated in this manner with a machine having a capacity of about 1 kw; 2-kw machines generating up to 100 kc were constructed, and also higher-power machines at frequencies of 50 kc and lower. Such alternators rated as high as 200 kw have been constructed, and at least one is still operated by the U. S. Navy in Japan.

Another type, called the "Goldschmidt Alternator" after its developer, Dr. R. Goldschmidt, was based on a theory of conjugate rotating vectors, a principle different from the Alexanderson alternator. Alternators of this type, with the advantage of lower revolving speed relative to the output frequency, had a maximum output of 200 kw and a normal output of 100 kw. Such machines were used at Hanover, Germany, and at Tuckerton, N. J.

The Edison diode effect was controlled by the three-element vacuum tube invented by Dr. Lee De Forest in 1906. Fig. 3 is a three-stage De Forest audion amplifier of 1912. At that time it was considered a receiving device only. Vacuum-tube transmitter development followed at a much later date. Fig. 4 is a 400-w, LF transmitter built by the General Electric Company for the Signal Corps in 1923.

Extensive replacement of the older spark, arc, and alternator systems with communications transmitters using vacuum tubes for generating the radio frequency began in about 1927. With this major advancement in the state of the art, later transmitter development is related closely to several factors which shaped the requirements and directed the trend.

Fig. 3—Three-stage De Forest audion amplifier of the type first built by the Federal Telegraph Co. in 1912. This was the earliest known commercial cascade audio frequency amplifier, and was the type demonstrated to the U. S. Navy in September, 1912. (Courtesy of *Elec rical Communication.*)

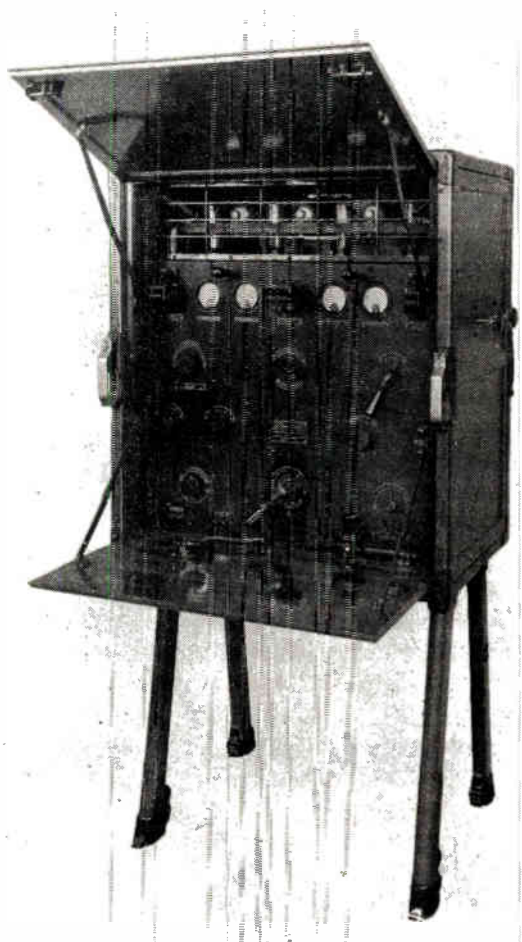

Fig. 4—Developed and designed, 1922–1923, by the General Electric Co., BC-127 400 watt, low frequency transmitter. It was transportable, and the first regular Signal Corps transmitter to use the MO-PA technique. Power-MG set. (Courtesy of *RCA.*)

Among the factors may be listed: 1) The rapidly expanding demand for such communications services by an increasing number of operating agencies. 2) The increasingly crowded condition of the frequency spectrum brought about by this demand, and by the use of the spectrum for types of services other than communications. 3) The continuous requirement for increasingly higher data rate to obtain greater use from a given frequency assignment. 4) Increasing knowledge regarding the modes of propagation of radio waves, permitting more intelligent assignment of frequencies to various types of services. 5) Collateral developments in circuitry, vacuum tubes and other components, which extended the state of the art and permitted transmitter improvement. Figs. 5 and 6 are representative of modern, high power transmitter installations.

International Morse Code was used for signaling by all the telegraph transmitters in use prior to the appearance of vacuum tube transmitters, and in all the early models of these. The International Morse Code characters were transmitted by interrupting the carrier (sometimes called "on-off" keying) to form the dots and dashes, with the interruptions of the carrier making the spaces between the elements of the characters. Variations of this type of transmission occurred in the case of the continuous-wave transmitters. In one method a "chopper" was keyed on and off to introduce interruptions into the continuous wave at an audio rate so that a tone could be heard. The carrier remained on continuously but, with the receiving systems used, it could not be heard except during the time it was interrupted at an audio rate by the chopper. Most of the receiving methods at that time required some modulation of the carrier for a signal to be heard. With the appearance of the vacuum tube receiving system, the regenerative detector and later the beat oscillator could be used to produce an audio note in the receiver so that reception of the continuous-wave signal with on-off keying became possible.

Keying was also accomplished by frequency shift on some of the earliest transmitters. Since the transmitter frequency was determined by the resonant antenna circuit and any associated resonant circuits, keying could be accomplished by short circuiting turns of an antenna inductor, for example, by means of a suitable contactor capable of carrying the current. The frequency of the carrier was shifted far enough by this method so the receiver tuned to it would not respond. The off-frequency radiation or "back side" of the signal was not used and, of course, represented a waste of spectrum space.

Because most of the receiving systems were designed to receive an interrupted carrier such as that generated by the spark transmitter rather than a continuous wave, many of the early vacuum-tube telegraph transmitters used ICW, interrupted continuous wave. The interruption was accomplished at an audible rate by a chopper similar to that previously described for use with the arc

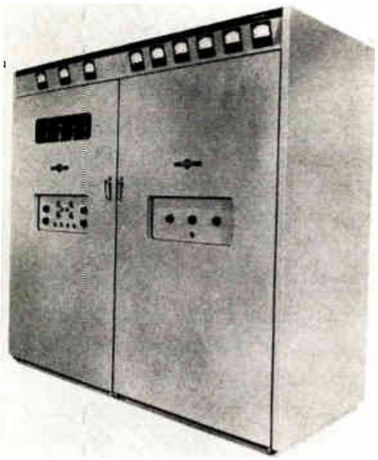

Fig. 5—Collins 205J-1 HF single-sideband power amplifier. This equipment is an automatically tuned 45-kw PEP linear power amplifier with an average power rating of 22.5 kw over the frequency range of 2 to 30 Mc. (Courtesy of *Collins Radio Co.*)

or alternator type transmitter. Spark transmitters were modified in some cases by the substitution of tubes, the anodes of which were supplied from the 500-c alternator through a suitable transformer. Thus, the ac supply to the anodes of the tube provided a modulation which made the signal audible to such receivers without the necessity of a chopper. These transmitters were classified as self-rectifying types.

The method of signaling by interruption of a continuous carrier, on-off keying, is still used in many types of simple transmitters and also in high-power, VLF transmitters where the Q of the antenna system so limits the bandwidth that the application of other methods is difficult, and where even the continuous-wave-type of keying is limited to as low as 25 words per minute because of the narrow bandwidth of the antenna. More sophisticated methods of keying have been adopted for most high speed point-to-point systems and for many communications systems to ships and aircraft. A popular method is that of frequency-shift keying, by which the frequency of transmission is shifted above the assigned frequency for the "mark" signal and below the assigned frequency for the "space" signal. This is at present one of the most popular methods for single-circuit teletype operation using the 5-pulse-character teletype code.

Another early development in signaling methods was the use of telephone or voice transmission. Attempts were made to apply voice transmission to spark transmitters with very little success. Considerable interest developed with the appearance of the arc transmitter, and Dr. Poulsen and Dr. P. O. Pederson demonstrated the transmission of wireless telephone signals by a continuous-wave arc transmitter in Denmark as early as 1909.

Other attempts at the transmission of voice by radio were made using the alternator type of transmitter, with modulation introduced into the antenna system by the absorption method or by modulating the current in the field coil of the generator. However, the completely successful development of telephone transmission came only with the vacuum-tube transmitter.

The system using suppressed carrier and single- or double-sideband signaling has become relatively important because of advantages with regard to selective fading and for the conservation of spectrum space. In such a system, a single sideband without the carrier is capable of carrying many independent teletype channels at signaling rates of up to 100 words per minute; or a sideband having a width of 3000 c can carry a single telephone conversation while the other sideband is used either for another voice channel or teletype channels. Transmitters capable of handling this type of signaling system represent an important part of contemporary communications systems.

Early frequency allocations were assigned to various types of service. Prof. J. H. Morecroft wrote, in 1920, "The laws of the United States specify the following wave lengths:

High Power Stations, over 1600 meters.
Navy, 600 to 1600 meters.
Ship Stations, 300, 450, 600 meters.
Amateurs, below 200 meters."

For transoceanic communications, wavelengths as long as 20,000 m, corresponding to a frequency of 15 kc, were used with transmitters utilizing as much power as the state of the art would permit. About this time, the amateurs assigned to frequencies of 1.5 Mc and higher, working with transmitters of a few watts or a few hundred watts, began making long distance contacts on frequencies up to 20 Mc.

The phenomenon of ionospheric reflection was discovered, and frequencies above 1.5 Mc, previously considered suitable only for short distances, became important for long-distance and transoceanic point-to-point communication. This started the development of many types of transmitters covering the frequency range from 4 up to 20 or 30 Mc. Because of diurnal and seasonal variations in the maximum usable frequency for a given distance, and the necessity for selecting the proper frequency as related to the distance between stations, requirements were established for transmitters capable of operating over wide frequency ranges with reasonably quick change from one frequency to another. Early transmitters of this type required discontinuation of operation while manual adjustment was made on inductors and capacitors. In some cases, interchange of conductors by plug-in methods was made to select a new frequency. Intensive development work, particularly for the military, has resulted in continuously decreasing the time required for frequency change. Transmitters were introduced wherein the tuning was accomplished by motors associated with a servo system so that a number of preset frequencies could be selected by a single switch, and the entire transmitter would align itself on the new frequency in a period of one or two minutes.

A further extension of the fast frequency change system is the application of automatic tuning, by which a stable variable-frequency oscillator is used to excite the transmitter and the tuned circuits of the transmitter are controlled by servo systems directed by impedance and phase-angle sensing devices, causing the system to adjust itself automatically to the applied frequency.

The wide variety of communications transmitters developed for service in the frequency range from 2 to 30 Mc covers a wide range of applications such as airborne transmitters, transmitters for teletype, telegraph and telephone, ship-to-shore and shore-to-ship, ground-to-air, ground-to-ground, higher-power long-distance point-to-point transmitters and the transoceanic telephone services.

The power of the transmitters ranges from 100 watts and lower for airborne units, through 1 to 5 kw for shipboard equipment and higher power for land-based stations. A rating of 10 to 50 kw is common for continuous-wave frequency-shift keying transmissions and for the peak envelope power in single-sideband transmissions. A linear amplifier for single- or double-sideband suppressed carrier service, capable of continuously tuning the 4- to 30-Mc range, was developed by the U. S. Army Signal Corps in 1953. These transmitters, with a peak envelope power of 600 kw and an average power of 300 kw are now used by the Army, Navy and Air Force.

In recent years the phenomena of tropospheric and ionospheric scatter came under investigation as frequencies in the VHF and UHF ranges came into use. These phenomena presented the possibility of extremely reliable transmission over long periods of time at fixed frequencies or at frequencies that changed only seasonally.

Ionospheric scatter circuits required the development of higher-power VHF transmitters in the range from 30 to 65 Mc. Concurrent with the development of the continuously-tunable linear amplifier, the U. S. Army Signal Corps developed a 600-kw peak, 300-kw average power continuously-tunable linear amplifier to cover this range. This amplifier is now being used for research at Stanford University.

The tropospheric scatter, using UHF frequencies to cover shorter distances with greater reliability, also introduced requirements for a new type of communications transmitter. Requirements were developed for long-range communications circuits, established by a series of tropospheric and ionospheric scatter transmitters and receiving systems. An example is the communications system which connects the Distant Early Warning (Dew Line) radar system across Canada, where a UHF system interconnects all sites and carries the gathered information to a central location.

Typical transmitters in the UHF range for tropospheric scatter have been developed for various frequencies between 300 and 1000 Mc and from 10-kw to 100-kw peak envelope power.

Thus, from the early systems which operated as low as 15 kc, the frequency range of communications transmitters has been extended to the area of 1200 Mc, at which point microwave communications systems begin and use frequencies through several kilomegacycles.

In spite of the trend toward higher frequencies, emphasis is even now being placed on the very low frequencies. Only frequencies below 20 kc have a usable capability of penetrating salt water, so signals can be received by submerged submarines. With the U. S. Navy Polaris program for nuclear submarines, a new emphasis is placed on this type of communication, and in 1961 the Navy put into operation a new VLF station capable of covering the frequency range from 14 to 30 kc and operating with a continuous output power of 2,000,000 watts. Other VLF stations are in the planning stage, including one for NATO, in England.

The most important collateral development contributing to the modern communications transmitter has been in vacuum tubes. By 1925, practical water-cooled triode tubes permitted the design of transmitters having power outputs several times greater than those of previous models using radiation-cooled types. Water cooled types have since been improved so that anode dissipation in excess of 500 kw is possible. At the same time, the introduction of forced-air cooled tubes with a fin-type structure on the anode has permitted the simplification of transmitters having output powers up to 50 kw. The introduction of the high-gain, high-power tetrode, and its development into ever higher power designs, has permitted circuit simplification by eliminating the need for neutralization and by the reduction of the number of amplifier stages. Ingenious design has continued to raise the upper limit of operating frequency for higher-power tetrodes so that the useful frequency limit of these tubes extends into the UHF region. For UHF and higher frequencies the klystron amplifier, now available in extremely high-power models, has been an important factor in extending both the power and frequencies of communications transmitters.

Improvements in many types of components have resulted in increased reliability and smaller size. This includes the introduction of ceramic capacitors and the development of vacuum capacitors, both fixed and variable. Variable vacuum capacitors have been of considerable importance, particularly in the development of transmitters for wide frequency coverage in the HF range, where the extension to the lower frequencies required lumped-component circuits and where the HF end of the range approaches an area in which cavity-type circuitry might be more applicable.

Early continuous-wave vacuum-tube transmitters used a power oscillator as the generator of the RF energy. The requirement for better frequency stability soon caused a change to the master-oscillator power amplifier system. A major circuit advance for that period was the suppression of self-oscillation in the power amplifier by neutralizing the interelectrode capacities of the triode tubes which were then in wide use. Various methods of neutralization have developed since, and circuit improvements have been continuous. One variation in the use of the triode is the grounded-grid amplifier or grid-separation amplifier in which neutralization is unnecessary. The tetrode mentioned previously provides a screen between the control grid and the plate of the tube which, along with other advantages, eliminated the need for neutralization.

As the frequency spectrum became more crowded, the need for more stable control of operating frequency became increasingly urgent. In 1929, the Federal Radio Commission (now the Federal Communications Commission) began establishing requirements for piezoelectric crystal control of frequency, and these requirements were applied to more types of transmitters to maintain frequency stability. The development in crystal stability has greatly advanced since that date to the point where stability of one part in 10^9 is now being specified in extreme cases and one part in 10^8 has become common. At the same time, while still less stable than good crystal oscillators, the development of variable-frequency oscillators has advanced so that they provide satisfactory stability for many operations.

Each increase in the available communications facilities seems only to create a greater demand, and this ascending requirement for the transmission of information, whether it be voice, printed word or data transmission of various types, provides the background for the current work and possible future work in transmitter development.

The information theory discloses a theoretical maximum of information which can be transmitted within any given specified bandwidth in the frequency spectrum. Present signaling methods do not closely approach the theoretical ultimate. Therefore, laboratory workers are seeking to develop methods for increasing the speed of transmission, multiplexing of more channels in a given bandwidth and at the same time improving circuit reliability. These developments take various forms and will undoubtedly place certain additional requirements on the capability of communications transmitters. Already in single sideband systems the requirements, for reduction of intermodulation products which require improved linearity and frequency response in the amplifier, have been changed to permit maximum use. Specifications have been changed from 30 db below either of two tones in the standard two-tone test to present-day specifications which require a reduction of such distortion to 47 to 50 db.

Certain of these systems depend upon increasing frequency stability for proper operation, and still further improvement in frequency stability will result in the transmitters. In this connection, there is an increasing demand in some types of service for the capacity to operate on any one of a very large number of closely-spaced frequencies with the same extreme accuracy of frequency control. This results in the development of synthesizers of improved design which are controlled by a single, highly stable source and develop instantly-selectable frequencies at close intervals throughout the operating range.

This leads directly into the requirement of ever-faster frequency change for the entire transmitter. As this requirement develops, we may expect to see more work on the development of broad-band transmitter systems where the amplification will be independent of frequency, and the process of frequency change will be merely that of shifting the frequency at a source which may be a variable-frequency oscillator or a synthesizer. Such a broad-band system has no selective circuit for the suppression of harmonic radiation or other spurious radiation. A further critical requirement is placed on linearity of the amplifying system to avoid the introduction of distortion products, whether they are or are not harmonically related. Such broad-band amplifiers are already available in lower power. In the natural course of development these will probably be used as driver stages where high power is required, with fast tuning arrangements retained for the extremely high-power stages until further development permits broadbanding at such power levels.

Work continues toward increasing the power of transmitters in all categories. It might be said that the present state of the art in the lower frequencies makes any power technically possible that can be economically justified. However, as we pass through the medium-frequency range into the high-frequency range and above, there is, at present, a definite technical limitation on power vs frequency.

Notwithstanding the improvements in reliability as the result of new signaling systems and new knowledge of propagation, the demand for greater reliability has always resulted in some increase in transmitter power, usually with simultaneous improvements in antenna systems. Therefore, the trend toward higher-power transmitters will continue.

Microwave Communications*

JOSEPH H. VOGELMAN†, FELLOW, IRE

Summary—**An historical summary of the development of microwave communications is presented, together with an examination of the present state-of-the-art. The current research and development efforts are used to forecast the extension of the present applications and techniques into the future.**

Introduction

THIS paper is an attempt to summarize the field of microwave communications, past, present and future, within an imposed limit of 4000 words. With almost this number of references bearing on the history and technology of microwave communications and hundreds of important contributors to its development, the allowable space precludes tabulation of references and acknowledgement of the individual contributors. To those whose names are omitted and those whose papers are not referenced, the author offers his apologies. For the purpose of this paper, microwave communications will be limited to technology where wavelengths shorter than 40 cm are used. Within these limits four major communications media will be considered:

1) Microwave relay using line-of-sight propagation.
2) Beyond-the-horizon systems using tropospheric scatter propagation.
3) Beyond-the-horizon systems using man-made satellites as reflectors or repeaters.
4) Closed circuit systems using the TE01 mode of propagation in circular cross-section waveguides.

The first two have reached maturity in the form of numerous operating systems around the world. The latter two are by comparison in their early infancy, yet on the threshold of full-scale operations.

The Past

In 1864 James Clerk Maxwell laid the foundation for microwave communications with the electromagnetic wave theory he used to explain the phenomenon of light-wave propagation. In 1888 Heinrich Hertz generated and received electromagnetic waves with wavelengths of 60 cm using a spark transmitter and parabolic antennas. By 1898 other experimenters using similar methods had generated wavelengths as short as 0.4 cm.

In 1893 J. J. Thomson published the first analysis suggesting the possibility of waves in hollow pipes in his book "Recent Researches in Electricity and Magnetism." In 1897 Lord Rayleigh published an analysis of propagation through dielectrically-filled pipes, both of circular and rectangular cross section. In 1895 Victor von Lang propagated electric waves in pipes of appreciable length.

The apparent advantages of the longer wavelengths, as demonstrated by Marconi, and the advantages of vacuum tubes for longer wavelength operation temporarily curtailed progress in microwaves.

In 1920 the Barkhausen positive-grid oscillator provided a means for the efficient generation of 40-cm waves. This revived the interest in the centimeter waves. In 1929 Andre G. Clavier, then associated with Laboratoire Central de Telecommunications in Paris, started an experimental project to challenge the then accepted principle that wire or cable circuits should be used in preference to radio whenever physically possible.

In 1930 a link was started between two terminals in New Jersey using 10-ft parabolic antennas. Just as testing started, the project was transferred back to France. On March 31, 1931, Clavier and his associates demonstrated that microwave transmission provided a new order of economy, quality, dependability and flexibility in communications over a 40-km path between Calais and Dover. The circuit provided both telephone and teleprinter service using 17.6-cm waves transmitted in a 4° beam by means of a parabolic reflector 3 meters in diameter with a power output of a fraction of a watt. Andre Clavier went on to establish the first commercial microwave radio link in 1933 from Lympne, England, to St. Inglevert, France.

In 1933 Marconi published results showing 500-Mc propagation well beyond the horizon.

In 1936, from the Bell Telephone Laboratories, Carson, Mead and Schelkunoff published their mathematical theory on "Hyper-Frequency Waveguides" while G. C. Southworth published his experimental results. These papers provided the basis for the TE01 mode cylindrical waveguide. In that same year W. L. Barrow of M.I.T. published his work on the "Transmission of Electromagnetic Waves in Hollow Tubes of Metal." Before 1934 Southworth had transmitted telegraph and telephone signals at 15-cm wavelengths in a 5-in diameter hollow metal pipe 875 ft. long with relatively small attenuation.

In July, 1939, Clavier published the results of his experiments on millimeter wave transmission, pushing the hollow circular waveguide closer to the day when it would become a major communications medium. In the early part of this same year magnetrons producing small power at 30 Gc came into experimental use.

In 1941 the first "beyond-the-horizon" 3000-Mc propagation tests were undertaken by Andre Clavier around Toulon in the south of France from May to

* Received by the IRE, July 20, 1961.
† Capehart Corporation, Richmond Hill, N. Y.

December of that year under a contract with the French Department of Defense. The transmitter consisted of a 10-watt frequency-modulated klystron. The antennas were 25-degree horns with the transmitter on land and the receiver aboard ship. A sizable gain margin of received signal above the noise level was found at 103 miles from the transmitter and 43 miles beyond the horizon. These experiments furnished basic information for practical utilization of microwaves in beyond-the-horizon links.

In 1944 Andre G. Clavier and V. Altovsky published the results of experimental work which established the technique of frequency modulation as the optimum method for use in microwave line-of-sight links. In 1946 a 12-channel FM microwave link was incorporated in the French Postal Telegraph and Teletype System between Paris and Montmorency.

During the same period the Bell Telephone Laboratories under Harald T. Friis were engaged in extending the one-hop microwave radio link into a long-distance repeater network. Their microwave repeater research delayed by the five war years, culminated in a New York-Boston system; results were published by Friis in April, 1948, in the *Bell System Technical Journal*. The horn-reflector antenna and the shielded metal lens antenna joined the paraboloid as basic antenna types for microwave relay systems.

Since 1950 the National Bureau of Standards, the Lincoln Laboratory of the Massachusetts Institute of Technology, and the Bell Telephone Laboratories conducted many theoretical and experimental investigations of microwave tropospheric propagation beyond the horizon.

The forward scattering is explained by H. G. Booker, J. T. de Bettencourt and W. E. Gordon in terms of a granular turbulent troposphere with "blobs" of refractive indexes that differ from the average value. It is explained in terms of partial reflections on various refractive layers by T. J. Carroll and R. M. Ring, and H. T. Friis, A. B. Crawford and D. C. Hogg. K. Bullington, the Lincoln Laboratory research group, D. Davidson and A. J. Pote, and members of the National Bureau of Standards have contributed greatly to our knowledge of microwave tropospheric propagation. This work has formed the basis for the implementation of beyond-the-horizon microwave communication.

In 1955, The United States Air Force started the installation of an operational chain of tropospheric scatter stations in an inaccessible region of Labrador. Within the next two years the world's first commercial over-the-horizon link from Sardinia to Minorca was installed to provide direct telephone communications between Spain and Italy.

The first step towards a communications satellite was made on October 4, 1957, with the launching of Sputnik I by the U.S.S.R. While this device operated in the HF range, it was the first communication transmitter to orbit the earth.

On December 6, 1958, Pioneer III took the first microwave transmitter at 960.5 Mc into space for a 38.1-hour trip. This was quickly followed on December 18, 1958, when the United States placed the first satellite communication system in orbit as part of Project Score. While this system operated at VHF, it was the forerunner of microwave "store and forward" message transmission service.

The passive communication satellite repeater became a reality when the Echo Satellite was launched by the National Aeronautics and Space Agency on August 12, 1960. It provided an effective mechanism for microwave communications experiments by the Bell Telephone Laboratories and Jet Propulsion Laboratory of California Institute of Technology along a cross-country east-west path, by the Rome Air Development Center on a north-south path, and by Collins Radio between Iowa and Kansas.

At the time of this writing, the electronics-communications industry is negotiating for the launching of a repeater satellite by NASA to inaugurate commercial communications on an intercontinental basis. This will give microwave communications a global capability not heretofore possible.

The Present

The state-of-the-art in microwave communications has advanced markedly in the thirty years since the first demonstration of a practical microwave single-hop communications link.

The Line-of-Sight Relay

Today microwave line-of-sight repeater systems are found all over the world providing reliable broad-band channels between major terminals, carrying thousands of voice and data channels, as well as television broadcasts. The accepted modulation method is FM with diversity in frequency serving as the prime method for insuring propagational reliability. Line-of-sight microwave links provide a communications method for major military traffic between remote sites and communications relay centers. Power levels in the order of one watt are used with ratio-squared-combining in dual-frequency diversity or combined space-and-frequency, four-fold diversity systems. The antenna systems consist of parabolic antennas and plane reflectors, shielded metallic lens antennas, and horn-reflector antennas in various combinations and sizes. Frequencies as high as 12 Gc are in common use, and transmission bandwidths of 50Mc are not uncommon. Ferrite load isolators have been introduced to insure a high degree of decoupling of the antenna reflections from the klystron transmitter and to minimize intermodulation. These contribute to the achievement of the extreme linearity required in long-haul multichannel microwave systems for transmission of color television signals. The line-of-sight microwave relay has become a standard medium for public as well as private communication systems.

Tropospheric Scatter

The major obstacle to the use of the line-of-sight relay has been the long over-water hop. Tropospheric scatter provided the transmission medium to overcome this natural obstacle as well as adverse combinations of geography and climate. Since the original Sardinia-to-Minorca installation, tropospheric scatter has developed to a world-wide importance, predominantly as an essentially American long-range communication system. The major impetus behind this development has been provided by the Department of Defense agencies. The path length for a single hop of tropospheric scatter has been extended beyond 700 miles while the number of channels of 4-kc bandwidth has been increased to 240. Transmitter power levels of 50 kw have been attained with antennas as large as 120 ft in diameter. At the other extreme, transportable tropospheric scatter systems installed in vans or shelters are finding more and more applications in the various military services. Systems have been installed to operate in the 755–985-, 1700–2400-, 4400–5000-Mc bands and experimentally in the 7125–8500-Mc and higher-frequency bands. The feasibility of ground-to-air use of tropospheric scatter out to 1000 miles has been demonstrated, though never implemented, as an operating communication system. This communication medium has been integrated into a long-range repeater network system for commercial as well as military use. The largest system at this time is the combined U. S. Air Force White Alice Dew-Line system which ties together all Alaska and northernmost Canada. The White Alice system has become the backbone of the far-flung commercial communication system of the State of Alaska.

Data transmission tests of multiple-hop paths have proven the inherent reliability and over-all linearity of microwave communications medium. Since the basic propagation medium is subject to deep fading of very short duration, various diversity systems have been proposed, tested and applied to reach the required reliability. The system in most frequent use is space diversity where two or more antennas are provided at both ends of the link for receiving and transmitting. In combination with polarization diversity, dual-space diversity is extended to quadruple diversity over a duplex communications link. Time-diversity reception and multi-beam angle-diversity systems have also been demonstrated. An angle-diversity system, designed at the Rome Air Development Center, utilizes a very large (compared to the wavelength) antenna with multiple beams clustered about the great circle path. In combination with frequency diversity it provides reliable communications for long-range hops at frequencies of 8000 Mc and higher. The signals received over these uncorrelated paths are then combined for greater system reliability.

Various combining systems have been successfully used. These include selector, linear-adder, and ratio-square combiners. In the selector combiner, the largest signal is accepted while all others are rejected. This type of combining does not benefit from the power received from smaller signals. The linear adder combines all signals by simple addition, giving equal weight to all signals. In this type a deep fade on one path results in the addition of noise to the other signal, thereby degrading it. The ratio-square combiner squares the level of each signal before combining is performed. It thereby gives emphasis proportionate to the level of the signal above the noise and comes within a decibel of the idealized combiner. Combining has been used in the IF circuitry where the local oscillator is varied to phase the IF signals to produce two signals for optimum addition. Post-detection combining is also found in many systems. In several systems with quadruple diversity both IF and post-detection combining are used. Over-all reliabilities as high as 99.999 per cent have been demonstrated in transmission of digital data.

Satellite Communication Systems

Microwave communications by means of a satellite repeater became a reality during 1960. While the circuits are considered experimental, they have demonstrated operational capabilities.

The Echo passive satellite was placed in orbit on August 12, 1960, and signals were transmitted between the Bell Telephone Laboratory installation at Holmdel, N. J., and NASA's Jet Propulsion Laboratory at Goldstone, California. This passive repeater consisted of a 100-ft diameter metallized plastic balloon in orbit about 1000 miles above the surface of the earth. The very-low-noise receiving system uses a low-noise horn reflector antenna, a broad-band maser amplifier using a ruby crystal refrigerated by liquid helium and a receiver using a feedback technique for recovering an FM signal which would ordinarily be lost in the noise. The combination of antenna and maser provide a background noise power about 1/100 of that encountered in ordinary microwave radio systems.

Simultaneously the Rome Air Development Center has been communicating on a north-south path using the same passive repeater satellite. They were the first to receive a message reflected from the man-made satellite. The transmitter is located at the RADC Trinidad, British West Indies site, and the receiver site is at Floyd, New York. A radar tracker at Trinidad is provided with a separate feed for simultaneous transmission of radar and communications signals. The radar acquires and tracks the satellite using normal back-scatter signals. Direction-finding antennas at the Floyd receiving site detect the radar signal and orient the 33-ft diameter parabolic communications receiving antenna. The communications signals, teletype signals as well as data signals, at 2270 Mc consist of PB-50 word lists for articulation tests. Both of these paths provide microwave communication links capable of extension into operational military as well as commercial systems using passive satellite repeaters. Collins Radio has been operating between Iowa and Texas.

The active repeater satellite Courier was placed in orbit October 4, 1960. This satellite is a delayed-repeater communications system capable of voice, facsimile and high-speed digital transmission. The satellite is a 52-in-diameter sphere weighing 500 lbs. Eighty per cent of the surface is covered with 19,152 solar cells to provide power to the electronic components. The satellite receives at a frequency in the 1.7- to 1.8-Gc band and transmits between 1.8 and 1.9 Gc. The storage capability is 13,200,000 bits in each of four magnetic tape recorders. The transmission rate is 55,000 bits/second. The ground stations transmit at a power of 1000 watts while the satellite transmits 4 watts. The stored data is retransmitted to ground upon ground command. Four minutes are required to transmit the storage of each recorder. In addition to the delayed mode, the Courier satellite can be commanded to act as a real-time repeater and retransmit immediately. The orbit is at 750 miles above the earth. The satellite has been used to transmit over 6,000,000 words of teletype information daily between the ground station at the United States Army Signal Research and Development Laboratory, Fort Monmouth, N. J., and the Puerto Rico station located at Salines, during periods of visibility.

TE01 Circular Waveguide

The major interest in the circular electric-mode TE01 waveguide has been stimulated by the need for large bandwidth toll trunks capable of long-range usage. The essentially unlimited bandwidth available in the millimeter wavelength band and the ability to obtain any reasonable attenuation by increasing the diameter of the tube has promoted great interest among telephone companies. The Bell Telephone Laboratories in the United States have developed the necessary components for long-range application of this waveguide system. Necessary mode filters as well as techniques which will allow reasonable radii of curvature have become available. A helically wound copper wire structure of 2-inch diameter is used as the basic structure. The tightly-wound helix is covered with a mode absorbing compound and enclosed in a steel tube. In England Standard Telecommunications Laboratories of the Standard Telephone and Cables, Ltd., demonstrated a flexible cylindrical waveguide for TE01 mode operation. A guide of approximately 3 in. in diameter is formed with helically wound aluminum wire. This tightly wound helix is covered with a water-proofing and a strengthening coating. In this structure type the electromagnetic waves follow small bends in the tube without prohibitive loss or excessive mode conversions. This waveguide structure is expected to operate in the millimeter wavelength band with an attenuation of 2 to 3 db per mile. Repeaters will be required every 20 miles to maintain a reasonable signal-to-noise level at the output terminals. The first demonstration of an operating cylindrical waveguide was held in 1960 at Frogmore Hall, Herts, England, using a 3600-ft-long loop of $2\frac{3}{4}$-in-diameter waveguide. The loop combined an 1800-ft helical section with an 1800-ft optically straight tube. Good quality television pictures were transmitted. For long-range operation the differential phase delay and the residual unwanted mode energies contribute to the distortion of the signals transmitted. To permit undistorted regeneration of the original signals, pulse-code modulation is essential and is proposed as the applicable technique. Spectrum bandwidths of 10,000 Mc and greater are obtainable in this waveguide mode. A bandwidth of this size will be sufficient for at least 400 television stations or a million voice channels.

The Future

The growth of microwave communications in the last twenty years has been phenomenal, and it portends becoming the major communications medium of the future. The pressure of frequency unavailability has forced and will continue to force more and more services into the higher microwave frequencies. A realistic future must be an outgrowth of the research and development programs of today. On this basis the future is presented.

Line-of-Sight

The basic line-of-sight microwave system will continue to be the mainstay of the broadband network. The power levels used will increase. The operating frequencies will go higher. In addition to the relay function, there will be increased usage of connecting links between subscribers and a communications relay center for retransmission by a more complex long-range system. Space diversity will be used in addition to frequency diversity for added propagation reliability. (The greater power and higher antenna gains will permit greater spacing between stations or increased signal bandwidths.) Except for improvements in equipment and components, the major change will be in extending the microwave line-of-sight service to vehicular terminals, both air-breathing and orbital. Solid-state components are receiving major emphasis for these and other mobile uses. Suppressed-carrier single-sideband multiplex techniques will be used to compress more channels in the same bandwidth. Wide index FM will allow greater concentration of stations.

Tropospheric Scatter

There is an urgent need for tropospheric scatter operation at higher microwave frequencies to relieve the RF interference problems. In many parts of the world only frequencies above 5 Gc can be made available for use in tropospheric scatter. The multiple-angle diversity system, under experimental evaluation at the Rome Air Development Center, promises to overcome the higher losses and restricted transmitter powers at the shorter microwave wavelengths (less than 4 cm) by better matching between antenna aperture and medium. When the 200–250-mile hops are operating at the higher microwave frequencies, the lower end of the band can be designated for long hops of 750 to 1000 miles.

The number of multiplexed voice channels is gradually being pushed towards 600, while the transmitter power is approaching 100 kw. The use of parametric amplifiers in the receivers will increase the signal-path reliability with a resultant increase in the over-all reliability. This will insure long-range multiple-hop relay systems capable of handling high-speed digital data.

Forward scatter at 400 Mc has been received at great circle distances in excess of 2500 miles. The propagation mechanism involved is believed to be that of incoherent scattering induced by electron-density fluctuations in the common volume of the antenna beams. Enough is known to postulate a special-purpose communication system designed to use this region for forward scatter.

Satellite Relays

Global communications by satellite relay is currently being undertaken as a commercial venture by the communications industry of the United States. A wide variety of systems have been proposed for the future. Among the more promising are the following.

Passive Satellites: The passive satellite offers the advantage of reliability and minimizes the complexity of the space vehicle. It requires greater transmitter power and extreme receiver sensitivity on the ground, but where a great flexibility is needed it will probably be the logical solution. Four types of passive satellites have been proposed. The first is a large-diameter spherical reflector based on the successfully orbited Echo satellite. It offers advantages of simplicity, since it does not require any stabilization. The second is the diffuse scatterer, made up of a belt of chaff dipoles in orbit. While it simplifies the tracking problem, the launching is greatly complicated by the need to space the dipoles in their orbits and maintain them in precise relative positions. The dipoles would be subject to solar pressure. The third satellite is a partially stabilized Van Atta array whose distance from the earth is such that its beamwidth includes the whole earth. Since the array will return energy in the direction from which it is received, over an angle of 45 degrees, the requirement of stabilization is greatly reduced. Lastly, the Lambertion surface has been proposed as a diffuse scatterer. Any surface of sufficient irregularity and roughness will reflect according to Lambert's law. A Lambertion surface cannot be distorted enough to produce an undesirable effect, and therefore a spherical shape is not necessary to produce a uniform bistatic cross-section. Crumbled sheets of reflective foil expanded into a loosely fitted covering on a support structure would suffice if the wavelength is short in comparison to the distribution in elevation of the individual scatterers.

Active Satellites: The active satellite relay divides the equipment complexity between the repeater and the ground environment and results in a reduction in the power requirement. The two types of active satellite are the "store and forward" or Courier-type communications satellite and the instantaneous repeater which shifts the frequency while reproducing the modulation. The Courier type offers global coverage in a single satellite vehicle for those services where several hours delay are tolerable. The instantaneous repeaters required a multiplicity of satellites as well as ground relay points to produce a global system. An active Van Atta array using amplifiers between corresponding elements has also been proposed as a communications satellite.

Various orbits have been proposed for both active and passive satellites. The stationary or synchronous satellite (24-hour orbit at the equator) has very useful orbital properties, but its 22,400-mile height above the earth complicates the electronic components of the communications system and introduces a significant time delay. However, the reduced tracking requirement and the continuous availability compensate for these complications. Polar and 45 degree orbits at 1000- to 3000-mile heights above the earth are the most readily realizable in the immediate future. Their use requires extensive tracking antennas at both ground terminals as well as provisions for jumping from satellite to satellite if continuous operation of the communications system is to be achieved. Various other satellites have also been proposed with orbits from 90 minutes to 96 hours.

Circular Waveguide

The TE01 mode circular waveguide will ultimately replace the multiconductor cable and the coaxial line as the carrier of underground or overhead trunk traffic in urban areas and between adjacent urban areas.

Conclusions

In the nearly 100 years since Maxwell microwaves have indeed become the highway of our electronic communications, but this is only its infancy.

COMPONENTS

Organized with the assistance of the IRE Professional Group on Component Parts

Historical Development of Component Parts Field*

J. T. BROTHERS†, FELLOW, IRE

Summary—**This paper reviews the history of the component parts field by equating the effects of the invention of active components to the resulting regenerative expans on of requirements for types and capabilities of components needed to make possible the development of new systems equipment to meet the demands of applications and, in turn, generate new applications for other system equipment.**

IN REVIEWING the history of the component parts field in the electronic equipment area, the most impressive factor that becomes evident almost immediately is the immensity of the magnitude of human endeavor in the entire field of natural philosophy, to use a historic term, that has resulted in our present day technological status. The contributions of Henry, Maxwell, Ampère, Volta, Kelvin, Ohm, Helmholtz, Herz, the Curies, Marconi, Loomis, Faraday, Edison, Fleming, to name a very few specifically, were known well enough to their contemporaries so that they have been signally honored; our recognition of their successes is perpetuated in some cases by the use of their names for units of measure, in other cases by the use of their names for certain effects. For each of these, however, there were thousands more who added their important contributions to the over-all sum of knowledge that formed the foundation of the wireless era at the beginning of the twentieth century. To all of these en masse we must pay homage and acknowledge our indebtedness.

The following sixty years may be arbitrarily divided into double decades and equally arbitrarily we can designate the first, to 1920, as the wireless generation; the second, to 1940, as the radio generation; and the third, to 1960, as the electronics generation. During the last fifty years, since 1912, which is at this point the historical part of the life of the IRE, there has been an explosive expansion of the capabilities in materials for, and concepts of, component parts for electronic equipment. This has been the effect of the continually increasing amount of research work done in the basic sciences field in both educational and industrial laboratories, the shift

* Received by the IRE, August 1, 1961.
† Philco Corporation, Philadelphia, Pa.

of emphasis in scientific work from the technique of experiment to the technique of analysis, and the aggressive exploitation of this work by further development work in the engineering field. These additional capabilities of the past 60 years are in turn due to the accomplishments of a myriad of workers in these fields and when we acknowledge the contributions of Alexanderson, Cady, de Forest, Dubilier, Eastham, Kusunose, Langmuir, Néel, Polydoroff, Rubin, Thordarson, we do it in the full realization that these are only a few of the important contributors who were responsible for the current state of the art and entitled to our eternal appreciation. It is beyond the scope of this paper to credit individuals adequately. It is also beyond its scope to cover the field completely or cite much more than a few examples.

In this short summary of the past which serves as an introduction to the other papers in this series it is necessary to bear in mind the cyclical nature of the end equipment requirements since the turn of the century. An example of this is the part of the frequency spectrum used. Although a great deal of work was done initially in the gigacycle per second region, by 1900 our transmitter frequency range for commercial purposes was in the 10- to 100-kc region; the emphasis shifted progressively higher in frequency and by 1920 the dominant range was 100 to 1500 kc (although there had been a great deal of emphasis on very low-frequency ground radiation telegraph systems during World War I for military communication), by 1930 the frequency range had shifted to between 200 kc and 20 Mc, by 1940 this had extended to 200 Mc, by 1950 important applications had been using the frequency range to the 10 Gc region, and by 1960 high-power stations were once again being built in the 15- to 50-kc range. At this point we have filled the gap between the 1900 spectrum usage, the one area of usage about a center frequency of 50 kc and the other area around a center frequency of 1 Gc, and extended the range to somewhat higher frequencies. Another significant point to keep in mind is the change in the method of generating radio-frequency power. Spark, arc, and mechanically rotated alternators have been partially superseded by vacuum tubes of all kinds, triodes, klystrons, magnetrons, and others, more recently the semiconductor devices have staked out a part of the field, each with its own applicable part of the power range and frequency spectrum, but it is interesting to note that the quenched gap spark system is still being used for low-frequency industrial and medical applications. It is equally significant that the magnetron remained a laboratory curiosity for 10 years until the need arose for a laboratory signal generator for UHF research and that another 5 years passed before the requirement for a significant amount of power in a specific frequency range accelerated the development of the tube to its present capabilities. Basic power supply systems have also gone through a full cycle. Fifty years ago transmitters were designed to operate from dc generators and/or storage batteries for the arc generators; the spark systems were operated from ac generators, (or mechanical interruptor which operated in turn from dc or low-frequency ac) that provided 250 cps, 500 cps, or 900 cps power, although some spark systems with nonsynchronous rotary gaps were operated from 50/60 cps lines. In the radio generation the dc required for vacuum tube transmitter plate supply was obtained successively from dc generators, mechanical rectifiers, pool type mercury arc, gas, and high-vacuum thermionic rectifiers, some code transmitters used raw ac of whatever frequency available in a self-rectifying circuit, and in 1930 there were three or four broadcast transmitters using storage batteries for plate supply. Airborne requirements were satisfied by batteries and dynamotors until the higher power requirements of the late 1930's and the consequent requirements for weight reduction revived the use of the higher frequency alternators, from 400 cps to 2400 cps with rectifier systems. This trend has continued in the electronic generation so that the larger airborne systems are now 3-phase 400-cps systems. The rectifying systems are also going through a transition phase from thermionic rectifiers to multicrystalline solid-state devices such as selenium, to single-crystal solid-state devices made from germanium or silicon, and now we have the silicon-controlled rectifier.

The historical background of the component parts field should be viewed from this perspective of ever-shifting requirements, purpose, and nature of the end equipment. In 1910, in order to build a receiver we would need a tuner, a detector, and a pair of headphones as shown in Fig. 1. The first element of the tuner, the loading coil *L*1, would be a coil in which the inductance could be varied by means of a tap switch; the second coil would be a pair *L*2 and *L*3, a loose coupler, with means for varying the coupling between them, preferably with different diameters and mounted coaxially so that the coupling could be adjusted by sliding one inside the other and the inductance of each variable by a tap switch similar to the loading coil. The detector could be one of several options:

1) A Marconi magnetic detector, the real basis of reliability for that era.
2) A Fleming tube—very unreliable because of short filament life and complex because it required a filament battery and rheostat.
3) A silicon carbide crystal detector—preferably entailed the use of a polarizing voltage, adjustable by means of a potentiometer to the most sensitive part of the rectification curve.
4) A de Forest triode—not very well known as yet, also very complex in that it required a filament battery and rheostat, a plate battery that was tapped or adjustable to a critical value by a potentiometer; further, it had a probable life as a detector of 20 to 30 hours and the filament could be expected to burn out in less than 50 hours. The

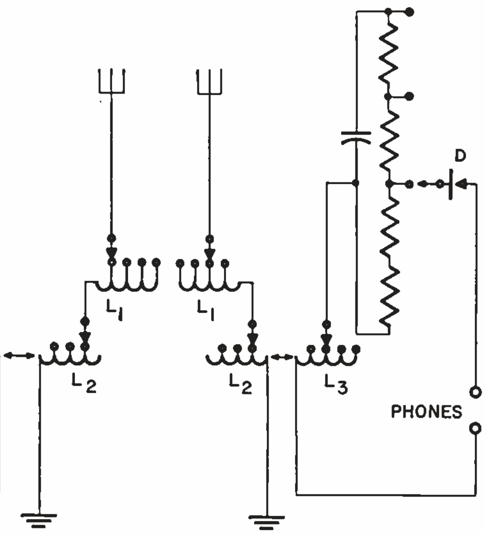

Fig. 2—Receiver.

headphones were pretty much as we know them today, preferably 3000 to 6000 ohms resistance for the pair in series, and a resulting impedance of 4000 to 8000 ohms at 1000 cps. A simple spark transmitter of the same era would be as shown in Fig. 2. *L*1, *L*2, *L*3 serve the same function as their counterparts in the receiver and if the power to be generated was within the dissipation capability of the receiver coils, they could be identical; usually the transmitter coils were wound of bare copper or brass strip, and were considerably larger physically because of the conductor size and spacing. The loose coupler could be cylindrical and coaxial just like the receiver coils, or it could be made as a pair of helical pancakes and the coupling adjusted by varying the spacing between the two coils on the axis, or shifting the axis of one coil. *C*1 was usually a Leyden jar, but it could have been made with brass electrodes inserted between flat glass plates. *G* is the spark gap which could be fixed or rotary. *T* is the interrupter coil, very similar in principle to an automobile ignition coil (as a matter of interest, somewhat later many amateur stations were built which used Ford coils), *P* being a few turns of heavy wire, *S* being a large number of turns of fine wire, both being wound on an open core composed of a bundle of iron wire, and the reed being physically located at the end of the core with the interrupter contact. *C*2 is the point capacitor and was made of sheets of mica interleaved between tinfoil or copper foil. *K* is the conventional key of today, *B* was the battery. As in the receiver, there were several alternatives. In the spark transmitters the battery shown in the *B* block could be replaced by a source of ac such as the 50/60 cps from a commercial power line, or the 115–120 cps generated on some ships, or the 250, 300, or 500 cps alternators specifically designed for this purpose, in which case the interruptor shown in the *T* block, from which frequencies from 250 to 1000 cps were obtained by design, was replaced by power transformers designed for this use. The simple spark gap in the *G* block could then be replaced by a nonsynchronous rotary gap for 50/60 cps, 115–120 and 250 cps supplies, or by a synchronous rotary gap or by a quenched gap for the higher frequency supplies. Similarly for an arc system the *B*, *T*, and *G* blocks were replaced by a dc generator and an arc converter. We should be reminded at this point that, despite the apparent crudity of the equipment of this period viewed with 1962 eyes, transoceanic wireless telegraphy was a flourishing business, ships at sea received news and directions, automatic code recorders were in use, voice transmissions had been sent over 350 miles and opera had been broadcast from both Chicago and New York City.

With equipment of this type, however, there were relatively few components as we know them today. Resistors were only used for adjusting the bias on silicon carbide detectors and these were usually air-supported turns of resistance wire connected to the contact points of an open rotary switch, miniature versions of the same type which were used to control field excitation on motors and generators. Because of the frequency ranges involved, receiving inductors were solenoids wound on large-diameter tubes (4 to 8 inches) adjustable by means of taps brought out to rotary switches, and the coupling varied by sliding one coil inside the other or rotating the axis of one coil with respect to the other. Transmitting inductances were helices of flat strap tapped by clamps that could be fastened directly to the strap, or a slider that could be rotated in continuous contact with the strap; the other popular style was flat strap wound edgewise into a cylindrical coil with similar clamps or a rolling or sliding contact that could be driven around the inner or outer periphery of the coil by a screw mechanism. Some of the lower power units were made with prefixed taps brought out to tap switches similar to those used for receiving purposes. Similarly, coupling between the coils was varied by sliding cylindrical coils inside each other, and the couplings between the pancake styles were adjusted by separating the axis edgewise or separating them on the axis. Supporting structures were wood, hard rubber or asbestos sheet depending on the size of the coil. Very few capacitors were used and most of these were Leyden jars arranged in series or parallel, depending on the voltages and capacitances required, in trays or holders. Where capacitance variation was required it was customary to remove jars or separate the trays. There were a few capacitors used which consisted of sheets of glass with electrodes on each side supported in racks immersed in oil. There were also a few variable capacitors used that were made much the same as present styles with semicircular parallel plates arranged so that the alternate plates could be rotated with respect to the fixed plates, but most of these were made so that they could be immersed in paraffin oil. Transformers were only required for power-supply purposes and were principally high-reactance types on shell cores, mostly open core and coil, although for very high power they were immersed in oil. Modulation was accomplished by means of carbon grain microphones cooled with oil, water, or forced air, inserted directly in the antenna circuit and usually arranged so that they could be rapped with a mallet when they stuck due to excessive current. The battery systems in vogue at that time were wet primary systems, such as bichromate, Bunsen, and Edison types, very few Le Clanché as we know present dry batteries, and the lead-acid secondary type.

It should also be remembered that the emphasis on receivers prior to this time had been visual indicators, such as galvanometers and coherers with their associated ink recorders, or perforators, on paper tapes rather than for audio indicators such as head phones; this is the reason why so much work was devoted to coherers, magnetic detectors, electrolytic detectors, etc. It was about 1910 that the emphasis changed to increasing receiver selectivity and sensitivity and the use of audio indicators (too many stations!).

The third quarter of this generation, 1910 to 1915, saw a marked change. One of the most important factors, from a long-range standpoint, was the recognition that the thermionic triode was capable of providing amplification and this almost simultaneously sparked cascade amplifiers and feedback; it was also recognized that the real function of the filament was to provide electrons and that high vacuum was not only desirable but necessary. This led to the replacement of the tantalum filament by tungsten, and accelerated means for obtaining higher vacuum. Simultaneously damped wave-spark transmission began to lose out to CW generated by arcs, alternators, and triodes. Special ballast resistors, iron wire in air and in hydrogen, were introduced to prolong triode filament life. The high input impedance of triodes provoked changes in coil design, the spider web coil was designed to decrease distributed capacity, facilitate coupling between coils, and increase Q; further emphasis on Q increased the usage of Litz wire for receivers. Improved magnetic systems were applied to headphones and the moving coil horn loud speaker with a separate electromagnetic field was produced.

The last quarter of the wireless generation, 1915 to 1920, had a considerably greater slope in the state of flux curve, accelerated beyond normal by the demands of World War I. The hard-vacuum triode was by now a reality, due to tungsten filaments, high-temperature bake-out of parts during evacuation, and diffusion vacuum pumps. Transcontinental wire telephony was made possible by the use of triode repeaters. Speech was transmitted to Honolulu and Paris from Arlington by means of a tube transmitter and it was demonstrated that the telephone land line could be coupled directly to the transmitter and used to talk to ships at sea. Simultaneously improvements in frequency and power made the alternator practical and the corresponding development of the magnetic amplifier for modulation combined to make practical another system for high-power radio telephony. During this period the lid of Pandora's box was opened wide and all of the problems of the past became small by comparison. Special resistors were required for grid bias supply and grid leaks were made by impregnating paper with carbonaceous inks or by carbonizing cotton string, power resistors for transmitter circuits became necessary and were made by winding bare resistor wire on ceramic and slate forms and protecting them with japan and vitreous enamel coatings. Grid coupling capacitors were required for receivers and made by stacking mica sheet and tinfoil together, the assembly rivetted together with protective insulation covers, and transmitter requirements for similar devices for tuning and coupling were solved by potting equivalent designs into ceramic and metal cases. Filter and bypass capacitors were required for high-voltage supply in transmitters and were made by winding rice paper and tinfoil into flat coils which were then impregnated with sulphur or castor oil and inclosed in metal containers which were sealed with bituminous waxes. Audio amplifiers created a demand for small signal transformers which were made with soft iron wire cores inserted through the core tube of the coil and then bent around the coil to form a closed core. It was not long before the leakage flux and the physical proximity of these transformers and the gain in the system made it necessary to enclose the transformers individually in cascaded iron and brass shield housings. Power transformers were required to step up the voltages for vacuum-tube rectifiers, and it was necessary to enclose the paper interlayer coils and cores in steel cans and seal them with bituminous pitch. Transmitting inductors started to shrink in size as the frequencies used increased and required better design and insulation. Honeycomb coils were invented for receiver tuner use and the wider frequency ranges required for tuners made the bank wound solenoid necessary. Broad-band iron core transformers were developed for untuned RF amplifiers. Spark transmitters were designed for aircraft to operate from batteries and separate wind driven generators. Small tube transmitters borrowed the old spark coil interruptor and developed it into a vibrator supply to transform 20-volt dc systems into high voltage at 350 to 500 cps for rectification by self-heated cathode gaseous rectifier tubes to supply 1000 volts dc at 50 ma for portable ground and aircraft use. The iron-wire magnetic recorder was invented.

The first quarter of the radio generation, 1920 to 1925, is perhaps best signified by the addition to the professional engineers, scientists, and experimenters previously engaged in the field, of an entirely new group of amateurs who became interested as a result of their exposure to wireless during the war, the publicity enjoyed by the "new science," or the advent of broadcasting. In any event, this was a period of digestion in the commercial field; silicon carbide, zinc chalcopyrites, and other semiconductor detectors were superseded by galena; more vacuum tube detectors came into use for shipboard use; arc and spark transmitters were the mainstay of the ships; arcs and alternators were the fixed location telegraph transmitters; and the vacuum tube reigned supreme in the new broadcast stations. The amateurs were banished to the nether regions below 200 meters where rotary gap spark transmitters created a veritable cacophony, and the serious amateur began to use vacuum tubes for both transmitting and receiving as soon as he could financially afford it. The principal changes in the component field were caused by the increase in production of radio receivers for the amateur band and the broadcast band. In both of these there were additional requirements for rheostats for filament controls which were made of wire wound on fibre, or asbestos covered steel forms, supported by brackets, or made of carbon, graphite and mica dust enclosed so that they could be compressed by a threaded screw plunger, or carbon disks similarly arranged. Filament voltage adjustment was the conventional means for controlling gain. Fixed and variable grid leaks made from carbonaceous inks on various substrates, with a slider for the variable ones, took the place of the previously used graphite pencil leads, and the ink or pencil marks across the grid condenser or piece of bakelite, fixed resistors for all purposes began to be marketed, one style of composition resistor being made of a mixture of binder resin, carbon, and silica which was compressed and cured into a rod to which wire leads were wrapped around the ends; another style was made of a silicon carbide mixture pressed into a rod and fired and finished with radial wire leads; another style was a carbon film on a glass rod which was enclosed in a glass tube, and connections, made to cast soft-metal terminations which sealed the assembly. High-resistance-value potentiometers and rheostats were made from pressed carbon and graphite half-toroids which could be bought as an element or complete with hardware as a completed unit. Variable-inductance tuning systems were found to be less suitable for shunt circuits and more attention was directed to the design of variable capacitors which began to appear in different forms; one style consisted of two coaxial, parallel, circular plates, separated by a small air space in which there was an insulating disk of mica, which were coupled by an insulated screw and nut so that the capacitance was varied by turning the screw and changing the air spacing; the book type consisted of two wooden blocks hinged at one edge arranged so that a cam could vary the angle between the two blocks—the metallic plates on the inner surfaces of the blocks were prevented from shorting, when closed on each other, by a sheet of mica dielectric. The mercury capacitor consisted of a closed cavity free to turn on a horizontal shaft in which a mercury pool in the lower half filled the space between two semicircular plates fastened to the inner surface of the cavity insulated from the mercury pool by mica sheets. Another multi-section capacitor for single-shaft operation had two circular die-cast zinc plates per section; each plate had a large surface area formed by concentric convolutions that were a mirror image of the other of the pair and the capacitance was varied by changing the spacing. Other styles of conventional rotary parallel-plate air capacitors were designed specifically so that they could be placed in tandem on a single shaft and varied simultaneously. Die-cast cradles and other mounting systems were introduced during this period. It was during the latter part of this period that variable capacitors began to be most widely used for varying resonance, and this led to the design of modifications of plate shape from the straight-line capacitance type to what were called straight-line frequency and straight-line wavelength shapes which had the effect of spreading the tuning characteristic more evenly over the dial. As rolled-paper capacitors came into more general use for lower voltage applications, beeswax, paraffin, and castor oil largely replaced sulphur as an impregnant. The introduction of the neutrodyne, and other forms of neutralizing tuned RF amplifiers, produced new varieties of coils, basket weave, spider web, and solenoids mounted at magic angles to each other to reduce feedback and interstage coupling, binocular style coils with limited fields, etc. The spherically shaped variometers were augmented by styles with **D**-shaped coils. Coils made by spraying molten copper on ceramic cylinders and cutting a thread into the ceramic (there were several variations of the process) to create a solenoid were used in low-power transmitters, anticipating the later efforts at "printed wiring." String drives and rack and pinion systems were added to loose couplers to provide more convenient means of coupling adjustment and facilitate back of panel installation. Belts and pulleys, and chain drives, were used to vary capacitance and inductance simultaneously, retrogressing to the Fleming cymometer wave meter of 1904 and the single-dial-control ideas patented in 1912 by Hogan. Sound-chamber adaptors to couple a pair of headphones to a horn "loud talker" were produced, and headphones with conical diaphragms and a variety of magnetic structures were devised for headphones and horns. The electrostatic speaker with a motor-driven drum appeared but won no friends. The friction sound amplifier and loudspeaker with motor power also flashed into the picture and disappeared. The double button carbon microphone made its appearance and contribution to higher quality and, in turn, the moving coil microphone made its contribution. Phonograph pickups, as we would call them now, of a magnetic type were placed on the market, and the enervation of the 1960's began to appear in the form of electric-motor drives to take the place of the spring-motor drive for phonograph turntables. Copper-oxide rectifiers and electrolytic rectifiers were competitors of the Tungar rectifiers and high-vacuum thermionic rectifiers as well as the gas-filled "S" tube. Le Clanché cells with the carbon serving as the container instead of the previously conventional zinc can appeared for a short time to disappear, until the 1960's. The dry-charged lead-acid storage battery was put on the market. The tape-code printer went through another phase and acquired the capability to print alphanumeric characters instead of the code characters and replaced the human being and typewriter link. Vacuum tubes acquired bases and the tube socket became a necessity.

The second quarter of the radio generation, 1925 to 1930, saw the broadcast receiver burgeon into reality principally due to the introduction of receivers capable of operation from electrical power lines. The first phase was the use of conventional filament tubes in series circuits with a dropping resistor directly from dc lines where they were available, and from a rectifier system using two Tungar rectifiers in full wave from ac lines; a simple double pole double throw switch served to convert the set from one service to the other. The second phase was the use of 60-ma battery-type tubes in series circuits from a full-wave rectifier system for all purposes except the final output stage; the output-tube filament could be operated from a filament winding, which provided raw ac, without too much hum. The third phase, of course, saw the application of indirectly heated cathode-type tubes and very low voltage and high current filaments that could be operated from the ac line by means of a stepdown transformer.

With the introduction of the tetrode and pentode, increased quantities of composition resistors were required, as well as greater quantities of wire-wound resistors, principally those made on ceramic forms and covered by japan enamels. Although the reflex systems made a strong bid, the great majority of receivers had tuned radio-frequency (TRF) amplifiers, and the inductors required were smaller in size so that they could be shielded either individually or in compartments, and inductance tolerance and matched sets of coils became a necessity for single dial tuning systems; simultaneously, Q-requirements increased greatly because of the multiplicity of stations. The mica capacitor molded in a bakelite housing was introduced, small paper capacitors were manufactured with paper wrappers and cylindrical cardboard housings, and chlorinated naphthalene became one of the most widely used impregnants for paper capacitors for low dc voltages. Wet electrolytic capacitors were introduced for power-supply filter applications and so-called dry electrolytics were introduced soon afterward. Variable air capacitors with three and four sections on a single shaft closely matched for capacitance vs rotation were required for the TRF sets with single-dial control, and trimmer sections were built into the gangs so that variations in circuit capacitances could be accommodated. Small compression mica capacitors were required to adjust circuit capacitances and for neutralization, although most of the neutralizing capacitors were made of tubing over part of the wiring. The cone loudspeaker became popular with a variety of magnetic drive systems and the flared exponential horn was designed for the phonograph industry. This was not adequate to stem the tide of radio, and the electrical phonograph went into production before the end of this period. Magnetic phono pickups were challenged by the capacity pickup, but the simplicity of the magnetic won out for that era. Improvements were made in the carbon-button microphones, but the condenser microphone became the preferred unit for high-quality work. The electrolytic rectifier and the storage battery supplies became history for applications where ac power was available. Another signpost was erected by the sale of the first battery-operated portable superheterodyne for entertainment use; rotating disk television was exhibited to the public and television signals were broadcast. The wideband coax cable was installed from New York to Philadelphia. One model radio receiver, TRF with 6 tubes, for battery operation, was made in which 90 per cent of the wiring, some of the capacitors, and the tube socket contacts, were automatically stamped from brass strips, positioned and self-rivetted to a bakelite sub panel, anticipating our modern printed wiring system.

The third quarter of the radio generation, 1930 to 1935, was extremely active and showed the direction that the industry was to follow. The super-heterodyne patents were released for license, and there was a frantic scramble to produce and merchandise the "supers." The combination of a radio receiver and a two-speed ($33\frac{1}{3}$ and 78 rpm) electrical phonograph was merchandised. $33\frac{1}{3}$-rpm records were released for general sale. Talking movies were produced in quantity, public-address systems came into general use, and radio receivers were installed in automobiles. Mechanically generated, but electronically displayed, television was demonstrated over the cable, and shortly thereafter all electronic television was demonstrated. All-wave radio receivers were introduced so that foreign broadcasts could be received, and transoceanic programs were broadcast throughout the United States on the newly established radio networks. The vacuum tube was becoming important for many industries, presaging the electronic generation and creating the electronic component industry. The use of composition resistors was increased by the additional requirements of the screen grid tubes, for decoupling and voltage dropping, the increased number of tubes in the super heterodynes, audio amplifiers, etc. and for use in the auxiliary systems, such as automatic volume control, automatic tone control, automatic frequency control, etc. In the capacitor field a similar expansion in demand took place and the bimetal temperature compensating capacitor became necessary to compensate for oscillator drift. Pre-tuned push-button station selectors amplified the use of mica trimmers. This also led to the development of the mechanical push-button system, which rotated the gang capacitor to predetermined positions; new mechanical systems for accomplishing this changed the appearance of gang capacitors considerably. In the inductance category, the super-heterodyne circuits permitted bigger coils and less shielding for the tuning system, but made greater demands on the shielding of IF transformers (of course, we soon found out that we had to do a better job of shield- the oscillator and antenna coils in order to reduce oscillator radiation). The iron-core permeability tuning system became a factor in design. Iron cores became useful in low-impedance antenna transformers for all wave receiving systems and desirable for other antenna coupling systems to improve signal-to-noise ratio. The wave switch became a major component in all wave receivers and made further demands on coil size reduction, and the use of Litz wire for broadcast frequencies became desirable. The push-button switches for the electrical station-selector systems assumed an important role. The electrodynamic cone loudspeaker system became the most universal reproducer, even to driving the horns of large theater and public address sound systems. Power-supply systems for the automobile radio receivers progressed from Le Clanché B-batteries to the dynamotor and then to the vibrator (here we are back to the spark interruptor again) transformer-rectifier system of providing plate power. Vibrator frequencies ranged from 75 to 250 cps, but the 100 and 110 cps vibrators were the most widely used. Electronic musical instruments (?) were introduced as well as electronic versions of the pipe organ.

The last quarter of the radio generation, 1935 to 1940, saw the extension of ac power lines to rural areas and the reduction of sales of battery-powered receivers in that field, but also saw the development of a whole new product line of battery-powered portable radio receivers due to the introduction of the low-drain battery-type tubes, and there was a real increase of sales in that area. Combination radio-receiver–phonographs with automatic record changers became more popular as the efficiency and performance of record changers increased and costs were reduced. The phonograph pickup emphasis shifted from magnetic devices to piezolectric pickups. During this period the performance of variable-composition resistors increased as the demands for lower noise level and greater stability increased. As the demand increased for more accurate tuning systems with less drift and push-button retrace error, particularly in automobile radio, the ceramic capacitors with fixed temperature coefficient of capacitance were introduced, semi-adjustable mica capacitors with bimetallic elements to provide temperature compensation became available, and the temperature coefficient of inductors was reduced or made more uniform. Temperature and time stability of IF transformers was increased by wider use of powdered-iron cores and silver-mica capacitors. The liquid-filled electrolytic capacitor gradually faded from the scene with the improvement of performance of the dry electrolytic, and the ability to make the larger capacitance values required in smaller cans as a result of etched anodes, and sprayed gauze and paper anodes.

This period was characterized by a further extension of radio applications and techniques to an area far beyond the transmission of information and entertainment. Scientific instruments of all sorts were improved or invented for a very wide range of uses in the laboratory and in industry for measurement and control of physical, chemical, and electrical properties, for use in medicine and surgery, for labor-saving applications in the home, etc. Television was almost at the point of emerging from the laboratory. FM radio was just beginning. Specialization in the various aspects of the field became more general, and as the number of radio-receiver manufacturers decreased there were more companies who specialized in more restricted aspects of the component parts field. The individual end equipment manufacturer did not, as a usual rule, have the volume nor the economic justification to pay for the research and development necessary for individual component parts and the mechanization necessary to compete with the component manufacturer who specialized in a limited product area, but who now had a considerably greater sales field than the receiver field alone.

The first quarter of the electronic generation, 1940 to 1945, started in a period that was to be another World War. All of the engineering and research personnel spared from other demands for manpower were engaged in developing new devices, such as radar, bomb sights, identification systems, navigation equipment, bomb and artillery fuses, gun-laying and fire-control systems, computers, and too many more to mention, for operation under a much wider range of environments than previously required or even thought practical. Many of these devices required parts which were beyond the state of the art in order to make the size and weight of the equipment practical.

The second quarter saw the expansion of research and development programs to meet these challenges and simultaneously the introduction of television broadcasting and increased activity in the frequency modulation entertainment field. A whole new class of components were required for the microwave spectrum. Variable inductance tuning systems reappeared and transmission line types of tuners were developed in which inductance and capacitance were varied simultaneously. Electrical and mechanical push-button-type tuners were devised for television and FM.

The third and fourth quarters of the electronic generation, 1950 to 1960, are too close to us to view with much of a sense of perspective. The most significant thing about this period is the introduction of the germanium class of transistors and diodes, the silicon devices that followed, and the other classes of semiconductor materials that are being developed. Cadmium-sulphide light-sensitive resistors, new materials, or the methods of synthetically producing old materials in more suitable shapes, sizes and purity, tantalum electrolytics, both solid and liquid electrolyte types, the magnetically soft and hard ferrite materials, and other new types of magnetic materials are just symptoms of this time. Infrared devices, photovoltaic cells, the reappearance of the magnetic-tape recorder, first for music, then for telemetry recording and now for television programs, thin-metal-film resistors, plastic dielectrics and very thin inorganic film dielectrics, and new ceramic dielectrics are only a few of the other things that should be mentioned, but are beyond the scope of this paper. For this purpose it is perhaps sufficient to say that once again a World War has changed the entire aspect of our scientific outlook and has wrought a revolution in the electronics industry. This acceleration and expansion of electronic techniques into all facets of industry probably has a much greater impact on our daily lives than most of us can realize because we are too close to it. Black and white television is now commonplace, color television after the false starts of 1928 and 1950 on a mechanically rotated disc-presentation system, has reverted to an electronic display system, the Hi-Fi that gave us problems in 1935 is now in 1960 commonplace, stereo phonograph records and reproducing systems are readily available in homes, we have been broadcasting stereo programs on one AM and one FM channel simultaneously and the rules have just been laid down so that both channels can be broadcast on one FM channel. The description of component parts and their requirements, for computers and business machines alone, would fill an entire issue of these PROCEEDINGS. The combination of components into subassemblies—such as the Module and Micro Module, PAC, the 2D ceramic substrate with lumped or distributed resistors and capacitors printed as units, the 2D systems of resistors and capacitors vaporized or deposited in successive layers on a substrate which in turn may be semiconducting material on which have been formed transistors or diodes, the selective doping of a single block of material to create a complete active circuit, printed wiring, automatically programmed component insertion machinery, etc.—have all had a great effect on design and manufacturing philosophies and promise even greater changes for the future.

The author would like to suggest that the 1960 to 1980 period may very well be the solid-state-physics generation, and to make the following gratuitous remarks. One of the most significant things to me in the history of our business is the recurrent manner in which parts, circuits, and philosophies are used and abandoned. There may be a moral here, only faintly concealed, that in our continual pressure for "Onward and Upward," we should not be too proud to stop occasionally and review our past lest we in ignorance not only retrace our steps, but what is worse, also repeat our previous mistakes in the application of parts and materials.

Although basic design concepts and even form factors of components may not seem to have changed very radically in the last fifty years, the design engineer of 1912 would be faced with an unbelievably kaleidoscopic vista if he were transported directly to the 1961 era. New materials, new methods of processing material, the ability to produce in quantities components which were once laboratory curiosities, the increasing complexity of end equipment and the resulting demands for more accurate control of component characteristics, the requirements for increased performance in more exacting environments, and the economic pressure to reduce cost have all combined to provide the present-day engineer with an array of parts with an extremely wide range of capabilities. The 1912 man might be almost frightened by this array, although in all due fairness he probably would not be anywhere nearly as nonplussed as the author was when, many years ago, he was ordered to repair and put in sufficiently reliable operation, so that the public could start and stop it with a push button, a tape sender and spark transmitter and a tuner, Wollaston detector and tape recorder of the vintage of 1910.

Resistors—A Survey of the Evolution of the Field*

JESSE MARSTEN†, FELLOW, IRE

Summary—**A survey is made of the evolutionary steps leading to the present state of the resistor field. The survey is confined to the resistance element which is the basic and most important factor in all resistors. The development is traced as nearly as possible from the origins of resistors, and proceeds from wire to composition, deposited carbon and films of metal and their compounds. Some future trends are indicated.**

I. Introduction

UNTIL the advent of radio broadcasting and particularly the use of the triode, industry needs were adequately served by wire resistors in a relatively small span of low to medium resistance values and from low to high power. The triode with its high-impedance input expanded the spectrum of values into the megohms region where resistances were required in ever increasing quantities by the burgeoning radio industry. However, size, cost and reactance limited the use of wire resistors.

Prior to radio, there was no organized research and development specifically directed to resistors. However, some very early work was so significant as to foreshadow the accomplishments today. There was considerable activity thereafter, largely disclosed in the patent literature. World War II, with its unusual environmental requirements, precipitated the major intensive research and development effort in resistors. Here special credit must be accorded the military for sparking, promoting and encouraging the major portion of this activity.

The factor common to all resistors, fixed and variable, which largely determines properties and performance, is the resistor element. It can be adapted to an infinite variety of types, shapes and uses of both fixed and variable resistors. It has therefore been the primary subject of significant investigations which fundamentally resolve into a search for new resistive materials. The evolution of the resistor field parallels this search.

II. Wire Resistors

Resistors utilizing alloys such as copper-nickel and nickel-chromium wound on insulating forms of varied geometry in a protective enclosure such as varnish, cement or vitreous enamel, are old and well-known. Advances have been the result of normal engineering improvements in structure and assembly, and need not be dwelled upon. The use of new resins for enclosures such as epoxy and silicones have made substantial improvements in humidity characteristics and have increased maximum operating temperatures.

Two developments of more technical merit warrant mention. Copper-nickel alloy has low temperature coefficient (20 ppm/°C) and medium resistivity (200 ohms/cmf). Nickel-chromium has higher resistivity (600 ohms/cmf) but high temperature coefficient (150 ppm/°C). In 1946, Lohr [1] disclosed a nickel-chromium-aluminum alloy, and in 1949, Allen [2] disclosed nickel-chromium-aluminum-copper alloy, both having a resistivity of 800 ohms/cmf with a temperature coefficient of 20 ppm/°C. The resulting gain was very substantial: greater temperature stability, increased maximum resistance available and space saving.

Differential expansion of the different elements in vitreous enamel resistors, causing shorted turns, loose terminals and crazing, results from the very high maturing temperature of the enamel. Leonard [3] in 1901 developed a glaze with low fusing point, 700°C instead of 1500°C, which helped but did not quite solve the problem. Ganci [4] in 1936 determined that the solution resided in the expansion coefficients of base, metal and enamel being properly related to each other. Formulations for the ceramic form and the enamel were developed which provide the proper coefficients relative to the metals employed. Thereafter it cannot be said that there were any major improvements. However, wire-wound resistors properly constructed are still the most stable and reliable in the limited values in which they are made, but in high values the size and cost are prohibitive. Future developments in other fields caused by these limitations are gradually narrowing the field of usefulness of wire resistors.

III. Composition Resistors

The urgent need for high resistance required by the triode was manifested in a rash of pencil and India ink line resistors. Future effort centered on "compositions of matter" as resistors. Such compositions have a long history. Thus in the field of solid compositions, Slattery [5] in 1885 described a high resistance comprising carbon and a refractory insulator molded into a cylinder with carbon terminations on each end. Voss [6] in 1896 shows a molding of carbon, metal oxides and binder fired to resistance value. In the field of composition film resistors, Gambrell [7] in England, 1897, disclosed a dispersion of carbon in a liquid medium containing a binder and volatile solvent which, applied to an insulating base, is heated to produce a resistive film.

Here we have the basic ingredients of both solid and

* Received by the IRE, May 2, 1961.
† International Resistance Company, Philadelphia, Pa.

film composition resistors of today. What was lacking to provide a satisfactory product capable of being produced uniformly in quantity, were the right materials and production techniques. These represent the technical contributions which resulted in today's product. As to material, it was the use of phenol-condensation products invented by Baekeland, used as molding powder and varnish binders which transformed the above early compositions into the present high quality product.

As for processing techniques which made possible prices of the order of one to four cents each, there were many workers in the field of solid composition resistors. The techniques were all based on hydraulic press molding of the materials, typical of which is that introduced in 1925 by Bradley [8] and Powers [9] disclosing specific formulations of materials and the simultaneous molding of the resistor body and end conductive terminations without wire leads.

Pender [10] invented an ingenious technique in 1925 for automatically and continuously depositing a composition film which, with engin ring refinements, is in use today. A solid or tubular glass fiber is continuously drawn to controlled dimensions through a liquid resistive solution and coated with a film of controlled thickness. The film is cured, measured for resistance value and cut to size, all in one operation.

The final stage in the development of the composition resistor, both solid and film, was the elimination of the so-called "uninsulated resistor," with thin varnish or lacquer coating. This was accomplished in 1933 by Pender [11] by molding an outer insulating casing around the resistor element, conductive terminations and leads. This is still the standard construction of not only the solid and film composition resistor, but precision film resistors as well.

The composition resistor is probably the most versatile of all resistors. It is miniaturized. It can be made in values from 1 to 10^9 ohms and higher. In the film form it is made for high frequency, high-voltage and moderately high power applications. As film, Brunetti and Khouri [12] introduced its use as a two-dimensional resistor for printed circuit applications. It is the lowest cost resistor, requiring minimum man-power and noncritical materials. For general purpose work requiring broad tolerances, it has been the resistor work horse of the electronics industry for four decades, still being used by the billions annually in the U. S. and throughout the world. Used within its limitations, it is now one of the most reliable components. However, it has two major deficiencies; stability and precision, properties so important to the war effort, which were directly responsible for the major effort in resistor research during and after the war.

IV. Deposited Carbon Resistors

The solution to the instability problem was the elimination of the organic binders in composition resistors. The use of deposited carbon resistors was the first important step in this direction. However, it is to be noted that this class of resistor was already developed and widely used in Europe in the twenties. Its use in the U. S. was precipitated by the need for precision resistors in great quantities in World War II and by the lack of facilities and critical materials for producing the necessary quantity of precision wire resistors.

The origin of this class of resistors appears to be German. The principle of cracking a hydrocarbon gas by pyrolysis to produce carbon may have had much earlier origin, but in 1925, Hartman [13] disclosed the basic method for depositing a hard carbon resistive film on an insulating substrate by pyrolysis of a hydrocarbon gas in vacuum or in a vessel containing an inert gas. Both methods are used today. The idea of increasing its resistance value by cutting a helical groove in the film was introduced in Germany much earlier in 1919 by Kruger [14]. Seibt [15], in Germany (1930), disclosed the process and equipment for producing the films by batch and continuous conveyor methods. Refinement of these basic disclosures resulted in the present semiprecision resistor having a stability in general terms three to five times that of composition resistors.

The resistance properties and performance of this film depends on its thickness. Resistance and temperature coefficient increase as film thickness decreases. Performance degrades with decreased film thickness. Maximum usable values are therefore limited. Temperature coefficient is variable and may be as much as three to four times greater at maximum usable resistance than at lowest resistance.

It is well-known that an alloy of metals shows increased resistivity and lower temperature coefficient than the individual components. This phenomenon also applies to films. In 1909, Weintraub [16] discovered that boron changed the temperature coefficient of carbon from negative to positive. Grisdale, Pfister and Teal [17] disclosed in 1950 a "boro-carbon" resistor film deposited pyrolytically from a mixture of a hydrocarbon and boron gas. Such resistors did show temperature coefficients very much lower than that of the conventional deposited carbon resistor, but only at low to medium values. Much higher values could also be made but deterioration of properties was so serious that its use was extremely limited.

Much activity continued along these general lines, and in 1952 Stein and Pugh [18] in research on high-stability resistors sponsored by the U. S. Signal Corps, described a deposited carbon film of carbon, silicon and oxygen which increased resistivity and improved humidity stability over that of carbon films. Such a resistor, originally called "pyrolytic carbon alloy" [19] in the trade, increased the usable maximum value fivefold, increased the hardness of the film so that resistance cannot be altered by abrasion or rubbing (a common procedure for adjusting the value of deposited carbon resistors), increased maximum operating temperature to 250°C for nonprecision work and enabled normal power ratings to be doubled for semiprecision applications. However, temperature coefficients were not improved. They were still too high and nonuniform for precision applications.

V. Metal Film Resistors

While carbon as resistive material was being fully explored, many parallel investigations were being conducted for other materials having greater stability and lower temperature coefficients, most being centered on films of metals and their compounds.

A. Noble Metal Films

The basic idea involved is the very old art of decorating chinaware with precious metals. In Germany in 1926, Loewe [20] developed a resistive film by atomizing a liquid solution of platinum resinate by forcing compressed air through it and applying the spray to an insulating base. Heating the film thus formed reduces it to the metal. Rosenthal Isolatieren Company [21] in 1937 included other metals in solution, *e.g.*, gold and silver, which lowered the temperature coefficient. Jira [22] (1942) gave minute detail of the entire procedure, which resulted in a practical product. While there is still some activity in this area, the improvements have not been noteworthy and the product has attained small use.

B. Tin-Oxide Films

The seed for this important contribution was provided by Littleton [23] (1931) who developed an iridized, conducting tin-oxide film coating for glass insulators. Its resistivity was sufficiently low to equalize potential across the insulator, thereby reducing corona effect, but too high for use in conventional resistors. Mochel [24] modified this film by the addition of antimony oxide which stabilized its electrical properties. By varying the tin-antimony proportions, negative or positive temperature coefficients are obtained.

The film is applied by atomizing a solution of tin and antimony oxides, applying the mist to a glass substrate heated to 500°C or more. Heating reduces the film to the metal-oxide state, integrally united with the substrate. This class of resistor has a very high degree of stability on all counts, can withstand temperatures of 225°C or more and has a wide field of use. It is, however, more limited in maximum value than either composition or deposited carbon resistors, and its temperature coefficient is high and of the order of deposited carbon.

C. Metal Films Produced in Vacuum

The resistor that most nearly approaches the properties and performance of wire resistors is one using a metal film produced in vacuum. There are two principal methods: 1) sputtering and 2) evaporation. While sputtering is not used today, the early developments have proved very valuable.

1) Sputtering: The principle is very old. A metal cathode is subjected to high voltage. Ionic bombardment of the cathode results in dislodgement of cathodic atoms which, falling on an insulating substrate, form a metal film. Richtmeyer [25] (1919) utilized this principle to produce resistors. The additional importance of his disclosure lies in the discussion of resistance instability caused by oxidation and in his use of heat treatment to stabilize the film. In the same year, Kruger [14] disclosed a high-resistance unit made by sputtering, in which adjustment of the film to desired value is accomplished by cutting a helical groove in the film, a technique which is almost universally used to-day.

2) Evaporation: The evaporated-metal film resistor is the latest useful step in the evolution of resistor development. While the general technique for producing evaporated metal films was known for a long time, very little was known about its properties. Extensive investigation by physicists [26] (the references cited contain extensive bibliography on the subject) disclosed that these films do not have the same properties as the bulk metal. For example, they show much higher resistivities, and temperature coefficients are lower and may be either positive or negative. Also, film properties are influenced by details of preparation and substrate history. Studies by Hoffman and Riseman [27] in research sponsored by the Air Force, indicated good possibilities for controlling these properties.

An early disclosure of metal evaporation was made in 1884 by Edison [28], who described the process of heating a metal to incandescence in vacuum, the vaporized metal depositing as a film on the material to be plated. This principle was utilized first by Loewe [29] in Germany, 1924, for making a resistor particularly for radio. An evacuated tube contains an insulator, with attached terminals coming out of the tube, surrounded by a metal cylinder heated by eddy currents induced in the metal. The evaporated metal deposits on the insulator, resulting in a hermetically sealed resistor.

In 1945 Weber and Johnson [30] described a procedure for evaporating nichrome on glass substrates and making precision resistors with temperature coefficients as low as 70 ppm/°C. The importance of evaporation parameters such as rate of evaporation, pressure, temperature, is emphasized. To protect against oxidation and aging, a protective insulating film is evaporated on the resistive film.

In 1954 Stein and Riseman [31] reported on the problems and conditions involved in the production of these resistors and disclosed the possibility of producing resistors with temperature coefficient controlled to any desired value and near zero. Not only can the temperature coefficient be controlled within limits, but unlike carbon and metal oxide films, it is relatively constant at all resistance values. Extensions of this investigation to precision resistors and power resistors, based on Signal Corps Contracts are described by Stein and Riseman [32] and Bohrer, Hauth, and Stein [33] and have led to successful production.

VI. Present Status and Future Trends

The absence of any important effort in wire resistor development is conspicuous and implies a declining use except for specific applications such as high power. Composition and film resistors have replaced wire in many applications and promise to continue doing so. The concentrated development effort on films has brought the deposited-carbon, tin-oxide and evaporated-metal film resistors to a stage of stability and reliability where they can meet most of the requirements in electronic and other applications. Even more so is the case with evaporated-metal film resistors since they can be made with temperature coefficients as low as wire and near zero and relatively constant over a wide range of values, thus affording greater temperature stability.

As to the future, while predictions are dangerous considering the rapid changes that are taking place, two trends are clearly perceptible. These trends are still dictated by the insistent demand for ever greater reliability and stability of components and by changes in electronic systems.

A. Inorganic Compositions

The route by which the present stage was reached proceeded from inorganic to organic compositions, to carbon films and finally to films of metals and their compounds. The trend now returns full circle to inorganic compositions with the expectation that much higher operating temperatures and stability will be obtained, and greater reliability by the elimination of catastrophic failures, occasionally experienced by film resistors.

As mentioned previously, very early work was not fruitful for lack of suitable materials. Later work by Hunt [34] in 1922 showed possibilities in fusing glass and carbon to form solid resistors. Some carbon-glass frit resistors were produced for a short time in Germany. This approach has been pursued by many investigators, and more recently by Hutter [35] in 1956 and Andrea [36] in 1958, who developed resistive and conductive glazes of borosilicate glass, fused with silver, copper and/or palladium. Other binding media for the conductor, such as ceramic, are also being investigated. Film resistors called "cermet resistors," have recently been produced by both methods. Many variations of this approach in film and solid form are being vigorously explored for use as composition, precision and power resistors. While it is too early to draw conclusions, the indications are that this promises to be a very important contribution with some potential in further limiting the uses for wirewound resistors.

B. Semiconductor Materials

1) The present trend toward micromodular systems and microcircuitry practically compels the use of film resistors made, because of space and geometry, with films of extremely high specific resistivity beyond that available now, if high values are needed. Research on thin semiconductor films of low conductivity is underway to meet this need. If successful, this could well eliminate the mechanical procedures of helixing and meandering currently used to increase resistance.

2) Film investigation in recent years has consumed most of the research and development man-power. It is not expected that this situation will change drastically since much remains to be done to make film production a science rather than an art. Also, other film materials will continue to be investigated. However, a departure is evident in increased activity in solid resistors as in Section VI-A, but also in bulk semiconductors utilizing doping methods to obtain necessary properties. Also, where discrete resistors are used, such materials, if successful, will be more amenable to subminiaturization.

3) Although the use of discrete resistors will still predominate, the semiconductor resistor effort will of necessity assume greater importance and result in greater activity because of the trend toward molecular electronics.

4) New areas in variable resistors will be explored. Noise and wear caused by sliding contactors are perennial problems. Programs [37] designed to investigate noncontact potentiometers utilizing semiconductors as the resistance medium are already underway. Among others, photo-conductive elements such as cadmium sulphide, and materials showing magneto-resistive properties [38] such as indium antimonide, are being studied. These promise to have value in specialized applications such as transducer functions. For general-purpose applications, there is nothing on the horizon to threaten the pre-eminence of the composition variable resistor [39].

Capacitors*

LEON PODOLSKY†, FELLOW, IRE

***Summary*—A review of the history and bibliography of the capacitor art of the 18th, 19th, and 20th centuries, prior to the founding of the IRE in 1912, compared to the explosive developments of the fifty years to 1962, shows the evolutionary nature of the advances in capacitor engineering. The dependence and parallelism of capacitor engineering with the mainstream of development in the basic sciences are clear and are further indicated for the future.**

IN THIS Fiftieth Anniversary Issue, the compulsion to review historically any sectional field of the electronics industry is inescapably strong. In the field of capacitors it is not only strong, but especially valuable to do so as a guide for our expectation of the future. For surely in these fifty years, as viewed from this time in the second half of the "Electronics Century," revolution and dramatic new invention in the capacitor field must have taken place. Certainly in the half century that saw atomic and electronic theory twice basically revised, and nuclear technology entirely developed, dramatic and fundamental changes must have taken place in our *concepts* of capacitors. Or so it would seem to the present generation of electrical and electronics engineers. But is it so?

Omitting most of the voluminous literature on dielectrics in general, there were more than *four hundred primary* references in the world's literature on the subject of "condensers" and their general properties and measurement at the time of the Institute's founding in 1912. In reviewing this extensive bibliography it is refreshing, sometimes shocking, to note the continuous flow of capacitor *ideas* and technology from the early 18th century, through the 19th century, and into the 20th century, well before the IRE was conceived. In addition to the extensive theoretical and practical publications in connection with the Leyden jar and its associated experiments beginning in 1745, there is a continuous literature of capacitor *ideas* dating at least from S. Grey's article "Electrical Experiments" in the *Philosophical Transactions of the Royal Society*, vol, 21, No. 366, page 104, of 1720. It is startling to find in this extensive literature before 1912 well-developed references, reports, and experiments on ideas, techniques, and structures which are today extant in the newest capacitors of our electronics technology.

To provide a frame of reference, Table I lists the most important properties and parameters of capacitors as we conceive them today in the light of our current needs.

Surely high performance in these parameters, or most of them, must evolve from the needs of our modern electronic apparatus and could hardly have been a matter of concern more than half a century ago! Let us see.

Without reference to any specific type of capacitor, what does the literature show us historically with regard to each of the major parameters of modern interest? The following fractional excerpt from the extensive bibliography will serve to show some of the more significant references to each of these important capacitor properties which existed *before 1912*.

* Received by the IRE, April 3, 1961.
† Sprague Electric Company, North Adams, Mass.

TABLE I

Capacitance (per unit volume, or volume efficiency)
Capacitance stability with time
Capacitance stability with temperature
Capacitance stability with applied voltage
High-frequency properties and effects
Voltage rating and dielectric strength
Insulation resistance
Insulation resistance variations with temperature
Dissipation factor (or dielectric loss)
Effects of humidity
Dielectric hysteresis
Pulse operation and surge rating
Effects of radiation
Effects of vibration and shock

Capacitance (Per Unit Volume, or Volume Efficiency)

1782—A. Volta, "Method of rendering very sensible the weakest natural or artificial electricity," *Phil. Trans. Roy. Soc. London*, vol. 72, p. 237; 1782.

1810—J. Wingfield, "A new method of increasing the charging capacity of coated electrical jars," *Phil. Mag.*, vol. 36, p. 259; 1810.

1855—W. Thompson, "On the electro-statical capacity of a Leyden phial, etc.," *Phil. Mag.*, pt. 4, vol. 9, pp. 531–535; 1855.

1862—J. M. Gaugain, "On the limit of the charge of condensers," *Phil. Mag.*, pt. 4, vol. 24, pp. 495–496; 1862.

1873—M. Neyreneuf, "On electrical condensation," *Telephone J.*, vol. 1, p. 257; 1873.

1879—C. V. Boys, "A condenser of variable capacity," *Phil. Mag.*, pt. 5, vol. 7, p. 108; 1879.

1884—R. T. Glazebrook, "Method of measuring electrical capacity of a condenser," *Phil. Mag.*, pt. 5, vol. 18, pp. 98–105; 1884.

1884—L. R. Wilberforce, "On some experiments on the measurements of the capacity of a condenser," *Proc. Cambridge Phil. Soc.*, vol. 5, pp. 175–182; 1884.

1900—L. Lombardi, "An Improved Process for Manufacturing Thin Homogeneous Plates, More Particularly Applicable for Use in Electrical Condensers," Brit. Patent No. 9133; filed May 17, 1900.

1904—G. F. Searle, "On the calculation of capacities in terms of coefficients of electrostatic induction," *Proc. Cambridge Phil. Soc.*, vol. 12, pp. 378–387; 1904.

1906—A. Zeleny, "Capacity of mica condensers," *Phys. Rev.*, vol. 22, p. 651; 1906.

1908—A. Zeleny and Andrewes, "The capacity of paper condensers," *Phys. Rev.*, vol. 27, pp. 65–75; 1908.

1909—E. H. Weiss, "Conditions for minimum volume of a condenser," *Lumière élec.*, vol. 8, pp. 326–29; December 11, 1909.

Capacitance Stability with Time

1874—Schiller, "Variation of dielectric constant with time of charge," *Poggendorfs Annalen*, vol. 152, p. 535; 1874.

1897—J. Hopkinson and E. Wilson, "On the capacity and residual charge of dielectrics as affected by temperature and time," *Phil. Trans. Roy. Soc. London*, vol. 189A, pp. 109–137; 1897.

Capacitance Stability with Temperature

1897—J. Hopkinson and E. Wilson, "On the capacity and residual charge of dielectrics as affected by temperature," *Elec. Rev.*, vol. 40, pp. 181 and 830; 1897.

1905—E. Terry, "On the variation of a capacity with temperature," *Phys. Rev.*, vol. 21, p. 193; 1905.

Capacitance Stability with Applied Voltage

1887—W. E. Sumpner, "On the variation of the coefficient of induction," *Phil. Mag.*, pt. 5, vol. 25, pp. 453–475; 1887.

High-Frequency Properties and Effects

1889—J. J. Thomson, "Specific inductive capacity of dielectrics at very high frequencies," *Proc. Roy. Soc.*, vol. 46, p. 292; 1889.

1891—R. Blondlot, "On the determination of the dielectric constant of glass by the action of very rapid electrical oscillations," *Phil. Mag.*, pt. 5, vol. 32, pp. 230–232; 1891.

1891—E. Lecher, "On the measurement of dielectric constants by means of Hertz oscillations," *Phil. Mag.*, pt. 5, vol. 31, pp. 172–182; 1891.

1897—E. S. Ferry, "The specific inductive capacity of dielectrics in slowly and rapidly changing electric fields," *Phil. Mag.*, pt. 5, vol. 44, pp. 404–414; 1897.

1898—J. Hanauer, "Influence of frequency on capacity," *Ann. Phys. u. Chem.*, vol. 65, p. 789; 1898.

1907—J. G. Coffin, "The effect of frequency upon the capacity of absolute condensers," *Phys. Rev.*, vol. 25, pp. 123–135; 1907.

1911—J. A. Fleming and G. B. Dyke, "The energy losses in condensers in high-frequency circuits," *Proc. Phys. Soc. London*, vol. 23, pp. 117–146; February, 1911.

Voltage Rating and Dielectric Strength

1881—E. Villari, "On the internal discharges of electrical condensers," *Phil. Mag.*, pt. 5, vol. 11, p. 541; 1881.

1892—W. H. Preece, "On the dielectric strength of a condenser," *Brit. Assoc. Paper*, Sec. A; August, 1892.

1893—A. MacFarland and G. W. Pierce, "On the electric strength of solid, liquid and gaseous dielectrics," *Phys. Rev.*, vol. 1, pp. 161–165; 1893.

Insulation Resistance

1897—P. A. Bates and W. C. Barnes, "Dielectric resistance," *Proc. AIEE*, vol. 14, p. 253; 1897.

1902—E. R. von Schweidler, "Conductivity and polarization in dielectrics," *Sitzungsberichte der Kaiserlichen Akad.*, pt. 111, p. 579; 1902.

1911—W. W. Stifler, "Resistance tests of insulators at high temperatures," *Phys. Rev.*, vol. 32, pp. 429–432; April, 1911.

Insulation Resistance Variations with Temperature

1889—H. Kouler, "On the electrical resistance of insulators at high temperatures," *Phil. Mag.*, pt. 5, vol. 23, p. 147; 1889.

1889—W. H. Schultze, "On the electrolytic behavior of mica at high temperatures," *Phil. Mag.*, pt. 5, vol. 27, p. 368; 1889.

1897—R. Appleyard, "Temperature corrections for dielectric resistance," *Elec. Rev.*, vol. 40, p. 737; 1897.

Dissipation Factor (or Dielectric Loss)

1891—P. Cardew, "Energy loss in condensers," *J. Inst. Elec. Engrs.*, vol. 20, p. 447; 1891.

1897—L. Houllevigue, "Electrical heating of condensers," *J. Phys.*, vol. 6, p. 120; 1897.

1899—E. B. Rosa and A. W. Smith, "Condenser losses," *Phys. Rev.*, vol. 8, p. 1; 1899.

1900—Pellant and Beaulard, "Energy losses in condensers with sinusoidal ac potentials," *Comptes Rendus*, vol. 130, pp. 1457–1460; 1900.

1901—C. P. Steinmetz, "Dielectric losses in condensers," *Elec. World and Engr.*; June 22, 1901.

1904—R. F. Earhart, "Absorption of energy in condensers," *Phys. Rev.*, vol. 19, p. 8; 1904.

1911—L. W. Austin, "Condenser Losses at High Frequencies," *J. Washington Acad. Sci.*, vol. 1, pp. 143–145; 1911.

1912—K. W. Wagner and A. Wertheimer, "Measurement of the dielectric angle of loss and the capacity with the ac bridge," *Physik. Z.*, vol. 13, pp. 368–375; May, 1912.

Effects of Humidity

1892—A. Johnstone, "Action of water on mica," *J. Chem. Soc.*, vol. 62, p. 573; 1892.

1898—E. Lethoule, "Effect of heat and moisture on dielectrics," *l'Eclairage Electrique*, vol. 17, p. 439; 1898.

Dielectric Hysteresis

1864—J. M. Gaugain, "On the residual charge of electrical condensers," *Phil. Mag.*, pt. 4, vol. 28, pp. 77–78; 1864.

1893—F. Bedell, N. Ballantyne and R. Williamson, "Alternate current condensers and dielectric hysteresis," *Phys. Rev.*, vol. 1, p. 81; 1893.

1895—A. W. Porter and D. K. Morris, "The question of dielectric hysteresis," *Electrician*, vol. 34, pp. 735–736; April 12, 1895.

1899—W. Schaufelberger, "Dielectric polarization and hysteresis," *Ann. Phys. u. Chem.*, vol. 67, p. 307; 1899.

1907—L. Malcles, "After effects in solid dielectrics," *Comptes Rendus*, vol. 144, p. 264; 1907.

1912—L. Decombes, "Electron theory of residual dielectric phenomena," *J. Phys.*, pp. 181–196; March, 1912.

Pulse Operation and Surge Rating

1864—W. Siemens, "On the heating of the glass plate of the Leyden jar by the discharge," *Berliner Berichte*, p. 612; 1864.
1889—J. Borgmann, "The heating of glass of condensers by intermittent electrification," *Phil. Mag.*, pt. 5, vol. 23, p. 472; 1889.
1908—B. V. Hill, "The variation of apparent capacity of a condenser with the time of discharge," *Phys. Rev.*, vol. 26, pp. 400–405; 1908.

Effects of Radiation

1896—J. J. Thomson and J. A. McClelland, "On the leakage of electricity through dielectrics traversed by roentgen rays," *Proc. Cambridge Phil. Soc.*, vol. 9, pp. 126–141; 1896.
1902—J. Curie, "Dielectrics under radium," *Comptes Rendus*, vol. 134, p. 420; 1902.
1904—Becker, "The influence of cathode rays on good dielectrics," *Ann. Phys.*, vol. 12, pp. 394–421; 1904.
1908—G. Jaffe, "On the ionization of fluid dielectrics by radium," *Ann. Phys.*, vol. 25, p. 257; 1908.
1909—B. Hodgson, "The conductivity of dielectrics under the action of radium rays," *Phil. Mag.*, pt. 6, vol. 38, pp. 252–258; 1909.

Effects of Vibration and Shock

1909—P. L. Mercanton, "Effect of mechanical shock on the residual charge," *Comptes Rendus*, vol. 149, p. 591; 1909.
1913—P. L. Mercanton, "Vibration and residual charge," *Arch. Sci.*, vol. 35, pp. 48–56; 1913.

Surprising as it may seem, the characteristics which are deemed essential today were under study in the old art, even to effects of supposedly modern environments such as acceleration and radiation. Surely, however, we might expect to find radical departures in types of materials used in capacitors. Let us look at the new materials in comparison with the old.

The most significant types of "fixed" capacitors in general use at this time, classed according to dielectric or structure, are those shown in Table II.

TABLE II

Glass
Mica
Vitreous enamel
Ceramic
Impregnated paper film and foil
Plastic film and foil
Composite dielectrics (paper and plastic films)
Metallized paper and plastic films
Vacuum or pressurized gas
Electrolytic—aluminum or tantalum oxide

Did the knowledge and use of these dielectrics and structures spring out of our mid-20th century electronics requirements? Let us again look at history before 1912 to gain perspective.

Glass

1788—E. W. Gray, "Observations on the manner in which glass is charged with the electric fluid," *Phil. Trans. Roy. Soc. London*, vol. 77, pp. 407–409; 1788.
1877—J. Hopkinson, "Residual charge of the Leyden jar—dielectric properties of various glasses," *Phil. Mag.*, pt. 5, vol. 4, pp. 141–142; 1877.
1891—R. Blondlot, "On the determination of the dielectric constant of glass by the action of very rapid electrical oscillations," *Phil. Mag.*, pt. 5, vol. 32, pp. 230–232; 1891.
1904—I. Mosicki, "Improvements in Electric Condensers," Brit. Patent No. 1307; filed January 18, 1904.

Mica

1874—M. Bauer, "Physical properties of mica," *Z. deut. geol. Ge.*, vol. 26, p. 137; 1874.
1888—C. Doelter, "On the artificial manufacture of mica," *Comptes Rendus*, vol. 107, p. 42; 1888.
1890—E. Bouty, "Mica condensers," *Comptes Rendus*, vol. 110, p. 486; 1890.
1893—P. Janet, "The Hysteresis and Dielectric Viscosity of Mica for Rapid Oscillations," Paris Academy of Sciences, Paris, France; February 20, 1893.
1906—A. Zeleny, "Capacity of mica condensers," *Phys. Rev.*, vol. 22, p. 651; 1906.
1910—H. L. Curtis, "Mica condensers as standards of capacity," *Bull. Bur. Standards*, vol. 6, pp. 431–488; November, 1910.

Vitreous Enamel

1912—W. Torikata and E. Yokoyama, "Enamelled condensers for radio telegraphy," *Electrician*, vol. 69, pp. 1072–1073; October, 1912.

Ceramic

1900—L. Lombardi, "An Improved Process for Manufacturing Thin Homogeneous Plates, More Particularly Applicable for Use in Electrical Condensers," Brit. Patent No. 9133; filed May 17, 1900.
1908—H. W. Brady, "Electrical porcelain," *Elect. Rev.*, vol. 62, p. 927; 1908.
1908—H. F. Haworth, "Electric properties of porcelain," *Proc. Roy. Soc. London*, vol. 81, p. 221; 1908.
1910—Rebora, "Experimental researches on insulators of glass and porcelain," *Atti Assoc. Electrotech., Italiano*, vol. 14, p. 665; 1910.

Impregnated Paper Film and Foil

1898—X. Boucherot, "Paper condensers," *l'Eclairage Electrique;* February 12, 1898.
1906—A. Campbell, "Electric inductive capacities of dry paper and solid cellulose," *Proc. Roy. Soc. London*, vol. 78A, p. 196; 1906.
1908—G. F. Mansbridge, "The manufacture of electrical condensers," *J. Inst. Elec. Engrs.*, vol. 41, p. 535; May, 1908.
1908—A. Zeleny and Andrewes, "The capacity of paper condensers," *Phys. Rev.*, vol. 27, pp. 65–75; 1908.
1911—F. W. Grover, "Experiments on paraffined paper condensers," *Bull. Bur. Standards*, vol. 7, p. 495; December, 1911.
1913—G. E. Bairsto, "Experiments on tinfoil contact with dielectrics," *Proc. Phys. Soc. London*, vol. 26, pp. 301–323; August, 1913.

Plastic Film and Foil

1910—"Measurements on a celluloid condenser," *Atti Assoc. Elettrotech. Italiano*, vol. 14, pp. 227–235; 1910.
1910—A. Hakansson, "Plastic materials for insulation," *Elektrotech. Z.*, vol. 31, pp. 953–958; September 22, 1910.
1911—G. L. Addenbrooke, "Electrical properties of celluloid," *Electrician*, vol. 66, pp. 629–630; January, 1911.

Composite Dielectrics

1892—A. Hess, "Heterogeneous insulators," *J. Phys.*, vol. 1, p. 459; 1892.
1910—W. C. M. Lewis, "Notes on the energy of a 'double layer' condenser," *Phil. Mag.*, pt. 6, vol. 19, pp. 573–575; 1910.

Metallized Paper and Plastic Films

1705—F. Hauksbee, "Experiments on the attrition of bodies in vacuo," *Phil. Trans. Roy. Soc. London*, vol. 24, 304, p. 2156; 1705. (First article on vacuum metallization.)

Vacuum or Pressurized Gas

1850—M. Faraday, "On the magnetic and diamagnetic condition of gases," *Phil. Mag.*, pt. 6, vol. 37, pp. 88–101; 1850.
1892—F. J. Smith, "Compressed air condensers," *Proc. Phys. Soc.*, vol. 11, p. 355; 1892.
1904—Lord Kelvin, "Electric insulation in vacuum," *Phil. Mag.*, vol. 8, p. 534; 1904.
1905—R. A. Fessenden, "High pressure electric condensers," *Electrician*, vol. 36, p. 112; 1905.

ELECTROLYTIC

1873—G. Little, "Condensers for the little automatic telegraph," *Telegraph J.*, vol. 1, p. 207; 1873.
1891—E. B. Rosa, "Specific inductive capacity of electrolytes," *Phil. Mag.*, pt. 5, vol. 31, pp. 188–207; 1891.
1894—Sheldon, Lietche and Shaw, "The capacity of electrolytic condensers," *Phys. Rev.*, vol. 2, pp. 401–411; 1894.
1897—A. G. Davis, "Electrolytic condensers," *Elec. Rev.*, vol. 40, p. 33; 1897.
1898—C. Pollak, "Improvements in electrolytical condensers," Brit. Patent No. 933; filed January 4, 1898.
1901—Siemens Brothers, "An improvement in electrolytic polarization cells having an aluminum electrode," Brit. Patent No. 17480; filed August 31, 1901.
1912—"An electrolytic condenser employed in connection with a sparkless contact," *Elektrotech. Z.*, vol. 33, pp. 889–891; 1912.

It is evident that not only the critical properties but also the basic types are the same today as a half century ago. Are we then to conclude that there is nothing new in the capacitor art, or that no progress has been made in these fifty years? Most certainly not! For although the bibliography clearly shows a long history of theoretical and practical ideas in capacitor art and engineering predating the formation of the IRE in 1912, modern capacitors are vastly different in every category of performance and structure from those of fifty years ago. The important properties are the same, and even the generic names of the principal dielectrics are the same, but a revolution in science has come between.

Advances in capacitors have actually been very real and very large, and have ensued from intensive and continuous development effort involving progressive aplication of the newest findings in physics and chemistry.

In an article of this length it is impossible to explore the full ranges of structure and performance which are available today. However, Table III lists the improvement factors for each of the major parameters originally

TABLE III
COMPARISON OF PERFORMANCE PARAMETERS

	1912	1962*
Capacitance (per unit volume)	2 mf/cu foot	>3000 mf/cu inch
Capacitance stability with time	±1 per cent per year	±0.01 per cent per year
Capacitance stability with temperature	±500 ppm/°C	±10 ppm/°C
Capacitance stability with applied voltage	Uncontrolled	Effect can be made negligible
High-frequency effects	Uncontrolled	±1 per cent, 1000 cycles to 1000 Mc
Voltage rating	100 volts per section 500 volts per capacitor	10,000 volts per section Unlimited per capacitor
Insulation resistance	5 to 10 megohms×mf	>1,000,000 megohms×mf
Dissipation factor	0.01 to 0.1 at 1 kc	3×10^{-4} at 1 kc
Effects of humidity	Somewhat uncontrolled	Eliminated by hermetic sealing
Dielectric hysteresis	No reference standard	Can be made negligible
Pulse operation	Highly destructive	Can be made negligible
Effects of radiation	Uncontrolled	Can be minimized or eliminated
Effects of vibration and shock	Highly destructive	Can be minimized or eliminated

* This is *not* to imply that *all* these properties can be obtained with a single dielectric material, structure, or rating, but only to indicate the performance which can be obtained in general commercial capacitors, at least for single parameters of importance.

TABLE IV
DIELECTRIC MATERIALS AND STRUCTURES IN COMMON USE

	1912	1962
Glass	Plate glass—0.1 in thickness.	1 mil thickness ribbon. Borosilicate or high K glasses.
Mica	3 to 5 mil thickness—generally unselected.	1 mil or less—high grade selected—silvered. Mica paper.
Vitreous enamel	Glass frit—low K.	High temperature vitreous enamel; K=20 to 120.
Ceramic	Porcelain—K approximately 20.	Titania, barium titanate, stannate, zirconate bodies. High K with controllable TC K=10 to 10,000.
Impregnated paper	1 to 3 mil sulfite paper. Beeswax, paraffin, or oil impregnation.	0.2 mil high purity Kraft—Polyisobutylene, chlorinated diphenyl, chlorinated napthalene impregnation.
Plastic film	Celluloid, 3 to 5 mils.	Polyethylene, Mylar, Teflon, polystyrene. 0.25 mil. 0.10 acetate.
Composite Dielectrics	Paper and shellac, etc.	Paper and plastic films.
Metallized paper and plastic films	Unused.	Highly developed. Vacuum metallized paper and plastic films of all types.
Vacuum or Pressured gas	Air or low vacuum.	High vacuum, pressured nitrogen, sulfur hexafluoride.
Electrolytic	Wet cell aluminum.	Dry electrolyte, aluminum foil, tantalum foil, tantalum porous pellet, solid electrolyte tantalum pellet.

shown in Table I which have resulted from the advances in the art in these fifty years.

What of the dielectric materials in use for capacitor structures of today? Table IV shows the outstanding materials in use now, for the categories of capacitors originally shown in Table II, as compared to those of 1912.

There are many other capacitor materials and techniques in more exploratory stages of application at this time which are worthy of mention. Among these are:

High-temperature mica (500°C).
Rolled-glass film.
Solid electrolyte—aluminum oxide—pellet.
Lacquer film (0.1 mil or less).
Mica paper.
Silicon dioxide.
Titanium, columbium oxide, etc.
Metallized spun film.
Polycarbonate film.
Cyanoethylcellulose film.

The most fundamental improvements which have been made in capacitors in the mid decades of this century have been in the following categories:

1) Improvements in reliability (at least 1000:1).
2) Reduction in size (at least 10:1).
3) Increased operating temperature range (−70°C to +150°C for general types).
4) Improved stability (at least 5:1).
5) Development of capacitors suitable for use in nuclear environments (progress).

What shall we say of the future that will have any significance to posterity on the 100th Anniversary of the IRE? We already have in operation electronic circuitry in which all the basic circuit parameters of capacitance, resistance, and inductance are produced within solid-state semiconductor devices. Can we predict the ultimate demise of integral capacitor units as circuit elements?

We must learn the answer from the long continuum of capacitor history. Examination of the extensive bibliography and history of the art shows clearly that improvements in capacitor materials and design have followed closely the increased knowledge in the fundamental sciences, and most particularly in chemistry and physics. All of the major advances of this half century have resulted from basic advances and the improvement of knowledge of the structure and performance of matter and the improvement of methods of measurement.

The advances in capacitor art and engineering have been largely evolutionary, seldom revolutionary, and have been one with the long continuum of advance in basic science. Undoubtedly this has also been true of all other electronic component fields.

There were no companies of record in 1912 which specialized solely in capacitor manufacture. Capacitors were made by the apparatus manufacturers for use in their own equipment. It is therefore impossible to obtain comparative figures on the numbers of capacitors produced or their dollar value in 1912. However, today the capacitor industry in the United States alone consists of more than one hundred fifty manufacturers. Production in 1960 of the major capacitor types shown in Table II is estimated at approximately 1,200,000,000 units with a total sales value of $274,000,000. This represents approximately 23 per cent of the total value of all electronic component sales, excluding tubes and semiconductors, in that year and 2.68 per cent of the value of all electronics manufacture in the United States.

No man can predict what the next half century will bring, just as no prediction made in 1912 could possibly have foreseen the directions of growth of the electronics industry or the development of nuclear science. We can only be sure that developments in the capacitor field will advance constantly with the mainstream of science and that the art will progress to meet the needs of the electronics industries for every application whether they be terrestrial or in outer space.

Piezoelectric Effect and Applications in Electrical Communication*

VIRGIL E. BOTTOM†, SENIOR MEMBER, IRE

Summary—**The phenomenon of piezoelectricity, discovered in 1880, is the basis of a number of devices which are essential to the art and practice of electrical communication. The discovery of the phenomenon, the development of the quartz resonator, and its application as a frequency-stabilizing element in oscillator and filter circuits are described. Some of the technical problems encountered in the design and fabrication of quartz-crystal units are discussed. Using quartz crystal units for short-term stability and atomic resonators for long-term stability, frequency standards which are reliable and reproducible to 1×10^{-11} are now available.**

The Piezoelectric Effect

MECHANICAL strains in certain crystals are accompanied by electrical polarization, the magnitude of which is directly proportional to the strain. This is the *direct piezoelectric effect.* The reciprocal effect in which the application of an electric field causes a mechanical stress in the crystal is called the *converse piezoelectric effect.* Both effects were demonstrated experimentally by Pierre and Jacques Curie [3] in the years 1880–1881. For the next forty years piezoelectricity remained a laboratory curiosity. During World War I Langevin revived interest in the phenomnon by using plates of quartz to generate and detect high-frequency sound waves in water.

While investigating the use of Rochelle salt as a transducer, Cady, in 1918, observed a peculiar reaction between the piezoid and the driving circuit when the driving frequency was near that of a mechanical resonant frequency of the piezoid. Cady described his discovery of a paper presented to the IRE on November 21, 1921, and in a subsequent paper, published in the PROCEEDINGS the next year. In this paper Cady [4] described the use of the piezoelectric resonator to stabilize the frequency of a vacuum tube oscillator circuit. The pioneer work of Cady was extended by Pierce [5] and others who devised a number of circuits employing piezoelectric resonators as frequency-stabilizing elements.

The Equivalent Circuit

The first investigation of the theory of equivalent circuits appears to have been made by Butterworth [6] in connection with his studies of the vibration galvanometer in 1915. In his paper Butterworth showed quite generally that any one-dimensional mechanical system excited by the interaction between electrical charges and an electric field may be represented by a circuit consisting of an inductance, a capacitance and a resistance in series. During the years 1925–1928, Van Dyke [7] and Dye [8] developed the theory of the equivalent circuit of the piezoelectric resonator and gave the equations relating the values of R, L, C and C_0 of the equivalent circuit (Fig. 1) to the piezoelectric, dielectric and elastic coefficients, and the density and dimensions of the resonator. Using the concept of the equivalent circuit, Espenchied [9] showed how to combine piezoelectric elements with conventional circuit components to provide improved band-pass filters. His work led to the development of the high-frequency carrier current telephone system and laid the foundation for coaxial and microwave transmission systems in which several hundred signals are transmitted simultaneously over the same communication channel.

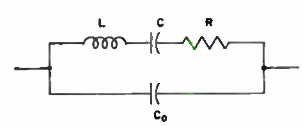

Fig. 1—Equivalent circuit of piezoelectric resonator.

Development of the Quartz Resonator

Although the piezoelectric effect is very much greater in several other crystals, quartz has always been a favored material for many applications because of its superb mechanical qualities. The earliest quartz piezoids were X-cut plates, so called because the plates are cut from the crystal in such a way that the XD-crystallographic axis is perpendicular to the faces of the plate. The application of an electric field in the X direction causes the plate to change its thickness, thus resulting in the propagation of a longitudinal wave in the thickness direction. The resonant frequency of an X-cut quartz plate decreases about 20 ppm/°C.

In 1933 a patent was issued to Tillyer [10] disclosing the Y-cut plate. The temperature coefficient of the Y-cut is much worse than that of the X-cut, being about 100×10^{-6} per degree C. Nevertheless the Y-cut soon came to be favored over the X-cut because the mode of vibration, which results from a transverse wave traveling in the thickness direction, permits the plate to be clamped, thus resulting in a more rugged device. In 1934 workers at the Bell Telephone Laboratories [11] and in Germany and Japan discovered almost simultaneously that by inclining the plane of the Y-cut plate at certain angles with respect to the optic or Z axis the resonant frequency could be made nearly independ-

* Received by the IRE, June 19, 1961.
† McMurry College, Abilene, Texas.

ent of temperature over fairly wide temperature ranges. These cuts were named the *AT*- and *BT*-cuts.

The development of the *AT*- and *BT*-cuts was quickly followed by the development of a number of others designed to have low temperature coefficients of frequency and to operate over different ranges of frequency. One of these is the *GT*-cut, discovered by Mason [12] in 1940. By ingenious use of coupling between modes of vibration having different temperature coefficients, the *GT*-cut provides a standard of frequency which is substantially independent of temperature over a range of 100° of temperature. Oscillators controlled by *GT*-cut plates have been used as standards of time and frequency almost universally since that date and are only now being replaced by more stable devices.

Use of Quartz Crystal Units in Communication

The radio-frequency oscillators in early radio transmitters were subject to severe frequency variations because of varying environmental conditions and loading. It was early recognized that precise control of frequencies is essential to reliable communication. In 1926 WEAF became the first commercial broadcast station to be crystal controlled. Between then and 1940 crystal control became universal in broadcasting and many amateurs used crystal units to control the frequencies of their transmitters. By 1939 the growing use of radio in mobile communication had created a small market for quartz crystal units, most of which were made by hand by a few skilled craftsmen using simple equipment.

Slight use was made of crystal control in military communication equipment until immediately prior to the outbreak of World War II when the advantages of reliability, convenience and reduced weight were demonstrated in field tests. The decision to convert military communication equipment to crystal control practically coincided with the entrance of the United States into the war. A crash program was organized to provide the needed crystal units with such success that an industry which produced fewer than 30,000 units in 1939 produced over 100 million units during the years 1943–1945. This vast increase in production was made possible by the development of a number of ingenious machines including diamond saws, lapping machinery and X-ray diffraction equipment for use in orienting the plates precisely with respect to the atomic planes in the crystal of quartz. This was the first commercial application of X-ray diffraction to a production process.

Improvements in Design

The modern quartz-crystal unit bears little resemblance to its predecessor of twenty years ago. Fig. 2 shows a modern crystal unit beside its counterpart of 1940. The earlier unit was enclosed in a plastic holder having a volume of approximately 3 cubic inches, whereas the current design employes a metal holder having a volume of about $\frac{1}{8}$ cubic inch. The 1940 unit operated with a frequency tolerance of ± 0.02 per cent within the temperature range $-40°$ to 70°C, whereas the modern unit meets a frequency tolerance of ± 0.005 per cent from $-55°$ to 90°C. The earlier unit contains a quartz plate $\frac{3}{4}$ inch square clamped between two stainless steel plates which serve as electrodes and provide mechanical support. The modern unit contains a circular plate having a diameter of less than half an inch with metal electrodes deposited on the quartz.

When the highest stability is required, units are often encapsulated in glass holders using the techniques developed for the production of electron tubes.

The maximum frequencies available with quartz crystals prior to 1945 was about 10 Mc. Today crystal units operating at frequencies above 100 Mc are readily available. Still higher frequencies are desired.

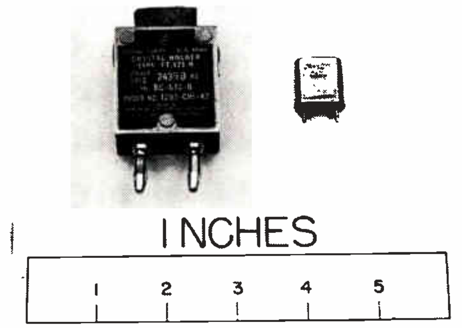

Fig. 2—Typical quartz crystal units of 1940 (left) and 1960 (right).

Technical Difficulties

The extreme precision required of the quartz crystal unit naturally imposes severe design and production problems. The thickness of a 10-Mc *AT*-cut plate is about 0.0065 in. To adjust the frequency of such a plate to within 100 cps of its assigned frequency, which is often necessary in production, the thickness of the plate must be adjusted with an accuracy of about 6×10^{-8} inch, which is equivalent to only two or three layers of atoms or about three thousandths of the wavelength of visible light.

With such critical dependence upon thickness, it is not surprising that the resonant frequency of a quartz plate should be highly sensitive to surface effects. Prior to 1943 the frequencies of quartz plates were commonly adjusted by removing quartz mechanically to obtain the desired frequency. Units prepared in this way are subject to "aging" which results from weathering of the surface of the quartz. Millions of units fabricated in this way were found, in 1943, to have become useless after a short period of storage. To prevent aging of this type, it is necessary to adjust the frequency of the quartz plate by chemical rather than physical means.

The deposition of as little as a monatomic layer of a foreign material on the surface of a quartz plate is often sufficient to render it useless for its intended purpose. It is therefore necessary to establish the most exacting standards of cleanliness and quality for the materials used in the fabrication of crystal units.

Other forms of aging, having less serious effects upon the device, are under investigation. These include changes in the physical structure of the metallic electrodes, rearrangement of the crystalline defects within the quartz and relaxation of stresses within the quartz and its supporting structure. Continued research and development has been necessary to keep abreast of the demand for tighter frequency control.

The variation of frequency with temperature is critically dependent upon the orientation of the piezoid with respect to the atomic planes of the crystal. In order to meet the requirements of modern specifications it is necessary to control the orientation with an accuracy of one quarter minute of arc. This accuracy is obtained using X-ray diffraction apparatus employing double-crystal techniques developed for the purpose.

Synthetic Quartz

Despite many investigations, no substitute has been found for quartz as a material for fabricating precision piezoids. However, quartz suitable for fabrication of quartz crystal units is relatively scarce and expensive and no significant domestic source has been discovered. To provide a reliable source of raw material, a program to develop techniques for producing synthetic quartz was instituted following World War I. This program was successful in developing techniques for producing synthetic quartz at a cost which is competitive with that of the natural product. Slight differences between the natural and the synthetic product make the present synthetic product inferior to natural quartz for some applications but superior for others. With further work it may be possible to produce synthetic quartz with special properties for specific applications.

Atomic Frequency Standards

Astronomical events such as the mean solar day have long been used as standards of time for reasons of permanence, availability and reliability. For the past thirty years quartz crystals have been used to interpolate between these relatively large time units and to provide standards of frequency based upon them. Quartz crystal units developed for the purpose and widely used as national standards of frequency are capable of accuracies of the order of 1×10^{-10} per day. If the clock controlled by such a crystal unit continued to operate with such precision it would deviate by only about 0.3 sec per century. But, however reliable a crystal clock is made, it cannot serve as a primary standard of time or frequency. The short-term accuracy is enough, however, to reveal serious discrepancies in the regularity of astronomical events.

Within the past ten years, devices utilizing atomic events have been devised which provide standards of time and frequency which are reproducible and reliable over periods of a few months to about 1.5×10^{-11}. Such devices will soon provide new standards of time and frequency far more accurate than those based upon astronomical observations. Most of these devices incorporate a high-quality quartz-crystal unit to furnish short-term stability, while the atomic standard provides reproducibility and long-term stability by correcting the quartz-crystal unit for aging and other effects.

W. P. Mason has remarked that the quartz crystal "... can be regarded as one of the cornerstones of the whole art and practice of electrical communication." It seems likely that it will continue to provide the foundation for a long time to come.

Relays and Switches*

A. C. KELLER†, FELLOW, IRE

Summary—**Relays and switches are among the most important components in the general area of electromechanical devices. Both of these have been in use for many years and continue, in modern form, to be essential elements in many modern switching applications including electronic systems.**

Early forms of relays were simple and controlled a single contact. Telephony created the need for more complex forms of relays and switches early in its history, and has continued ever since to require advances.

Switching functions such as counting, registration, translation, etc., are accomplished by relays and switches. The most difficult and complex switching functions arise from centralized or common control types of automatic control systems including telephone central offices and computers. These are often referred to as the "brains" of the system.

Modern trends in relays and switches are in miniaturization, hermetic sealing, improved reliability in the presence of shock and vibration and in higher operating speeds. Glass-enclosed contacts of the "dry reed" and mercury types have had an important part in achieving better performance. Another important trend is for them to become competitive, compatible and combinational with solid-state switching devices and systems as illustrated by the ferreed.

Research is continuing actively with miniaturized relays, piezoelectric relays, glass-enclosed contact relays, higher-speed relays, transistor-operated relays and combinational devices such as the ferreed. One form of ferreed will operate from a 5 μsec pulse and remain operated until released by a similar pulse.

RELAYS and switches are among the most important components in the general area of electromechanical devices. Both of these have been in use for many years and continue, in modern form, to be essential elements in many modern switching applications including electronic systems.

For the purpose of this paper *relays* are, essentially, remotely controlled switches which can open or close electrical contacts when suitable electrical conditions are met and are, therefore, two-state devices, *i.e.*, on or off.

Switches on the other hand are often two-state devices, but are also multi-state or multi-position devices. The names of switches often indicate the intended use or function such as, Limit Switch, Sensitive Switch, Coaxial Switch, Pushbutton Switch, Momentary Contact Switch, Pressure Switch, Thermal Switch, Lever Operated Switch, etc. Multi-state switches include Rotary Switches, Stepping Switches, Unidirectional Switches, Two-Motion Step-by-Step Switches, Crossbar Switches, Commutating Switches, Scanning Switches, etc.

Many switches are of the manual type, but equally important are those electrically operated in which case they might be considered to be relays.

* Received by the IRE, June 16, 1961.
† Bell Telephone Laboratories, Inc., New York, N. Y.

Switches and relays have many problems in common but none of more importance or more involved than that of the contact materials and the contact supporting members. Contact materials vary from expensive noble metals used for the best reliability with low-contact forces to the less expensive base metals often used with large contact forces. Modern relays and switches are often hermetically sealed to prevent contamination from external dust, dirt, and other environmental conditions. However, in some cases of sealed relays and switches, the entire structure is encased including the actuating coil, insulators, etc., which usually contain organic materials. These conditions are likely to result in polymer formation and the resulting high-contact resistance when certain precious metals are used for the contact surfaces. This is particularly true for metals in the platinum family including paltinum, palladium, rhodium, etc., when used in "dry" circuit applications, *i.e.*, those in which no contact arcs are involved and the circuit current is neither made nor broken. Important improvements have resulted in such cases by a separate sealed chamber in which all organic materials are eliminated.

Contact arcing is another type of problem which may cause excessive erosion of the contacts in certain types of circuits. Contact protection in the form of electrical components or networks is used, at times, to extend the life of contacts. To be successful in reducing contact erosion the protection must control the voltage to keep it below the breakdown voltage and also control the current to keep it below the minimum arcing current for the particular materials involved, and for the surface conditions of the materials, *i.e.*, clean or contaminated, smooth or rough, etc.

Early forms of relays were simple and rather large, controlling one contact. These were actually modifications of telegraph instruments and, in fact, the name relay came from telegraph practice, *i.e.*, the Morse Relay, etc.

Telephone created the need for more complex forms of relays and switches early in its history and has continued ever since to require advances. The advent of automatic or dial telephone switching systems resulted in rapid and important new forms of relays and switches (see Fig. 1). These were required to have more contacts, higher speeds, etc., and to be smaller in size. Other new features were switch selectivity involving 100 or more circuits and relays that responded to dial pulses or, on the other hand, were of the slow-release type to be held operated during a series of pulses.

As automatic dial-switching systems developed to become more completely mechanized, as automatic-con-

Fig. 1—Some steps along the road to modern relays. *Right*—the wire spring relay used in modern telephone switching systems.

trol systems for many other uses developed and as computers came into use, switching functions became more complex. Switching functions and switching units were given names, sometimes new and sometimes duplicate names; such as counting, registering, translation, selectint, decoding, directing, sender, marker, memory, etc. Many of the most difficult and complex switching functions arise from the common control types of automatic control systems. These are often referred to as the "brains" of the system. In a modern crossbar telephone system which uses essentially only repetitive units of crossbar switches and various kinds of relays, one marker may have 1500 relays. This type of circuit unit performs many logical operations. These are chiefly based on the two-state relay. Circuit requirements in terms of these can set up logical interrelationships of circuit paths and apparatus to meet the needed conditions. Twenty such two-state relays can be used to give more than 1,000,000 combinations. Logic such as "and," "or," "but," etc., can be easily obtained with simple relay circuits as well as "add," "substract," "divide," etc. These form the basic building blocks for the brains or common control switching functions.

Electromechanical relays and switches are now made in more forms by more manufacturers in larger quantities than ever before. This is of interest in view of the recent rapid development of solid-state switching devices and systems. In general, solid-state devices operate in microseconds compared to milliseconds or longer for electromechanical devices. The reasons for the continued expansion of the uses of electromechanical switching devices are several: 1) they often result in equipment designs which are simple and inexpensive, and yet operate fast enough to make unimportant any increase in operating speed; 2) they can be used singly and in small numbers without the associated common equipment often required to take full advantage of the sensational speeds of solid-state devices; 3) the rapid expansion of switching of all kinds (which requires more of everything including electromechanical and solid-state devices); and 4) relays and solid-state devices are developing a compatibility, and in fact, combinations of both have been developed.

The most widespread present trend in switches and relays in all types of switching systems is in miniaturization and in hermetically sealed types. (See Fig. 3). Relays have been manufactured and used in size steps down to "postage stamp" or "crystal can" sizes and smaller. These are not, in general, fully functionally equivalent to the larger sizes but they are being used in increasing quantities in many applications.

Several other important trends in relays have been: 1) code card operation by which notches in the actuating card determine the contact sequence; 2) magnetic latching which provides relay operation or release under the influence of pulses; and 3) frequency selective relays.

Reliability has also become increasingly important and low failure rates are required under severe conditions of shock, vibration, temperature and humidity as in missile and other military switching systems. The miniature relays are often better under shock and vibration than larger types of the same form because of the smaller inertia of the moving parts.

Another important trend for switching systems in general is for relays and switches to be competitive, compatible and combinational with solid-state switching devices and systems.

Glass-enclosed contacts represent another trend in improving the reliability of relay and switch applications. The glass-enclosed contacts are either the "dry reed" type or the mercury type. (See Fig. 2.) In either case they are free from external influences such as dust, corrosive atmospheres, ambient pressures, etc. In addition, relays using glass-enclosed contacts, particularly of the miniature type, are fast in operation and release, often less than 1 msec for each of these. Glass enclosed contacts of the mercury type have the least chatter (often none) and have the longest operating life (greater than 1,000,000,000 operations) of any relays yet designed.

Research is being actively continued in the areas of miniaturized relays and switches, printed-circuit relays, thermal relays, piezoelectric relays, glass-sealed contacts using dry and mercury contacts, higher-speed relays, frequency-sensitive relays (selectors), relay arrays, transistor-operated relays, and combinational devices such as the ferreed.

One form of the ferreed (see Fig. 3) is a combination

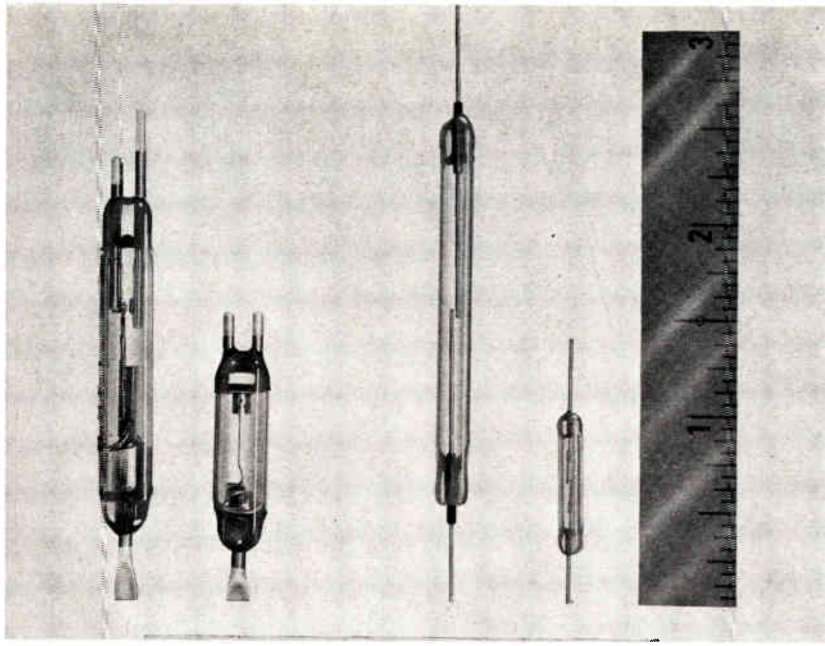

Fig. 2—Glass enclosed contacts for relays. *Left to right*—mercury-wetted type, small mercury-wetted type, dry reed type and miniature dry reed type.

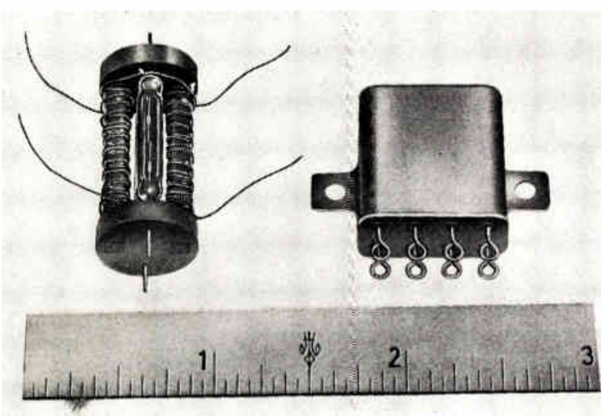

Fig. 3—Modern trends in relays. *Left*—ferreed with two contacts; *right*—DPDT "crystal can" relay.

of one or more miniature glass-sealed contacts and one or more pieces of ferrite or other suitable remanent material. Operating pulses as short as 5 msec can be used to operate the contacts of a ferreed. This is the time required to change the magnetic state of the ferrite to a magnetized condition. Later, perhaps $\frac{1}{2}$ msec later, the glass enclosed contact will operate. Another way to describe a simple ferreed is to say that it is basically a "magnetically latched" relay that can be operated or released by pulses. Ferreeds do not need holding power to hold them in the operated condition. The basic properties of the ferreed, *i.e.*, sealed contacts, control times in the μsec range, coincident selection, memory without holding power, and small size, make them compatible with solid-state circuit applications.

Transformers, Inductors and Filters*

HAROLD W. LORD†

Summary—**Transformers, inductors and filters have continually played important roles throughout the field of electronics. Relatively crude electromagnetic devices were employed in early telephone and radio communication systems and today their vastly improved descendants are still found in most electronic systems.**

The sizes of electronic power transformers have been reduced through the development of new core materials and suitable high-temperature insulating materials. Design methods for audio and video transformers have been evolved which, in combination with improved core materials, made it possible to provide broad-band transformers having low distortion effects. Pulse transformers were developed for radar systems and made practical the hydrogen thyratron type pulse modulator.

The performance characteristics of intermediate-frequency and radio-frequency transformers have been improved and their sizes reduced through the development of pressed-powdered iron and ferrite core materials.

The linearity and stability of iron-cored inductors for filters have been improved through core materials development. Nonlinear inductors were made more nonlinear through the development of rectangular hysteresis loop magnetic alloys and ferrites, providing many new types of electromagnetic devices for electronic circuitry.

Advances in electronics have made obsolete some applications of transformers and inductors but also have opened up other opportunities for inductive devices of novel or new characteristics.

INTRODUCTION

THE transformer, the inductor and the filter have continually played roles throughout the field of electronics. As relatively crude electromagnetic devices, they were employed in early telephone and radio communication systems. Today, vastly improved, their descendants are still found in most electronic systems.

TRANSFORMERS

General

A transformer performs one or more of the functions of 1) electrical isolation between circuits, 2) impedance matching, 3) voltage or current step-up or step-down, and 4) phase inversion. The voltage appearing between the terminals of a transformer coil must be an alternating voltage with a cyclic average value of zero, except for the effects of resistance voltage drops produced by a direct current through a coil. This characteristic is an advantage in many applications but prohibits their use in other circuits where their isolation and impedance matching functions might be advantageously employed.

Transformers for electronic applications are often divided into the general categories designated by the terms *Power*, *Audio*, *Video*, *Pulse*, *Intermediate frequency* (*IF*) and *Radio frequency* (*RF*).

* Received by the IRE, June 29, 1961.
† Res. Lab., General Electric Co., Schenectady, N. Y.

Power Transformers

Electrical isolation and voltage-changing are the chief functions of power transformers. For electonic use power transformers cover a range of ratings from a few watts to a few megawatts, the very large sizes being employed in rectifier circuits.

The most common power transformers are those supplying filament voltages and/or rectifier input voltages. The supply frequency is usually fixed and is from 50 cycles to a few kilocycles. A nominal frequency of 400 cycles is employed in many military applications.

Since 1945, considerable effort has been expended on reducing the size and weight of electronic power transformers with the most dramatic size reduction attained in 400 cycle operation. The development of reduced core loss materials at 400 cycles with high values of peak flux densities, coupled with the development of insulating materials suitable for use at high temperatures has led to this reduction. Recent developments in high-temperature transformers has culminated in units which operate for over 1000 hours at hot-spot temperatures of 600°C.

Audio and Video Transformers

Audio transformers have been employed since the infancy of electronics. Their chief functions are impedance matching, but all of the other basic functions of transformers are often employed. Prior to the development of high voltage-gain electron tubes, interstage transformers were employed to provide a part of the voltage gain between the relatively low output impedance of a tube plate circuit, and the high input impedance grid circuit of the following tube. Impedance-matching transformers made it practical to develop the wide-frequency range dynamic speaker with its low-impedance voice-coil and to drive it by efficient and low-distortion class AB push-pull amplifiers. Audio transformers range in size from those used in transistor audio amplifiers to the high-level modulation transformers in high-power AM transmitters, which include ratings up to several hundred kilowatts.

For many years, the designs of audio transformers involved some cut-and-try procedures. Even as late as 1948, the designs of the wide-range audio transformers for FM studio equipment often required a development effort consisting of several successive trial designs and tests in the specific electronic circuit in which they were to be used. Today, the design of high-quality low distortion, audio transformers capable of operating over a frequency range of 20 cycles to 20 kc and higher is standard engineering. This has been accomplished through core materials development and research studies of the interrelations of transformer parameters and electronic circuit parameters.

When the frequency range of a wide-band transformer includes frequencies much above the audio range, it is often referred to as a video transformer even though it does not cover the range of frequencies required by television video amplifiers. The development of thin high permeability alloys has made possible low-power tube-to-line transformers with practically linear response from about 50 cycles to above 1 mc in suitable circuits.

Pulse Transformers

Pulse transformers have played a key role in the development of radar. Most microwave transmitters include a pulse modulator circuit for supplying the input pulses to the microwave transmitter tube. In the first magnetron radar transmitters, the negative-going plate of the hard-tube pulse modulator was coupled through a capacitor to the cathode of the magnetron. The impedance level of the coupling between pulse modulator output and transmitter input was from 1000 to 1500 ohms. The pulse power level was about 100 kw, and the voltage level was 10 to 12 kv. Cables for these levels were not available, so the transmitter tube was required to be located close to the pulse modulator.

Recognition of the advantages of efficient transformers, capable of handling rectangular pulses of one or two microseconds duration and peak powers of 100 kw, led first to the development of transformers capable of matching the pulse modulator to a 50-ohm cable and the 50-ohm cable to the magnetron input. Low-power pulse transformers were developed along with the high-power types. These led to the development of pulse-forming blocking oscillators capable of operating at high repetition rates. The blocking oscillator replaced the less reliable low-level thyratron pulse-forming circuit employed in early hard-tube pulse modulators. In addition, a third winding on the blocking-oscillator transformer inverted the output pulse and eliminated the awkward "boot-strap" circuit employed in early pulse modulators.

The development of cable-to-magnetron pulse transformers made practical the hydrogen thyratron modulator. This consists of a resonant charged pulse-forming-network which the hydrogen thyratron discharges periodically into the cable supplying the pulse power to the cable-to-magnetron pulse transformer.

Present pulse transformers range in size from the tiny torroid-type employed in computer logic circuitry to large types weighing several thousand pounds for handling peak pulse powers of more than 50 Mw.

Intermediate Frequency (IF) and Radio Frequency (RF)

Intermediate-frequency transformers are in reality band-pass filters. They were an important part of the invention of the superheterodyne receiving circuit as they are the chief means for accomplishing high selectivity with reasonably uniform response within the pass-band.

The first superheterodyne receiver for entertainment use employed an intermediate frequency of 40 kc. The small IF transformers had cores consisting of thin laminations of iron. When, in later models, the intermediate frequency was raised, much larger air-core coils in shield cans were used as the Q of laminated iron core and coils was too low.

Subsequently, pressed powdered cores and more recently ferrite cores, have permitted efficient 456 kc IF transformers to have a small fraction of the volume of an equivalent air-core IF transformer. The size of ferrite cored IF transformers are commensurate with the sizes of transistors.

Radio-frequency transformers were originally air-core type coils. Impedance matching was effected by tapping or by a separate untuned secondary coil coupled to a tuned primary or vice versa.

Coefficients of coupling of air-core coils are too low for efficient operation as untuned broad-band transformers. Ferrite core materials have made possible the design of close-coupled untuned transformers for impedance matching purposes which operate satisfactorily over frequency ranges of three or four to one. Ferrite has also provided means for reducing the sizes of RF transformers where the operating frequencies are less than 20 Mc.

Inductors and Filters

General

Inductors employed in electronic circuitry vary from small loops of wire with a fraction of a microhenry inductance, to large filter chokes in dc power supplies. Those for high-frequency operation are either air-core or have cores of pressed powdered iron or ferrite. Those for operation at frequencies below about 5 kc may have laminated iron cores.

When part or all of the magnetic circuit linking a coil is ferromagnetic, the inductance of the coil is not a linear function of the current. For a given magnetic material, the nonlinearity of inductance increases with increasing ratios of core material length to the total length of the magnetic circuit.

Some magnetic materials are much more nonlinear in permeability than others. Temperature effects are quite different for various magnetic materials. If a variation of inductance is deleterious to the application of an inductor, care must be exercised in choosing the core material to be used and in choosing the percentage length of air-gap.

Linear Inductors

Linear inductors are required for most tuned circuit and filter applications. Magnetic materials have been specifically developed to meet requirements for linear inductors and have virtually eliminated the use of air-core inductors in filters and tuned circuits for frequencies below 20 Mc at low power. At high-power levels and/or at high frequencies, air-core coils are still used almost exclusively.

Nonlinear Inductors

There are a number of electronic circuit devices which depend for their operation upon the nonlinearity of the magnetization characteristic of magnetic materials. The magnetic amplifier is such a device. It is interesting to note that Dr. E. F. W. Alexanderson invented the magnetic amplifier to provide a means for voice-modulating the current which was supplied to the antenna by his high-frequency alternator. Thus the magnetic amplifier originally performed a function which was later performed by high-power electron tubes.

The utilization of nonlinear inductors was not very extensive until about 1940. Since then, new rectangular hysteresis loop magnetic alloys and ferrites have been developed. Nonlinear inductor devices employing these new magnetic materials are now used in combination with electronic devices (especially semiconductor devices) to perform functions which include: 1) amplification and control of voltage and/or current, 2) forming pulses for operating radar transmitters and firing thyratrons, ignitrons and silicon controlled rectifiers, 3) static switching, 4) frequency multiplication and division, 5) computer logic and memory, and 6) static permeability tuning.

Trends in the Areas of Transformers, Inductors and Filters

The trend toward miniaturization of low-power electronic circuitry may reduce the role which inductive devices play in low-power electronics. When one or more inductors (L) are combined with one or more capacitors, (C) to form a resonant circuit or a filter, the frequency selective functions can be performed by combinations of electro-mechanical transducers and mechanically resonant structures of metal or ceramic. The upper frequency limit of such electro-mechanical filters is presently about 5 Mc. Their size can be made less than LC type resonant circuits of comparable selectivity. This fact, plus microminiaturization, where the equivalent of LC functions are combined with the functions of other basic circuit elements in a semiconductor material, are factors which may cause inductive devices to disappear from low-power electronic circuitry.

The trend toward electronic devices of increased power capacity will call for rectifier transformers and possibly pulse transformers of higher voltages and power ratings. While the development of new electronic devices sometimes displaces certain inductive devices, they often create new uses for other inductive devices. The designers and manufacturers of inductive devices for the rapidly changing electronics industry may find it difficult to forecast the demands for a specific device, but if past performance can indicate future trends, the introduction of a new electronic device is likely to need an inductive device having novel characteristics.

Printed Circuits and Microelectronics*

S. F. DANKO†, MEMBER, IRE

***Summary*—In the two decades since the concept of ceramic based "printed circuits" was first suggested for an Army Ordnance application, substantial changes have taken place in the techniques of electronic circuit construction in the United States. Today, such ceramic circuits, in simple and complex networks, are complemented by printed wiring assemblies in several variations. Both technologies, now well established and in mass use on production lines, represent the current plateaus in miniature circuit construction for general commercial and military usage.**

Other construction philosophies and technologies are now shaping in the country's industrial and military laboratories, all aimed at new orders of size reduction of electronic equipments. In the several microelectronic techniques under development, the elemental electronic part appears destined to lose its logistic identity completely, and yield its classical position as a building block to black boxes called "circuit functions."

The paper provides a summary review of the evolution of current ceramic printed circuits and printed wiring practices and, in the light of today's microelectronic activities, frames the trend in equipment design in the years ahead.

* Received by the IRE, July 10, 1961.

DOZENS OF REFERENCES (some dating back 100 years) have been compiled to trace the subtle origin of some of the concepts and technologies upon which today's varieties of printed circuit systems are based. But the earliest coherent history of the printed circuit arts in the United States began in the Ordance Development Division of the National Bureau of Standards (NBS) in 1942 when a decision to explore two-dimensional printing of electronic parts for the Army's VT fuze was made by Ellett[1] and Diamond.[2] The successful implementation of this decision by Khouri,[3] and by a NBS research team under Brunetti[4] led to the first mass production of screened ceramic based printed circuit fuzes in 1945, and triggered the sequence of developments in the United States that, in the next two decades, profoundly affected the size, weight and physical appearance of commercial and military electronics.

The post-war electronic industry found this concept of screening of resistor inks and silver pastes useful for the manufacturer of miniature hearing aids, and radio and TV networks (Fig. 1). Aside from size reduction, the cost advantages inherent in mass-produced pre-assembled networks, inspection reduction, maintenance simplification, etc., were some of the attributes that attracted volume usage by commerical equipment manufacturers, and introduced the "module"[5] as a useful entity in electronic assembly. By 1950 a substantial market had developed for such ceramic based circuits and many innovations, and process refinements were introduced by the original contractor (Centralab) and other firms. By May, 1962, over 140 million screen deposited circuits have been manufactured by the Centralab Division alone in hundreds of varieties of simple and complex network configurations.

Continued military development of the related technologies by Franklin[6] led to usage of other techniques of part deposition and attachment, use of recessed substrates and improved protective coatings; today, this military derivative[7] of the screened ceramic circuit concept is specially oriented to weapons applications.

This early screening technology, however, could not satisfy the full spectrum of electronic circuit usage. The necessity for attaching "nonprintable" components (tubes, transistors, quartz crystals, transformers, etc.) and limitations in power-handling capacity did not permit realization of some of the optimistic projections made in 1946–1948 regarding the ultimate universal applicability of these screen deposition techniques. However, with this war-born success as a stimulant, Brunetti, in a 1947 Symposium,[8] sparked national interest in other technologies applicable to miniature circuit fabrication. Although the 1947 Symposium was (in retrospect) truly a brainstorming conference, it served as a springboard for dozens of independent and fruitful pursuits of electronic miniaturization and mechanical assembly (Fig. 2).

The U. S. Army Signal Corps, hard pressed for reduction of volume and weight of its mushrooming electronics systems, had established a miniaturization group in 1946 at the U. S. Army Signal Research and Development Laboratory (USASRDL) at Fort Monmouth. Following an intensive study and experimentation period, Danko and Abramson in 1949 announced the Laboratory's development of a rapid one-shot solder-dip system of component assembly to copper circuit (printed wiring) boards.[9] Etching of copper coils in runs of millions was then current at RCA under the technical guidance of Mackey and Black;[10] experimental copper-forming techniques were being used by J. Beck;[11] etched circuits on flexible plastic with surface attached parts were being fabricated by Henderson-Spalding,[12] and the Franklin Airloop Corporation[13] was embossing copper coils on plastic; the copper metal patterns being produced by all four were found compatible with the suggested Signal Corps solder-dip assembly system.

In the period 1949–1951, collaboration between Fort Monmouth and industrial laboratories led to considerable experimentation with solder-dipped etched circuits for commercial usage. The comparatively simple process steps involved in the fabrication of etched circuits from commerically available copper-clad laminates led many of the large manufacturers to establish in-house facilities for manufacturing printed wiring boards. Swiggett,[14] in organizing one of the first vendor sources exclusively for production of printed wiring and assemblies in 1951, provided a substantial stimulus to usage by a cautious industry. Figs. 3 and 4 reflect the growth of etched printed wiring usage in the subsequent years.

As with the screen stenciled ceramic circuits, innovations and process improvements in the printed wire concept came quickly as industry acceptance developed (Fig. 5). Single-sided printed wiring was followed by double-sided circuit boards, then plated circuits and plated-through holes, and multi-layer etched circuits; the manual dip-soldering technique of the early 50's yielded to mechanized soldering stations, wave soldering and selective soldering. In addition to the original copper-clad phenolic laminates for etched circuits,

melamine, teflon, and epoxy laminates became available. By 1955, mechanized lines for production of etched and plated circuits were in operation and component insertion machines for sequential assembly of parts on boards were commercially available.[15] Several mechanized production lines for electronic radio and TV sets came into being and "automation" became a new theme for symposia discussions.

Design innovations were introduced to increase the density of parts that could be placed on a printed wiring board. Three-dimensional stacking of commercially available miniature parts in cordwood fashion represented one of the more fruitful efforts to achieve greater packaging densities in military applications while retaining the inherent simplicity of the printed wiring concept.

These process, assembly, and design improvements, however, though individually contributing to the increasing quality and producibility of printed wiring circuitry, did not provide the "seven-league" steps toward further equipment size reduction that the future seemed to demand, particularly for the military's mushrooming electronic complexes. In 1957, this growing pressure for a radically new dimension for electronics veered many of the country's laboratories into: 1) modifying, extending or reducing to practice some of the miniaturization techniques and concepts suggested and tried years before, or 2) probing the realm of solid-state physics for the purpose of designing processed single crystal semiconductors to perform electronic functions conventionally performed by aggregates of individual parts. This revitalized pursuit of size reduction of electronics immediately picked up the term *microminiaturization* as a general identification; in the next few years dozens of proprietary names were attached to processes and technologies used to fabricate ultra-small experimental electronics (Fig. 6).

This microminiaturization activity can be broadly classified into three major categories: 1) *high-density packaging*[16] in which individually fabricated parts in extremely small sizes or in special shapes from established vendor sources are compactly packaged and interconnected by handwiring, printed wiring, or welding, 2) *thin film techniques*[17] in which two-dimensional parts are formed in place directly on a common substrate by any appropriate technique such as screening, vacuum evaporation, sputtering, etc., 3) solid-state circuits, one form of which, called *integrated circuits*, consists of single crystal semiconductor chips which are processed by etching, diffusing, alloying, and evaporation to duplicate, on an equivalent part-by-part basis, the conventional circuit schematic; within this general solid-state classification is another more general concept called *molecular electronics* which does not recognize this part-for-part equivalence, but attempts to apply appropriate materials phenomena to perform the same circuit function.[18]

Whether the circuit function is fabricated using high-density packaging, thin films, or solid-state phenomena, it appears that the next decade will see substantial growth in the acceptance of the electronic functions in the form of "little black boxes" with specific performance characteristics guaranteed (Fig. 6). It appears very likely that each of the systems being explored today will find individual "black box" applications in which it will show distinct performance, reliability, or cost advantages. The history of electronics, as a matter of fact, reflects continuous hybridization of technologies. Our electronic systems today, for example, are hybrid constructions using handwiring, printed wiring, ceramic printed circuits, module construction, and thin film techniques applied to the manufacture of some of the parts; even examples of the molectronics concept (perhaps not in the microminiature dimension) can be pointed out in today's systems. It is a certainty that industry and the military will accept and use any technological advance in electronic parts, in assembly techniques, or in the physical form of the elemental building blocks if the economics, reliability, logistics, and producibility of the final product (the equipment) are enhanced or, at the very minimum, stay the same. Accordingly, an open and inviting field for accomplishment and acceptability waits for the products of all three of the current approaches on a broad competitive basis which includes more than just microminiaturization. It is highly unlikely that tomorrow's designer, once convinced that the use of packaged electronic functions is to his advantage, will arbitrarily reject one technology for the black boxes he procures, any more than he would question the mixture used in the composition resistors he uses today. Performance, reliability and price will be the principal criteria for acceptance.

The current substantial research and development effort by industry and government in the microelectronics area is evidence enough of the importance of the microminiaturization objectives for the military purpose. However, it is expected that, as in the case of the ceramic based printed circuits and printed wiring, the by-product benefits of this military motivation will accrue to the entire body of commercial and industrial consumers.

[15] United Shoe Machinery Corp., Boston, Mass.

[16] The Micro-Module (RCA-Signal Corps), using standard-shaped (0.31 in×0.31 in) notched wafer parts stacked and interconnected by riser wires is in this category. So are the several varieties of cordwood assembly and the several variations of using miniature parts with one disciplined dimension (thickness or width) recessed within the thickness of a board which is then surface printed to provide interconnections.

[17] Thin film circuits today are still hybrids of deposited and attached parts; this approach is rooted in the screened ceramic circuits of World War II (Fig. 1) which first developed the concept of two-dimensional parts processed *in situ*. The ultimate goal of thin film technologists is the substrate deposition of most (if not all) parts, including the semiconductor devices.

[18] Molecular Electronics (also called Molectronics) is the principle behind an Air Force-Westinghouse microminiaturization program.

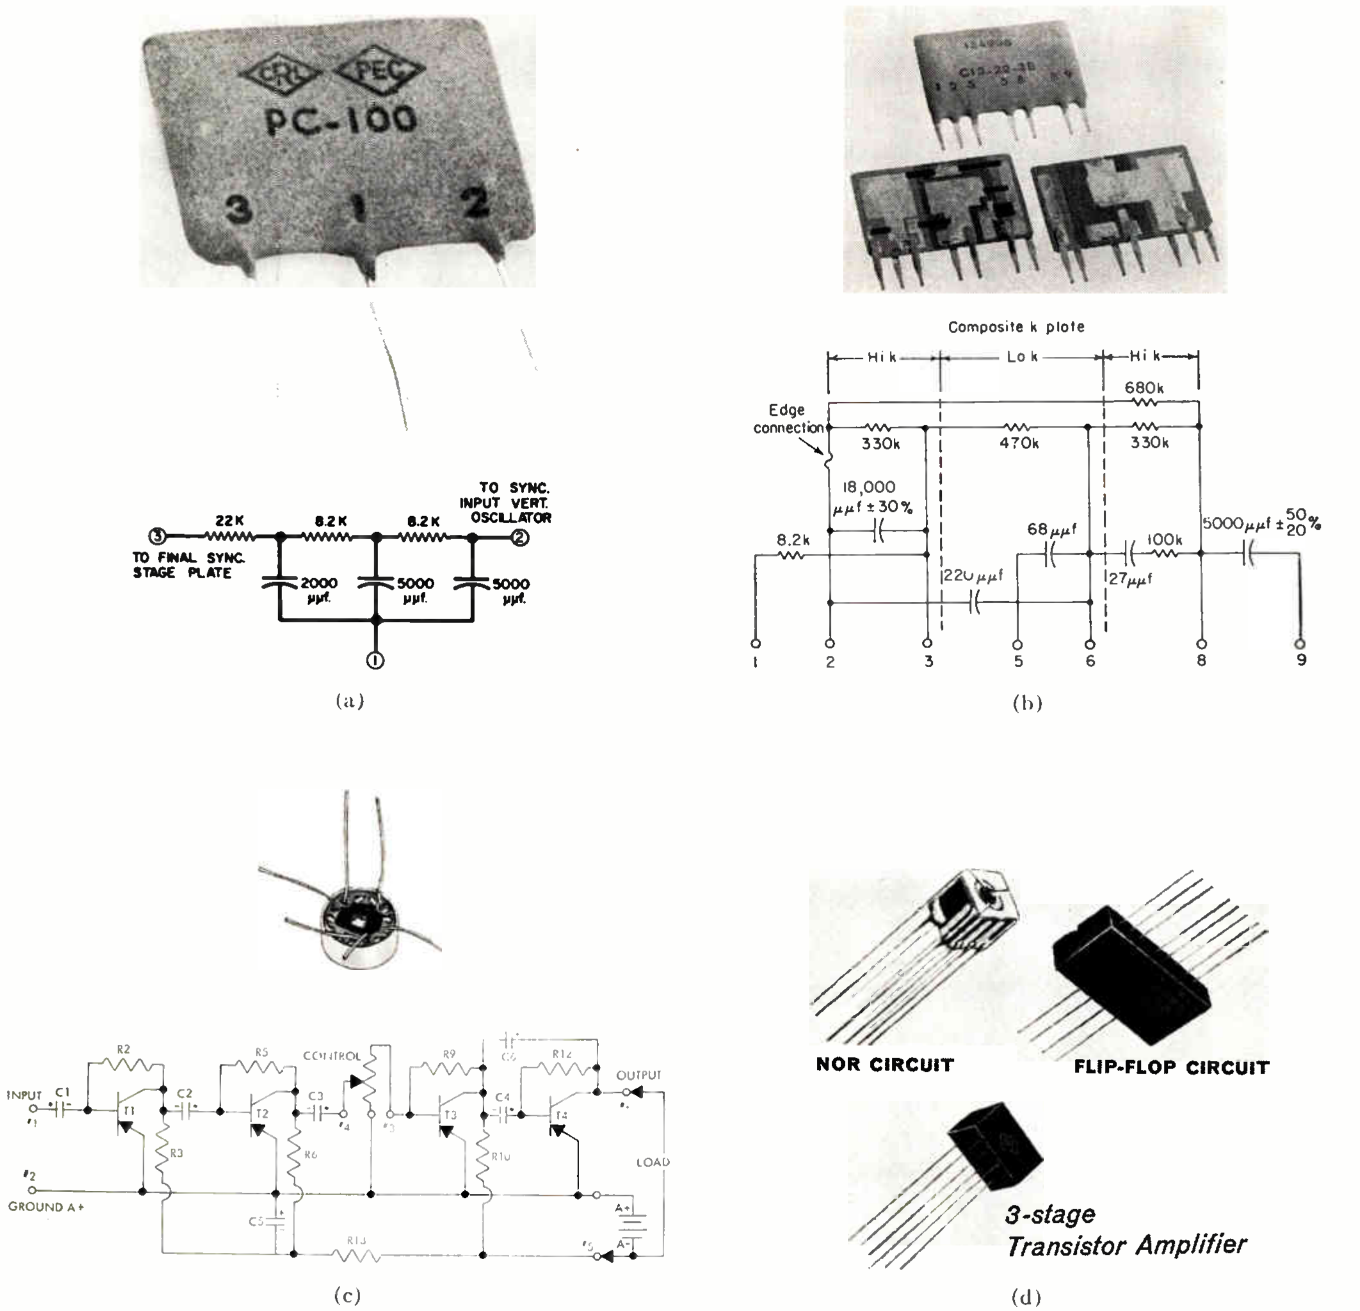

Fig. 1[19]—*Ceramic Based Printed Circuits:*

Screen deposition of resistor inks and silver pastes today is a matured, versatile technology applicable to two-dimensional RC networks for interconnecting tubes or semiconductor devices, and to fabrication of three-dimensional complete circuit functions with enclosed conventional semiconductor elements. Well over 140 million of such ceramic circuits have been manufactured by Centralab since World War II.

(a) A relatively simple vertical integrator for TV applications uses a high K plate as a substrate; the $1\frac{3}{32}$ in $\times\frac{13}{16}$ in $\times\frac{1}{8}$ in unit has 450 v dc working voltage capacitors and $\frac{1}{5}$ watt ± 20 per cent resistors. Over 16 million units of this integrator have been manufactured, indicative of the mass producibility, and the performance and economic acceptability of this form of packaged RC circuitry. Steatite is also used as a substrate in other designs.

(b) A more complex network showing use of a composite substrate having different dielectric constant areas. Ratio of capacity values up to 1000 to 1 and resistance values up to 10 to 1 can be achieved in one screening operation. Maximum capacity values approximate 0.03 μf. Resistor inks and geometric patterns are selected to suit resistance values desired (5 to 100 megohms); resistor tolerances down to ± 5 per cent can be controlled in production if desired.

(c) A three-dimensional audio amplifier module made up of stacked ceramic circuits and transistor elements. Unit is hermetically sealed, and typifies the capability for higher density packaging using stacking techniques. Unit size is 0.531-in D$\times$0.228 in thick.

(d) Other three-dimensional module configurations based on assembly of planar ceramic circuits: a nor circuit (top left) in a $\frac{3}{8}$ in $\times\frac{3}{8}$ in $\times\frac{13}{32}$ in configuration containing 8 resistors and 1 transistor; a flip-flop circuit (top right) $\frac{1}{4}$ in $\times\frac{1}{2}$ in $\times 1$ in (approximately) containing 8 resistors, 6 capacitors, 6 diodes and 2 transistors; a three-stage transistor amplifier (bottom) $\frac{1}{4}$ in $\times\frac{1}{4}$ in $\times\frac{1}{2}$ in. Module parts densities up to about 1 million parts/cubic ft can be realized in practical, mass producible designs.

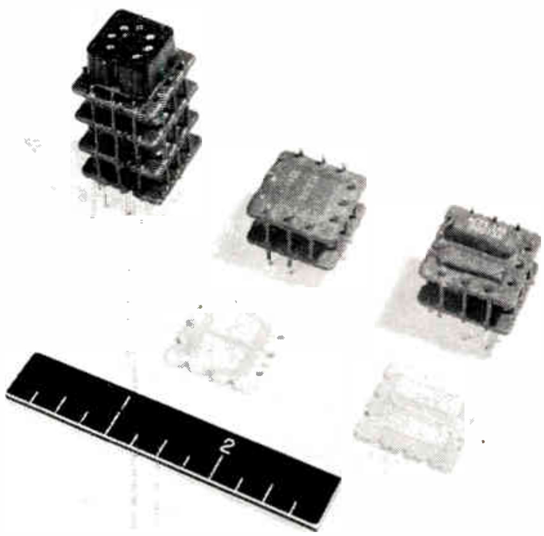

Fig. 2—*Mechanize Production of Ceramic Wafer Assemblies*

In the early 1950's, Robert Henry of NBS, working under Navy sponsorship, completed development of an experimental mechanized line for producing finished electronic assemblies using a novel stacked ceramic wafer approach with riser wire interconnections. The system (called "Tinkertoy" at that time) considered component manufacture from processed materials as part of the mechanized production complex. Assemblies such as these with considerably re-designed machinery are being produced to-day by Paktron, Division of Illinois Tool Works; about 5 million of these stacked wafer modules have been manufactured as of May, 1962.

In an independent 1957 study of feasible approaches to automatic production of microminiature circuits, RCA also concluded that a physical system such as Henry's, based on uniformly shaped miniature parts with riser wire interconnections, offered the best features for automatic assembly (see Fig. 6).

Fig. 5—*Printed Wiring:*
(a) 1948–49—TV tuner coils mass produced by photo-resist etching of foil clad laminates (RCA).
(b) 1949—Rapid multiple-pattern fabrication via photo-resist etching, insertion of conventional electronic parts into pre-punched holes, and one-shot solder dip assembly provided size and production advantages which attracted industrial and military equipment designers to the printed wiring technique (Signal Corps).
(c) 1952–1953—The first mass produced printed wiring (PW) home radio sets appeared in the 1952–1953 period, with manually inserted parts and solder dipping being done manually or by semiautomatic machines. Motorola (left) introduced its plated circuit (Placir) process as a mass production technique; laminate etching process was used by Admiral (center) and Hallicrafters (right).
(d) 1953—Selective solder-dipping (solder resistricted to joints only) was used by Philco in its mass production of this home radio receiver.

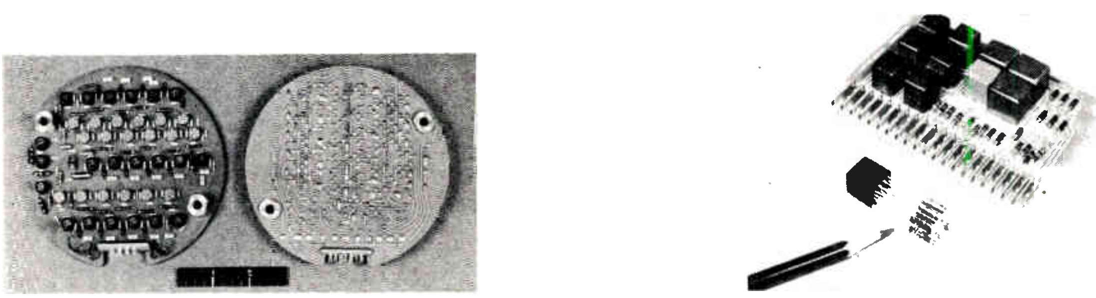
(f)



(g)

Fig. 5—(*continued*)

(e) Curved laminates suggested by Signal Corps (left) found one of its first military applications in an Army Weapons System (right).

(f) 1953–1954—Mechanization of the electronic circuit assembly operation, a thwarted ambition of Sargrove,[20] became a reality in the United States in the early '50's. The United Shoe Machinery Company (left) developed individual component insertion machines which could be coupled in multiple to a conveyer system and a solder dipping apparatus to assemble most of the PW electronic chassis automatically; hand insertion and attachment of special components was required to complete operation. In this period too, Motorola was operating its highly mechanized Placir process for pattern fabrication. In 1954, the Admiral Corporation (right) operated an impressive automatic assembly line for its 21-in TV receiver, fabricating a substantial part of the circuitry (shown beside set) on a mechanical line having sequential insertion stations fed by reeled components and an automatic dip-soldering position. Other mechanized assembly lines were being independently developed at Sylvania, IBM, RCA, etc.

(g) 1956–1960—Military usage of printed wiring gathered momentum in this period; one out of every 3 new equipments developed at the Fort Monmouth Laboratories of the Signal Corps used printed wiring in whole or part. Weapons systems, computers, satellites, portable and mobile communication receivers, airborne electronics swelled the number of applications of printed wire so that in 1961, authoritative estimates placed the military consumption of processed printed wiring boards at about 50 per cent of the dollar value. Photo shows a high density deck of the Explorer VII Satellite, fabricated with PW solder-dip technqiues by the Army Ballistic Missile Agency; cumulative experience and improved techniques permitted greater and greater use of such high-density designs in ground and airborne equipments. Four military specifications and standards[21] were in effect in 1960 and helped stabilize the quality and performance of assemblies. A technique of packaging parts between two printed wiring end-plates ("Cordwood"), suggested by Roman[22] a number of years previously, matured into commercial and military applications; the figure on the right shows a hybrid of such molded "Cordwood" modules and conventional PW constructions, which can yield up to two times better space efficiency (Republic Aviation Corp.).

[20] In 1943, J. A. Sargrove, England (U. S. Patent No. 2,474,988) had suggested a production line system of circuit fabrication involving spraying metal into a grooved phenolic base for form conductors, capacitors, coils and switches and spraying graphite suspensions to form resistors. The system was abandoned after considerable effort was put into physical construction (see Bibliography).

Fig. 6—*Functional Circuits* (*Illustrative*):

(a) *Micro-modules* (*Signal Corps-RCA*): A high-density packaging approach consisting of standard shaped 0.31 in×0.31 in ceramic based parts (micro-elements) vertically stacked and interconnected by[12] riser wires soldered in notches. From 5 to 10 times size reduction of modules has been achieved over the best conventional printed wiring constructions. Final product can be treated as a functional entity for machine insertion and solder dipping on printed wiring boards.

(b) *Thin film circuits* (*International Resistance Co.*): Thin film circuits on substrates of glass are plastic encapsulated and appear as functional nuggets with stiff wire projections for use with PW boards. Illustration shows a half-adder consisting of five such circuits mounted on a multi-layer PW board. Thin film circuits consist primarily of conductors, R's, and C's at this stage of the art. Plastic encapsulation for climatic protection and ruggedization very substantially increases the effective size of the basic thin film circuit and this problem is one of the prime targets of researchers in the field. Size reductions of 20 to 1 over conventional PW circuits using miniature R's and C's appear attainable.

(c) *Solid-state circuits* (*Texas Instruments*): Processing of single crystals of silicon to duplicate circuit schematics yields this tiny hermetically sealed flip-flop circuit. Applications up to now have been limited almost exclusively to digital circuits. Practical size reductions of modules up to about 350 to 1 over conventional PW units are expected in the full application to computer circuitry.

(d) Illustration of hybrid use of conventional parts, printed wiring and functional circuit modules (micro-modules in this instance). It is expected that hybrid use of conventional thin film, solid-state, and high-density packaged functional circuits will become increasingly common in the next decade (RCA).

Acknowledgment

The author appreciates the generous help and constructive observations of a number of individuals and organizations in the printed circuit field, in particular: Robert Henry, Paktron Division; Robert Swiggett, Photocircuits Corporation; Institute of Printed Circuits; Robert Gerhold, USASRDL; J. G. Reid, Fort Huachuca; Robert Curran, Electralab; W. S. Parsons, Centralab; Harold Stral, Stral Company; Vincent Kublin, USASRDL; C. Rayburn, Paktron; Donald Mackey, RCA, and W. J. Electronic Materials, 1912-1962*

PRESTON ROBINSON†, MEMBER, IRE

***Summary*—"Electronic Materials" is taken here to include dielectric materials with plastics and gases; magnetic materials, including permanent magnet materials, soft magnetic materials, magnetic powders, magnetic ceramics; resistive materials; ferroelectric materials; wire insulation; insulators; semiconductor materials; and conductors. In a general statement, as given here, fine distinctions have been avoided, and there is necessarily some overlap in these categories.**

Introduction

All the original electronic materials are still with us. The first condenser recognized as such was the Leyden jar, employing glass as a dielectric, and glass is still extremely popular today. The oil-paper dielectric of the condenser Galvani used to accumulate the charge from his galvanic cells is still with us. The galena, as used with the first cat's whisker, is still used in many photoelectric devices. Mica is still a popular dielectric. Lodestone, until very recently, was still used in some cores for permeability tuning. Further, many of these old materials are among those most stable to high temperatures and nuclear radiation, so that a good question is: what have we been doing the last 50 years?

* Received by the IRE, August 28, 1961.
† Sprague Electric Co., North Adams, Mass.

Dielectric Materials

As stated, glass, mica and oil-paper are still with us. The glass has a higher dielectric constant now and is thinner. Higher temperature glasses also are available. There is now synthetic mica which employs fluorine instead of hydroxyl ion in the molecule constituting the mica, and this permits a mica to be melted and retain many of the other good characteristics of mica. Films consisting of compacted mica particles and also of bentonite particles are in use. The oil-insulated paper is thinner, and while originally vegetable fibers were used, today wood pulp treated by the Kraft process has perhaps wholly replaced the other because of the superior temperature stability and lower power factor. And the vegetable oils originally used for impregnating purposes have, with the possible exception of castor oil, been replaced by minerals oils together with synthetics such as chlorinated diphenyl and liquid polymers of isobutylene. For solid impregnants, chlorinated naphthalene and high melting olefins have replaced the natural waxes. Silicone oils have found use as impregnants to a considerable extent, and liquid perfluoro compounds to a much lesser extent.

Plastics

As a sheet dielectric for use in capacitors as well as a spacer for cables, there are a number of new materials. Polystyrene, with its vanishingly small power factor and low temperature coefficient of capacity, is widely used in low temperature applications for condensers which previously used mica. Mylar is increasingly used as a dielectric in condensers where an extended temperature range and less severe temperature requirements make it possible. Newer materials are the polycarbonates, which have excellent temperature characteristics, the cyanoethyl cellulose films, which, while they have not found their way into production, are of interest because of the high dielectric constant, 15 to 20. At higher temperatures, fluorinated materials are available of which polytetrafluoroethylene (Teflon) has the highest temperature, although other fluorinated materials for somewhat lower (but still high) temperatures are also available.

Plastics are widely used as containers for electric components, and these usually consist of the phenolics, the polyesters, epoxies, diallyl phthalate and triallyl cyanurate.

Monomers which polymerize to form plastics have two functional groups which can form links with other monomers, and which, for example, can be called head and tail. Ordinary polymers, now called atactic, have large numbers of monomers joined up randomly. Syndiotactic polymers have monomers joined head-to-head and tail-to-tail. And, finally, isotactic polymers where the monomers are uniformly joined head-to-tail, have much better thermal and mechanical properties than the earlier versions. Thus, isotactic (high density) polyethylene and polypropylene are having spectacular success. Isotactic polystyrene is still in the laboratory but has promise for the future.

Linear polymers which have been cross-linked to form fairly rigid three-dimensional structures by the effect of radiation have found success, particularly with cross-linked polyethylene. Radiation is also one method used to form so-called "block and graft" polymers, where polymers of one species are grafted to the chain comprising a polymer of another species. These, too, are largely in the laboratory stage.

Gaseous Dielectrics

Where once we used air, nitrogen and carbon dioxide, there are now other gases available to permit higher breakdown field strengths, of which the most notable are, sulfur hexafluoride, selenium hexafluoride and the family of fluorocarbons, and of the fluorochloro carbons known as freons. These are all "electronegative" gases, and, while not as stable as nitrogen under all conditions, can be used with proper precautions.

Finally we should not forget "nothing" as a dielectric. While "vacuum" condensers have been known for a long time, new outgassing techniques and new "ion-pumps" have made the attainment of much higher vacua possible, and this permits increased ratings of these condensers.

Magnetic Materials

Permanent Magnet Materials

In the early days of radio, available magnet steels containing tungsten, chromium and cobalt, or all three, had too low an energy product to be seriously considered for speaker applications. With the discovery of the aluminum-nickel-cobalt magnetic compounds in Japan, commonly called alnico in this country, together with the similar compounds containing titanium, called ticonal in the Netherlands, their high energy product has made possible the use of permanent magnetic speakers and has largely done away with the solenoid magnets. More recently, ceramic magnets consisting of the ceramic chemical $BaFe_{12}O_{19}$ have existed in two forms: a randomly oriented ceramic and an oriented, one where the crystals are lined up with the hard direction of magnetization of the individual crystals aligned. These materials, while having a lower energy product than the alnicos, have higher coercive forces and are thus permissible to use in magnets thinner than alnico without demagnetization setting in. Another material, manganese bismuthide, of even higher coercive force, was discovered in France and has been the object of a great deal of study but has not found its way into many commercial applications as yet.

There are also available now permanent magnet metal foils, which, while having a relatively low energy product, are ductile and can be manufactured into various shapes quite readily, whereas the alnicos and the ceramics are somewhat refractory to deal with. These alloys are called Cunife and Vicalloy.

With the discovery in the 1930's that fine iron particles of single domain size can be agglomerated to make a permanent magnet, there has been an extensive development program in many countries. The highest energy products are now obtained with particles of ellipsoidal shape, of the order of 5×10^6. The theoretical maximum is much higher and work is still progressing.

Soft Magnetic Metals

Metallic iron at the start of this period had a maximum permeability in the neighborhood of 5000. Over the years it has continued to be made with ever higher permeability both as a result of removing impurities and in removing strains from the metal. Maximum permeability as high as 350,000 has been reported. However, iron of this quality is a little too delicate for use in most applications and, therefore, iron alloys have largely taken over the field.

The addition of a few per cent of silicon to iron increases the resistivity, thus cutting down the eddy current losses, and this metal is universally used as a core material for power transformers and low-frequency transformers. Aluminum can be substituted in whole or in part for silicon in these steels, but these materials, of which alfenol is an example, have not yet achieved large production. A major breakthrough in the development of silicon steel was achieved by Goss in the 1930's. He developed a process for the grain orientation of silicon steel whereby the easy direction of magnetization is in the direction of rolling. (In America, where it was discovered, it is called grain-oriented steel; in Europe it is called "Goss-iron)".

Iron nickel alloys—the permalloy family—started during this period with the work of Elmen. The 78 per cent nickel, 22 per cent iron permalloy has nearly zero magnetostriction and an extremely high permeability. Over the years this permeability has been increased by greater skill in refining the impurities out of the material and in superior heat treatments. The resistivity of permalloys has been increased by additions of other metals, notably chromium and molybdenum; molypermalloy containing 4 per cent molybdenum is possibly the most popular permalloy at present, and possibly represents the greatest advance to date in the control of manufacture and in meeting more rigid specifications.

Supermalloy contains about 70 per cent nickel, 5 per cent molybdenum, 15 per cent iron and 0.5 per cent manganese, all of extreme purity. Maximum permeability in the neighborhood of 1,000,000 is possible with this material if properly heat-treated.

The 45 per cent nickel permalloy is also used and the 50 per cent nickel have also found wide use particularly as cores for pulse transformers and for magnetic amplifiers, because it can be made to have a rectangular hysteresis loop. Iron-cobalt-nickel alloys called Perminvars are characterized as having permeabilities independent of field strength over a wide range.

Permalloy-type materials with 5 per cent copper added are known as mu metal and are useful for magnetic shielding as well as core material for electromagnets.

Iron-cobalt alloys have the highest saturation induction (and probably the highest Curie temperature). These have been given the name "Permendur" and also were invented by Elmen.

Magnetic Powders

Magnetic metals reduced to fine-particle size, coated with insulating material (usually of polymerizable resin), and molded have extensive use particularly in permeability tuning and in high-frequency application. The materials used in addition to magnetite are iron and permalloy, all of which have found wide use, and also include sendust, a Japanese alloy consisting of 14 per cent silicon, 14 per cent aluminum and the rest iron. This is a brittle material, easily reduced to powder and fabricated. While it has found extensive use in Japan and Germany during World War II, it does not seem to be able to compete successfully with permalloy dust cores.

Magnetic Ceramics

In addition to the original lodestone (or magnetite), a large family of synthetic magnetic ceramic compounds called ferrites was originally developed by Snoek in the Netherlands. These materials have lower permeabilities and lower saturation magnetization than the magnetic metals but, because of their high resistivity have more greatly reduced eddy currents than the metals, permit coils to have much higher Q's, and can be used at much higher frequencies than the metals, up to hundreds of megacycles. The principal use commercially is made of manganese zinc ferrites which have the higher permeabilities but also moderately low resistivity; that is to say they have high resistivity compared to metals but low as compared to other ferrites. They are useful up to the broadcast band. At higher frequencies, nickel zinc ferrites with much higher resistivity are used, and the still higher frequency ferrites containing cobalt are used. Ferrites containing cobalt may also be annealed in magnetic fields to produce B-H curves quite similar to the Perminvar metals mentioned above.

Many of these ferrites are also used in the microwave region, where use is made of the fact that their application of external magnetic fields causes the plane of polarization of the microwave radiation within a cavity containing the ferrite to be rotated, thus permitting for the first time the existence of non-reciprocal electrical networks.

More recently, a family of magnetic materials called garnets, of the general formula

$$(R_2O_3)_3\ (Fe_2O_3)_5,$$

where R stands for a rare earth metal, has been developed in France. These materials, in contrast to the ferrites, do not contain any ferrous ions and therefore can be made to have even higher resistivities than the ferrites and thus are even more efficient when used at microwave frequencies. The width of the resonant absorption band is also much narrower.

Another new series of magnetic ceramics discovered in the Netherlands has been called Ferrox-Plana. The crystals making up these ceramics are hexagonal and have asymmetric properties in that the C axis is often a hard direction of magnetization whereas the plane of the crystal has two easy directions of magnetization. These materials can be oriented in the manufacturing process similar to the oriented barium ferrite mentioned above. While unusual uses could be found for these materials at present they have been chiefly used to extend the frequency range in which ferrites can be used.

Families of ferrites containing copper or magnesium have been made to have rectangular hysteresis loops and these have found extensive use in saturable pulse transformers and as information storage elements in digital computer memories.

Resistive Materials

While the nickel-chromium alloy, Nichrome, is still with us and still to be improved on, various forms of carbon are perhaps in more general use. These go all the way from various inks consisting of mixtures of various carbon blacks with synthetic resins, through the form of carbon known as deposited or cracked carbon, which is the form of carbon obtained by decomposing an aliphatic hydrocarbon gas on a hot ceramic surface at a temperature of several hundred degrees C, up to some graphites. Graphite is unusual in that it is made up of hexagonal crystals with low resistance along the plane and high resistivity in the C axis. Oriented graphites are now available, and possibly use will be made of this asymmetric conductivity. Nickel-chromium alloys with aluminum added are also in wide use. Also, recently a number of organic salts sometimes called π complexes have been found with low value of resistivity together with some asymmetric properties, and these may possibly be considered as electronic materials.

Alloys of the noble metals (platinum, rhodium, palladium, etc.) formed from resinates and sputtered tantalum films are also being used for resistors.

Temperature sensitive resistors called thermistors use Ge, B, U_3O_8 and compounds comprising the transition metal oxides in two valence states, so that electrons can migrate from a metal atom in one state to another metal atom in the other state, for example,

$$Li_xNi_{(1-x)}O$$

where some of the nickel atoms are divalent and the others trivalent. These all have strongly negative temperature coefficients of resistivity.

Voltage sensitive resistors called varistors are largely limited to silicon carbide with or without some added carbon. Bismuth and more recently the semiconductor indium antimonide have been used as magnetic-field-sensitive resistors, while doped germanium and silicon have been used as pressure sensitive resistors.

Resistors of positive temperature coefficient are made from highly doped silicon, and from barium-strontium titanates containing a fraction of a per cent of lanthanum or indium (these types sometimes called "controlled valency semiconductors").

Ferroelectric Materials

For a long time Rochelle salt was the only known ferroelectric, but even here, the phenomenon was discovered as recently as 1921. This material had a comparatively low Curie temperature of 30°. This was increased to some extent by substitution of deuterium for hydrogen in the salt. While a number of other materials were found to have ferroelectric properties at temperatures below room temperature, the big impetus to this field was given early in the forties by Wainer who discovered that barium titanate was ferroelectric with a Curie temperature of 120°C.

Since that time a large number of other ferroelectrics have been discovered. These consist not only of compounds which contain barium titanate but other titanates as well, for example, lead titanate. Niobates and tantalates have been found to be ferroelectric, for example sodium niobate and lead niobate. (A number of antiferroelectric compounds have been formed, for example lead zirconate, as well as solid solutions of lead zirconate and lead titanate up to a certain percentage of titanate, when they become ferroelectric.) Of these, compositions can be made to go through from the antiferroelectric to the ferroelectric state by application of a high enough field. A new family of bismuth titanates (in which partial substitution of other metals is possible) gives high Curie temperatures which can to some extent be preselected. In addition, a number of organic solids have also been found to be ferroelectric of which possibly the most important one at the moment is guanidine aluminum sulfate hexahydrate, commonly called GASH.

Previously polarized ferroelectrics have found wide use as transducers (phonograph pickups, ultrasonic generators and receivers) and show some promise for microwave devices and as substitutes for IF transformers.

In piezoelectrics proper, as contrasted to the ferroelectrics above, there is substantially nothing new since the Curie brothers discovered the phenomenon in 1880 in quartz, tourmaline and Rochelle salt. However, LeCraw and co-workers at Bell Laboratories have recently discovered that oscillators using magnetostrictive yttrium iron garnet (also, under some circumstances, cobalt ferrite) have Q's several times the Q of oscillators based on quartz oscillators.

Wire Insulation

Wherein in an earlier day varnishes, cotton and silk were used, these have been to a considerable extent replaced respectively by polyvinyl formals (sometimes with the addition of phenolics), cellulose acetate or cellulose acetate butyrate, and the vinyl chlorides. At higher temperatures silicones and Teflon insulations are available. At still higher temperatures ceramic insulation with or without some of these plastics are also used.

Insulators

While originally steatite and porcelain were used as insulators, a number of additional ceramics, forsterite, spinel, magnesia, alumina and zircon are used, particularly at high frequencies. (While porous alumina has been with us for a long time, high density alumina as used for radomes and the like have only reached production in the last 20 years.)

Single crystals of alumina doped with a suitable transition metal element such as chromium are the functional elements in masers and lasers. Mycalexes comprising mica and a glass, have been extended to higher temperature ratings with the advent of synthetic fluorine mica. There are several new materials proposed for high temperature use including boron nitride, aluminum nitride and silicon nitride. Considerable effort is also being expended to prepare these materials in sheet form as dielectric spacers.

Semiconductors

The original materials used in cat's whiskers, rectifiers, and photocells were selected from lead sulphide (galena), lead telluride, selenium, cuprous oxide and cadmium sulfide. While these are all still used for one purpose or another, the present semiconductor art is mainly concerned with devices based largely on germanium and silicon, often in the form of extremely pure single crystals which have been doped with selected impurities to a precise level. Intermetallic compounds of elements lying in the IIIB and the VB columns of the periodic table, for example indium antimonide and gallium arsenide, have been synthesized and permit the manufacture of improved Hall generators, magnetic field detectors, Esaki diodes and so on. Some of these materials also have found use in thermoelectric generators and thermoelectric coolers, but presently solid solutions of lead selenide and lead telluride are more widely used. There are several new families of semiconductors containing as many as four or five elements which show great promise for use in this field. In an earlier day when the thermocouple materials, chromel, constantan, alumel, only were always available, such applications were given little consideration.

Conductors

While copper always was and always will be the principal conductor used, in recent years it has taken new form in the form of so-called "wiring boards", where sheet copper is laminated to plastic, either paper based Bakelite or polyester-impregnated Fiberglas. For high-frequency applications, copper conductors are now often plated with silver. For high temperature application they are plated with nickel. For applications where tensile strength is of great importance, iron wire with a heavy coating of copper is in common use. Conducting "paints" of silver and gold are in common use, as well as "conducting epoxies" consisting of metal particles dispersed in a polymerizable resin.

More recently superconductors lead, tin, niobium and tantalum have been used in switching circuits near helium temperatures. Niobium nitride at slightly higher temperatures has been used as a sensitive infra-red detector. In addition to superconducting alloys of superconducting metals, a new family of superconductors has been found at Bell Telephone Laboratories consisting of alloys of metals.

The first superconductors, now called "soft" superconductors, lose their superconductivity when the (self-generated) magnetic field exceeds a critical amount. The superconducting region is confined to a thin surface layer. "Hard" superconductors is the name for a family in which the maximum current density is uniform over the cross section of the material. Thus the "hard" superconductors will permit the establishment of high magnetic fields. In the order of increasing possible field strength these new materials are: Mo_3Re, Nb_3Zr, V_3S_1, Nb_3Sn, V_3Ga.

Hybrid Materials

We recently have had a glimpse into the future of electronic materials. Thus, the Bureau of Standards has synthesized materials which show *both* ferroelectric and ferrimagnetic properties. And Bell Telephone Laboratories have synthesized alloys which show both superconducting and ferromagnetic properties. In addition to the asymmetrical resistance materials, we can expect to utilize materials with asymmetric dielectric properties. Thus, to sum up, we can look forward to a complicated and exciting future.

Conclusion

While the over-all review of 50 years shows considerable accumulated result, progress in electronic materials has been slow and painful. The skills necessary to produce new or better materials require so many different scientific disciplines, that each new development must pass through many hands before maturing.

Future of the Component Parts Field*

P. S. DARNELL†, FELLOW, IRE

Summary—**Increasingly complex electronic systems are creating the need for greater numbers of components, with consequent serious problems of systems reliability and maintenance. Rockets, satellites and space vehicles demand small, lightweight, highly reliable electronic equipment. It is noted that miniaturized assemblies, integrated circuits, and functional solid-state devices provide solutions to these critical demands. Opinions are offered as to the time scale of availability of these new approaches. However, a continuing need for conventional parts in certain applications is noted, and possible trends in further development of several kinds are discussed. To derive maximum benefits inherent in the application of truly functional devices, the necessity of changes in points of view and design philosophies of both systems and device engineers is indicated. Certain factors other than those of a technical nature are considered which may have an important influence on the rate of transition from classical components to functional entities. Finally it is opined that the device engineer of the future should have a breadth and depth of intellectual disciplines which not only allows him to appreciate systems objectives, but also enables him to implement these objectives by functional devices through the media of basic properties of substances.**

Introduction

THE GREAT importance of electronics in performing communication, detection and guidance functions in World War II, and the emergence of solid-state technology into increasing prominence at the mid-point of this century, gave rise to conditions profoundly influencing the future of electronic component parts. As if those factors were not enough, the forces shaping the future for these parts are becoming even more intensified and diverse as the demands of the Space Age necessitate consideration of the effects of extraordinary terrestrial and interplanetary environments. At the bewildering pace with which these forces now are driving the field of electronics ahead, it is impossible to prophesy the long-range future with any assurance. Moreover, trends in technological development will be sensitive to influences created by the political, social and economic pressures associated with the international contests for power and position in the world today. Recognizing the vagaries of long-range prediction let us turn our attention to trends which it seems reasonable to expect during the next decade or so.

Systems Complexity

Electronic systems developers are continuing to design systems of greater and greater complexity, requiring more and more parts. For example, Baldwin, Crowley and Rosenthal [1] in discussing the application of computer techniques to the design of digital systems remark that " . . . the complexity of future digital systems leads one to the conclusion that such techniques are a virtual necessity. There are many systems now contemplated as utilizing hundreds of thousands, or even millions, of active elements." Another frequently quoted example is that more than 90,000 electronic component parts are required for a B-58 bomber. Of course, coupled with the unlimited growth in numbers of parts are the increasingly serious problems of interconnection and reliability. How many years more can the elaboration of electronic systems be continued on the basis of the classical concepts and approaches of the past? It seems that the time is not far off when this issue must be resolved. Although conventional components as we now know them will be with us for a long time to come, other ways and means must be pressed into service to alleviate the "tyranny of numbers."

Functional Entities

Types

As is well known, other ways and means in terms of physical embodiment under very active development today are packaged assemblies, integrated circuits, functional devices, etc. These vary in method of accomplishing in a physically unitary form the same function as a collection of discrete components. Packaged assemblies are essentially modular arrangements of regular circuit elements, so constructed and miniaturized as to result in high-density packaging of components. Integrated circuits may be either two-dimensional thin-film type on an insulating substrate, or a three-dimensional variety on a base of semiconductor material. In such forms of integrated circuits, the electrical components of which they are comprised are electrically distinguishable, but mechanically inseparable. In functional devices, or functional electronic blocks as they are sometimes called, the realization of the desired circuit function is accomplished by direct application of basic material properties. In this instance, circuit elements are no longer either electrically or mechanically identifiable as classical entities. Additional examples of functional devices are the maser, the Esaki diode, and the four-region semiconductor switch.

Miniaturization

A primary objective of packaged assemblies, integrated circuits, functional devices and the like is reduction in size and weight to yield miniature and so-called microminiature electrical building blocks. The importance of such miniaturization is emphasized by the demands for minimum size and weight of the electronic equipment for space vehicles. Noble [2] points out that in high-performance Air Force systems and space craft, " . . . the ratio of airframe and fuel weights to payload weights may run as high as one thousand to one." Hence the payoff for low weight load may be very high, and so justify the use of very costly electronic parts and equipment in the interest of minimizing weight.

Schedule

As regards the time when the types of functional assemblies above discussed will find practical usage, there are many divergent opinions. It seems reasonable to expect that initial applications will be for military purposes. Industrial and commercial usage undoubtedly will follow, but the extent to which functional units are employed by industry will be strongly influenced by economic consideration. The following time schedule is suggested.

1) The state of development of packaged assemblies and the less complex forms of thin-film type integrated circuits is now at a point where operational systems or equipment embodying these approaches are to be expected within a year or less. Also, some of the simpler structures of semiconductor integrated circuits will become commercially available during this period.
2) The period 1965–1970 should see the commercial use of circuits based upon semiconductor substrates.
3) Possibly toward the latter part of this decade some types of functional electronic blocks may be in pilot line production. However, the current state of the art is such that large quantity manufacture of functional electronic blocks before 1970 seems unlikely. It is believed that considerably more research and development effort is needed in this area to bring devices of this kind to the point where they can be produced on a commercial scale.

Conventional Component Parts

While packaged assemblies and functional electronic blocks provide approaches on which systems of the future may be founded to a large degree, there will continue to be a need for discrete components. For example, there is as yet no generally satisfactory solution to the problem of replacing the inductive functions of coils and transformers in two-dimensional arrays and in blocks of semiconductor material. Moreover, although functional entities are ideally suited to miniaturization and microelectronics, they are not compatible with high-power applications where large voltages and currents must be accommodated. The ability to put a new circuit together readily in the early design phases with discrete parts provides a flexibility to circuit engineers which may not be attainable with functional units. Until a new philosophy and technology of systems and circuit function design are evolved which provide other means of quickly demonstrating circuit feasibility, circuit designers will be loath to relinquish present procedures employing conventional components.

During the past several years, improvements in the classical forms of discrete components have been incremental in nature [3]. This situation will continue during the 1960–1970 decade with particular emphasis on performance in satellite environments and reduction in failure levels in all environments. Advantage will be taken of new materials as they become available. Generally speaking, no breakthroughs are foreseen which will radically affect the form, structure or function of our present line of classical components. Specifically, the following opinions relating to the future of these components are offered.

Resistors

Marsten [4] observes that there will be further development in inorganic resistance elements, such as carbon-ceramic structures. He also foresees continuing activity in the development of film-type resistors and increasing emphasis on semiconductor resistive devices. New areas in variable resistors will be explored to get away from the perennial problems of noise and wear caused by sliding contacts. In this connection it should be noted that the solid-state field-effect tetrode described by Stone and Warner [5] may be used as a voltage-controlled resistor exhibiting either positive or negative resistance depending upon the circuit configuration in which the tetrode is connected.

Capacitors

In reviewing the developments by which capacitors have evolved, Podolsky [6] notes that the " . . . history of the art shows clearly that improvements in capacitor materials and design followed closely the increased knowledge in the fundamental sciences, and most particularly in chemistry and physics." He recognizes that there is now " . . . electronic circuitry in which all the basic circuit parameters of capacitance, resistance and inductance are produced within solid state semiconductor devices." Of course, one well-known example of a semiconductor capacitor is the variable voltage diode [7], [8]. In conclusion he offers the opinion " . . . that developments in the capacitor field will advance constantly with the mainstream of science and that the art will progress to meet the needs of the electronic industries for every application whether they be terrestrial or in outer space."

Relays and Switches

With respect to relays and switches, Keller [9] states that the most widespread present trend in these devices in all types of switching systems is in miniaturization, and in hermetically sealed types to increase reliability. He notes the development of new high-speed relays such as the ferreed, a magnetically latched relay that can be operated or released by pulses as short as 5 μsec. He observes that, despite the recent rapid development of solid-state switching devices and systems, electromechanical relays and switches are being manufactured in more forms and larger quantities than ever before. In his opinion an "... important trend for switching systems in general is for relays and switches to be competitive, compatible and combinational with solid state switching devices and systems."

Coils and Filters

In considering trends in the field of transformers, inductors and filters, Lord [10] holds the view that miniaturization of low power electronic circuitry may very significantly reduce the role which discrete inductive devices play in low-power electronics. Particularly with respect to size reduction of filters, he cites the trend to combinations of electromechanical transducers and mechanically resonant structures of metal or ceramic to accomplish frequency selective functions. Others [11] have also noted efforts to circumvent transformers and inductors as circuit elements because of miniaturization difficulties and because of the difficulties of duplicating their functions in solid-state circuits. In the latter connection, however, Stone and Warner [5] have shown that the solid-state field-effect tetrode may be made to exhibit the behavior of a low-Q inductor by using its properties as a gyrator to invert capacitive admittance.

Selection Criteria

In his review of printed circuits and microelectronics, Danko [12] foresees high-density packaging of components, integrated circuits, and functional electronic blocks becoming competitive in equipment applications. Among these various approaches the criteria of choice will be the economics, performance, reliability, producibility and logistics of the end equipment rather than the particular technology associated with a functional assembly.

Frequency Control

In considering frequency-control devices, Bottom [13] notes that quartz crystal units used for national standards of frequency are capable of accuracies in the order of one part in ten billion (1×10^{-10}) per day. He further states, "Within the past ten years devices utilizing atomic events have been devised which provide standards of time and frequency which are reproducible and reliable over periods of a few months to about 1.5×10^{-11}." In this connection, recent work with the hydrogen maser at Harvard shows that frequency stabilities in the order of 1×10^{-13} part per day are feasible. Looking ahead, a frequency stability of 1×10^{-15} may be attained within the decade by means of the maser approach.

Materials

As Robinson [14] indicates, the development of new materials and improvements in the purity and processing of present materials holds the key to significant advances in the field of component parts. Not only will such activities permit improvements in conventional components, but they are essential to the advance of new concepts in component development and design. For example, the great impact of the ferrites during the past decade in the development of improved types of conventional components, and in opening up entirely new areas for microwave devices is well known. In the decade ahead, thin-film forms of conductors, dielectrics and semiconductors will continue to be of extensive interest in relation to further miniaturization of components and integrated circuits. Single-crystal purification and growth will also continue to receive extensive support. New semiconductor materials with new properties will be investigated with the objective of enabling the accomplishment of new functions in both discrete devices and functional electronic blocks. The effects of radiation on materials will continue to be studied both as to the properties of materials in components, and as a tool for the polymeric combinations of materials not normally susceptible of polymerization.

Reliability

Whatever are the roles played in the years ahead by the continuation of classical approaches and by the application of new integrated and solid-state devices as above described, the matter of reliability will continue to be of paramount importance. For example, an assumption often used is that the maintenance of military electronic equipment throughout its lifetime may cost as much as ten times the purchase price. Hence the initial cost becomes relatively unimportant. If extremely complex electronic terrestrial systems are to have economically reasonable mean-time periods between repairs, and if extraterrestrial systems are to give acceptable performance, failure rates must be known and controlled so that systems operation can be predicted and evaluated. Furthermore, it appears that continual improvement of classical components to the extent consistent with their continued application will be required. Similarly, the reliability aspect of integrated and functional devices will have to be kept up to the demands of over-all systems performance. Although some information is now available on packaged assemblies which show good reliability capabilities, there are not yet sufficient data at hand to permit assessment of functional solid-state circuits from the reliability viewpoint. It may be a matter of years before enough of such data are available to justify valid statements concerning the reliability of integrated and solid-state circuit devices [15]. It is generally believed that since functional electronic blocks will be derived from the same general materials and processing techniques as are now employed for transistors, they should have a high potential level of reliability. Furthermore, virtual freedom from the element interconnection problem should enhance their life expectancy.

Design Philosophies

Thus far, component parts and functional electronic entities have been reviewed principally from the standpoint of their technical aspects. Perhaps factors which have even greater influences than purely technological considerations on trends in the field of electronics are the development and design philosophies of people working in this field. As Morton [16 has stated, "Our heritage in components is essentially the physical embodiment of the mathematical concepts of circuit theory. With this viewpoint, the system designer has translated his over-all system requirements to those for components, thinking only in terms of classical inductance, capacitance, resistance, tubes and transistors. The component designer, adopting this viewpoint, therefore has been limited in his permissible solutions only to finding new techniques and materials for the classical elements. . . . After all, the aim of electronics is not simply to reproduce physically the elegance of classical circuit mathematics—rather, it is to perform desired electronic system functions as directly and as simply as possible from the basic structure of matter."

It is quite clear, therefore, that realization of the maximum benefits of truly functional approaches will necessitate major reorientation in the design philosophies of both system and device engineers. The system designer in following the principles of systems engineering [16] must start at a new level of synthesis and specify his needs only in terms of basic system functions and not in terms of the means by which the functions are to be accomplished. In turn, the device engineer must seek the attainment of these desired functions by going directly to the basic physics and chemistry of matter without becoming preoccupied with electrical circuit element concepts.

In achieving the higher levels of technical sophistication necessary to meet the challenges of the future new combinations of intellectual disciplines will surely come to pass. As Noble [2] observes, the future device engineer will have to be a "versatile specialist." Not only will he need to understand fully the purposes of systems functions in order to formulate device requirements, but he also must know how to cause electrons, atoms, phonons and photons to do what he wishes to accomplish the desired functions. The demarcation between systems, circuits and devices which has generally prevailed during the past will certainly become increasingly vague and may disappear entirely as more and more sophisticated devices provide complete electronic systems functions.

The Future

In summation, present trends and influences in the component parts field are of such a nature that the future of this field may be characterized as follows:

1) There will be a continuing need for discrete or single function components for many years ahead. *Relative* to the total requirements for electronic devices to support manufacture of systems, the production of conventional component parts will gradually diminish as new functional devices play an increasingly important role. However, if the current unprecedented rate of expansion in scientific and technological fields continues [17], the *absolute* level of demand for conventional components may show little change during the 1960–1970 decade.
2) The use of more sophisticated devices to perform complex circuit functions will gradually increase. Physically unitary forms of functional circuits will replace arrays of discrete conventional parts. Growth in systems complexity will inevitably force this replacement. Transition from classical to advanced approaches will be most rapid in applications where major benefits result. For example, the Aerospace Industries Association [18] in forecasting usage trends in aerospace electronic equipment predicts that in general, in 1970, conventional parts will constitute about 80 per cent of total usage. The remaining 20 per cent will be provided by microminiaturized discrete parts and by functional electronic devices, there being roughly equal division between these two approaches. However, in specialized applications, such as space craft, missiles and certain aircraft, miniaturized assemblies and functional devices may account for as much as 50 per cent of the total electronic componentry.
3) Improvements in the operation of conventional components will continue to be made. Reliability will become a quantative performance parameter of paramount importance with respect to both classical components and the new embodiments of functional circuits.
4) Continuing research into the basic nature and properties of matter will pave the way for the development of new components which individually or in combinations will perform functions that were either not possible or practical of accomplishment within the past state of the art. For example, the Peltier effect has been known since 1834 but it was not until the advent of modern semiconductor technology that the practical implementation of this effect in thermoelectric cooling could be considered [19], [20]. Another illustration is superconductivity. Discovered by Onnes in 1911, it is only recently that this phenomenon has received attention for technological purposes [21].
5) The rate of transition from conventional techniques to new approaches in the device field will depend in part upon many factors other than those of purely technological nature. There is a momentum tending to perpetuate the status quo, generated by the great amount of engineering effort in the past decade on improvement and refinement of classical

components. Development procedures and design practices founded upon years of application of classical methods have become strongly ingrained and the implementation of advanced concepts in system and device engineering will force a break with this past. The consequent reorientations in attitudes and thinking will not occur rapidly. The education and training of a new breed of "versatile specialists" to equip them with the breadth and depth of scientific knowledge necessary to cope with the problems inherent in advanced concepts of functional devices will take many years. In Morton's judgement [22], "The most profound understanding of solid state physics and chemistry will be needed to bring forth functional devices; indeed, it is likely that functional device invention will produce new science as did the transistor."

In conclusion, the wish is expressed that future efforts in the field discussed here could be devoted mainly to the instrumentalities of peaceful purposes. The political climate abroad in the world today makes this a forlorn hope and dictates major attention to keeping military facilities on the forefront of technological advance. Whatever the path ahead in these regards, the future of electronic componentry in its various forms will provide both stimulating challenges and exceptional opportunities for all those pursuing this exciting field of scientific and engineering endeavor.

EDUCATION

Organized with the assistance of the IRE Professional Group on Education

Electrical Engineering Education Today*

FREDERICK EMMONS TERMAN†, FELLOW, IRE

Summary—**Education in electrical engineering has changed greatly since World War II and continues to change. There is greater orientation towards science and much more emphasis on graduate work, while student interest in electrical power as a field of specialization has virtually disappeared. Student participation in research conducted at a highly sophisticated level has become a major element in the training at the Ph.D. level, and the Ph.D. degree has come to symbolize the electrical engineer with superior technical training.**

Faculty members in electrical engineering departments have available rewarding and stimulating opportunities such as never before existed. Generous research support is available, there are numerous opportunities for consulting, and the services of professors are in demand for government advisory committees, membership on boards of directors, etc.

Educational institutions with strong graduate programs in electrical engineering are becoming centers for the development of growth industries. They are therefore important economic influences in the industrial world.

In summary, our universities today are turning out young electrical engineers far better equipped to meet the new challenges that are ahead of them than they did in the period before World War II. Concurrently the importance in today's world of the electrical engineering departments and faculties of our better schools is high, and is growing steadily.

EDUCATION in electrical engineering today is in a state of flux. Great changes have occurred during the fifteen years since the end of World War II, and changes still continue. Noteworthy is the greater emphasis being placed on fundamentals at the expense of attention to engineering practice and applications, the increasing orientation toward science, and the virtual disappearance of student interest in electrical power as an area of specialization. The latter has made electrical engineering and electronics virtually synonymous. Of particular importance is the enormous expansion of graduate work as compared with the prewar period, and the fact that graduate work carried on in electrical engineering departments now deals with many topics that were once the exclusively property of the physicist, such as electromagnetic theory, electron dynamics and much of solid-state electronics.

In order to understand the significance of the changes that have taken place in recent years in electrical engineering education, it is necessary to review some history. Before World War II, electrical engineering curricula were strongly influenced by an electrical power tradition, so that even those in the "communications" option were required to have a thorough background in rotating machinery and electric-power systems. Also, at this time only a very small fraction of the students graduating with a B.S. in electrical engineering engaged in graduate work, and very very few carried their studies as far as the doctorate. With the coming of World War II, electrical engineers with this four-year background augmented by practical experience were found to be wanting in the exciting new areas of electrical engineering involving microwaves, pulse technology, computers, diodes, etc. Instead, Ph.D. physicists who knew very little conventional electronics and no engineering, but whose education included three or four years of graduate work and a sound background in classical physics and mathematics, took over almost to the exclusion of the electrical engineer. At the end of the war, many of these men went back to being nuclear physicists, but they had shown the electrical engineers what was needed to handle the newly developing areas. Since then electrical

engineering education has never been the same.

Graduate training, at least to the master's level, has become almost a necessity for the man with good ability who wishes to make full use of this ability in the technical aspects of such challenging new fields as solid-state electronics, computers, communication theory, controls, microwave electronics, etc. The nature of these fields is such that practical "on the job" experience is not a substitute for formal training. A man does not learn the quantum mechanics involved in semiconductor behavior from the experience gained on a beginning job in industry—such knowledge requires formal study, best carried on in an organized class under the guidance of an instructor. Today nearly 20 per cent of those graduating in electrical engineering go on to the master's degree, while two or three per cent of the B.S. graduates complete work for a doctorate. The doctor's degree is now beginning to be almost a prerequisite for a faculty position in the better electrical engineering departments, and is also given a high value by industry.

Research has become a major factor in electrical engineering education. Before World War II, only a few educational institutions carried on really significant research in electrical engineering, and even at these places the volume of such activity was not large because funds were so very limited. In contrast, the availability from government sources of large sums for basic research in electronics, and even larger sums for applied work in this field, has made it possible for many institutions to develop strong research programs. This has had its effect on the character of electrical engineering education. Undergraduate teachers either do research or are closely coupled to research activities, and so bring to the classroom a vitality and a spirit of adventure based on an interest in new ideas. This is in contrast with the prewar era, when the wisdom of the faculty member tended to be in a knowledge of the existing practices of the industrial world. In balance, this change has been for the good.

At the graduate level research tends to be an integral part of the educational program in electrical engineering. Through participation in research activities the graduate student not only obtains financial support, but also receives training in the methods of research. As a result, a large fraction of the products of our electrical engineering departments who carry their training to the doctorate level are true engineer-scientists. Moreover, they have the background necessary to enter new fields that open up, just as the physicists were equipped to go into microwave radar at the beginning of World War II. Never again will electrical engineers be caught short, as they were at that time.

The faculty man in electrical engineering never had more interesting and rewarding opportunities than are available to him today. If he has demonstrated creative ability, he can obtain research funds in sufficient amount to exploit his talents effectively, and he will have the help of bright, eager, and well-grounded graduate students to aid him in working out his ideas. As a result, he will be able to accomplish several times as much during his active career than his counterpart of an earlier generation, and will probably train five or ten times as many students at advanced levels. During the summer, he can stay on the campus and concentrate on his research activities, while receiving summer pay from his research project; this increases both his research productivity and his income. In addition, the electrical engineering faculty member will commonly spend up to one day a week as a consultant for one or more companies in connection with advanced development work which relates to his own special knowledge. For this he is well paid, and sometimes has opportunities to purchase stock at the employee's price. He may sit on the board of directors of a company for which he consults, or which was founded by one of his friends or former students. If he likes to get around, today's professor finds plenty of opportunity to travel in connection with his government contracts and consulting activities, and in connection with the affairs of professional groups. Today's electrical engineering department is no ivory tower, and its faculty members tend to be men of the world.

Finally, educational institutions with strong graduate programs in electronics attract industry. This is because industry is beginning to discover that its creative activities are best carried on near a center of brains, *i.e.*, near a good educational institution, and that for creative work such a location is far more important than a location near markets, raw materials, transportation, or factory labor. Substantial concentrations of research-oriented electronic activities are already associated with many of our best educational institutions, and this trend is rapidly increasing. The result is that a strong graduate program in electronics is an important economic influence in the industrial world, and not merely a place where young people can get a good technical education.

In summary, electrical engineering education has responded to the new age of electronics, and is now capable of meeting new challenges of this field as they arise.

Future Trends in Electrical Engineering Education*

J. D. RYDER†, FELLOW, IRE

Summary—**Maxwell started the electrical field on the mathematical analysis path, and the field will continue to successfully exploit the mathematical method. It can be expected that engineering will more completely take over the teaching of its own basic principles, as engineering becomes more accurately described as applied science. Future progress in electrical education will be built about mathematics, and especially employ systems analysis and materials science. Without further advance in his science base, the engineer may be in danger of becoming an order-taking technician. Such progress in fundamental will require the elimination of many present-day barriers between areas of specialization.**

SOME may say it started with Thales and his amber, or Galvani and his frogs, or Volta and his batteries. But the path of modern electrical education was really established by Maxwell, with his 1864 statement of the basic laws of electrical science in mathematical form—precise, rigorous, and so far, all inclusive. From this mathematical research also came the statement that light was electromagnetic in character, and the additional prediction of electromagnetic radiation of energy at other and nonvisible wavelengths. Thus was the future pattern of electrical research and education set—that knowledge of electrical science should come from logical reasoning and be expressed in mathematical language.

By its nature invisible, electricity made its presence known only by indirect phenomena, variously described by the early experimenters in terms of imperfect concepts of flow, flux, or force, borrowed from the field of mechanics. With this quasi-qualitative background, no matter how right the quantitative results, electricity could have remained much longer an area of metaphysics and legerdemain, had not Maxwell's basic statements channeled research into the mathematical realm.

To be honest, one must also admit that electrical phenomena, in their usual forms of exhibition, obeyed linear differential equations to which mathematical solutions were already available. Thus answers to many problems in physical situations were provided to the early investigators. In this, electrical science differed from some other early engineering fields which were advanced by the experimentalist or the practioner who made things work, without much use of the mathematical or analytical process. On their side, it must be recorded for fairness that many of the early problems involved turbulence, boundary layers, microscopic material phenomena, or nonlinear processes not even yet fully amenable to mathematical statement and solution.

Following the lead of Maxwell, similar mathematically-trained investigators unearthed and applied the methods of Heaviside, LaPlace, Fourier, Cauchy and others to develop further electrical theory. The mathematical method has continued in use, and has provided the profession with a medium of communication and a method of analysis, not only useful in electrical discovery but also suited to the solution of problems in related fields. Thus it should have been no surprise for the electrical engineer to aid and abet the development of the electronic computer in logic as well as in circuitry, or for him to apply mathematical logic to the switching problem, or quantitative methods to information transfer or communication in general.

There is no reason to believe that this continued usage of and profiting from the methods of mathematical analysis will cease. Therefore it seems possible to predict with reasonable surety that future progress in electrical science will be coincident with progress in application of mathematics to that science. In fact this writer has previously proposed[1] as a theorem: "That a field of engineering can advance only as fast as the mathematical abilities of its members advance." Electrical science, a term here used as inclusive of all *applied science* concerned with electrical phenomena, seems an area providing adequate proof of this theorem. The recent rapid advances of other fields of applied science and engineering, as they have begun to utilize higher mathematical methods, seems to provide further confirmation.

If this prediction of the mechanism by which we will further advance in electrical science and engineering is correct, then the converse of the theorem is important. If we are to advance, better and additional mathematical education must be provided to future members of our profession. As far as can be foreseen, these programs will be well suited to students in all of the engineering or science-engineering disciplines, since advance in all fields is to be hoped for, if our science-based civilization is to continue forward.

Engineering college mathematics will continue to begin with the calculus, giving to the high school or preparatory school the responsibility for laying the foundation in prior forms of mathematics. This will call for further changes in an already-changing high school pattern to provide more work in trigonometric identities,

* Received by the IRE, July 14, 1961.

[1] Poles and Zeros, "D-day in engineering education," PROC. IRE, vol. 46, p. 1571; September, 1958.

more algebraic manipulation, and a thorough understanding of analytic geometry. The more advanced high schools will provide introductory work in the calculus itself, but such opportunities in the average high school may be beyond the time scale of this paper, unless greater encouragement is made available to attract more capable people into high-school teaching, and more rigorous mathematics courses are required for their training.

College departments of mathematics may have to be reoriented and in some cases, reorganized to insure interested teaching of the kinds of mathematics desired and needed by engineers and other workers in applied science. Assuming such reorientation, then the college teachers of calculus must recognize that the engineer of tomorrow (and tomorrow is nearly here) will work almost always with a computer, of at least reasonable capability, figuratively in the next room. The treatment of a Table of Integrals as something approaching the level of a clandestine crib must cease, and the Table recognized as a place of first resort upon meeting an integral sign. The classroom development of the solutions to the integrals of a great many functions can be eliminated, and the time formerly so utilized given to insuring that the student has a thorough understanding of the significance and limitations of the process of integration. This work should include a much expanded discussion of change of variable, limits, integrability, existence, and other areas of mathematical rigor now treated much too lightly. Given a thorough understanding of the process and limitations of integration, the end point of any integration will then most usually be the Table of Integrals, or an application of Simpson's rule. The latter will lead directly to a piece of tape or a program in the computer library, and a short time on the local computer.

It will then be apparent to the teachers that the treatment of differential equations in a separate and distinct course is undesirable. Just as the teaching of methods of solving a wide variety of integral forms is unnecessary, so also is it unneccessary to teach methods of solution to a variety of differential equation forms. The computer will provide the answers; student abilities in setup of the original equations, and manipulation into computer-suited forms can become the emphasized topics. Solution of a differential equation can be presented as a problem in simultaneous integration, and at this point the methods and analysis employed in setting up an analog computer will justify the presence of such a computer in the mathematics classroom.

It is realized that appropriate textbooks and course syllabi do not yet exist in most schools. However, if new material is appropriate to a course or curriculum it should be introduced and taught with whatever aids are available. The textbook will surely follow.

So much is prologue—a part of the preparation for the professional education in electrical science to follow. In view of the diversity and breadth of the field served by today's electrical engineers—from costs and studies of new communications systems to development of erotic methods of space-ship propulsion, from abstract logic to gallium arsenide diodes, from transfer functions to information channel capacity, from sales to research—it is not easy to determine the trends. An extrapolation of present movement allows the prediction that the electrical engineer will become an electrical scientist-engineer, a man interested in the discovery of new knowledge which he hopes to apply in useful new devices and systems.

To become such he will require a thorough knowledge of electrical and allied science as his background, a rigorous coverage of mathematics as his language, and methods of analysis and synthesis in engineering application as his tools. He will not lack for scientific fundamental nor for ability in engineering analysis and synthesis; his interest will be in the application of scientific phenomena for human benefit. Where scientific fundamental may still be lacking, he will have an engineer's ability to design around the lack.

In tomorrow's starkly competitive scientific world such an education will be required of all who will originate, innovate, face the challenging problems, make the broad decisions, and reap the large rewards; any education less than this will fit the recipient only to take and carry out orders. Which do we select for the engineer of tomorrow? Can the engineer afford to be second best?

To provide the training for leaders in electrical and applied science a college must attract the best students, must excite and challenge their abilities from the moment of entrance, and this cannot be done leisurely. Included must be basic work in physical phenomena on a broad front; at least the areas of solid and fluid mechanics, heat, and atomic and nuclear structure, taught at a level which recognizes the parallel advancement in the mathematical ability of the student. Engineering schools in this near time scale will have overcome the traditionalism which today keeps the teaching of classical chemistry and physics in those science departments.[2] Subject matter in the classical physical science areas is now the basis on which engineering is built, and, as engineering becomes more a field of applied science, it will no longer be logical that engineering should turn over the basic preparation of their students to others. A basic mechanics or heat course, taught by a theoretically-inclined engineer will not differ from a course taught by a physicist, and will be much better than one taught by a graduate assistant. Engineers today teach such classical material at the graduate level; can we long tolerate the duplication of effort at lower levels? While we have here named chemistry and physics, many of the same points need to be discussed on the teaching of mathematics, as well.

[2] J. G. Brainerd, "Cooperation among electrical engineers, physicists and mathematicians in engineering education," *Proc. Syracuse University Sagamore Conference*, p. 78; 1960.

The teaching of the fundamental science material in courses supervised and taught by engineers of science bent will provide definite gains by coordination of treatment with later engineering courses. As an example, a new approach to mechanics will be required. It should not be necessary for the electrical engineer to analyze trusses to learn about forces, and he should care little whether the forces are coplanar or noncoplanar. Work, energy, power will be introduced with greater breadth and more mathematical and physical rigor than has been past practice. It will be found that learning in this field can be expedited by resort to some of the fundamentals common to all fields,[3] but usually associated with network theory, namely: forces to a point sum to zero, displacements around a path sum to zero. There are other similar broad analogies covering many fields. Such unification of treatment cuts across traditional departmental lines, and barriers between departments must be removed to allow such free interchange of ideas, and free movement of teaching staff.

Electrical studies may begin with field or continuum theory as one stem, network theory or lumped-element treatment as the other. Field work will later expand into fluids and other field processes, and into transmission and radiation of energy, all areas where the partial differential equation rules. Such unity in the study of continua would also cut across the departmental barriers of today—perhaps we are already hearing the trumpets of Joshua before these walls of Jericho?

Network theory will be developed not only for its answers to response of networks, or for design to stated conditions, but also to develop skill in the application of rigorous and systematic methods of solution for systems of equations. The voltages, currents, frequency response, or transient performance may still be needed in engineering application, but often these figures will be determined by the computer after the student has set up and manipulated the basic system equations by matric techniques. Electronic study will be more systematized than it is today—being recognized as the study of the active network. Generality will be the byword, and devices when discussed will be largely solid-state in nature.

In the electrical area, as it was in mathematics, we find that what has been already said is largely prologue. Major emphasis at higher levels will go to two areas—systems analysis and synthesis, and solid-state phenomena or materials theory. A third, but less important, area will employ statistics or statistical mechanics in the study of noise, random phenomena, and the information capacity of communication systems.

The study of a system, as contrasted with the "isolated machine" concept of an earlier day, probably began as a formal discipline with the interconnection of components or machines for control purposes three decades ago. With such interconnection the transient performance was at the heart of the study; the steady state so avidly studied in an earlier day is now seen as only an occasional end-point of a transient. The popularization of the LaPlace transform and the fundamental work on feedback by Black, Bode, Nyquist, and others lead to understanding. Thus were poles and zeros, complex plane analysis, Nyquist diagrams, and stability brought into electrical parlance.

Understanding, however, is not enough for the electrical engineer. It remains to analyze the system in terms of its interconnections and the characteristics of its component parts, and here again mathematics supplies at least a partial answer in topology and linear graph theory. Through such mathematical methods the analysis and synthesis of systems, regardless of operating media or type of component, will become a major responsibility of the electrical engineer. This will require that he once more break down the barriers between today's disciplines; he will require basic knowledge of pneumatics, hydraulics, heat transfer, thermodynamics, even chemical reaction. Given the proper breadth in his basic education, he will discover that his mathematical training plus his network analytic methods can readily carry his systems analysis and design into nonelectrical areas.

Materials science will receive great emphasis in the future educational process of the electrical engineer. Needing knowledge of the magnetic, thermal, and conductive processes in metals and alloys, in the past he all too often received instruction in the mechanical properties of steel and concrete, and so he chose to study none. Tomorrow he will study materials in the atomic sense, since his devices will employ lattice arrangements to secure their operative properties, and his design of circuit elements may depend on crystal growth. Courses in this area are today far from usual; in fact, syllabi and texts must still be written. However, when a complete amplifier or subsystem can be designed into a wafer of germanium or silicon, or, when new operating properties appear by reason of quantum tunneling of thin films, there can be little reason to doubt the importance of the area.

Interest in broadening of the engineer in nontechnical fields will continue. His path in these directions must also be prepared by questioning of tradition, and coordination and integration of subject matter. Perhaps a few walls of Jericho may fall in the areas of the social sciences as a result. We must keep constantly in mind that, if the engineer of the future is to make the proper decisions for the major problems he will face, he must be able to live, to work, to communicate, and to lead in a world of nontechnical but well-educated people.

While all engineering will tend toward further emphasis on research, the electrical engineer will look upon this as his major function—graduate preparation for this and other areas of work will become commonplace for all capable of carrying on with their education. Engi-

[3] H. E. Koenig and W. A. Blackwell, "Electromechanical System Theory," McGraw-Hill Book Co., Inc., New York, N. Y., 1961.

neering will have become more fully recognized as a field of applied science, and the electrical engineer will have become a scientist-engineer, interested in the search for new knowledge and in the development of new devices and services employing that knowledge. Engineering education in general will have blown down the walls of Jericho which isolated its many fields, and will have achieved a closer understanding in a technical sense, through broadening and deepening of our common science base. Engineering will also have achieved a better understanding of the relationships between, and the differing objectives of, scientists, scientist-engineers, engineering operators, and engineering associates.

Thus will real unity be achieved through teams of diverse function and training, all working to employ nature's phenomena for the benefit of man.

Graduate Study in Electrical Engineering*

ERNST WEBER†, FELLOW, IRE

Summary—**Graduate study in electrical engineering developed significantly after World War I when radio engineering came of age. The many new scientific discoveries preceding World War II and exploited technologically during and following that war lent tremendous impetus to the further growth of graduate study, particularly towards the doctor's degree. The keen competition for the outstanding students between industrial research laboratories and the faculties of the leading institutions has retarded the growth of the genuine full-time student body and has enormously accelerated the part-time enrollment for graduate degrees with the result that the numbers of degrees awarded have increased at a lesser rate. This has accentuated evaluative studies of graduate education and drawn the attention to national needs; namely, large-scale support of a sufficient number of outstanding graduate study and research centers with adequate support for genuine full-time graduate students in order to supply faculty needs as well as the needs of industry in this highly technological society.**

The Evolution of Graduate Study

GRADUATE EDUCATION in the United States could be said to have become significant about 1876, when The Johns Hopkins University in Baltimore, Md., established a graduate school organized pretty much along the German pattern of the time, which strongly emphasized research. In his rather exhaustive study, B. Berelson,[1] in fact, distinguishes the following periods concerning graduate study in the United States: Prehistory (before 1876), University Revolution (1876 to 1900), Consolidation and Standardization (1900 to World War I), Growth and Diversification (World War I to World War II), and Revival and Reappraisal (since World War II).

Engineering generally, and electrical engineering particularly, had very little graduate study interest and, therefore, facilities before 1900 were few. As a matter of fact, the total graduate enrollment in engineering schools in 1921 was 368 students in 40 institutions, whereas 124 engineering schools had an enrollment of over 64,000 undergraduate students! By 1933, however, interest in graduate study had become significant enough so that the U. S. Office of Education in cooperation with the Society for the Promotion of Engineering Education initiated a survey[2] which was published in 1936 and which could point to the fact that the 126 doctoral degrees in engineering awarded in 1934 gave it second place in the science group, chemistry being first with 590 degrees, and physics third with 121 degrees. Engineering had thus leaped over more than 50 years of evolution and, of course, had created quite a host of problems concerning standards, objectives, and administrative functions. The impetus to this first growth came clearly from the general growth of population with the increasing emphasis upon college education, from the general prosperity of the early twenties which induced tremendous industrial developments, and from the technological innovations that had transformed the transportation, communication, and manufacturing systems of the country, and had created the modern home with all its appurtenances.

Alarmed by the seemingly boundless expansion, the Committee on Graduate Study of the Society for the Promotion of Engineering Education prepared a Manual of Graduate Study in Engineering[3] in 1945, which set down the philosophy and objectives and established guide lines for the organization, conduct, and administration of graduate study in engineering, both towards the Master's and the Doctor's degrees. Though in principle still valid, a revised edition was issued in 1952

to take care of special problems connected with the changing patterns of graduate study. Finally, a graduate study commission[4] concentrated on these same problems of motivation, financing, patterns of study and development of faculty in greater detail.

It is of interest to note that all of these studies and surveys encompass all disciplines of engineering and therefore are of a compromise type between the strongly professionally oriented representatives, who would like to see in engineering primarily design and development, and between those representatives who see engineering as applied science with strong emphasis upon research. Depending upon one's views, experience, and personal ambition, the evaluation of trends and programs and the statement of problems will differ.

The Growth of Graduate Study in Electrical Engineering

Graduate education in electrical engineering has exhibited a growth pattern that runs rather parallel to the development of IRE, and in fact, has confronted us in recent years with the same kind of explosive growth which has caused serious reappraisal of objectives, standards, and modes of operation.[5] Peculiarly enough —or perhaps for very logical reasons—the two world wars have provided the greatest stimuli for growth.[6] World War I initiated the development of the world-wide communication systems with the need for systematic analytical as well as experimental treatment of signal shaping, propagation, and reception. The foundations of network theory,[7] operational analysis,[8] and early applications of electromagnetic theory[9] were laid in that period and introduced into the graduate programs of progressive schools of engineering. World War II brought the fruition of the feedback concept,[10] and its extensions into automatic control systems,[11] opened the whole new world of microwave systems of radar, navigation, air traffic control, and communication links,[12] and fathered the penetration of modern quantum physics into material technology.[13] Today we find ourselves exposed to a dynamic development at an exasperating pace with which even the professional group system of the IRE has difficulty to keep step, notwithstanding its unrivalled flexibility and practically unlimited scopes of interests.

Statistical data are not reliable before the first survey of graduate study in the so-called Hammond report,[2] but we find it illuminating to compare enrollment figures and degrees awarded from 1933 on. Table I gives the data published by the ASEE for five selected years avoiding the war years and the immediate post-war period. Even so, the number of Doctor's degrees in 1948 is low as a post-war effect because of the residence requirement for doctoral studies, and the number of day students in 1952 is low because of the effects of the Korean war. Over-all, these facts stand out:

1) Total enrollments for Master's degrees have increased by a factor of 14.5 between 1933 and 1960, but at a much greater rate in the part-time category than in the full-time group.

2) The number of Master's degrees awarded per year has increased in the same period only by a factor of 6.4, suggesting a high and apparently increasing attrition rate which one might not expect in graduate study.

3) Total enrollments for the Doctor's degree were not significant before 1939, and have grown since 1948 at a greater rate than enrollments for Master's degrees.

4) The number of Doctor's degrees awarded per year has not kept step with the enrollments in spite of the fact that the doctoral enrollments are mostly classified as day students.

TABLE I

Graduate Students in Electrical Engineering

	1933	1948	1952	1956	1960
Master's programs					
Enrollment:					
Day (Full and part time)	469	2267	1686	3035	5710
Evening and Special	214	1133	3575	3822	4168
Total	683	3400	5261	6857	9878
Degrees awarded	301	866	990	1128	1934
Doctoral programs					
Enrollment:					
Day (Full and part time)	105	361	567	747	1548
Evening and Special	7	106	269	208	230
Total	112	467	836	955	1778
Degrees awarded	21	36	121	136	203

As a matter of fact, the number of Doctor's degrees awarded in electrical engineering has remained at about two per cent of first degrees, which is the same ratio as for all graduate education in the United States, whereas in physics and chemistry the corresponding ratio is more like 14 per cent. This leads necessarily to a discussion of the

Objectives of Graduate Study

As a profession, engineering has been defined by the Engineers Council for Professional Development (ECPD)[14] in terms of application of " . . . a knowledge of the mathematical and natural sciences gained by study, experience, and practice, . . . with judgement to develop ways to utilize economically, the materials and forces of nature for the progressive well-being of mankind." In its earliest phases, engineering was the art of providing roads and river crossings, of supplying fresh water and disposing of waste, of building homes and implements for defense, briefly what we call civil engineering. This is clearly illustrated by the very first school of engineering, founded by Napoleon as the Ecole Polytechnique in 1794, to provide properly trained men for his génie civile corresponding to our present Corps of Engineers. Significantly, the earliest engineers in civilian practice in the United States were graduates of the U. S. Military Academy, organized in 1802, underlining the tremendous value that the military have always placed upon the systematic utilization of technological achievements. The very large expenditures of the military establishments all over the world for the development of technologically more perfect weapons of defense, and also of offense, are clear evidence of this fact today.

Perhaps we should keep in mind that the faculty at the Ecole Polytechnique included the mathematicians Lagrange and Laplace who evolved the systematic formulation of mechanical science and of potential theory, as well as the chemist Berthollet and the crystallographer Haüy![15] Unfortunately, this example was not emulated generally, and the early schools of engineering in this country stressed the art of application of mathematical and natural sciences and thus could rest satisfied with a four-year undergraduate curriculum until the turn of the last century as outlined earlier.

In electrical engineering, it was the advent of wireless or radio communications coupled with the invention of the vacuum tube and the selective filter circuits that introduced higher mathematics and electromagnetic theory into the technical literature. True, wire communications and electric power transmission along long lines led in their theoretical treatment to the complex hyperbolic functions. However, it was the partnership with physics and applied mathematics, which the young profession of radio engineering cultivated, that eventually reacted catalytically upon electrical engineering education and generated the graduate programs for Master's degrees in the middle twenties. We had the strange anomaly that, for practically two decades, the undergraduate curricula—with few exceptions—were entirely power oriented whereas many of the Master's programs offered a majority of communications related subjects with emphasis upon advanced mathematics and modern physics.

The objective of the early graduate programs was thus primarily to bring the student up-to-date again with few significant exceptions.

It is quite appropriate to quote here from the so-called Hammond Report the "general characteristics" of graduate study[16] in 1935:

> If the situation as to graduate work in engineering can be characterized in a sentence, it may be said that work for the Master's degree has become the regular order of things in more than half of our institutions and for an important fraction of our students, while work for the Doctorate is beginning to assume a place of significant importance. The committee ventures to express the opinion that it would be just as well if work for the doctorate were not to expand too quickly or spread too widely. Expansion of work for the master's degree has been extremely rapid. . . . It may be well for engineering education to consolidate this gain and to strengthen its position in graduate work before making any wholesale expansion in to the still more advanced field of work for the doctorate.

Little could the committee and, indeed, the Office of Education, anticipate the fantastic change in the rate of scientific discoveries and technological applications which occurred in the span of a few years and which confronts us today, at least in electrical engineering, with the indomitable demand to re-evaluate our objectives and to critically examine our curricula.

It has now become clear that all electrical engineering education must have a sound and solid foundation in the basic sciences followed by extensive exercise in the engineering sciences and culminating in the senior year in project work, in integrative efforts, and in systems concepts. Above all, the student must be made to realize that he is at the start of knowledge and that he needs to cultivate the ability to learn and to study. As yet, the four-year program will be satisfactory in many cases where truly professional contributions are not expected. However, to be able to contribute significantly in advanced areas of development, it has become necessary to add another year, usually leading to the Master's degree. This additional year must include advanced physics and mathematics as well as professional subjects which lead to basic understanding and mature exercise of the design function, the primary objective of engineering education in accordance with the definition quoted earlier. It has been suggested to recognize this five-year program which includes one year of graduate study as the first truly

professional degree and even make it a general requirement for the engineering profession, relegating the four-year program to a nonaccredited status.[17] However desirable it might be to decree such requirements, the present patterns of graduate study and industrial employment practices do mitigate against it.

The objective of graduate study towards the Doctor's degree has traditionally been guidance towards independent investigational work. It is true that this objective is adopted from the graduate schools of arts and sciences. On the other hand, the vast expansion of the horizons in science and engineering has opened a large sector that can be classified as engineering research, independent investigation that sets itself certain more or less clearly defined goals. The difference between science and engineering is, then, one of attitude rather than of method or depth of training. Pure scientific research is entirely aimed at increase of knowledge, at exploration of the universe in systematic and methodical manner with a philosophical view towards better comprehension of the observed phenomena. Engineering research is related to the basic engineering function of design, even though it uses frequently the same methods and devices as scientific research. We need only to scan the titles and scopes of the Professional Groups of the IRE to realize the close partnership of science and engineering on the one hand, and the vast areas open to engineering research, say directed research, or "applied science"-research, on the other hand.

Because the objectives of the Master's and the Doctor's programs are different, though not mutually exclusive, it is most desirable to guide the senior student into the appropriate graduate program best fitting his abilities. Particularly gifted students could, if they are so inclined, be exposed to guidance towards independent research even within their undergraduate studies, be it in formal honor's programs or on the initiative of an individual faculty member.

A major objective of graduate study in most areas other than engineering, has traditionally been the training of teachers. Engineering on the other hand, has primarily furnished professional talent for industries, relying upon the normal feedback into faculties because of innate interest of a sufficient number in teaching as a career. Within the last decade, however, industrial operations have become more and more complex so that their requirements for manpower with advanced degrees could not be fully met. This has now placed faculty recruitment into a state of urgency, so that we must add as a significant special objective of graduate study, preferably to the Doctor's degree, the education and training of teachers.

Patterns of Graduate Study

The traditional pattern of graduate study as prevalent at the time of the Hammond report[2] was also taken over from the schools of arts and sciences whose faculty in many of the larger universities had full cognizance over all graduate work. Actually, as we see from Table I, the majority were day students, most of them studying full time for their advanced degrees, only about $\frac{1}{3}$ of the master's and $\frac{1}{4}$ of the doctoral students studying part-time, having some assistantships or junior instructorships to enable them to study at all. Master's theses were required. Doctoral dissertations were carried on under tutelage of a faculty member who had his own research laboratory and his well-known field of interest. The student's choice was in a sense free, in a sense dictated by available counsel and guidance.

Just as World War II changed the whole structure of science and technology as it created research and development efforts on gigantic scales, as it organized the whole scientific potential of the universities, so also has it left behind a complete social reorientation and with it a change in concept of support of our higher educational system. The impact upon graduate study in science and engineering has been enormous.[18] Whereas in the earlier days the student made a very weighty decision when he embarked upon graduate study and frequently anticipated years of struggle for a living and hard learning under rigorous and unrelenting tutelage, he is now apt to expect complete support and definitive requirements which, if met, practically guarantee the advanced degree. He has practically been promised that a considerably higher salary level will ensue so that graduate study is evaluated in terms of an investment. Of course, we still have the innately creative type of student whose urge to produce spurs him to effort, but more often than not, he will command an industrial position and not return to graduate school except for specific information.

To appreciate the radical change in patterns of graduate study and the effects upon the output of advanced degrees, it is necessary again to refer to statistics such as are given in Table II and prepared for ASEE[19] in order to clarify the almost meaningless categories of day and evening students, often confused with full time and part time. Unfortunately, the figures are available only for all of engineering but they allow readily the same conclusions for electrical engineering:

1) Genuine full-time enrollment has increased between 1933 and 1960 about fourfold; most of these students have full fellowships, available from various sources. Practically all foreign students are included because they cannot earn money, they subsist on fellowships and must study full time.

[19] C. Wandmacher, "Follow-up survey of enrollments and staff in various patterns of graduate study," *J. Engrg. Educ.*, vol. 51, pp. 410–418; February, 1961.

2) The number of students employed by the university has increased over tenfold, the large majority being engaged in research which under today's conditions is almost all government sponsored research.
3) Part-time students, employed outside the university, *i.e.*, by industry or government, constitute today the largest sector of graduate student enrollment, having had comparatively little significance in 1933. To the largest part, these are evening students.

TABLE II
THE CHANGING PATTERN OF GRADUATE STUDY IN ENGINEERING

Graduate students, enrolled (Fall)	1933	1948	1960
Full time*	1695	4100	7064
Part time, employed at University			
In Teaching	585	1234	2274
In Research		1053	3931
		2287	6205
Part time, employed outside University			
Studying on main campus	360	4607	12,996
Studying at University Center	—	546	3088
Studying off-campus	—	110	1608
		5263	17,692
In cooperative programs	109	42	102
Total enrollments	2749	11,692	30,063
Master's degrees awarded (June)	1071	4303	7128
Doctor's degrees awarded (June)	126	252	786
Total advanced degrees	1197	4555	7914
Ratio Enrollment / Advanced degrees	2.3	2.6	3.8

* Taking a minimum of 12 credit hours per week; employment, if any, is only incidental.

Little more can be said about the full-time student enrollment than that it is far too low and that every effort should be made, nay *must* be made, on a national scale to entice the really bright seniors to study on in graduate schools for the good of the nation. The total number of doctoral degrees given in any one year in electrical engineering excluding foreign students, who must return to their respective countries, could just about suffice to furnish the needed faculty members for the engineering schools, or it could cover about half of the requirement of industry and government, but it is hopelessly too small for the total demands.

University employment of graduate students has been a device of self defense in order to retain the qualified students who could not gain sufficient support with a fellowship even with the more liberal stipends that are now often available. The tremendous expansion of government sponsored research at universities has created a new kind of partnership which, with proper regard for academic freedom, has made possible the present scope of graduate work. Again this phenomenon is related to the social reorientation of the nation, which has changed the tax structure so radically that university income has been impaired. In turn, this meant that universities no longer can afford the costly and complex modern research equipment out of their own funds. The growth of sponsored research has also raised questions of interference with the freedom of university faculties,[20] inasmuch as availability of funds might dictate the orientation of research programs. Enlightened university administrations will, however, value the full unfoldment of faculty talents and will strive for support where it is of greatest benefit to the educational objectives.

The evening programs of graduate study, initiated by the Carnegie Institute of Technology in 1912, were expanded substantially by the institutions in the New York metropolitan area[21] in the 1920's. The real growth took place during and at the end of World War II. Many programs are centered in heavy industrial areas and have, in fact, had the character of cooperative programs in the broader sense.[22] The benefit to students employed in industry, and therefore to industry itself, is very great. This has been recognized by the tuition refund plans of many industrial concerns. Perhaps the most attractive mode of cooperation is release of employees for substantial fractions of day time to permit attendance of normal campus classes.[23]

The growth of part-time, and in particular, of evening programs throughout the United States has caused recurrent discussions of the desirability of accreditation at least of Master's programs in the same manner as the Engineers Council for Professional Development (ECPD) accredits the undergraduate curricula in engineering. It is agreed, however, that the caliber of graduate study rests squarely upon the caliber of the faculty so that accreditation would essentially mean a critical appraisal of faculties and this would raise the pertinent question of how to select the judges. It might also be argued that graduate students, being more mature and having professional experience, can gauge fairly well by themselves the caliber of graduate courses and thus appraise the value of an advanced degree in certain programs. The need for protective action might thus be less urgent than in undergraduate programs where the choice is often made or supported by the parents.

Centers of Graduate Study

The fact that the growth of graduate enrollment cannot be accepted as a measure of available manpower with advanced degrees has given concern.[24] A recently published study by Dean Hollister of Cornell University[25] tries to provide an over-all picture of the performance of engineering schools at various academic levels. Separating the schools which offer strong graduate programs and taking as criterion the award of at least 25 Master's degrees and at least 5 Doctor's degrees in any one of the three years from 1952 to 1955, and using the figures published by the U. S. Office of Education for 1957–1958, the statistics in Table III result, leading to these conclusions:

1) Of the 220 institutions giving degrees in engineering, only 37 (20 privately supported, 17 state institutions) did offer the minimum number or more of advanced degrees specified above.

2) The total of these 37 institutions actually awarded 40 per cent of first degrees, 67.5 per cent of the Master's degrees and 91 per cent of the Doctor's degrees, thus establishing them essentially as the centers of graduate study in the country.

3) These same institutions also awarded about half of the Master's degrees in physics and mathematics, and more than two thirds of the Doctor's degrees in these fields, thus emphasizing the modern concept that strong graduate work in engineering must have as a corollary strong graduate programs in the basic sciences. Chemistry is also listed in Table III though its closeness is primarily important for chemical engineering.

Graduate study and research are inseparable components of advanced work so that one can also expect that the same institutions carry a large part of the sponsored research programs.

A recent study by the Engineering College Research Council of the ASEE bears out this correlation[26] as shown in Table IV. Taking the data as supplied by the institutions responding to the questionnaire on research expenditures for the fiscal year 1958–1959 and combining with the ASEE data on degrees conferred, we find 24 institutions that gave more than 10 Ph.D. degrees in engineering or 83 per cent of all Ph.D. degrees in engineering and whose research expenditures averaged $2,360,000 per institution. Converting then the Ph.D. degrees into equivalent Master's degrees by a factor of 3, we find an average annual expenditure per equivalent Master's degree of $10,900, which is remarkably close to the same averages computed for the other two groups B and C, demonstrating perhaps a uniform educational efficiency, though, of course, the larger programs afford larger and often much more expensive research equipment.

TABLE III

Summary of Degrees Granted in 1957–1958

Field and Degree	Total (220 Institutions)	Group A	Group B	Both Groups	Per Cent of Total
Engineering:					
First degrees	35,332	5325	8733	14,058	40.0
Master's degrees	5788	2275	1633	3908	67.5
Doctor's degrees	647	326	260	586	91.0
Mathematics:					
Master's degrees	1097	202	293	495	45.2
Doctor's degrees	210	80	65	145	69.2
Physics:					
Master's degrees	795	197	215	412	51.8
Doctor's degrees	464	186	133	319	69.0
Chemistry:					
Master's degrees	1125	178	259	437	39.0
Doctor's degrees	939	252	350	602	64.6

Notes: Group A comprises the 20 privately supported institutions that granted at least 25 Master's and 5 Doctor's degrees in engineering at least once during the period 1952–1955. Group B comprises the corresponding 17 publicly (state) supported institutions.

TABLE IV

Relationship Between Research Expenditures and Engineering Graduate Degrees Conferred 1958–1959

Group	Number of Colleges	M.S. Degrees	Ph.D. Degrees	Equivalent M.S. Degrees	Total Research Expenditures 1958–1959, Dollars	Annual Expenditure per Equiva-M.S., Dollars
A	24	3386	594	5168	56,703,000	10,900
B	32	1715	115	2068	20,296,000	10,000
C	46	948	—	948	9,436,000	10,000
Totals	102	6049	709	8184	86,435,000	
Grand totals	125	6562	714			

Notes: A—Institutions who awarded 10 or more Ph.D.'s in engineering in 1958–1959.
B—Institutions who awarded less than 10 Ph.D.'s in engineering in 1958–1959.
C—Institutions who only awarded Master's degrees in engineering in 1958–1959.

It is very interesting to note the inverse relationship of numbers of institutions in the three groups A, B, and C and their total research expenditures. In fact, one could argue that established strength appears to provide attraction for graduate students so that regenerative forces will build strength to greater strength and make it nearly impossible for new centers of graduate study to build up. On the other hand, should graduate enrollments continue their present trend, the problem of

handling large numbers of candidates in any one institution will arise, attention to the individual is bound to suffer and standards of performance might—unwittingly—be sacrificed. This has happened to a fair degree in the Master's programs where in many places the thesis has become optional or has been completely abolished. Certainly, this must not happen with doctor's programs or the necessity of formalized post-doctoral programs will appear!

Concentrating our attention upon electrical engineering, we find that 114 institutions gave Master's degrees during 1959–1960, and of these, 39 also awarded Doctor's degrees.[27] It is again interesting to note as shown in Table V, that 11 institutions of these 114, or about 10 per cent, conferred 25 or more Master's and 62 per cent of all Doctor's degrees! One must expect the question as to whether there exists a critical scope of graduate offerings supported by strong research and outstanding faculty members that leads to a natural grouping on a national scale. Certainly, the comparative data emphasize that graduate students, if given the opportunity, make choices of institutions on the basis of more pertinent information than undergraduate students.

TABLE V

Graduate Degrees in Electrical Engineering 1959–1960

		Master's		Doctor's	
		Number	Per cent	Number	Per cent
11	Institutions giving 25 or more Master's and 5 or more Doctor's degrees.	736	37	125	62
4	Institutions giving 5 or more Doctor's degrees but less than 25 Master's degrees.	53	3	26	13
24	Institutes giving less than 5 Doctor's degrees.	346	17	52	25
39	Institutions awarding 1 or more Doctor's degrees.	1135	57	203	100
75	Institutions only awarding Master's degrees.	858	43		
114	Institutions awarding graduate degrees.	1993	100

Problems Confronting Us

Graduate education in electrical engineering has experienced a very dynamic expansion, a radical reorientation, and a spectacular growth of research. It is obvious that many problems have been created for which solutions are not at hand. Some of these problems, actively discussed in many educational circles as well as by the general public, are:

1) *Faculty:* Securing and holding faculty members, particularly those who contribute creatively in basic research and who stimulate graduate students to associate with them, has become a more severe problem[4] in the face of insufficient output of men with doctoral degrees in spite of rising graduate enrollments.

2) *Students:* Genuine full-time graduate students have become a relatively small fraction of the total graduate enrollment so that the number of advanced degrees awarded each year is lagging more and more severely behind the number of students admitted to graduate study.[24] A systematic effort is required to make full-time graduate study more attractive to students and to industry who employ the students.

3) *Support:* The costs of graduate study facilities and of student support are increasing beyond any feasible increase of university incomes. The federal government laid the original foundation for this country's growth of technological education by the Morrill Act in 1862. It will require a similar farsighted and broad act by the federal government to assure the adequate development of a sufficient number of first-class graduate study and research centers[28] to satisfy the national need.

4) *Curricula:* A very definite trend towards interdisciplinary graduate study and research has been evident. This poses questions of maintaining, altering, or abolishing traditional departmental patterns of operation, immediately in the graduate schools, and in the longer range, probably in undergraduate schools as well.

5) *Accreditation:* The proliferation of programs and relative increase in part-time study impress more urgently the need for setting appropriate standards and practices of graduate study, though it is generally agreed that the stature of graduate study depends primarily upon the faculty associated with it.

ELECTRON DEVICES

Organized with the assistance of the IRE Professional Group on Electron Devices

Recent Developments in Space-Charge Control Tubes*

KARL R. SPANGENBERG†, FELLOW, IRE

***Summary*—In spite of being the oldest in the family of electron tubes, the space-charge control tube or conventional tube continues to experience continual development and improvement. Recent developments include extensions of power-frequency limits, improvements in emission, and extensive improvements of structure. Of particular novelty are a high g_m tube using secondary emission multiplication and a distributed-amplifier type tube.**

I. Introduction

IN A TIME when many stirring developments and new devices are coming into being, it is possible for the steady progress in certain well-established electronic devices to escape almost unnoticed. Such is the case with the conventional vacuum tube types which employ a control electrode to modify a current flow through space-charge modulation. Although the basic forms of such space-charge control tubes have been known for many years, there have been steady advances in almost all features of their operation. This paper will be concerned with developments within the last ten years of the operation of such tubes up to and including the ultra-high frequencies which is the portion of the frequency spectrum where they are most effective. These tubes have undergone significant recent improvements in form and operating capabilities, in addition to which the theory of their operation has been significantly advanced.

In a paper of this length it is not possible to refer to all of the developments in detail. Accordingly, an effort will be made to mention at least the significant developments and to give the pertinent references in which more detailed information can be found.

II. Emitters and Emission Studies

The theory and operation of thermionic electron emitters continues to be the subject of considerable study. Developments of oxide emitters are covered in several excellent review papers [1]–[3]. L-type emitters find increased application [4], likewise thoriated tungsten emitters have found increased application for heavy duty requirements [5]. Cold emission from magnesium oxide coatings has not developed to the point where extensive practical application seems imminent [6].

* Received by the IRE, July 5, 1961; revised manuscript received, November 16, 1961.

The development of film cast oxide cathode, known as Sarong Cathodes, has excited considerable interest. These cathodes may be formed with a thickness tolerance of 0.05 thousandths of an inch, which is an order of magnitude better than can be achieved with spray cathodes. Resulting improvement in lower filament power and more careful control of electrode spacings and current are significant [7]. Attention to design has made possible the reduction of cathode ray tube filament power by factors of one-third [8]. There have also been developed cathodes with a 5 second warmup time, 0.5 seconds for filamentary cathodes [9]. RCA has developed a "black" heater insulation which reduces heater wire temperature and so increases reliability and life.

III. Low Voltage Operation

The hybrid circuit design concept in automotive radios calling for 12-volt operation has led to the development of a series of space-charge grid tubes, especially for this purpose. Such tubes include the types 12K5, 12DS7, 12DV8, and 12AL8. These tubes contain tetrode or pentode sections, which are operated with a low positive voltage on the first grid and a slightly negative voltage on the second grid, which is the so-called space-charge grid and control grid for this type of operation [10]. This same principle has been used in certain cathode-ray tube guns [11].

IV. Developments in Form

A. Grid Structures

Many of the major tube companies have gone over to what is commonly called a frame grid construction. Notable among these are the structures of Philips and Sylvania [12], [13]. These structures make use of a rectangular grid frame which is designed to have a greater stiffness in all directions as well as increased ease of mounting. Techniques for winding extremely fine grids have been improved. It is now possible to form grids from 500 wires per inch with a positional accuracy of $\pm 5\mu (\pm 0.2$ mils) [14].

B. Metal Envelopes

Small and medium power electron tubes were originally made with envelopes which were mostly of glass. In the 1930's a number of metal envelope receiving type tubes were developed, which later were abandoned in favor of glass. Once more, low power metal envelope tubes have begun to appear. These include the RCA Nuvistor. This tube was designed to operate up into ultra-high frequencies and also have as low a filament power as possible. The first objective was achieved by using what is essentially the medium powered transmitting tube electrode configuration which supports all electrodes from a common base with a minimum of insulating material between electrodes. The principal features of these tubes are small size, low filament power, and low noise [15]. The use of the metal envelope combined with a ceramic base, giving a tube with no glass, makes possible operation at higher temperatures and, hence, a smaller tube for a given power level.

C. Metal-Ceramic Tubes

Metal-ceramic tubes were first manufactured in Germany during World War II. Later, there was considerable development of such techniques in the United States, notably by the General Electric Company for very small tubes and by Eitel-McCullough, Inc., for larger sized tubes. Some of the most recent additions to the metal-ceramic family include the RS1032 of Seimens and Halske (10 kw at 790 Mc, TV service), the TSP347 of Nippon Electric (100 watts CW at 2 kMc), and numerous tubes by American manufacturers including particularly RCA and the General Electric Company.

At still somewhat higher frequency, RCA has for several years been manufacturing a beam power tube, type 6952, which gives two Mw peak power output at 425 Mc. Another recent development is the RCA type 2054 super-power triode which gives 5 Mw peak power output in long pulse service at 440 Mc. More recently, RCA has described an integral circuit high-power amplifier triode for 420 Mc operation known as the coaxitron [16]. This tube is capable of 5 Mw peak power output over a frequency band extending from 385 to 465 Mc. Most of the tubes mentioned above are air cooled. Some related developments which are able to use glass because of careful water cooling include the TH470 of Compagnie Francaise Thomson-Houston which is capable of 2 Mw pulse operation at 200 Mc [17]. This tube uses the vapotron principle of cooling which makes use of the heat of vaporization of water to effect a maximum heat transfer by boiling water in a chamber about the anode. Improvements in smaller sized earlier type vapotrons take the form of improved corrugations in the anode for better heat transfer [18].

V. Super-High Frequency Operation

There have recently been extensive analyses of super-high frequency operation of conventional tubes both for small signal operation [19] and for large signal operation as part of the extensive studies of Professor Gundlach's group at the Technical University of Berlin [20], [21]. These studies have been supported by experimental observations [22], [23].

A remarkable series of super-high frequency lighthouse type triodes have been developed by Philip engineers. These tubes cover the range from 4000 to 6000 Mc with output powers as high as 1 watt at 6000 Mc for an air cooled tube and 10 watts at 6000 Mc for a water cooled tube [24]–[27]. Most of these tubes are, however, in a developmental form with only two types, namely the EC157 (1.5 watts at 4000 Mc amplifier operation) and the 22EC (5 watts at 4000 Mc amplifier operation) available as production items. These tubes use L-type cathodes and feature cathode-to-grid spacing as low as 25 microns (1/1000 of an inch). Such spacings have also been achieved in certain Western Electric and General Electric types.

VI. Ruggedized Tubes

Many modern tube applications require tubes which have been ruggedized to withstand rather severe shock and vibration. Outstanding among these are the RCA metal-ceramic pencil triodes types 7553 and 7554. These tubes are capable of being mounted in an integral pencil tube-cavity unit capable of withstanding 10,000 G's of longitudinal acceleration and 850 G's of transverse shock [28].

VII. Distributed Amplifier Tube

Another interesting recent development is a distributed amplifier tube, a new type of wide-band amplifier tube, in a single vacuum envelope. The anode and grid of this tube are helical lines across which an electron beam passes. An early model of this tube has given a gain of 17 ± 5 db over a 150 Mc video band. Gain drops from the low to the high frequencies but could be equalized to give an output constant within 3 or 4 db. The grid line has an impedance of 200 ohms and the anode line has an impedance of 450 ohms [29].

A later version of the tube gave a voltage gain of 9.0 ± 1 db (power gain of 7.0 db) from a 150-ohm grid line to a 200-ohm plate line over a 320-Mc bandwidth [30].

VIII. High-Current Grid-Controlled Electron Multiplier Tube

A grid-controlled secondary-emission electron multiplier tube has been designed and built which can deliver an output pulse of 5 amperes into a load impedance of 100 ohms, with a rise time of less than 10 nsec and a transit time of less than 20 nsec. The measured transconductance of the tube is 0.6 amperes per volt, and it can provide a positive output pulse with a positive grid input [31].

IX. Conclusion

A study of power-frequency limits shows an inverse square law barrier for space-charge control tubes. This situation continues with the barrier having moved up by a factor of ten in the last decade or two. Conceivably another factor of ten could be achieved in the next decade or two. More likely the most significant new devices will be unconventional structures performing more complex operations in a single vacuum envelope.

The Development of Gas Discharge Tubes*

J. D. COBINE†, FELLOW, IRE

Summary—**The paper is an historical review of the development of gas discharge tubes. The material is divided into five classifications based on discharge types, namely:**

1) **Ionization tubes,**
2) **Cold-cathode discharge tubes,**
3) **Hot-cathode arc discharge tubes,**
4) **Liquid metal arc tubes, and**
5) **Plasma tubes.**

INTRODUCTION

ELECTRICAL DISCHARGES in gases have had a long and fascinating history. If the natural phenomena such as lightning, St. Elmo's fire, etc. are excluded, one of the earliest manifestations of electrical discharges in gases was observed in 1683 when Otto von Guerick [1], of Magdeburg produced spark and corona discharges by a static-electricity machine. Low pressure glow discharges in "exhausted" glass spheres were observed about 1700 by Newton and Hawksbee also using static-electricity generators. The first steady electric arc was produced by Davy in 1808–1810. He first observed transient arcs in 1801 when opening a short circuit on a voltaic pile. Aside from flames, these examples were the first time man had produced the strange state of matter named *Plasma* by Langmuir (c. 1923) that has been receiving great attention recently in both science and engineering.

In 1856, Heinrich Geissler [1]–[3], an artist and skillful glass blower of Bonn, Germany, originated the low pressure discharge tubes that were to bear his name. The Geissler tubes were long, small-bore glass tubes, usually shortened by the use of many coils and bends, which were filled with various gases at low pressures and originally excited by high-voltage alternating current. Many beautiful effects could be produced by Geissler tubes filled with different gases and they were often used for decorations. As, for example, a display used to commemorate Queen Victoria's Diamond Jubilee [4]. However, sputtering of the electrodes together with gas clean-up resulted in a short life for the tube. The principal use was for spectral analysis and lecture demonstrations.

The first public demonstration of a mercury arc lamp was by Prof. J. T. Way on the Hungerford Suspension Bridge in London on September 3, 1860. Two British patents were issued to him in 1857. The electric arc was first used commercially for illumination in Paris in 1863. Much later, low-pressure arc "tubes" were used for illumination. In 1879 John Rapieff described mercury arc lamps in British Patent No. 211 but there appears to be no evidence that they were built. Peter Cooper Hewitt showed in public his mercury-arc lamp on April 12, 1901. Georges Claude, a French inventor, demonstrated the first Neon sign [4], an improvement of the Geissler tube, at the Grand Palais in Paris in 1910. Developments in luminous tube discharges were made by Moore [5], in 1920. Since these tubes did not have a high light output, they were largely confined to sign applications.

Low-level ionization was present in some of the early radio tubes, and had considerable effect on their characteristics. The focusing of early Braun cathode-ray tubes and the Roentgen "gas" x-ray tubes depended on the focusing action of positive ions produced in the residual gas by the electrons. These ions, of course, resulted in slow response and short cathode life. The necessity of converting ac to dc gave rise to the mercury-pool arc rectifier. The first observation of the rectifying properties of an arc between a mercury and a carbon electrode was made by a French scientist, Jamin [6], in 1882. Probably the earliest scientific study of the low-voltage high-current arc was by Arons at Berlin [7]. In 1903, Cooper Hewitt announced [8] his mercury-pool rectifier. As early as 1905 Cooper Hewitt made metal-tank mercury-pool power rectifiers. In those days when electric automobiles and trucks enjoyed considerable favor, many two-anode mercury-pool, glass envelope rectifiers were in use for battery charging. After the dominance of the gasoline engine automobile, these pool tubes continued to be made for automobile-starting battery charging, being finally displaced by the *Tungar* [9] arc tube. Tungar was a trade name (G. E., Westinghouse called it *Rectigon*) resulting from the contraction of tungsten and argon. This arc tube had a tungsten cathode, which was operated at higher than normal temperature to attain several amperes of emission, and argon gas at a pressure of several Torr to prevent excessive evaporation. The Tungar has since, in many applications, been replaced by various members of the growing family of solid-state devices. The family of gas discharge tubes of interest to the radio and electronic engineer has been growing at a slow but steady rate ever since. There have been many contributions to this development. Most, if not all, were empirical solutions to special problems. Usually, theoretical explanations were developed after the fact, if at all. The discharges are extremely complex phenomena and have occupied the attention of many of the world's best scientists.

* Received by the IRE, August 23, 1961; revised manuscript received, November 15, 1961.
† General Electric Research Laboratory, Schenectady, N. Y.

The gas tubes with which we will be concerned may be grouped for convenience in five divisions:

1) Ionization tubes, *i.e.*, non-self-sustained discharges,
2) Cold-cathode glow discharge tubes,
3) Hot-cathode arc discharge tubes,
4) Liquid metal (or pool) arc tubes,
5) Plasma tubes.

These types of gas tubes will be reviewed in this order in the following sections. In order to provide proper perspective for the following discussion, the relations of the various discharges are shown by the composite volt-ampere characteristics of Fig. 1 and will be discussed briefly.

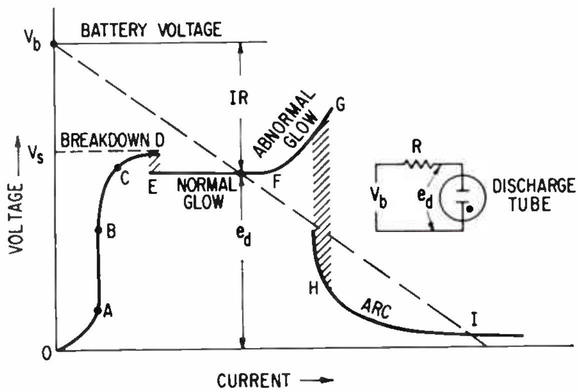

Fig. 1—Gas discharge volt-ampere characteristics.

The region *O-D* is roughly representative of the ionization type of tubes, group 1. In *O-A* partial collection of background ionization is represented. From *A-B* the tube is "saturated" and all ionization produced by external means is collected. From *B* to *C* is represented by the simple gas amplification of the Townsend [10], [11] type where the number of electrons increases exponentially with distance, by collision ionization. From *C* to *D* additional ionization processes develop, usually involving additional emission from the cathode as a consequence of earlier emission and ionization increases greatly to result in breakdown at *D*. Following *D*, all the discharges are self-sustained, *i.e.*, independent of the initiating ionization event. The region *E-F* is a normal glow, characterized by a large and substantially constant voltage drop of the cathode. This is the low pressure discharge of the familiar voltage regulator and voltage reference tubes of group 2, the indicator glow lamps are also cold-cathode tubes operating in the region *E-G*. Region *F-G* is the abnormal glow, in which the current density of the cathode surface increases with current, and the cathode glow becomes more intense. The glow-arc transition occurs at about *G*. Hot-cathode (group 3) and pool arcs (group 4) operate in the region *H-I*. These are essentially low-voltage high-current discharges. Both the cold-cathode glow and the hot-cathode arcs have regions of glowing gas outside the cathode glow region that are known as positive columns. This zone has a low voltage gradient, as it is a state of near electrical neutrality usually called a plasma. This part of the discharge may be used in the plasma tubes (group 5) for light, or for microwave purposes. The point *D* represents a breakdown of the gas, and in the case of the spark gaps, a very rapid transition takes place to some point such as *I* on the arc characteristic.

It is clearly impossible to cover properly the scientific aspects of the phenomena involved in the above discharges. The interested reader is referred to texts and treatises on the subject, some of which are included in the bibliography [12]–[15].

Ionization Tubes

The study of "simple" ionization in gases has contributed enormously to man's knowledge of the universe, ranging from the constitution of the stars and the transformation of matter into radiant energy, to the density of space. In 1785, Coulomb [16] noted the loss of electricity to the air from a charged insulated body. Both Geitel [17] and Wilson [18] found that the rate of leakage from an insulated body did not increase in proportion to the applied potentials, but soon saturated for a closed volume. With the determination of the charge in the electron in 1909 by Millikan, the number of ionizing events per second per cubic centimeter could be determined accurately. In 1912, McLennan [19] found this rate to be 9 over land and 6 over the sea.

About this time, experiments were being conducted with the collection of current by a positive wire and negative cylinder arrangement that were to have a profound effect on science. These experiments were reported in a paper by Rutherford and Geiger [20] which showed that the number of charges of an ionizing event could be multiplied several thousand times by the ionizing action of electrons in the high field region near the wire. This was the start of what for a time were called *Geiger-Müller counter* tubes and now simply *Geiger counter* tubes. The technique of the proportional type of counter was established [21] in 1928, and the following year, schemes for determining the coincidence of ionizing events were presented [22]. Thus direction, scattering, absorption, etc. types of experiments were possible and the modern era of cosmic-ray and nuclear research developed.

The mobility of electrons is very high compared to that of the positive ions and an electron avalanche in the high field region develops with great speed, so that, as far as the electrons are concerned, the count of an initial ionizing event can be made in less than 10^{-9} second. The ions may take of the order of 100 μsec to cross the gap. Spurious counts and self-sustained discharges can be produced by the emission of electrons at the cathode by ion-bombardment. Organic vapors were found [23] to quench the discharges and spurious counts were suppressed by attachment of the ion-emitted electrons. This speeded up the counter. It was found necessary to avoid pure inert gases because of the long life of the metastables formed by the action of initial avalanche. The counters for a time represented a considerable body of art, but with advancing knowledge these have become reliable and trustworthy devices for a wide range of applications.

The simple triode ionization gauge [24] is one of the oldest devices for the measurement of low gas pressures. With various modern refinements, it is the most widely used device for vacuum measurements. The device is based on the simple ionization of residual gas by electrons traversing the space between cathode and anode. As long as the electron energy is considerably greater than the ionization potential of the gas and the pressure less than that for which the electron mean-free-path is of the order of the interelectrode distance, the positive ion current will be proportional to the gas pressure. The anode is an open wire spiral, and the ion collector in the early tubes was a solid cylinder surrounding the other elements. Because of the open construction of the anode, many electrons oscillate on approaching it so that the effective distance traversed by the electron is considerably greater than the anode-cathode spacing. Because of the large number of electrons emitted by an incandescent filament, a measurable positive-ion current is present at pressures as low as 10^{-8} Torr. Below this pressure, the lowest that the tube could measure before 1948, the ion current for a gauge having 150 volts on the anode and a sensitivity of 10/Torr was just equal to the photoelectron current from the collector due to the soft x-rays produced when the 150-volt electron struck the anode. The effect was pointed out by W. B. Nottingham in 1947. In 1950 a modified structure was devised [25] which greatly reduced the area of the collector that could intercept x-rays. This was done by making the ion collector a centrally located wire, which reduced the lower pressure limit to 10^{-10} Torr. The lower limit was recently further reduced to 10^{-14} by the development of a hot-cathode magnetron ionization gauge [26]. This tube has the added advantage of being of ceramic construction which permits a high temperature bakeout of the tube and greatly reduces the helium diffusion into the tube. The use of the magnetic field results in a great increase in the distance an electron travels before reaching the anode so that its probability of having an ionizing collision is proportionately increased.

Several other vacuum gauges depending on ionizing the gas can only be mentioned. These are the Alphatron [27], which depends on collecting the ion current produced by alpha particles from a radioactive source, and the Penning type ionization gauge (PIG) [28]. The type of discharge found in the Penning gauge is often loosely referred to as a "PIG" discharge. The latter is a cold cathode tube in which electrons emitted by the collector are forced by a magnetic field to make many oscillations before reaching the anode, thus greatly reducing the minimum pressure that can be measured. The mass spectrograph tubes [29] are much more discriminating ionization gauges, *i.e.*, partial pressure gauges, which are becoming very important in fusion and space studies.

Cold Cathode Discharge Tubes

Experiments with low-pressure glow discharges started very early in the electrical art. Most of them were in small diameter glow tubes, often in the form called Geissler tubes. The first recognition of the fact that such a glow tube having its two electrodes of different size was capable of rectifying the oscillating current from an induction coil appears to have been that of Gaugain [30] in 1855. However, for many years, the only use for these discharges was as light sources. The early glow lamps all required high voltage excitation. With the availability of the rare gases neon and argon and by means of low work-function cathodes, glow tubes were developed for low voltage applications [5].

The first glow discharge rectifier tube appears to have been what was called an "S-tube." This tube is described in a paper by Bush and Smith [31] and consisted of closely spaced electrodes, the cathode being hollow. The authors attribute its rectifying properties to the characteristics of the low pressure branch of the Paschen curve [11], where short path breakdown voltage is high, but a much lower voltage will break down the gas if a long path is available. The hollow cathode permitted long path breakdown when that electrode was negative, but the close spacing of the two electrodes prevented breakdown on the inverse voltage. The tube discussed was rated for a current of 50 ma and an inverse voltage of 1500 volts. Magnetic control of the glow discharge was also demonstrated in the above paper.

In 1927 Bareiss [32] published a paper on a small glow discharge rectifier and showed the rectification to be due to the different volt-ampere characteristic obtained with the two sizes of cathode. Referring to Fig. 1, onset of the abnormal glow F, with its rapidly rising volt-ampere characteristic, occurs at a much smaller current for the small cathode than for the large cathode. Thus, although current (ac) will flow during both half-cycles of an impressed voltage, more flows when the large electrode is cathode and a net dc current results [33]. The low-voltage glow lamps, better called negative or cathode glow lamps, have found many applications [34] as long-life, dependable, voltage indicators and relaxation oscillators. The relatively constant potential characteristic of the normal glow discharge has permitted their use as voltage-regulator tubes and as voltage-reference tubes. In the former application, the tubes are made with quite large cathodes to permit as wide a range in current fluctuation as possible. For reference purposes as in a regulated power supply [35], the tube can be made smaller as it works at a small and substantially constant current. An important advance in construction of glow tubes was made by Lafferty [36] with the ceramic voltage regulator and voltage reference tubes. The high temperature (~1000°C) to which these tubes are heated during processing ensures that all parts are thoroughly outgassed. The gettering action by the titanium parts as they cool down is very great so that any chemically active gases that may be present in the fill gas are completely removed. Thus a truly clean tube is possible. This eliminates the discontinuous steps taken by most voltage regulator tubes as current variation causes the negative glow to spread over cathode areas whose emission properties are nonuniform due to a random distribution of impurities. The individual ceramic glow tubes can be made in disk form so that they can be stacked to form a high voltage regulator. Regulator tubes for voltages of 2,000 volts per inch of tube length are possible. These new ceramic tubes are more rugged than conventional tubes and can be operated at temperatures up to 500°C. Fig. 2 shows a variety of forms of developmental ceramic glow discharge tubes [36].

Voltage regulator tubes maintain a constant dc voltage where the input voltage changes slowly. However, the glow discharge represents an extremely complex circuit element whose impedance may be quite frequency sensitive [37]–[40]. For this reason they should not be expected to remove the higher harmonics of a ripple voltage.

Controlled glow discharge tubes were developed rather early [41], [42]. Until rather recently these have been confined largely to standby applications where a minimum of nonoperating power is required. With the increasing use of counting devices, computers, etc. the glow tube, either in the form of a multicathode device [43]–[46] or as tubes with a third control electrode [47], [48], has found many applications. The speed with which the glow tubes can react to recurrent events is limited by their de-ionization time. The upper frequency limits have been for 40–100 Kc, although in one case [47], megacycle frequencies are cited.

Early attempts [49] were made by Nienhold in the period 1916–1919 to utilize the plasma of a cold cathode glow discharge as the source of electrons for a multi-element "vacuum" tube. Noise and fluctuations in the primary discharge prevented this idea from being practical. Interest has recently revived in the possibilities of this discharge application [50].

The new ceramic techniques have been applied to spark gaps with the development of sealed gaps of great reliability and capable of operating at temperatures as high as 400°C. As simple two-electrode devices, these tubes are used to protect capacitors from over-voltages. With the addition of a third electrode, to be used as a trigger, they are used to control the stored energy in certain systems. The type Z-5369 is an example of this triggered spark gap, the construction of which is shown in Fig. 3. Gaps have been designed for application in the range of 2 to 10 Kv with a very rapid glow-arc transition [41], [36].

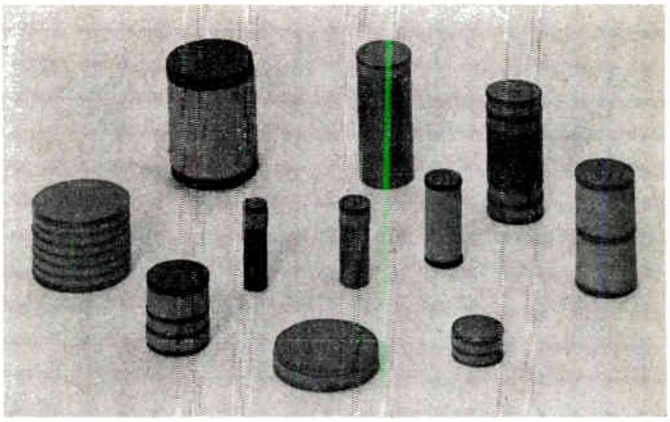

Fig. 2—Developmental high-temperature, glow-discharge tubes.

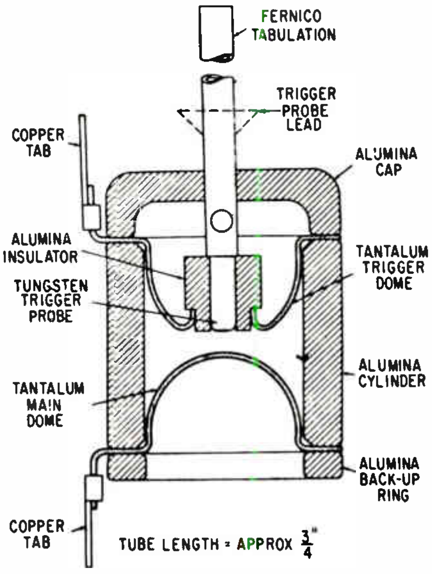

Fig. 3—Ceramic triggered spark gap Z-5369.

Hot-Cathode Arcs

In common with most gas discharge devices, the applications of hot-cathode grid-controlled arcs developed experimentally long before a reasonable understanding of the phenomena involved was attained. In fact, even today it is not difficult to find arc phenomena that are not understood. It was only natural that attempts should be made to control the flow of current in a gas discharge by means of a grid such as was used in the vacuum triode. Apparently, both Pierce [52] at Harvard University and Langmuir of the General Electric Research Laboratory were experimenting along these lines in the period 1913–1914. In 1914 Langmuir applied for a patent [53] on a method of controlling the current in a mercury arc. In this application he was particularly interested in controlling the flow of high-frequency power from an alternator, presumably an "Alexanderson" alternator, for antenna radiation. The Langmuir grid controlled arc tube is shown in Fig. 4 where it is seen to be an adaptation of the old two-anode pool-type mercury-arc rectifier mentioned in the introduction. At very low currents it was observed that the grids in these gas tubes functioned like the grid of a vacuum tube in controlling current. However, once the gas was ionized the grid lost its control, *i.e.*, it could prevent or start the flow of current, which once started was independent of the grid potential. This was a baffling behavior and one that was not explained until Langmuir wrote his classic papers on plasma [54]–[56]. It is interesting to note that this scientific study that so greatly advanced knowledge of the plasma state was undertaken as a consequence of the stimulation provided by practical problems, namely mercury-arc rectifiers. Langmuir's study demonstrated that the ability of the grid to control the flow of current through an ionized gas was due to the screening of the grid potential by a positive ion sheath. Thus, a negative potential placed on the grid resulted in the collection of a positive-ion current from the plasma and a positive-ion space charge (obeying the Langmuir-Child relation [14]) that completely shielded the grid from the balance of the discharge. Originally the name thyratron (Greek θυρα, a door) was given to a grid-controlled arc, both pool- and hot-cathode. Usage has confined the term to the hot-cathode, grid-controlled arcs. Following the basic papers by Hull and Langmuir [57]–[59] on hot-cathode thyratrons, these tubes have found many applications.

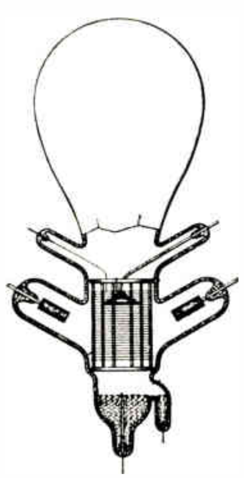

Fig. 4—Langmuir's thyratron.

Prior to World War II, a considerable number of thyratron types had been developed using either mercury vapor or one of the inert gases. Most of these tubes had rated currents falling in the range from about 50 ma to 5 amperes. The practical design of the various tubes are empirical and the result of engineering compromises to meet specific requirements. Many of the factors involved have been authoritatively summarized by Knight [60]. These tubes were ideal for many relay and control operations, motor speed regulators, etc. The requirements of radar modulators provided a special stimulus for the development of a thyratron with a short de-ionization. In 1949 papers were published [60]–[62] which reported the development of hydrogen thyratron devices which exhibited two advantages over the conventional thyratron. First, the de-ionization time was about one-tenth that of conventional thyratrons; and second, the oxide cathode was not destroyed by cathode-fall voltages below 600 volts—the maximum cathode fall permissible for mercury tubes where the positive ions are very much heavier was 30 volts. Hydrogen thyratrons for pulse power ratings from 10 to 2500 kw were developed and in production during World War II. Loss of hydrogen (clean-up) has been eliminated by the use of hydrogen reservoirs, usually consisting of temperature-controlled filaments of titanium. In recent years the increasing speed of airplanes and the development of high-speed missiles has greatly stimulated developmental activity in high-power hydrogen thyratrons for very long distance radar application. Ceramic construction applied to the hydrogen thyratron has made possible single tubes of the very high power rating [63] of 50 megawatts and greater for modern radar modulators. The hydrogen thyratron shown in Fig. 5 has a

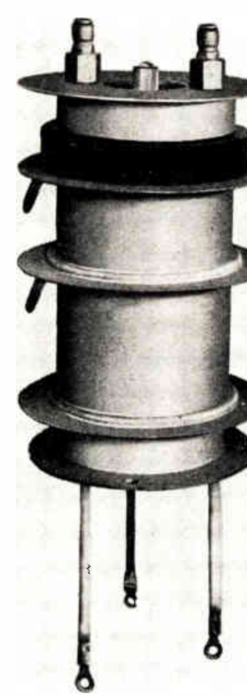

Fig. 5—Ceramic hydrogen thyratron GL-7890. Peak power=48 megawatts at 44 kw; peak current=2400 amperes; body length $=13\frac{1}{4}$ inches; ceramic diameter $=4\frac{1}{2}$ inches.

rating of 48 megawatts peak power and makes an interesting comparison with the original thyratron of Fig. 4. The new ceramic construction [36] has been adapted to both inert gas thyratrons and rectifiers [64] which can be operated at ambient temperatures up to 500°C and in the presence of considerable atomic radiation and shock.

The arc rectifier tubes, often called phanotrons (Greek φαινω appear or will be visible), developed along with the thyratrons [65]–[67]. They overcame one of the important limitations of the Tungar tube, namely its low inverse voltage rating. Both higher currents and very much higher voltage ratings were possible. The tubes had wide applications, but are slowly being replaced by solid-state devices. However, ability of the gas tubes to stand high surge currents and very high inverse voltages has not been equaled yet in the new devices. The relatively high arc drop of the gas tubes (8–12 volts) has been greatly reduced by the use of cesium vapor. The cesium-vapor rectifier [68] tubes have arc drops of from 2–4 volts for currents from 600–2400 amperes.

In common with all arc discharges and most gas discharges, thyratrons generate noise and oscillations over a wide frequency range. The variational voltages were studied [69], [70] as early as 1923 and analyzed in some phases by Tonks and Langmuir [71]. The need for noise sources for airborne radar-jamming transmitters during World War II led to the development [72]–[74] of high level gas discharge noise generators. The inherent noise output, which is of the order of 16 volts peak-to-peak for an argon tube, can cause considerable disturbance in adjacent circuits. It was found [75] by an important and thorough study [76], [77] of hot cathode arcs that, by operating a tube in the anode glow mode, the noise could be largely eliminated. A tube designed to operate in the anode mode was called a Tacitron [75]. This same series of arc studies led to the development of a new type of arc tube called the Plasmatron [78], [79] (Bendix RXB-103005). This is a rediscovery of a phenomena that was once known as the "Found Effect" [80], [81] and which had been forgotten. In the plasmatron tube, a plasma is established by an electron beam from an auxiliary cathode and its "constricting" grid. The main anode-cathode potential may then be as low as a few volts and the current can be modulated by varying the beam current. The tube of LeVan and Weeks [82] made use of a screened plasma as a source of electrons which could be modulated much as had been done earlier with glow discharges.

The gas-, or vapor-, type thermionic converter is a new type of hot-cathode gas discharge tube of considerable potential value for the conversion of heat to electricity. It was anticipated by the study of the vacuum thermionic converter by Schlicter [83]. The basic phenomena of the gas phase type was first reported on by Medicus and Wehner [84]. Later studies [85], [86] developed the principles in considerable detail and produced relatively efficient devices. In this tube a discharge is maintained by the difference in temperatures and work functions of the cathode and anode. Electrons emitted thermionically from a cathode have *thermal* energy (small) corresponding to the cathode temperature and *potential* energy corresponding to the work function of the emitter. If these electrons are collected by an anode whose work function is lower than that of the cathode, current may flow in an external load connected between cathode and anode due to the difference in work-function potentials. Since the range of work functions is rather limited, the output voltage is relatively low at best and it is extremely important that internal losses be minimized. Cesium, whose ionization potential is 3.87, is rapidly ionized by contact with hot tungsten whose work function is 4.52. Thus, a plasma may be produced and also the electron space charge at the cathode may be neutralized by the resulting positive ions. Cesium vapor condensed on the colder anode will result in the desired lower work function. Since cesium vapor must be maintained at a pressure of the order of 1-Torr, the temperature of the coldest point within the envelope (where cesium starts to condense) must be of the order of 275°C. Thus, a lower limit for the anode temperature is set. Efficiencies of 17 per cent have been realized and of 20 to 25 per cent may be reasonably expected of present developments. These converters have potential application to space vehicles for the conversion of nuclear or solar heat to electricity as well as many military applications requiring light weight, silent conversion of heat (nuclear or fossil) to electricity.

Liquid Metal Arc Tubes

As indicated in the introduction, one of the earliest applications of gas discharge tubes was as rectifiers. Initially, these were two-anode, glass-envelope mercury-pool tubes. By 1905 metal tanks were tried and developed into the large multianode, metal-tank mercury-pool power rectifiers such as described by Hull and Brown [87]. An important advance in the rectifier art was made by Slepian [88], with the discovery of the resistance, or immersion, ignitor. This is a semiconducting rod of boron carbide or silicon carbide immersed in the mercury pool. The discharge of a pulse of current from the ignitor to the mercury initiates a cathode spot. This permitted single-anode-pool tubes to be made and reliably started at any point in a positive half-cycle of anode potential. Thus, large current, controlled arcs could be used for straight rectification with voltage control, or the tubes could be applied to half-cycle welding, large motor control, etc. Although in some rectifying applications the pool tubes are being replaced by solid-state devices, the pool tubes possess the unique advantage of being able to recover from extremely high surge currents and withstand high inverse voltages without damage. As examples of the size of ignitrons now being used, two welding ignitrons (7151) in inverse parallel can switch 4,800 kva at 250 to 600 volts controlled precisely from 1 to 30 cycles if desired, while the locomotive ignitron (6878) shown in Fig. 6, has an average current rate of 675 amperes, a maximum peak anode current of 2500 amperes and a maximum peak inverse anode voltage of 4000 volts.

Ceramic construction [89], the use of metal anodes and the use of the alkali metals [90] added to mercury have greatly extended the useful possibilities of ignitron tubes. These metal anode ignitrons have been used in

Fig. 6—Locomotive rectifier. Body length $23\frac{1}{4}$ inches; peak anode current = 2500 amperes; peak fault current = 40,000 amperes; maximum peak anode voltage = 4,000 volts.

nuclear studies to control 20 kv, 1,000,000 ampere (GL-7703) capacitor discharges. The use of the metal anode avoids the release of gas which took place from the old carbon anodes and consequently produced a rapid deterioration of voltage capabilities. The alkali metal additives have reduced the arc drop from the order of 12 volts to about 4 volts. Although this is somewhat higher than the drop of the solid state devices, the large overload capacity and high inverse voltage ratings of the pool tubes with alkali additives should prove attractive for many applications.

The resistance ignitor requires rather high values of peak power to start an arc cathode spot satisfactorily. Attempts have been made since Cooper-Hewitt's band or capacitor starter to develop a low-current ignitor. A capacitor-type arc ignitor would require quite low power and would greatly simplify the control apparatus. Ignitor tubes of this type [91] have been made to operate for some time. However, none have proved commercially reliable over extended periods of time. This problem may eventually be solved using new materials and better vacuum techniques.

Plasma Tubes

The tubes to be considered here are those that function because of the special properties of a discharge plasma. They may utilize the plasmas of the negative glow or the positive column of a glow discharge or the plasma of a low-pressure arc discharge. All applications are as microwave devices. Early observations of high frequency discharges were made by Lodge [92], Thompson [93], Tesla [94]. A considerable number of experimental studies of high frequency discharges, mostly below 300 Mc, were performed over the years without yielding a very clear understanding of the phenomena. No important applications were made until 1941 when the requirements of radar opened up a new field of gas discharge applications and studies [95], [96]. In order to use a single antenna for both transmission and reception, a reliable device was needed to protect the receiver from the initial power pulse. This requires a device with an accurately reproducible breakdown voltage and uniformly low impedance to the power pulse and rapid de-ionization of the discharge at the end of the pulse. At first a simple spark gap was used. The next stage of development was to alter a local oscillator vacuum-tube by the addition of gas at a moderately low pressure. This "new" gas tube was called by the British a TR box, or TR tube, for the function transmit-receive. If the device is so placed in the wave guide array to disconnect the transmitter during the receiving period it is called an ATR tube for anti-transmit-receive. The TR and ATR tubes, as components of a waveguide system, developed empirically, and quickly became a vital part of radar systems. These TR tubes and similar devices are now grouped under the general term "duplexer" [97]. Because of the stimulus provided by the war, many workers both in the United States—particularly at Bell Laboratories and at the MIT Radiation Laboratory—and in England studied and modified the TR tube. The author has been unable to determine who made the first one. The long de-ionization time of pure gas discharges was reduced to the order of microseconds by the simple expedient of adding water vapor to the low pressure argon, thus permitting ranging over relatively short distances. The availability since the war of microwave apparatus of considerable power and versatility has made possible a wide range of scientific studies of gas discharges and has helped provide solution for many problems [98].

The present requirements for very long range radar necessitates very high power transmitters. This has required the development of new techniques to extend the power capabilities of the TR tubes. It has been found [97], [99] that tubes filled with quartz crystals, hard glass fragments or hollow ceramic beads, would have about ten times the power capacity of the water vapor tubes. A further factor of 10 is obtained by a "folded" tube [97], [99], in which the active zone is in a closely-spaced concentric cylinder portion of a tube with a dc "keep-alive" discharge in the larger cylindrical portions at one end.

Gas discharge tubes can be adapted to the controlled attenuation of microwaves [100]. Varying the dc current alters the electron density and temperature so that variation in attenuation is effected. These tubes may introduce noise of two types. The first is the low frequency variational effects [72], [73] due to space charge fluctuations, etc., and the second is a pure noise similar to resistance noise which depends on the electron temperature [101]–[103]. The electron temperature may be typical in the range 5000° to 30,000°K. Positive column discharge tubes, as, for example, fluorescent lamps, can be used as stable, broad-band, noise generators for use in making measurements of the noise figure of radio receivers in the microwave region [101].

Rotation of microwaves by discharge tubes has been accomplished by what are known as polarization duplexers. These consist of a series of small discharge tubes placed diametrically across a circular wave guide, each tube being rotated relative to the preceding tube. The gyro magnetic properties of a plasma in a constant magnetic field can also be used to produce rotation of an electromagnetic wave [104]. This is analogous to the Faraday effect for light.

Switch Tubes

Discharge devices such as circuit breakers, switches, etc. are clearly beyond the scope of the present review. However, mention should be made of the vacuum switch. Small vacuum switches [105], [106] have been used for many years as low capacitance devices for antenna switching. The vacuum switch will hold off very high voltages for a small separation of the contacts. When they open ac under load, current continues to flow for one-half cycle, the discharge being an arc supported by metal vapor from the electrodes. After the first current zero, the metal vapor disperses with great speed and the full strength of the gap is attained in a few microseconds. Recently, interest in vacuum switches has been revived with new developments that greatly extend the range of applicability [107].

Conclusion

The study of the physics of gas discharges is very old, and many famous scientific names are to be found in its voluminous literature. The author, in the limited space permitted for this review, has been able to touch on only the more important practical developments in gas discharge tubes. In each development, many interesting scientific facts have been revealed, many of which have been the subject of extensive study. These interesting studies obviously could not be included. However, it may be said safely that in spite of years of intensive study there remain many baffling and unanswered scientific problems in the field of gaseous electronics. As these problems are solved, the field of application of discharge phenomena will continue to expand.

Acknowledgment

The author wishes to acknowledge helpful suggestions made by Dr. J. M. Anderson and H. C. Steiner. The unpublished historical compilations of W. C. White were very useful source material. The triggered spark gap of Fig. 4 was the joint development of H. S. Dunkerley and J. Illingsworth. The author is indebted to H. S. Dunkerley for the figure.

History of the Microwave-Tube Art*

J. R. PIERCE†, FELLOW, IRE

Summary—**Many ideas important to microwave tubes, including the interaction of electrons with waves, occurred very early. An orderly understanding came much later. The RF diode equation (1933–1944) gave quantitative results concerning microwave tubes rather than insight. The klystron and the concept of velocity modulation and phase focusing (1938–1939) led to a clear picture of important phenomena as well as to powerful microwave devices. Insight and performance were extended by the traveling-wave tube and the wave analysis of its behavior (1946–1947). This led to explorations in terms of the behavior of coupled circuits (1951, 1954) and negative-energy waves (1951). Backward-wave oscillators provided further understanding and a new tool (1952–1953). This background of understanding which grew up concerning microwave tubes led to analysis of and improvement in noise behavior (1950–1959). Finally, the invention of the parametric amplifier led to very-low-noise microwave tubes (1959–1961). Crossed-field tubes have always been highly effective but difficult to analyze and design. Nonetheless, useful high-power amplifiers and oscillators have been built.**

IT IS VERY HARD to give any satisfactory account of discovery, invention and development in the field of microwave tubes during the last half century. The period began close to the first effective use of triodes, and it closes with a current art which is almost beyond the power of description.

It is particularly difficult to give a proper account of early work on Barkhausen-Kurz tubes and on magnetrons. By 1931 the Barkhausen-Kurz tube [1] had enabled Clavier to demonstrate microwave telephone transmission across the English Channel [2]. In 1936 Kilgore had produced a CW power of 100 w at a frequency of 600 Mc by using a magnetron [3], and Cleeton and Williams had used magnetrons to produce small CW powers at wavelengths as short as 6.4 mm [4]. Thus, microwave tubes had a considerable record of accomplishment at a very early date.

Too, the variety of early microwave devices is astonishing. Llewellyn's negative-resistance critical-transit-time diode goes back to 1937 [5]. Wave circuits in connection with electron streams were used by Haeff [6] prior to 1936, and were proposed by Lindenblad [7]. Other uses of wave circuits are shown in a patent granted to Llewellyn late in 1940 [8]. In 1935 A. A. Heil and O. Heil described a tube which we would now consider a special form of klystron [9].

If we were to give a historical account of all of this progress in terms appropriate to its day, the account would be very hard to follow. Early workers sometimes did not fully understand the operation of devices they used. Sometimes they had valid but special theories of their operation. Today, we can look back and understand early devices easily, but in doing this we are necessarily led into a misinterpretation of the past. Still, in an article of reasonable length the sort of intellectual organization which has now come into being affords the only reasonable framework for discussion, and we will have to follow it.

In retrospect, then, we see that there have been several extremely important advances in the understanding of microwave electronic phenomena. Each can be associated with certain inventions, but the influence of these advances in understanding has gone beyond the inventions involved, illuminating past work, and making further work possible. Thus, certain areas of understanding afford the best means for describing and assessing progress in the field of microwave tubes during the last half century.

Diode Equations

The exact and useful formulation of the high-frequency electron flow between parallel grids was a vital step toward our understanding of microwave tubes. These equations were worked out in various forms by Müller [10], North [11], Benham [12], Llewellyn [13] and Llewellyn and Peterson [14]. Their original purpose was to provide an understanding of the high-frequency operation of triodes, tetrodes and pentodes, but their consequences were much greater. They led Llewellyn to the negative-resistance diode. They formed and still form part of the stock in trade of men who work with all sorts of microwave tubes.

The weakness of these equations, which give the RF properties of electron flow between parallel grids, is not so much their specialization as their failure to furnish physical insight. They describe phenomena which we would now speak of in terms of velocity modulation and wave phenomena; indeed, Gray derived the equations in a waveform [15]. But early workers did not recognize these features in the equations. To early workers, the equations provided more a mathematical tool than a deep understanding.

Production and Focusing of Electron Beams

Klystrons, traveling-wave tubes and some other microwave devices make use of long electron beams of considerably higher current than is usual in electron optical systems. The successful production and focusing of such electron beams has been extremely important to the success of microwave tubes. Some important advances were a rational method of gun design [16], "Brillouin" flow [17], [18] and periodic focusing [19].

Klystrons and Velocity Modulation

Perhaps the first great step in understanding the phenomena in microwave tubes came with the invention of the klystron. Brüche and Recknagel discussed "phase focusing" in 1938 [20] and the work of the Varians [21], Webster's theoretical treatment of the klystron [22], and the work of Hahn and Metcalf [23] were published in 1939.

With the klystron came a well-thought-out theory of its operation, the concept of velocity modulation, and a full appreciation of the value of microwave resonators.

With the klystron too, there came from contemporary workers, and notably from Hahn [24] and Ramo [25], the idea of space-charge waves and their use in explaining the operation of velocity-modulated tubes. But the chief impact of the wave phenomena of electron flow was to be in another field—that of traveling-wave devices.

The idea of velocity modulation is powerful because it gives a direct physical insight into the operation of microwave devices. If the electrons of a stream are alternately speeded up and slowed down prior to their injection in a drift tube, the faster electrons will catch up with the slower electrons, and the beam will become bunched, so that it can produce power in an output resonator through which it passes. Similarly, when a velocity-modulated beam is injected into a retarding field in the reflex klystron, the faster electrons go further and return later, and so the beam is bunched through a somewhat different mechanism.

Although klystrons produced powers as great as 50 w by 1939, and EMI klystrons [26] produced pulsed powers of around 30 kw during World War II, as power sources they were overshadowed by magnetrons during that war. They were, however, widely used as local oscillators in radar receivers. Particularly, it was found to be possible to build reflex klystrons for 300-v operation, using glass with copper disk seals and an external resonator at wavelengths around 10 cm, and an all metal construction around 3 cm [27].

Such low-voltage tubes had high-perveance low-impedance beams, and changing the reflector voltage changed the frequency of oscillation by tens of megacycles. This electronic tuning has proved to be an extremely valuable feature of reflex klystrons. They are now widely used, not only as local oscillators, but as sources of frequency-modulated waves in microwave transmitters, and, of course, as convenient sources in test equipment. Today, reflex klystrons are available in the power range from milliwatts to tens of watts, and for wavelengths ranging from a few millimeters to the long-wavelength end of the microwave band, wherever that may be.

While magnetrons beat the klystron out as high-power sources during World War II, klystrons have subsequently provided the highest microwave powers to be generated. In the klystron there is a clean separation of functions: gun, buncher, drift tube, catcher and collector. Rational and optimum design of each part is possible. The greatest early progress was through work at Stanford by Hansen, Ginzton, Chodorow and others, in connection with the construction of an electron linear accelerator. By the end of March, 1949, a pulsed power of 14 Mw with an average power of 1 kw had been produced at a wavelength of 10 cm.

The subsequent development and manufacture of high-power klystron amplifiers have provided powerful tools for all sorts of microwave applications including accelerators, electronic heating, radar and space research and communication. The fact that the klystron can act as a stable high-power *amplifier* has made feasible such sophisticated radar techniques as chirp.

Table I gives a rough idea of the sorts of gains and powers that are commercially available in klystrons today.

interact powerfully with a beam of electrons if the wave velocity and the electron velocity were nearly the same. He built a tube and found a gain of around 10 db for a wave traveling in the same direction as the electrons. A mathematical analysis agreed with this performance.

The traveling-wave tube turned out to be a device which amplifies over unprecedently broad bands, and which can function over an astonishingly wide range of frequencies and powers. A traveling-wave tube with a helix circuit can amplify over a frequency range of more than an octave. More typically, bandwidth is limited to 500–1000 Mc by input and output couplers.

Understanding and analysis of the phenomena of traveling-wave tubes were made easier when Pierce expressed their low-level behavior in terms of waves on a medium consisting of the electromagnetic circuit and the electron beam [29]. For example, this made it easy to investigate the effect of circuit loss.

The first traveling-wave tubes had considerable gain in the forward direction and negligible loss in the backward direction; reflections at source and load led to oscillations above a moderate gain. By means of a wave analysis, it was easy to show that the forward gain would be reduced by only about a third of the amount of loss, measured in db, which was introduced into the circuit. Thus, it was practical to make a truly stable tube with a backward loss greater than the forward gain. Lumped loss extending for a fraction of the length of the tube has led to even superior results.

While the wave theory of the traveling-wave tube made calculations easy, a simple intuitive understanding of traveling-wave devices required further insight. This has been provided in two ways. In 1951 Chu pointed out [30] that the slower of the two space-charge or plasma waves of an electron stream has a negative energy [31], in the sense that energy is taken from the electron stream in setting up the slow wave. Hence, the increasing wave in a traveling-wave tube comes about through a continual increase in excitation and hence in energy of the electromagnetic part of the wave, and a continual increase in excitation and hence decreases in energy of the space-charge or plasma part of the wave.

TABLE I

KLYSTRONS

Frequency kMc	Peak Power Mw	Average Power kw	Efficiency Per cent	Band-width Mc	Gain db
0.4	8	30	40	50	30
1.3	25	80	36	100	40
3	22	22	45	15	60
8	CW	20	32	29	44

Traveling-Wave Tubes and Wave Phenomena

We have noted that progressive waves and electron flow occurred in some of the early thinking about microwave tubes. It remained, however, for Kompfner to take the decisive step of reasoned approach and effective experiment which gave us the traveling-wave tube and led to a host of related devices [28].

Kompfner reasoned that an electromagnetic wave on a slow-wave structure, and especially a helix, should

This concept led naturally to a consideration of the coupling between electromagnetic waves and plasma waves [32], a subject which Mathews [33] had investigated at an early date. We now understand the behavior of many electronic devices in terms of the coupling between slow negative-energy space-charge waves and various environments. Near a lossy medium such a wave grows by losing its energy to the environment (resistive-wall amplifier) [34]. Periodic variations along a beam can give gain through coupling a fast positive-energy space-charge wave to a slow negative-energy space-charge wave (velocity-jump [35] and scalloped-stream [36] amplifications). Or, gain can be obtained by coupling the fast space-charge wave of one electron stream to the slow space-charge wave of a nearly or interpenetrating stream (double-stream amplification) [37]–[39].

While wave phenomena are important in explaining the low-level operation of traveling-wave tubes, their large-signal behavior can be understood chiefly through digital computation [40]–[42] and through experiment [43], although Paschke has made progress toward an analytical theory [44]. Actually to make effective high-power traveling-wave tubes required a great deal of work on circuitry. Particularly, satisfactory iterated resonator-like structures had to be used instead of the simple helix, and problems of unwanted modes and spatial frequencies and of matching and terminations had to be solved. Typically, the bandwidths of tubes with such circuits is around 10 per cent. In addition, many advances had to be made in techniques of construction.

In the early 1950's traveling-wave tubes giving a few watts power were in use in British and Japanese microwave radio relay systems. Today they are used in microwave radio relay in the United States and in Continental Europe.

Today, high-power traveling-wave tubes are available for a number of commercial and military purposes. Table II gives some ideal of what is commercially available.

TABLE II
TRAVELING-WAVE TUBES

Frequency kMc	Peak Power Mw	Average Power kw	Efficiency Per cent	Gain db
2.8	1.5	6	23	30
5.7	3	5	25	35
9	0.1	500	20	54
50–60	CW	1 w	5	40

Backward-Wave Oscillators (O-Type Carcinotrons)

In 1951 Millman [45] reported oscillations in a traveling-wave-type tube which were due to an interaction between the electrons and a spatial harmonic of the circuit wave with a phase velocity opposite to the direction of energy flow in the circuit. Work by Guenard, Doehler, Epszstein and Warnecke [46] and Kompfner [47] deliberately exploited such interactions to give oscillators of very wide voltage-controlled tuning range, sometimes of several fold. Backward-wave oscillators are particularly useful in test equipment, and they provide good millimeter-wave sources. Table III indicates the sort of performance that is commercially available.

TABLE III
BACKWARD-WAVE OSCILLATORS

Frequency kMc	Power mw
2.0– 4.0	50
8.2–12.4	50
12.4–18	65
23.5–37.5	250
27 –40	5

Low-Noise Tubes

All good low-noise microwave tubes, except parametric amplifiers, are of the traveling-wave type. Theoretically, low-noise klystrons could be made, but practically, traveling-wave tubes are what we have. This is partly because of the convenience and stability of an untuned broad-band structure. Partly, it is because of the strong interactions which can be attained without lossy, high-impedance circuits. Partly, it may be historical accident.

In inventing the traveling-wave tube, Kompfner was seeking a low-noise amplifier. The attainment of useful low-noise traveling-wave tubes, however, came about only with increased theoretical understanding. The understanding came in several steps.

The first was a wave analysis of the behavior of the traveling-wave tube [29].

The second step was an experimental demonstration by Cutler and Quate of the fact that the noise in an electron stream propagates as waves, just as a signal impressed on the stream would [48].

The third step was the reduction of the effect of noise due to velocity fluctuations at the cathode by using the velocity jump technique to reduce the amplitude of the noise waves on the electron beam. By this means Watkins [49] and Peter [50] attained noise figures around 10 db.

The fourth step was a realization, foreshadowed by Watkins, that there are two independent sources of noise, associated with current and velocity fluctuations at the cathode. This led to theorems indicating a minimum noisiness of an electron beam from a cathode of a given temperature [51], and a corresponding minimum noise figure for *any* beam-type amplifier [52].

The fifth step was the experimental and theoretical demonstration by Siegman, Watkins and Hsieh that in space-charge-limited flow the noisiness may be less than the supposed minimum [53]. Later, Currie and Forster showed how a very-low-noise beam can be attained over a broad band of frequencies [54].

If a backward-wave oscillator structure, and especially a backward-wave oscillator structure with a two-section circuit, is operated at a current lower than required for oscillation, and if a signal is applied at the downstream end of the circuit, the device acts as a narrow-band voltage-tuned backward-wave amplifier. Low-noise backward-wave amplifiers are commercially available.

Table IV shows the sort of noise performance attained in commercially available traveling-wave tubes and backward-wave amplifiers.

TABLE IV
LOW-NOISE TUBES

Type	Frequency kMc	Noise Figure db	Gain
TWT	2.6– 3.5	4	26
TWT	5.25– 5.75	4.5	22
TWT	10.7–11.7	6	35
BWA	2.4– 4.0	5	20
BWA	8.5– 9.6	5.5	20

With the coming of the parametric amplifier, Adler devised a transverse-field electron-beam parametric amplifier and attained a noise figure of 1 db at a frequency between 400 and 800 Mc [55], [56]. Further work elsewhere has led to a noise figure of 0.8 db at a frequency of 4140 Mc [57]. The Cuccia coupler [58], which at once removes noise from the electron beam and transfers signal to it, has been an important contribution to such low-noise parametric amplifiers.

CROSS-FIELD TUBES

The magnetron has a venerable history, dating back to ideas of Hull as early as 1921 [59]. There was much early work of considerable merit [60]–[62]. The idea of traveling-wave operation, a condition for it, and the considerable efficiencies which could be attained were discussed by Posthumus [63] in 1935. Structures of a multicavity type were described in 1936 [64] and 1940 [65]. Yet, the practical development and use of the magnetron occurred suddenly during World War II, following the production of the first high-power high-efficiency pulsed multicavity magnetrons by Randall and Boot [65].

The ability of the cavity magnetron to produce the short intense pulses required for radar depended on a hitherto unsuspected ability of oxide-coated cathodes to emit currents of many amperes per square centimeter in pulses of short duration.

The crossed-field configuration has a tremendous practical advantage. Electrons can give up energy to the RF circuit and yet stay in step with electromagnetic wave; as they lose energy to the RF field they gain it from the dc field.

The performance of microwave tubes making use of electron beams, with or without longitudinal magnetic focusing fields, can be analyzed in some detail and with some accuracy, so that performance accords well with design calculations. Thus, progress in the klystron and traveling-wave-tube art has exemplified a strong interaction between experiment and rather detailed theory. Crossed-field tubes are effective but very complicated in their operation. This is particularly true of oscillators. Thus, in the heyday of the magnetron workers were guided by a few theoretical considerations, such as the Hartree line, which relates operating voltage to magnetic field and mode number by appropriate means for expressing the operation, as the Rieke diagram, in which power and frequency are plotted against load impedance by cold circuit measurements and by endless building and measurement in the tradition of experimental physics. Happily, there are two fine records of this wartime work on magnetrons [67], [68].

Wartime work saw a rapid rise in the power and efficiency of magnetrons, so that by the end of the war powers of over a megawatt had been attained, efficiencies were well above 50 per cent and operation with tens of kilowatts of power had been attained at a wavelength of 1.25 cm. Further, tunable tubes had been produced, chiefly through pins which moved into and out of resonators.

The chief problem encountered with the multicavity magnetron was moding. Once this was understood to be a natural phenomenon in a system of coupled resonators, two remedies were found. One was strapping, invented by Sayers [69] and Spencer [70], that is, tying various anode elements together with short leads. Strapping separated the modes in frequency. Through strap breaks, degeneracy was overcome, so that all modes were coupled to the output. Besides this, strapping distorted the field pattern of undesired modes.

In the rising sun structure mode separation was attained by using alternate resonator slots of different depth or frequency. Some Japanese wartime magnetrons had rising sun structures.

Postwar advances have led to more highly developed magnetron oscillators of improved performance. One notable new advance in tuning and stability has been the CEM (circular electric mode) magnetron [71], in which a tunable high-Q cavity with a circular electric excitation is ingeniously coupled to the interaction slots. This gives a tube with a high degree of frequency stability.

Another tube in which high stability has been achieved is the stabilotron, in which the circuit is interrupted and the gap bridged by coupling through an external cavity [72].

Attempts to make wave-type magnetron amplifiers date back almost as far as the traveling-wave tube [73]. Early experimenters had many rude shocks awaiting them. It is hard to control electron flow in crossed electric and magnetic fields. Such flow can be inherently unstable [74]. Early attempts to make crossed-field amplifiers led to oscillation and noise but not to gain.

It has been possible to obtain substantial (10–13-db) though not high-power gain in the amplitron [72], which is essentially a cylindrical magnetron with an interrupted circuit.

The idea of a crossed-field device with a linear circuit has remained attractive. Perhaps the most useful devices of this kind are voltage-tuned oscillators called M-type carcinotrons [46]; these are avilable at a range of frequencies for CW powers up to hundreds of watts.

Table V shows what sort of performance is commercially available in crossed-field tubes.

TABLE V
CROSSED-FIELD TUBES

Type	Frequency kMc	Peak Power Mw	Average Power kw	Efficiency Per cent	Gain db
Magnetron	1.3	10	17	30	—
Magnetron	2.8	4.5	4.5	50	—
Magnetron	9.4	1	0.875	46	—
Amplitron	2.9– 3.1	3	15	70	8
M Carcinotron	2.5– 3.3	CW	0.27	—	—
M Carcinotron	8.5–11.0	CW	0.20	—	—

Current European Developments in Microwave Tubes*

A. H. W. BECK†, FELLOW, IRE

Summary—**The paper gives a brief description of the present state of the European microwave tube art. Developments on lines which differ from those common in the U.S.A. are stressed. After a few specialized tube types have been described, current research is surveyed, covering devices using electron beams in high vacuum, electron beam parametric amplifiers and microwave amplification in plasmas. Purely theoretical material has been omitted except where it is vital to the understanding of any device.**

Introduction

In looking back over the developments which have taken place in the microwave tube art since the end of World War II, one is conscious of both wonder that so many new devices should have been investigated, and of disappointment that the extent of their employment should have been so restricted, restricted not so much in numbers but in range of applications. If we leave aside purely military applications, the major European uses for microwave tubes are in marine and airfield surveillance radar and in high channel capacity microwave links, which mostly operate in the range between 2 and 7 kMc/sec.

In preparing this survey no attempt has been made to tabulate data on commercially available microwave valves because this information is readily available in manufacturers' catalogues. A few specialized types of valves are described but the major part of the article is devoted to research and possible future advances. It is perhaps necessary to emphasize that lack of space has forced the exclusion of any material on ancillary techniques such as: electron optical developments, cathode development and measurement techniques, all of which are vitally important in attaining the standards of performance and reliability vital in modern microwave valves. Moreover, purely theoretical work has also been omitted.

I. Some Tubes for Specialized Applications

A. Reflex Klystrons

A useful range of reflex klystrons is due to E.M.I.[1] who have produced two basic plug-in tubes of the external-resonator copper-glass disk-seal construction, one of which operates from 0.5 to 5.0 kMc and the other from 3.0 to 11.0 kMc [1]. These valves can be clamped into resonators whose design can be adjusted to optimize the performance for specific requirements. Using a $\frac{3}{4}\lambda$ radial cavity with a tuning device at the current node, a 30 per cent tuning range is combined with good efficiency [2]. Since the tubes themselves are relatively cheap, this system has considerable economic advantages. Other reflex klystrons which should be mentioned in view of their importance in research applications are the Philips 4-mm and 2-mm valves. Early samples of the 2-mm version gave 10 mw at 2.5 kv, 15 ma [3] but it is understood that considerably greater powers have now been achieved. Workers at S.T.L.,[2] using higher perveance guns, have achieved powers of 300 mw at 4 mm using voltages below 2.0 kv [4].

B. Traveling-Wave Tubes

In the traveling-wave tube field many developments are of interest. Several German laboratories have produced high-gain medium-power traveling-wave amplifiers. Of these, perhaps the most interesting is the Lorenz LWS4 [5] with a small signal gain of 55 db, giving a saturation output of over 5 w at about 45-db gain. This tube uses periodic permanent magnet focusing and an elegant package design has been developed.

Ferranti Ltd. has developed a grid-modulated 20-kw peak *X*-band tube with a minimum gain of 13 db. The grid is held at −250 v and is pulsed to about 1.6 kv to turn on the 26–30 kv, 4–6 a beam. The pulse power in the grid circuit is only about 0.1 per cent of that in the beam [6]. The same company has also worked on high-power CW tubes in which the helix was cooled by passing coolant through the helix under high pressure [7]. The main problems were technological and related to the pump and coolant arrangement. At *X* band an output of over 200 w for a 6.2-kv 450-ma beam with a gain of 20 db was achieved without apparently reaching the limit of the cooling system.

C. Backward-Wave Oscillators

Perhaps the most important series of tubes in the present category are the "M" (crossed field) and "O" (beam type) carcinotrons or backward-wave oscillators developed by C.S.F.[3] [8]. Recent developments in the high-power field are described in [9]. Very significant advances have been made in the millimeter region using "O" type tubes with finned-line (Millman-circuit) slow-wave structures. Five tubes cover the band 27.5–110kMc/sec. with a minimum power of 1 mw increasing

[3] Compagnie Général de Télégraphie, Sons Fil, Levallois-Parret (Seine), France.

to over 4 mw below 50 kMc. The power output vs frequency curve is very peaky and the peak powers at selected frequencies are many times these minimum figures [10]. Narrow-band tubes with very high convergence electron guns and unspecified improved circuits using watercooling have given spectacular results, for example, 2 w in a 7 per cent band around 70 kMc [10]. Tubes for bands around 200 kMc and 270 kMc have been made and have given useful powers. An "M" type oscillator giving 10 w over the 27 to 36-kMc band has also been developed. These achievements, and those with reflex klystrons mentioned earlier, all of which relate to tubes which are available, at least for laboratory use, make it appear certain that it will not be necessary to resort to megavolt electronic devices to produce oscillations at wavelengths above a few tenths of a millimeter.

D. Power Klystrons and Traveling-Wave Tubes

A 10-kw peak *L*-band klystron which is pulsed by a simple apertured anode has been described [11]. Here, the pulse anode works at one-third of the main beam voltage and the pulse power required is only about 1/300 of the main beam power. Although the arrangement requires a little more power than gridded-pulse electrodes, the extreme mechanical simplicity is attractive.

In the high-power field S.E.R.L.[4] have been especially active, and they have described stagger-tuned multicavity klystrons and cloverleaf T.W.A.'s [12] and [15]. The circuit used in the latter is that developed at Stanford University. In France, klystrons giving 20-Mw peak, 20-kw mean, powers in the *S* band have been developed both by C.S.F. and C.F.T.H.[5] They differ from the original Stanford tubes in using guns of perveance 2×10^{-6} and therefore function at 250 kv. The maximum efficiency is about 45 per cent [13]–[14].

E. Magnetrons

Conventional pulsed magnetrons for the 4-mm band have been described by S.E.R.L. in England [16] and by Philips in Holland [17]. The S.E.R.L. tube gave 5-kw peak with about 7 per cent efficiency while the Philips 18-vane tube gave an output of 34 kw, and an efficiency of 19 per cent at a field of 1.8 Wb/m².

Some very light and cheap magnetrons, intended for radiosonde transmitters, have been described by the Mullard Co. [18]. These use an interdigital circuit attached to a Lecher line, in a manner used in some low-power German war-time magnetrons. *S* and *X* band models have been studied, that in *S* band giving 2.2-kw peak with an efficiency of 50 per cent at 4,500 gauss field.

II. Current Research and Development on Microwave Valves

We have space only to mention briefly some of the more interesting projects recently reported.

Several versions of an electrostatically focused BWO using a novel focusing principle have been studied by the G.E.C.[6] [19]–[21]. These tubes, called "Ophitrons" use the inhomogeneous electrostatic fields set up between the delay line or lines (Figs. 1 and 2) and the external negative focusing plate to form a strip beam of sinuous shape. Tubes for *S* and *X* bands have been successful and the resulting oscillator is very small and light because of the absence of focusing magnet and seems most attractive for all low power applications of B.W.O.'s. W. E. Willshaw [21] reports an attempt at a 2-mm version with a line comprising 200 slots 0.004 in wide and 0.036 in long. The mechanical problems of such a tube are naturally formidable.

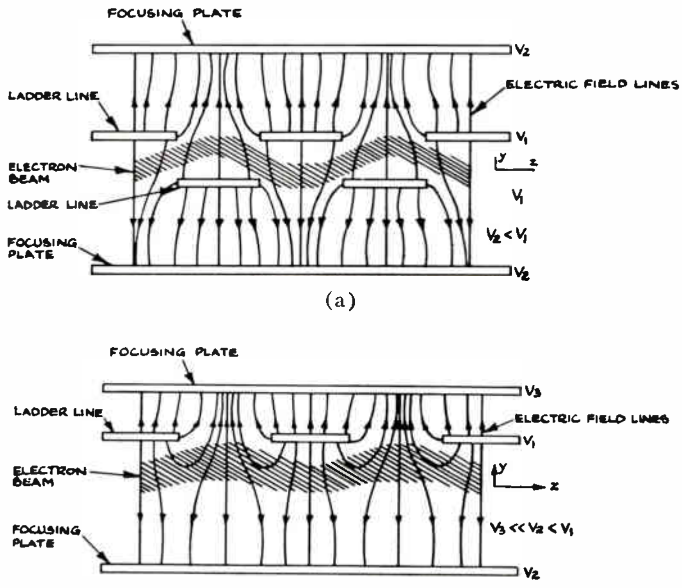

Fig. 1

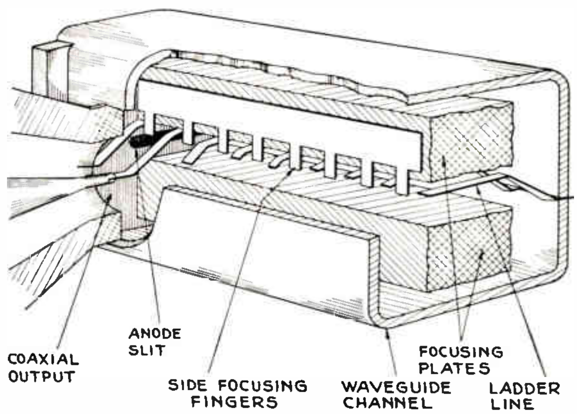

Fig. 2.—Cut away view of ophitron structure.

[6] General Electric Company Ltd., London, England.

A novel device, which appears to have been studied only in Russia, is the "Spiratron" (Fig. 3). Here, the slow wave structure has axial symmetry and is normally a helix. A focusing wire, at a different dc potential, runs along the axis of the helix. The injected beam is annular and the individual electrons perform helical trajectories whose pitch depends on the injection system [22]–[24]. The advantages of the Spiratron are claimed to be the following: First, with an annular beam, the change of coupling impedance with frequency is less than with a solid beam and broader bandwidths are obtained; second, the annular beam gives a bigger coupling impedance and therefore more gain and efficiency for a given current; third, the annular beam can transmit more current before unwanted dc radial potential variations become important; finally, under large signal conditions the beam is thought to conserve its cylindrical shape without radial displacement of charge and possible loss of efficiency.

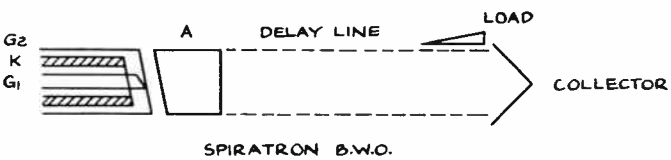

Fig. 3.

Most of these claims are borne out by the excellent results. For example, in amplifiers, bandwidths in excess of 3:1 have been achieved with 20-db gain. For the 12 to 20-cm band, outputs of 10 to 12.5-w C W were obtained with efficiencies of 25–30 per cent and a current of 25 ma, *i.e.*, at about 1.6 kv. Further results on Spiratron B.W.O.'s are given in [24]–[25]. Over the band 2.4–4.4 kMc/sec, requiring a voltage range of 250 v to 2.1 kv. output of up to 50-mw CW have been obtained for 12-ma beam current. The problem of the B.W.O. is more difficult than that of the amplifier, since, as the beam enters the interaction region where the RF fields are strongest, any tendency to RF beam instability has very serious consequences in beam interception, etc.

Russian investigators have studied some devices rather more thoroughly than has been the case in other European countries. One instance is the double stream-amplifier where at 3-kMc CW outputs of ≑ 5 w were achieved for beam currents of 40 ma when one stream was at 1550 v and the other at 1100 v. In this case the streams were very well mixed by making the second cathode of an emitting grid heated by interception of some of the beam from the first cathode [26]. Another group has used a reflex klystron as a frequency multiplier. Here, the reflector region was built into the low-frequency cavity while the ordinary cavity operated on the third harmonic. The device operated with a power drop of about 30 db from the 3.3 to 10-kMc band [27]. Also, in an intriguingly vague article, Golant [28] mentions a reflex klystron with 10–15 per cent electronic tuning range working at 150 v.

Of more importance are the recent achievements of cyclotron interaction between beams and waves on fast wave structures (Lecher lines) by the late S. I. Tetelbaum and his collaborators [29]–[30]. Such ideas had been discussed in Germany [31] but Tetelbaum was first to produce useful powers which he did with a very simple structure (Fig. 4). The electrons perform cycloidal paths when the magnetic induction is adjusted to the correct value $\omega_s = \eta B$. Theory shows that we may then consider that the electrons exhibit an effective phase velocity

$$p = \frac{u_0}{1 - \omega_c/\omega_s} \cdot \qquad (1)$$

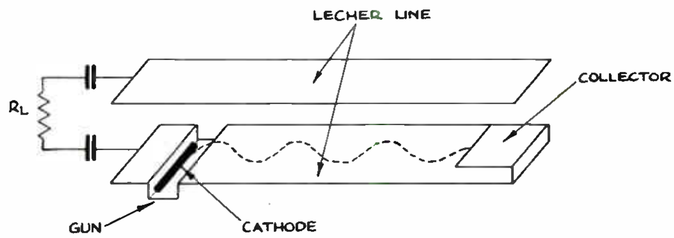

Fig. 4.

Thus, when $\omega_c = \eta B \doteqdot \omega_s$, the phase velocity is very large, and the beam will interact strongly with waves of high-phase velocity, which in Tetelbaum's case was the velocity of light c. His device was arranged as a B.W.O. and in spite of its simplicity gave 0.5 to 3-w CW over the band $\lambda = 6 - 18$ cm. This work is similar to the more refined experiments made at higher frequencies by investigators in the U. S. [32]–[33], and carried out with cylindrical beam devices. The investigation of magnetron-like devices was carried further in England [34]–[35].

Both Tetelbaum and Karp have given essentially steady-state analyses of the operation of the device. Tetelbaum's results agree fairly well with his measurements, but, of course, such a theory does not say anything about the starting current and buildup of oscillations. Pantell has given such a small-signal traveling-wave theory for his device which does predict these conditions.

Following on from the work of Karp, Reddish [36] has further examined the steady-state theory of the crossed-field version and has suggested means for improving the efficiency which are basically methods for operating with depressed collector potential. Experimental work has given promising results, when the electron optics of the gun were such that the cycloidal paths were not destroyed by space-charge forces.

Since these particular devices all use interaction at the cyclotron field, they require rather large magnetic fields, for example, about 13,000 gauss at $\lambda = 8$ mm, and the field increases linearly with frequency. Thus, it is not possible to go to very short wavelengths with existing means of producing magnetic fields (this should be qualified by noting recent successes in the production of 100-kilogauss fields with superconducting magnets). Since the fast wave structure is smooth, it has no mechanical problems comparable with those of slow wave structures and can certainly be accurately made even at very high frequencies. Also, the volume available for the electron beam is great and so large currents can be forced into the structure. These considerations made workers at Cambridge consider interactions between the beam and fields when angular frequency of the helical motion was adjusted to equal a submultiple of the cyclotron frequency. This is possible if a correct higher order waveguide mode is chosen. As an example, consider the case of half the cyclotron field. A spiralling electron beam is introduced into a waveguide propagating the TE_{11} mode. For square waveguide, the interaction is shown in Fig. 5. Consideration of the fields shows that the electrons always see fields which are accelerating or decelerating, depending only on the phase of entry. Thus, bunching takes place and the device behaves electronically like a traveling-wave tube in which the beam has been twisted into a spiral. Either forward-wave or backward-wave interactions can be used since the phase velocity is now

$$p = \frac{1}{1 - \eta B/n\omega_s}, \qquad n > 1.$$

Beck and Mayo [37] have outlined the theory of this device and are about to conduct an experimental test at 10 kMc/sec.

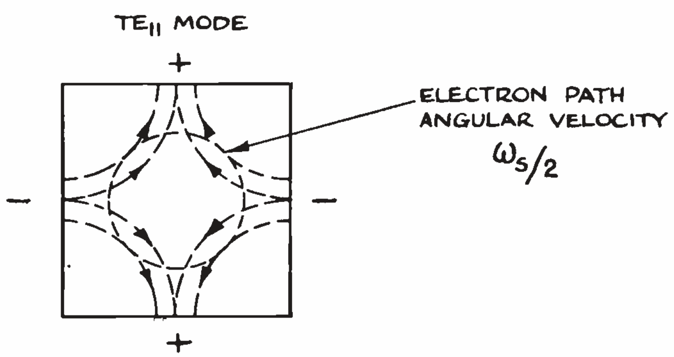

Fig. 5.

A novel device, whose practical embodiment is a little hard to visualize, has been described by Russian workers who call it the "Wavetron." In this a number of finite electron beams with differing velocities are considered to circulate in a waveguide of constant cross-section bent into a ring. Without detailed application of the theory it is difficult to say how this differs from linear multiple-beam tubes, but some solutions of the dispersion equation have been worked out [38] and of course regions of gain and instability appear.

The Siemens Company [39] have reported on the properties of a B.W.O. using a short interdigital line structure, which instead of being matched at both ends, is short circuited at the ends. Such a circuit exhibits a number of discrete resonances depending on the number of unit circuits in the particular line. Naturally, the resonance in the π mode has the greatest coupling impedance and will have the lowest starting current, but for higher beam currents, other modes may be excited at the appropriate beam velocity. In each mode only a small frequency bandwidth is expected. The experimental tube showed two modes, at 3.7 and 4.6 kMc, with tuning ranges of about $\frac{1}{2}$ per cent. The power output is not reported, but reasons for believing that this device can be developed for millimeter or submillimeter wavelengths are discussed.

III. Parametric Amplifiers

The successful development of the Adler type of low-noise parametric amplifier naturally aroused considerable interest in Europe and several developments were started. Publication in this field has been meagre but the English Electric Valve Co. has made Adler tubes for the 600-Mcs band.

Work at Cambridge [40] was directed towards investigating the question of whether the higher-order instabilities, which are predicted by the study of the unstable zones on Mathieu's equation, can be excited and if they give rise to useful values of gain. It has been shown both experimentally and theoretically that useful values of gain can be achieved in the particular unstable region which in the low-loss case starts at $\omega_p = 2\omega_s/3$. To obtain gain one must either pump the tube harder, or use a longer quadrupole, or improve the electronics over those of the standard $\omega_p = 2\omega_s$ device. Using a quadrupole about three times the normal length, Carroll has shown that over-all gains of over 10 db can be achieved in spite of circuit losses of order 3 db. The experimental tube used tuners sealed through the glass and worked at about 350 Mcs. The bandwidth was about 10 Mcs. When used at maximum gain the pump frequency was 254 Mcs, the shift from $\omega_p = 233.3$ Mcs $= 2\omega_s/3$ being predicted by the theory as the gain increases. Used conventionally, $\omega_p = 2\omega_s$ the tube gave $\doteqdot$ 33-db gain. Noise figures have not yet been measured. The work may be of value in exploiting parametric amplifiers at extreme frequencies where provision of the $2\omega_s$ pump would be difficult. It is also of theoretical interest in showing that the Adler tube can be described in terms of two coupled Mathieu equations.

Some work has been done by the G.E.C. [41] on the space-charge wave amplifier, orginally described by Louisell and Quate. The fundamental weakness of the simple form of this device is the small dispersion of ordinary space-charge waves and several methods of increasing the effective dispersion have been discussed.

The Philips Company [42] have made a comparison of the results obtained with an Adler tube operating at 550 Mcs/sec when the electron gun, of perveance 3×10^{-6}, was operated with the cathode first shielded (Brillouin flow) and then unshielded (confined flow). For the *Brillouin* gun the tube gave a noise temperature of 90°K, at 30-db gain while the saturation gain was 50-db. For the confined flow gun the noise temperature was 116°K at 22-db gain, saturation gain 30 db. The noise temperatures are a little higher than those of Adler's tube, probably because the cathode temperature is 1400°K. The gun has quite a low perveance (0.9×10^{-6}) in the cathode—1st anode region and the beam is then decelerated to the final 6-v value. The noise temperature at the first coupler is high, 5000°K, so that noise stripping is effective.

Workers at S.E.R.L. [43] have reworked the theory of the dc pumped quadruple tube to show that the noise temperature, previously thought to be high, can be made low by using beam cooling. A design with a theoretical noise figure of about 0.24 db is described.

IV. Microwave Plasma Phenomena

The world plasma is often misused in microwave tube literature to invoke the idea of a particular model of an electron beam in which the mean space-charge is neutralized by positive ions of infinite mass. Since this model involves none of the physical phenomena which occur in real plasmas it would be more logical to call it the ion neutralized beam. In this section, however, we are concerned with experimental work on real plasmas in which the collective interaction between the ion space-charge and the electronic space-charge is important and in fact gives rise to the observed phenomena.

This is not the place to review plasma theory but to make a description of the experiments intelligible one must say something about the propagation of waves in an infinite plasma. A characteristic frequency depending on the charge density is defined through

$$\omega_{pe}^2 = \frac{n_e e^2}{\epsilon_0 m_e}.$$

The theory then shows that if an electron beam density modulated at angular frequency ω is introduced into the plasma, gaining waves result for the frequency range $0<\omega<\omega_p$. For this range the plasma can be regarded as a dielectric medium with permittivity $\epsilon=\epsilon_0(1-\omega_{pe}^2/\omega^2)$, which is negative for the region under consideration. Maxwell's equations show that there is no ac space-charge in the medium and we may therefore, from a qualitative viewpoint, say that the requirement of charge neutrality has forced the plasma to assume a configuration giving gaining waves as in an inductive wall amplifier. The gain exhibits an infinite peak at the plasma frequency and then drops to zero. Above the plasma frequency ordinary transverse propagation of plane em waves takes place. For the noninfinite plasma, especially when confined in waveguides, the phenomena are complicated by the presence of the conductors. Above the plasma frequency, waves similar to the normal modes propagate, while below f_p waves with phase velocities less than that of light can propagate.

Even more complication is caused by adding a magnetic confining field because the plasma then becomes an anisotropic medium and new modes of propagation result.

The first successful attempts to confirm this picture were due to Boyd, Field and Gould [44]. They obtained amplification up to 4 kMc, with maximum gains at the plasma frequency. Russian workers [45], [46] have used increased plasma densities by providing magnetic ion traps at both ends of the interaction region and have thus been able to reach higher frequencies. A gain of 33 db at 3.0 cm is reported. Studies of the dependence of gain on discharge current, beam current and frequency have been made.

Other Russian groups are also active in the microwave plasma field as [47], [48] show. In Sweden, Agdur [49] has reported on amplification observed when a modulated electron beam is injected, by means of a helix coupler, into a gaseous atmosphere, the whole apparatus being immersed in a kilogauss magnetic field. In this case amplification of over 1 db/cm was observed, substantially at the electron cyclotron frequency. The qualitative explanation given is that slow electrons are created by the ionizing collisions and that the beam interacts with the slow wave carried by these electrons. The theory shows that gain should occur in the frequency range $\omega_c^2<\omega^2<\omega_c^2+\omega_r^2$ where ω_r = plasma frequency of the slow electrons. In the experiments, $\omega_r\ll\omega_c$ so that the range was small and near to ω_c.

Workers at Philips have obtained amplification of nearly 60 db in a low pressure mercury arc 3.0 cm long when working at 4.4 kMc [50].

In England, workers at the G.E.C. have started to study phenomena in plasma filled waveguides [51]. The theory has been extended [52] to cover the case of an electron beam penetrating the stationary magnetized plasma. If the slow wave velocity on the plasma column is nearly equal to the beam velocity gain results. Experiments on a hydrogen discharge gave partial confirmation of the theory and electronic gains were observed.

In the light of the experimental work so far performed, it is clear that very careful and prolonged series of measurements under carefully prescribed conditions will be necessary before the full details of all the interactions possible between electron beams and plasmas are understood. In particular, two difficulties have to be surmounted before operation at short millimetre wavelengths becomes possible. The first of these are the achievement, without excessive use of high-powered discharges, of sufficiently high-plasma densities and secondly, the solution of the problem of coupling to the plasma rather than to the beam, for, if beam coupling is used, most of the constructional difficulties of hard valves remain. Finally, one might guess that there are many engineering problems of stability and life to be solved before plasma devices take their place in microwave systems.

V. Conclusion

In this brief survey I have attempted to emphasize work not being done in the United States and by so doing I have to ask to be excused for ignoring a large amount of worthy research and development.

Perhaps the major conclusion one can draw is that conventional microwave tube types are now being developed for wavelengths in the region of 1 mm and that megavolt electronics does not appear necessary in this region, especially as the potentialities of cyclotron and subcyclotron fast wave tubes have, as yet, hardly been explored.

By contrast, it would appear that too much of the strictly limited European tube development effort is devoted to the production of competing types in well-known fields. It seems doubtful whether the microwave tube market will ever be sufficiently large to warrant the production of more than a few of the most efficient types.

Acknowledgment

The author wishes to acknowledge his indebtedness to Professor M. Chodorow for extending the hospitality of the Microwave Laboratory of Stanford University where most of the research for this survey was carried out. Acknowledgment is extended also to all the individuals and organizations who sent papers and catalogues to the author. Special thanks are due to W. H. Aldous and D. H. O. Allen.

Beam-Deflection and Photo Devices*

K. SCHLESINGER†, FELLOW, IRE, AND E. G. RAMBERG‡, FELLOW, IRE

***Summary*—The development of practical beam-deflection and photo devices coincides with the lifetime of the Institute of Radio Engineers. The intimate association of these two electronic elements is illustrated by the development of the television camera tube. In more detail, both the historical development and the more significant recent advances are described for beam-deflection devices such as the cathode-ray oscillograph, storage tubes, and television display tubes. Similarly, advances are indicated in the field of photo devices such as photoemissive, photoconductive, and photovoltaic cells; multiplier photo-tubes; image tubes; and light amplifiers.**

I. General Introduction

A. Historical Background

FIFTY YEARS ago, at the time of the founding of the Institute of Radio Engineers, beam-deflection and photo devices were virtually nonexistent, although their basic principles were well-known. The cathode-ray oscilloscope for the study of the time variation of electron currents was developed by Ferdinand Braun [1] in 1897, the same year in which J. J. Thomson [2] measured the specific charge of the electron by its deflection in electric and magnetic fields. The photovoltaic effect was discovered by Edmond Becquerel [3] as early as 1839. In 1873, Willoughby Smith [4] first observed the photoconductivity of selenium. In 1887, finally, Heinrich Hertz [5] described the photoemissive effect of ultraviolet light on metal electrodes. In 1905, Albert Einstein [6] introduced the guiding theoretical principle for the photoelectric effect, showing how the laws of photoemission demonstrated the validity of Planck's quantum principle as applied to light.

Nevertheless, in 1912 there was not a single beam-deflection or photo device on the market. The reason is simple. In the absence of electronic amplifiers and oscillators, their utility was too limited to warrant commercial production.[1]

B. Purposes of Beam-Deflection and Photo Devices

Beam-deflection and photo devices serve essentially two purposes. These are:

1) Measurement: Thus, the cathode-ray oscillograph records the time variation of currents and voltages and the photoelectric cell measures light flux. As compared with the galvanometer, the cathode-ray oscillograph has the advantage of being able to represent extremely rapid variations of current and voltage. The same advantage of the representation of rapid variation of light intensities is realized by combining the photoemissive cell with the cathode-ray oscillograph.

2) Pictorial Representation: Thus, in television, instantaneous picture reproduction at remote points is made possible by a camera tube, a combined beam-deflection and photo device, and a beam-deflection device in the form of a viewing tube coupled by an electrical transmission channel. In radar and ultrasonic ranging, the pictorial reproduction utilizes a similar

* Received by the IRE, July 25, 1961; revised manuscript received, October 5, 1961. K. Schlesinger is primarily responsible for the section on beam-deflection devices, and E. G. Ramberg for those on television camera tubes and photo devices.
† Cathode Ray Tube Dept., General Electric Co., Syracuse, N. Y.
‡ RCA Laboratories, Princeton, N. J. (Presently on leave at Technische Hochschule, Darmstadt, Germany.)

[1] There were indeed a few uses which could have been satisfied without electronic auxiliary devices, exemplified by photographic exposure meters, relay-operated door openers and closers, and sealed-off cathode-ray oscillographs for measurements on rotating electrical machinery. The former had to await improvements in the sensitivity of photocells, while the latter, in the earlier stages of their development, could not compete with mechanical oscillographs in the low-frequency range of primary interest.

beam-deflection viewing tube. Storage tubes are beam-deflection devices which permit the delayed transmission of an electrical picture signal or its modification. Image tubes and image amplifiers are photo devices which translate an image formed by invisible or very-low-level radiation into an observable image.

A further use, which has achieved increasing prominence in the last few years, is the application of the photovoltaic cell as a solar energy converter. Still others, such as the use of photo devices as infrared signaling detectors, as scintillation counters, and as sensors in automatic industrial equipment are simply special examples of the measuring function.

C. Beam-Deflection and Photo Devices in Electronic Television

The association of beam-deflection and photo devices is best illustrated by the development of electronic television. Photo devices are essential in the conversion of the light values which compose the information content of the scene to be transmitted into electrical signals. Beam-deflection devices, on the other hand, were soon recognized as the most practical means for deriving a single time-dependent signal which described both the space variation *and* the time variation of the light distribution in the scene in sufficient detail to satisfy the ultimate viewer.

Even before this, the reconstitution of the picture from the electrical signal was found to be the special province of the suitably modified cathode-ray tube, the viewing tube or kinescope.

In addition, the needs of television have played a major role in the genesis of important photo devices such as the multiplier phototube and the image tube, as well as in the development of some types of storage tubes. Finally, the development of photoconductive materials has received important stimulation from the requirements of simplified camera tubes such as the vidicon, as well as from the precursor of a panel-type television display, the light amplifier.

II. Combined Beam-Deflection and Photo Devices: The Television Camera Tube

A. Basic Transmission Techniques

Television, or the instantaneous[2] electrical transmission of pictures, may employ any one of three basic techniques of signal generation (Fig. 1). Thus, it may utilize an array of photosensitive elements on which the picture to be transmitted is projected and employ individual transmission channels for every picture element to the picture reproducer [Fig. 1(a)]. This procedure was proposed as early as 1875 by G. R. Carey, but has survived only in animated cartoon advertising. The second procedure, reputedly first proposed by De Paiva

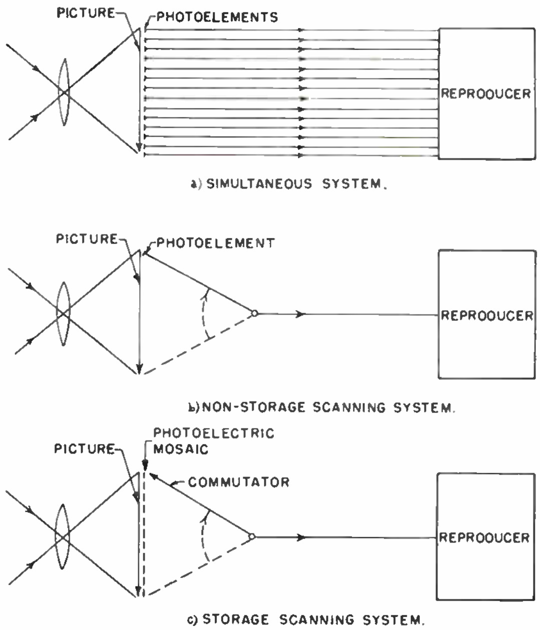

Fig. 1—Television picture transmission.

in 1878, employs a single photosensitive element which explores or scans the picture in a period comparable with the time of persistence of vision, transmitting the light value of every picture element once within this period over a single channel to the reproducer [Fig. 1(b)]. This procedure finds expression in all the various mechanical television pickup systems which played a leading role in television experimentation up to the early thirties. Its most famous realization is the Nipkow scanning disk. The fact that here, and in all except the earliest proposals, the photosensitive element is stationary and the picture element to be transmitted is selected by a great variety of scanning procedures is indifferent. The common features are 1) the single transmission channel; 2) a commutation system capable of sampling at a rate equal to the ratio of the number of picture elements to the time of persistence of vision—a quantity of the order of several million per second for pictures which are regarded subjectively as adequate; 3) reduction in the light available for signal generation (as compared with the simultaneous system) by a factor equal to the number of picture elements[3] and correspondingly increased requirements in sensitivity and lighting; and 4) the employment of photoelectric elements with signal lag smaller than "picture element time," or, approximately, the ratio of the time of persistence of vision to the number of picture elements. With present standards, picture element time is a fraction of a millionth of a second.

B. Electronic Nonstorage Systems

In brief, the simplification of a single transmission channel was purchased at the cost of imposing very stringent requirements on the signal generator. In the

[2] "Instantaneous" here has the practical meaning that delays between transmission and reception do not exceed the persistence of vision of the human eye.

[3] Except when the scene is scanned by the source of illumination, as in the flying-spot system.

early days of mechanical television, the second feature, *i.e.*, the high commutation rate, was regarded as particularly onerous, since it demanded the construction of rotating or reciprocating machinery operating at great speed and with high precision. This difficulty was eventually overcome by substituting the deflection of electron beams by alternating electric or magnetic fields for mechanical motion, as in Farnsworth's [7] image dissector [Fig. 2(a)] and in the flying-spot cathode-ray-tube pickup system [Fig. 2(b)]. In the former, the picture was projected on an extended photocathode. The emitted photoelectrons were accelerated and focused by a longitudinal magnetic field in a plane containing an aperture in front of a sensitive electron detector (*e.g.*, a secondary-emission multiplier), forming there an electron image of the light distribution on the photocathode. This electron image was swept across the aperture, a picture element in size, by alternating transverse magnetic fields synchronized with the deflection fields in the receiver. In the flying-spot system [8], [9], a scanning pattern is described by an electron beam in a simple cathode-ray tube on a short-persistence fluorescent screen. This pattern is imaged onto the scene to be transmitted, and the reflected or transmitted[4] light is collected by a phototube generating the picture signal.

While these electronic nonstorage scanning systems overcome the difficulty of high-speed commutation, they still suffered from the third characteristic, namely, high lighting requirements or inadequate sensitivity. These have limited their use to a few special-purpose applications. The required high-speed response of the photosensitive elements, on the other hand, has not proved a limitation, since the speed of response of photoemission in vacuum fully meets the need.

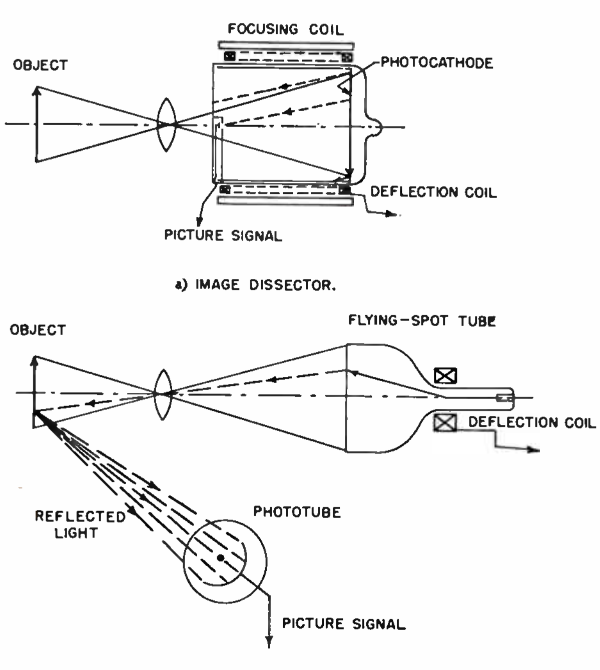

Fig. 2—Nonstorage scanning pickup systems.

[4] If the scene has been recorded on film or on a transparency.

C. Electronic Storage Systems

With the third procedure [Fig. 1(c)], the storage scanning system, the array of photosensitive elements is restored and the scanning takes place between this array and the transmission channel. The individual elements store charge by photoemission continuously[5] and release their charge for signal generation at the instance of commutation. Here, the single communication channel is obtained at the cost of only the high-speed commutation; the sensitivity and speed-of-response requirements for the photosensitive elements are the same as in the simultaneous system.

Mechanical commutation of the photosensitive elements at the required speeds was clearly out of question. Thus, all television storage scanning systems have employed camera tubes with electron beam scanning for commutation. The combination of electron beam scanning and storage was first proposed and carried into practice by V. K. Zworykin [8] in 1923—at a time preceding any other electronic pickup system. The original tube in which this was realized is shown in Fig. 3. The target was an aluminum film oxidized on one side, which was photosensitized with cesium vapor and faced a metal grill serving as collector for photoelectrons. The metal side, which served as signal plate, was scanned by a high-speed electron beam, which penetrated through the oxide layer, forming a temporary conducting path permitting the locally stored charge to flow off through the signal plate.

1) Iconoscope: While the tube as described was capable of transmitting only rudimentary patterns, it became the ancestor of the extended line of storage camera tubes which dominate all phases of television picture transmission. Their common features are electron beam scanning and a picture target with small transverse conductivity capable of storing charge released in response to light. The principal types are indicated in Fig. 4. The first practical storage camera tube was the iconoscope [11]. Here, the picture was projected on a mosaic of photosensitive elements capacitatively coupled to a signal plate. The mosaic was then scanned by a high-velocity beam, restoring the mosaic to a uniform potential and releasing photoelectrically stored charge for forming the picture signal. The secondary-emission ratio was greater than unity, so that the equilibrium potential under the beam was close to that of the electrodes facing the mosaic. The efficiency of the tube was low owing to the unfavorable field conditions for collecting the photoelectrons and secondary electrons; furthermore, redistribution of these electrons gave rise to shading errors in the picture.

[5] This requirement is not realized in the interesting early proposal for a cathode-ray camera tube with a mosaic target of A. A. Campbell-Swinton [10] (1911).

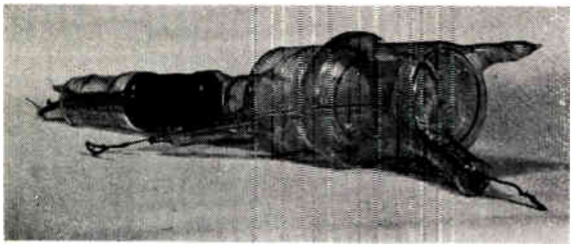

Fig. 3—Prototype of storage-type camera tube (Zworykin, 1923).

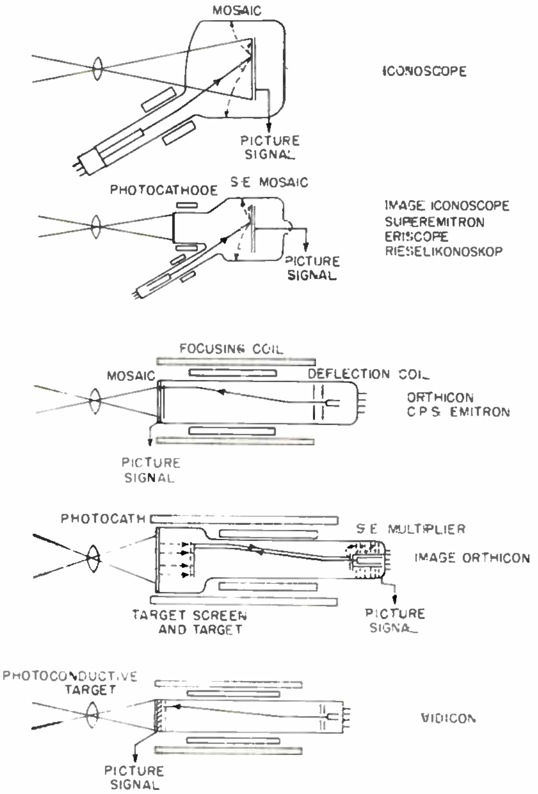

Fig. 4—Storage camera tubes.

2) *Image Iconoscope:* The first important improvement of the iconoscope consisted in the addition of an electron imaging stage [12], [13]. In the image iconoscope, the picture was imaged on a transparent photocathode, and the photoelectrons were then focused by an electron-optical accelerating and imaging system on the mosaic. This led to greater sensitivity of the camera tube as a result of the greater photoelectric sensitivity of the transparent photocathode as well as the secondary-emission gain at the mosaic. At a later date, a spray of photoelectrons from the photosensitized tube wall controlled by suitably distributed electrodes also served to eliminate shading [14]. Improved image iconoscopes of this type enjoy considerable popularity in European studios.

3) *Orthicon:* A more radical approach for improving sensitivity and correcting shading is represented by the orthicon [15], [16]. Here, the mosaic is scanned by the beam at low velocity. Since, then, the secondary-emission ratio is much less than 1, the beam drives the surface to a potential slightly below that of the cathode, so that no additional electrons can reach it. Collection is complete and there is no redistribution. At the same time, such low-velocity beams required new methods of beam focusing and deflection, making use of extended focusing and deflection fields. Earlier tubes of the orthicon type suffered from the disadvantage of instability at excessively high light levels.

4) *Image Orthicon:* In the image orthicon [17], this instability was overcome and the sensitivity of the camera tube was made to approach the theoretical limit for a pickup device with a photocathode of given sensitivity. The gain in sensitivity resulted from the addition of an electron-imaging stage ahead of the storage target and an electron multiplier for raising the signal level of the tube output. In this manner, sensitivity limitations imposed with earlier tubes by the camera amplifier were nullified. In addition, a target screen at a potential slightly above that of the gun cathode prevented charging of the target to a point at which unstable operation could result. Signal multiplication of the output signal in an electron multiplier was made possible by employing the beam returning from the target as signal carrier. The target itself was a thin glass foil with sufficient conductivity to permit charge equalization in a number of frame periods, or also a thin film of some other near-insulator, such as magnesium oxide.

5) *Vidicon:* With the image orthicon, the scope for material improvements in sensitivity was limited. On the other hand, there was considerable room for simplification, even at the cost of lower sensitivity. This was realized in the vidicon [18], a low-velocity tube with a photoconductive target. A potential difference of the order of 20 v is maintained, in darkness, between the front surface, in contact with the signal plate, and the back surface, brought to cathode potential by the scanning beam. Light liberates carriers within the photoconductive layer. These diminish the potential difference in the interval between successive scans. At the instant of scan, the beam deposits enough electrons on the back surface to restore the equilibrium condition and induces a corresponding charge displacement in the signal lead. In the dark, the photoconductor must be an insulator, with a resistivity of the order of 10^{12} ohm-cm, so that the relaxation time (the product of restivity and dielectric constant) may be large compared to the frame time, 1/30 sec. It is interesting to note that the decay of photoconductivity is, for all practical materials, far too slow to permit the use of photoconductors in any but storage systems. On the other hand, in such systems, their sensitivity can be made greater and their preparation is simpler than for insulating photoemissive mosaics in tubes of the orthicon type. This applies particularly for camera tubes of very small dimensions.

6) *Special-Purpose Tubes:* In addition to the standard camera tubes listed above, numerous camera tubes have been developed to serve special purposes. We may mention here in particular tubes which have been made

suitable for operation at extremely low light levels by placing multiple image amplifiers ahead of the storage target [19]; vidicons with special target materials for the infrared, and both vidicons and image orthicons for the ultraviolet [20], [21]; and photoconductive tubes for the reproduction of X-ray images [117].

III. Beam-Deflection Devices

A. The Cathode-Ray Oscillograph

1) Historical Background: The recording of time-varying electrical signals, or "waveform display," was the first technical application for the early cathode-ray tube. The turn of the century was marked by the fundamental work of Lord Kelvin and Heaviside on signal distortions in telegraph lines and cables, and by Ferranti's early experiences with transients and voltage surges on power transmission lines. This was also the era of Hertz and Marconi, the dawn of the "Radio Age."

All this contemporary work established a need for oscillographic instrumentation. It does not seem accidental, therefore, that it was a radio pioneer, Ferdinand Braun, who constructed the first cathode-ray oscillograph at the University of Strassbourg in 1897 [1].

Just like the early X-ray tube, the "Braun tube" used gas discharge phenomena for the emission and formation of an electron beam. Even after the introduction of a thermionic cathode into cathode-ray tubes by Wehnelt in 1905 [22], an argon atmosphere of about 10^{-3} mm Hg was still retained in commercial oscilloscopes [23], [24] for another 25 years [25]. The effect of ion focusing [26] facilitated the formation of long, filamentary, electron beams.

Electrostatic deflection does not perform ideally in an imperfect vacuum. On the other hand, the cathode-ray oscillograph must use electrostatic rather than magnetic deflection, since it is to handle wide-band signals and fast writing speeds with low deflection power. The development of the first high-vacuum tubes by Zworykin around 1930 [27], [28] marks, therefore, the date, for cathode-ray-tube design to be put on the firm scientific foundation of electron optics [29].

2) Oscilloscope Gun and Deflection System: A typical modern oscilloscope tube with intensifier is shown in Fig. 5. The electron gun is of the "zero current" focus type [30], implying negligible interception of beam current by the large-diameter focus cylinder *F*. Both pairs of deflection plates are flared to increase sensitivity. The first pair displays the signal waveform vertically with an average of about 16 v/cm·kv. The second pair provides the horizontal time base with about 20 v/cm·kv. Its contour is shaped to correct for pincushion distortion. There also exists an electrostatic yoke for deflection up to 60° from a common center [31]. This "Deflectron" is free from keystone distortion and has equal sensitivity in both axes. It has been used in industrial [33] and military [34] applications.

3) Post-Acceleration Techniques: Post-Deflection Acceleration (PDA) has become standard practice in modern oscilloscope tubes. It offers the immediate advantage of brightness intensification. In some designs, it also contributes to resolution by permitting to focus at a shorter effective throw. A disadvantage of PDA is its adverse effect on deflection sensitivity (for fixed beam velocity in the deflection plane) and scan linearity. In the simple dual-band intensifier shown in Fig. 5, these factors restrict the maximum usable PDA to 2:1.

Later designs of beam intensifiers are shown in Fig. 6. This includes the multiband intensifier [Fig. 6(a)] and also the helix-type [Fig. 6(b)]. These devices show much improvement in scan distortion since the ideal non-restoring, uniform field is more closely realized [35], [36]. As a result, very high screen voltages are feasible and this, in turn, permits the use of aluminized screens with their additional brightness gain. Even in a helix-type intensifier, a deflection loss still remains, amounting to 50 per cent at a PDA of 10. A configuration not beset by this difficulty is Allard's "ideal post-accelerator" [37] [Fig. 6(c)], which has been reduced to practice in the laboratory [32], [34].

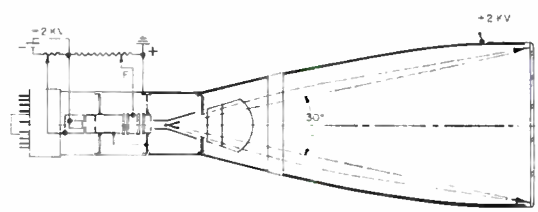

Fig. 5—Modern oscilloscope tube.

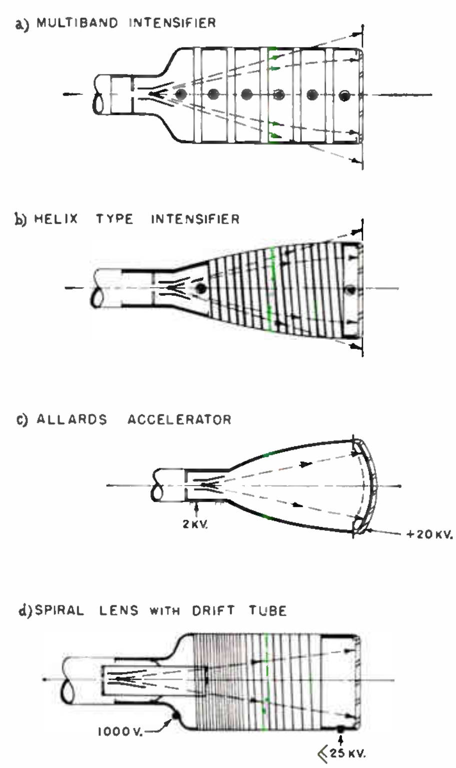

Fig. 6—Beam intensifiers for oscilloscopes.

Another more recent development in this field is the "spiral lens accelerator" of the General Electric Company [38] [Fig. 6(d)]. This design uses, in combination, a nonlinear spiral anode, acting as a negative lens, and an equally long drift tube after deflection at low voltage. With this combination, linear beam, propagation has been realized, resulting in a relatively high deflection factor (3.2 v/cm·kv). It has been found that the scanning width is practically stable over a screen voltage range from 1–22 kv.

4) Special Oscilloscope Tubes: Many special cathode-ray tubes for oscillography, including multibeam, switching, and low-voltage types, are listed in the recent reference book by Parr [25]. At present, advanced development is active mainly in these areas:

a) Ultra-high frequency
b) Ultra-high resolution
c) Storage-type oscilloscopes
d) Printing CRT's.

Space does not permit mention of more than a few examples.

a) and b) UHF oscilloscopes: Very broad-band oscilloscopes are needed for the observation of millimicrosecond pulses [39]. These tubes must have no deflection cutoff up to several hundred megacycles. Unfortunately, transit time limitations restrict the use of conventional "lumped" deflecting fields to frequencies not exceeding the lower VHF range [40]. Means to reduce transit time may include higher beam voltage (50 kv) and very short deflecting fields [41], [42]. Both approaches are hampered by loss of deflection sensitivity. Some relief is forthcoming from gun designs for ultra-fine resolution, whereby the deflection sensibility [43] is increased. As an example, a spot size of 0.0005 in, or 12 μ, was achieved by G. M. Lee in his "micro-oscilloscope" as early as 1946 [44]. Unfortunately, the use of optical [45] or electron-optical [46] magnification becomes necessary for observation of such microtraces.

In 1949, J. R. Pierce suggested the use of a distributed rather than lumped deflection system, whose individual segments were connected to a delay line with a phase velocity matching the beam velocity [47] (Fig. 7). This "traveling-wave" approach to CRT deflection was then further developed by Owaki [48], Smith [49], and others who actually incorporated a slow-wave structure into the cathode-ray tube. Germershausen [50] and Niklas [51] developed similar TW oscillographs for larger deflection angles. At present, the frequency range of the cathode-ray oscillograph has been extended through the entire UHF spectrum [46] and reaches far into the microwave range [52]. A recent report by Feinberg [53] shows the photograph of a magnetron oscillation at 9500 Mc. Similar results were also reported by Haines and Jervis in 1957 [52]. At present, the bandwidth capabilities of the CR oscillograph are far ahead of the availability of suitable signal amplifiers.

c) Storage-type oscilloscope: The introduction of picture retention is of great value in the oscillography of transients. With this in mind, several types of long-persistence screen materials have been developed [54]. These include the well-known cascaded double-layer screen [55], the "dark trace" KCL screens [55], [25], and also a new type of phosphors, whose persistence may be controlled by infrared light to reveal a latent image [56], [53]. A more ideal solution is offered by oscilloscope tubes with built-in electrostatic storage. Fig. 8 shows the "Memotron" of the Hughes Aircraft Company. This tube uses typical storage tube techniques (see Section B, below), including a dielectric mesh, for the transmission control of a flood beam. It writes at 100,000 inches per second, resolves 60 lines per inch, and retains scope traces at a brightness level of 50 foot-lamberts, until they are intentionally erased.

d) Printing with cathode-ray tubes: In most recent times, increasing attention is being given to the problem of obtaining lasting recordings by other than photographic methods. Recent approaches have included the development of several "printing" types of cathode-ray tubes, using either a thin mica window [57] or a metallic mosaic stripline target with over 60,000 wires per inch [58]. A high-resolution line scan in the tube will produce a charge image on moving paper outside. Pigmented plastic, charged tribo-electrically, can be used to "develop" this latent image. Other approaches have used xerographic methods [59] or paper with photoconductive surfaces [60]. Fiber optics [61] is being tried to improve optical coupling between tube and film. CRT's have been used to record on magnetic film [62] and also to detect such recordings [63], [64].

Thermoplastic recording (TPR) is a promising new method of recording with electron beams. This system

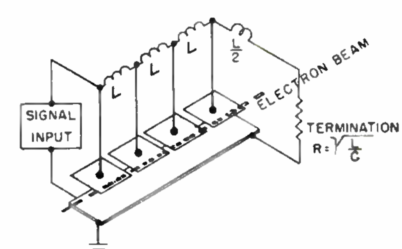

Fig. 7—Traveling-wave deflection (Pierce).

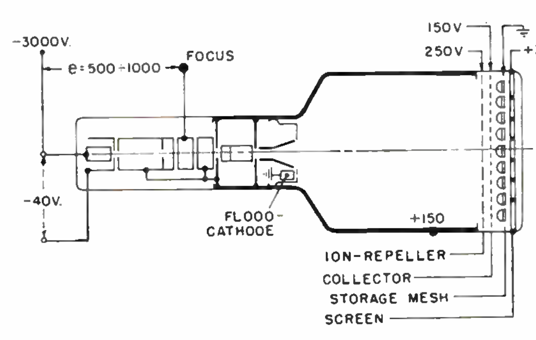

Fig. 8—Memotron (Hughes Aircraft Corp.).

has been described by W. E. Glenn of the General Electric Research Laboratory [65]. TPR uses a clear-film substrate charged by a microspot tube of ultra-fine resolution and read out by means of a "schlieren" optical system.

B. Storage Tubes

Storage tubes are multiple-beam tubes with built-in electrostatic memory [66], [67]. One beam writes the video signal into the storage target as fast as it is received. Another beam reads the charge-image in one or many recurrent frames, but not necessarily at the same time, nor at the same scanning rate (scan converter tubes).

In another type of storage tube, the stored charge image is made directly visible on a built-in viewing screen. These "direct view" storage tubes, or "bright displays," employ a nondeflected flood of slow electrons to project the entire stored image on a built-in viewing screen.

Historically, the addition of electrostatic memory to a cathode-ray tube was conceived long ago by some television pioneers, either in search of brighter pictures [68] or of bandwidth reduction [69]. However, the major development effort in storage tubes had to wait until the end of World War II [70]–[72]. At that time, radar developments had matured and had established a definite need for displays with practically no degeneration for the order of one second. Long-persistence phosphors could not meet this demand. Storage tubes have contributed, not only an improvement of three orders of magnitude in the brightness of radar displays [73], but also an apparent reduction in background noise [74], [75] and a new facility in the detection of moving targets [78].

1) Principles of Operation: The basic memory element in most storage tubes is the dielectric mesh. This is a fine, metallic screen with high transparency (about 50 per cent) and high resolution ($\frac{1}{4}$ to $\frac{1}{2}$ million holes per square inch). The first surface of the storage mesh is coated by a dielectric film with high secondary emission capabilities. Suitable materials include silica, anodized aluminum, the oxides or fluorides of magnesium, etc.

Fig. 9(a) shows a typical secondary emission characteristic of the storage mesh insulator. The two crossover points e_1 and e_2 for unity gain define three areas, *A*, *B*, and *C*, with three typical modes of operation, to be summarized below:

Mode A: Beam voltage below e_1 (approximately 100 v). At these slow velocities, the insulator receives more electrons than it can emit. The surface potential moves in a negative direction until it is "stabilized" at cathode potential. Mode A can be used for total, uniform erasure, and also for uniform "priming" of the target potential.

Mode B: Beam velocity is 1–2 kv, *i.e.*, intermediate between crossovers. High secondary emission causes the target potential to seek the potential of the collector grid.

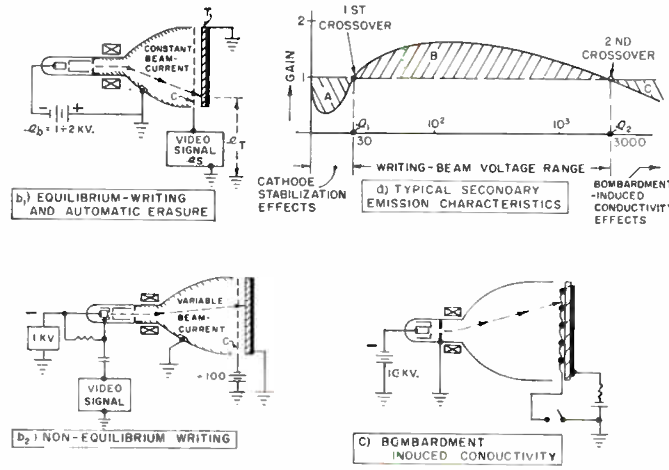

Fig. 9—Storage tube principles.

b_1: *Equilibrium writing:* Fig. 9(b_1) shows writing with constant current-variable collector voltage (*C* is on signal e_s). This process is bidirectional, has limited halftone capability and permits automatic erasure of previous information [70].

b_2: *Nonequilibrium writing:* Fig. 9(b_2) shows writing with constant voltage but variable current. The beam is signal-modulated. The target must be cathode stabilized, or "primed," prior to writing. Secondary emission drives the surface positive at a rate determined by instantaneous beam current. Nonequilibrium writing is the preferred mode of operation, since it offers a good halftone rendition and high speed.

Mode C: At very high beam voltages (6–10 kv), the beam interacts with the target material. Many hole-electron pairs are created in the dielectric by each primary electron. Bombardment induced conductivity (BIC) may cause currents in excess of beam current to flow as a field exists across the target [76].

BIC was first used by L. Pensak (RCA) in his "Graphecon" [77]. This pioneering tube used a film-target, rather than a dielectric mesh. The film was about 1μ thick and was scanned by a high-velocity (10-kv) beam from one side, and by a 1-kv beam from the other. The 10-kv beam was writing by relaxing a uniform charge through BIC. The 1-kv beam was used for reading and also for priming of the target, both in Mode B. The depth of penetration which is proportional to the square of beam voltage accounted for the difference in target behavior in response to the two beams.

2) Electrical Output Types: Of the large family of modern storage tubes, only four typical examples are shown in Figs. 10–13. Fig. 10 is the "Radechon" by A. S. Jensen (RCA, 1948) [78], [79], one of the earliest storage tubes for electrical output. Redistribution effects are reduced by the use of a "barrier grid," *i.e.*, a high-resolution mesh placed in direct contact with the storage surface. Writing can be done by either one of the two above modes in range B. Signal output is taken from the metallic target substrate. The number of readout frames is limited by incidental erasure (readout-decay).

Even so, the "Radechon" principle has found many important applications, mostly as a noise integrator [74] and also for the detection of moving targets by radar (MTI service). Here, the "Radechon" is used as a "frame-subtractor." It can be differentially connected so as to give zero output on identical frames [78]. Recent improvements of the "Radechon" include a high-resolution, 60° version [80], and also an adaptation to a high-speed, random-acess store for digital information [81].

Fig. 11 shows a modern scan converter of the Raytheon Company [82]. This tube is double-ended, with two high-resolution beams (1200 lines) scanning each side of a dielectric mesh. Sets of conductive bands on the envelope secure proper beam landing and deceleration. The reading beam is transmission-modulated and passes through the storage mesh at very low voltage (5–15 v). Thus, readout is practically nondestructive and up to 20,000 good halftone output frames can be read following a single writing frame. Simultaneous recording and reading without crosstalk is made possible by subcarrier modulation of the read-gun at 30 Mc. This separates the sidebands of the output signal from the video spectrum of the write-in signals.

3) *Visual Output Types:* Fig. 12 shows a display storage tube [83], [84]. In this particular version, the writing gun is on the tube axis and the floodbeam gun has a concentric, annular geometry. The low-voltage floodbeam is first collimated by a system of slotted anodes and accelerating rings, and is then transmission modulated by the storage mesh. With screen voltages of 8500 v, this tube can give 4000 foot-lamberts on a $2\frac{1}{2}$-inch screen. It is designed as a cockpit display in high ambient illumination.

Other developments in this area include viewing storage displays of large size [85], [86], a storage tube for the display of printed characters [87], and a large display for a stored tricolor image [88].

Fig. 13 shows a most recent development in the storage tube field, the "Multimode Tonotron" by N. H. Lehrer (Hughes Aircraft Company) [89]. This tube uses erasure by BIC. As Fig. 13 shows, the "Multimode Tonotron" has three electron guns, one for the low-voltage floodbeam, and the two others for nonequilibrium writing at 2 kv and for erasure by BIC at 6 kv. Since the erase beam is focused, erasure can be affected over selected areas, with high speed and with good uniformity of background. By varying the erase beam energy, BIC can be made to swamp secondary emission effects, or just to cancel them. At balance, the erase gun can be used to write nonstored information. At overbalance, dark-trace writing on a white background is practical. These many new capabilities, including a good, six-step, halftone rendition, mark the "Multimode Tonotron" as a major advance in storage tube technology.

C. *Picture Display Tubes*

1) *Monochrome Tubes:* Modern cathode-ray tubes for picture display are characterized by relatively strong beam currents and by very wide deflection angles. Both features are a consequence of the large picture size and the shallow depth required by modern television sets.

The standard P-4 phosphor (ZnS-CdS, Ag) used in picture tubes has an average efficiency of 30 lumens per watt, or about five per cent quantum efficiency. On this basis, a simple calculation shows that the display of a 21-inch picture area at 200 foot-lamberts brightness requires 600 μa of focused beam current at 16 kv.

A highlight brightness three times as great has been achieved recently in picture tubes of the same size [102] by a corresponding increase in beam current. With other conditions equal, beam current capability of the gun should increase with picture area. The latter has grown by one order of magnitude during the past decade.

During the same period, similar progress was made in picture tube deflection techniques. The diagonal sweep angle rose from 52° to 110° and beyond. Such very wide scanning angles were realized in field-free envelopes, that is, without the use of post-acceleration, and also without any but magnetic methods of deflection.

The development of electron guns for picture tubes until about 1955 is very well outlined by Zworykin and Morton [90]. For progress since then, only a few typical examples can be presented here. Fig. 14(a) shows a kinescope gun as used in picture tubes with magnetic focus. This is a "tilted-barrel" type of gun which requires only a single, rather than a dual, magnetic ion trap [91]. A similar gun, but with adjustable spot size, is reported by Francken, *et al.* [92]. In these early tubes, in view of the limited effect of magnetic deflection on ion beams, ion traps were widely used to prevent ion spot formation on unaluminized screens and to protect the cathode from positive-ion bombardment.

However, later experience has shown that, as a result of improved aluminizing, exhaust, and gettering techniques, long life without ion-burn can be achieved in a straight gun, without an ion trap. This is all the more noteworthy, since magnetic focus has yielded, in the meantime, to focusing by electrostatic lenses, which are effective on ions.

The gun assembly of a modern picture tube is shown in Fig. 14(b). It features a unipotential focus lens of the "zero-voltage" type [93]. This type of lens obviates the need for a separate bleeder string across the high-voltage supply. To do so, manufacturing tolerances in the lens must be kept within 0.002 in [94].

Another feature of Fig. 14(b) is the re-entrant high-voltage barrel, which protrudes deeply into the Grid No. 2 cup. The resulting very low screen-grid voltage (+50 v) leads to less stringent cutoff and drive signal requirements. In this gun, a 30-v signal modulates 900 μa of beam current.

Circuit economy considerations as well as the trend towards transistorization have recently stimulated efforts to increase picture tube transconductance by electron-optical means [95]. Notable progress has been made in this direction, both here [96]–[99] and abroad [101]. Many of these low-drive guns employ planar grids made of extremely fine wire [100].

Fig. 14(c) shows a more recent type of high-transconductance gun which has been developed for the U. S. Signal Corps by the General Electric Company [102]. This gun uses a retarding-field type of hyperbolic electron lens to image a large cathode surface into a much smaller virtual point cathode, where the current density is greatly increased. Current from the virtual cathode is drawn forward through a spot defining aperture, or it is reflected back to the first anode. This process is called "Focus Reflex Modulation" (FRM). It modulates 1600-μa screen current by an 18-v signal, and maintains a more constant spot size than conventional guns.

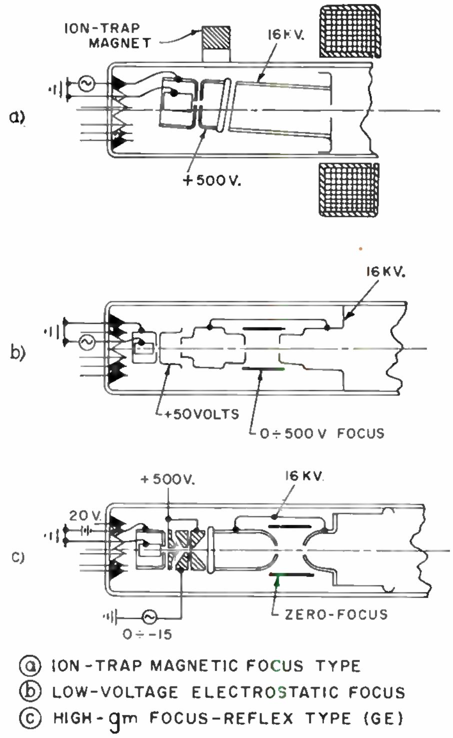

Fig. 14—Electron guns for picture tubes.

2) Flat Picture Tubes: There is, at present, a growing interest in developing "very-thin" picture tube displays [103]. Most of these approaches include radical departures from conventional scanning techniques. This is true of the Gabor tube [104] and also of the Aiken tube, [105] whose complex electron optics has been analyzed by Ramberg [106]. Magnetic mirrors for beam folding have also been proposed [107] and were demonstrated in the laboratory [103].

A very interesting new "flat tube" is the "Reflected-Beam Kinescope" by Law and Ramberg [108]. This tube gives a large picture (21-in diameter), has only 10-in depth, and permits a considerable saving in sweep power and space, particularly with large picture sizes.

3) Color Tubes: As a display device for color television, the cathode-ray tube has risen to the greatest challenge in its history! Early attempts to solve this problem are well-documented by E. W. Herold [109]. At present, the field is dominated by the triple-gun shadow mask tube [110] which produces an excellent color picture of large size (21 in) at medium brightness levels (25 foot-lamberts). In this tube, the three electron beams modulated by the red, green, and blue component picture signals strike a perforated mask with some 357,000 round apertures, which transmits only those electrons of every beam which are directed toward a phosphor dot of the corresponding color on the phosphor screen. The latter is deposited directly on the curved face-plate of the tube [111]. A photographic procedure for forming the screen, employing optical projection through the mask from three appropriately chosen light-source positions, assures precise alignment between the mask apertures, the phosphor dots, and the deflection centers of the scanning beams. An intensive development of manufacturing technology by RCA has resulted in color tubes characterized by consistently high color purity and simple adjustment [112a]–[112c].

The progressive improvement of the shadow mask tube has been paralleled by the investigation of other designs calculated to increase the picture brightness or to simplify the tube construction. Most attempts to realize high-intensity color have utilized the "post-focusing" principle, or the converging lens action at the apertures or slits in the mask structure, to increase the beam transmission of the mask [113a]–[113d], a principle applied by the late E. O. Lawrence [113e] among others. In a relatively recent demonstration by the General Electric Company, a brightness of 80 foot-lamberts was realized on a 22-in picture in this manner [114]. The attempt to eliminate the mask structure altogether by directing a very narrow scanning beam to the appropriate color phosphor elements with the aid of signals elicited by a guide beam and to simplify the tube construction in this manner has been carried forward in particular by Philco and has resulted in the so-called "Apple" system [115]. A still more radical departure from the conventional color tube is represented by the "Banana Tube" system recently announced by Mullard [116]. Here, a projected picture is formed employing a beam tube for scanning a color-line triplet and a rotating lens cylinder for frame scan.

IV. Photo Devices

A. *Photoemissive, Photoconductive, and Photovoltaic Cells*

The 50 years which have elapsed since the founding of the IRE lead from the introduction of the first useful vacuum phototubes, the hydrogenated alkali phototubes of Elster and Geitel [118] with maximum quantum efficiencies in the visible of the order of 1 per cent, to the multi-alkali phototubes with quantum efficiencies up to 40 per cent. The most important steps in this development are the introduction of silver-oxygen-cesium photocathodes by L. R. Koller [119] in 1929, sensitive in the entire visible spectrum as well as the near infrared; the preparation of alkali-antimony and alkali-bismuth films, typified by the antimony-cesium photocathode with quantum efficiencies up to 25 per cent, by P. Goerlich [120] in 1936; and finally, the introduction of the multi-alkali compounds by A. H. Sommer [121] in 1955.

Characteristic curves for the variation of the photoemission with the wavelength of the exciting light are shown, for various commercially important photocathodes, in Fig. 15. While the semicylindirical photocathode and rod anode remain common features of the simple phototube, the introduction of the semitransparent photocathode has aided the solution of special design problems. Gas amplification by collision-ionization of a low-pressure noble gas filling of the phototube, a process known since the beginning of the century, finds only limited application.

The developments in solid-state photocells in the 50 years which have elapsed since the founding of the IRE are perhaps even more striking. Though the discoveries of the photovoltaic and photoconductive effects date back to 1839 and 1873, respectively, the former came into wide use only after the discovery of the cuprous oxide cell by Grondahl [122] in 1926 and of the reintroduction of the selenium photovoltaic cell by Lange and others [123], [124] in 1931, principally as photographic exposure meters. Photoconductive cells have found, until recently, their major application in the detection of infrared radiation. The thalofide cell of Case [125], introduced over 40 years ago, was the pioneer in this field. It was followed by the lead salt detectors (PbS, PbSe, PbTe) first investigated in detail in Germany [126], the improved thallous sulfide cells of Cashman [127], and, more recently, by indium-antimonide and tellurium [128] as well as impurity-doped silicon-germanium cells [129]. Another photoconductive material, cadmium sulfide, initially introduced by Frerichs [130] in 1947, as well as the closely related cadmium selenide, have provided cells of very high sensitivity in the visible—10^5 that of ordinary phototubes—particularly well suited for light-operated relay applications [131].

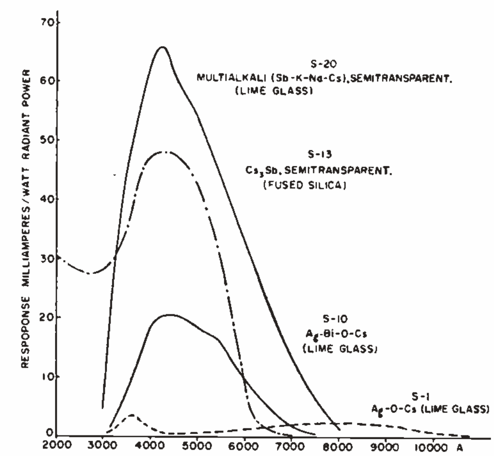

Fig. 15—Spectral response of typical commercial photocathodes. (After R. W. Engstrom, "Absolute spectral response characteristics of photosensitive devices," *RCA Rev.*, vol. 21, pp. 184–190; June, 1960.)

Apart from the photoconductive cell, single-crystal photovoltaic cells [132], commonly called photodiodes or phototransistors when provided with a bias in the blocking direction, and photoelectromagnetic (PEM) cells [133], provide effective radiation detectors. The principle of operation of the three types of cells is illustrated in Fig. 16. Neither photovoltaic cells nor PEM cells require an applied voltage. Negative electrons and positive holes generated by light are separated in the photovoltaic cell by the internal field of a *p-n*-junction, and in the PEM cell by a transverse magnetic field, and give rise to the cell potential or a current in an external circuit. Their output currents are relatively small (less than one electron per absorbed light quantum) and their response is rapid. In photoconductive cells, an applied field serves to separate the mobile charges. However, one of them (*e.g.*, the hole) is commonly trapped for a prolonged time in a recombination center and, by space-charge compensation, permits the passage of many electrons through the cell before its lifetime is terminated by recombination. Thus, photoconductive cells commonly deliver very large photocurrents and exhibit correspondingly slow response [134]. They are thus well suited for light relay operation. The high speed of response, favorable noise characteristics, and extraordinary compactness make the germanium photodiode valuable for sound pickup from film as well as for computer applications. Thus, cells of this type are employed in electronic route information translators in long-distance telephony [135].

Modern photovoltaic cells satisfy one other important objective: the conversion of solar energy with reasonable efficiency [136]–[138]. Thus, they provide an inexhaustible power source for the instrumentation of space craft. Whereas the usual exposure-meter selenium cell converts less than 1 per cent of the incident radiant energy into electrical power, single-crystal *p-n*-junction photocells have achieved conversion efficiencies of 14 per cent, not too far removed from the theoretical maximum of 24 per cent for a simple single-junction photocell.

B. Multiplier Phototubes

One of the most important by-products of television research is the multiplier phototube. When electrons of one or several hundred electron volts energy impinge on a suitably prepared conducting surface, they eject 4 to 10 low-velocity electrons, multiplying the initial current by a corresponding factor of 4 to 10. Repetition of this process leads to current multiplication by an arbitrarily high factor, practically without the addition of amplification noise. If the initial current is derived from a photocathode, the tube output reflects the variation of the light incident on the photocathode with a precision which depends only on the quantum efficiency of the cathode; with proper design, the dispersion in the transit time of the electrons from the cathode to the final collector can be held to quantities of the order of 10^{-10} second [139].

Several multiplier designs are sketched in Fig. 17. In the earliest effective multipliers (Zworykin, Morton,

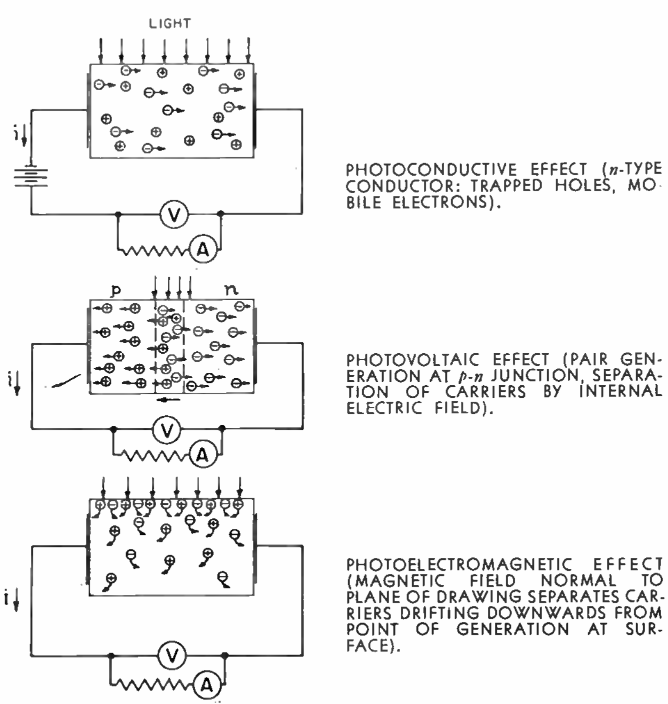

Fig. 16—Internal photoelectric effects.

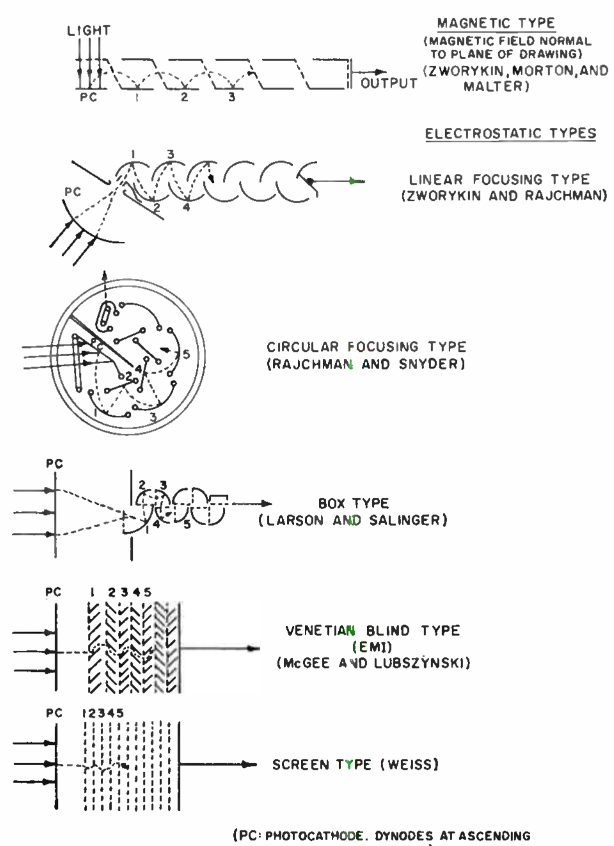

Fig. 17—Basic multiplier phototube structures.

and Malter, 1935) [140], the electrons were guided from dynode to dynode along an approximately cycloidal path by crossed electric and magnetic fields. Purely electrostatic focusing and acceleration sytems were developed subsequently by Zworykin and Rajchman [141] and Rajchman and Synder [142], as well as by Larson and Salinger [143]. These may be regarded as the prototypes of present-day multiplier phototubes of RCA and DuMont. The venetian-blind design utilized in the image orthicon is also employed by EMI and RCA for multiplier phototubes. Finally, the early and very simple screen multiplier of Weiss (1936) [144] does without focusing altogether, at the expense of materially lowered multiplication efficiency.

The multiplier phototube finds application wherever high sensitivity and high speed of response must be combined in the measurement of light values. It has become indispensable in the scintillation counter [145], [146] for high-energy particles and gamma rays. Here, the particle or quantum excites fluorescence in a crystalline or liquid medium, and as large a portion of this light as possible is made to fall on the photocathode of a multiplier phototube. Since every particle excites many light quanta in the phosphor, the multiplier phototube is not only capable of counting every absorbed particle, but provides in addition the possibility of classifying the particles according to energy as measured by the height of the output pulse. Finally, the high time resolution of the multiplier phototube permits the determination of coincidences.

C. Image Tubes

The image tube, also, owes its origin largely to the development of electronic television. It consists essentially of an extended semitransparent photocathode, an electron lens system for forming an image of the photocathode by means of the photoelectrons emitted by it, and a fluorescent screen for rendering this image visible. Tubes of this type, with combined electric and magnetic fields, were built in the middle thirties by Pohl [147] and Schaffernicht [148] in Germany and, with purely electrostatic lenses, by Zworykin and Morton [149] in the United States.[6] Most of the later image tubes have, also, been electrostatic. Image tubes have served principally four different functions:

1) The viewing of objects in illumination to which the eye is insensitive; apart from its obvious military applications [151], the infrared-sensitive image tube has been found useful in ophthalmic diagnosis [152] and in photographic film processing. Beyond the other end of the visible spectrum, the RCA Ultrascope image tube [153] converts the ultraviolet microscope into a direct-viewing instrument.
2) The utilization of the higher quantum efficiency of the photocathode as compared with that of a photographic emulsion in astronomic photography; this is accomplished for example in the direct photography on fine-grain plates within the image tube by A. Lallemand [154].
3) Brightness enhancement of low-level images. Thus, X-ray intensifier tubes [155], [156] introduced by J. W. Coltman and manufactured by Westinghouse, Philips, RCA, and others achieve, through electron acceleration and image size reduction, brightness enhancement by factors up to 1000, overcoming losses in detail recognition arising from the inefficient utilization of light by the human eye in normal viewing.
4) Electronic shutter action for high-speed photography [157], [158]. The provision of a gating grid in front of the photocathode permits photography with exposure times of the order of 10^{-8} sec.

In the examples cited above, single-stage image tubes have been used throughout. However, it has been found possible to greatly increase the brightness gain by staggering stages. Of the several types which are under investigation, the fluorescent-screen-photocathode sandwhich type (Morton and Ruedy [19] and Stoudenheimer [159]) and the transmission secondary-emission type as realized by W. L. Wilcock [160] have already attained excellent results. The former consists essentially of a sequence of complete image tubes. Good optical coupling is achieved by depositing the fluorescent screen of one stage and the photocathode of the next on the two sides of a thin glass membrane. In the

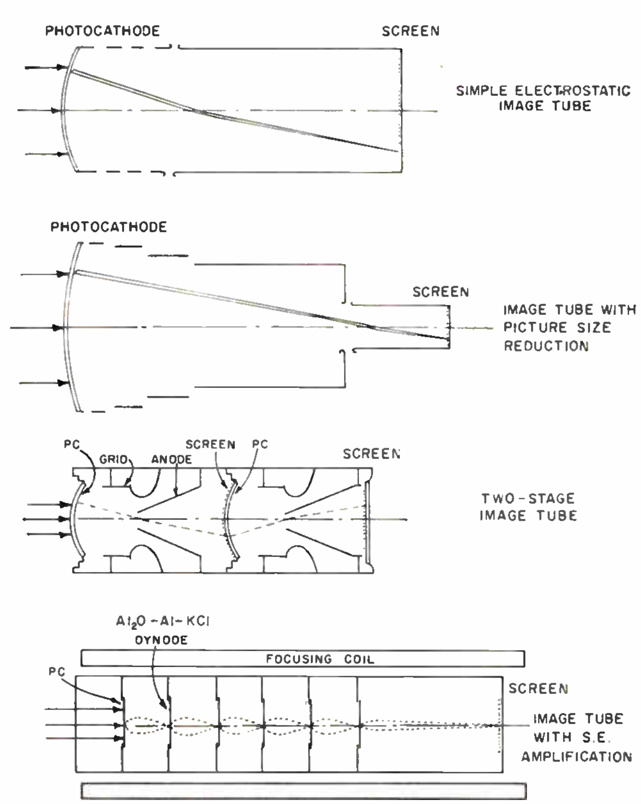

Fig. 18—Image tube structures.

[6] Image tubes without electron imaging were built by Holst, de Boer, Teves and Veenemans [150] in The Netherlands in 1934.

secondary-emission tube, a longitudinal magnetic field images the emission from one dynode, consisting of a thin aluminum—aluminum-oxide film coated with potassium chloride, to the next, achieving secondary-emission gains of the order of 5 with 1000 v between stages. Fig. 18 shows schematically a number of image tube structures.

D. Light Amplifiers

The solid-state counterpart of the image tube is the light amplifier [161]. In its simplest form, it consists of a sandwich of a powdered or sintered photoconductive layer and an electroluminescent layer separated by a light barrier to prevent feedback (Fig. 19). An alternating voltage is applied across the sandwich. In darkness, the potential drop across the electroluminescent layer is reduced by that across the photoconductive layer to a value below the threshold for effective light excitation. When the photoconductive layer is irradiated, its impedance drops, the potential difference across the electroluminescent layer increases, and light is emitted by it. With certain refinements, such light amplifier panels have yielded light gains in excess of 100. Furthermore, when employed for X-ray fluoroscopy [162], the image brightness of the panel could be made over 100 times as great as that of a conventional X-ray screen. Unfortunately, the slow response of the cadmium-sulfide photoconductor layers employed so far has limited the utility of this application. However, both experimental and theoretical work indicates that great improvements in this respect are obtainable.

Apart from the simple light amplifier, the combination of photoconductors and electroluminescent elements permits the construction of a wide range of storage and logical devices covered by the collective term optoelectronics [163]. This may well be one of the fields in which photo devices will demonstrate their expanding utility in the years to come.

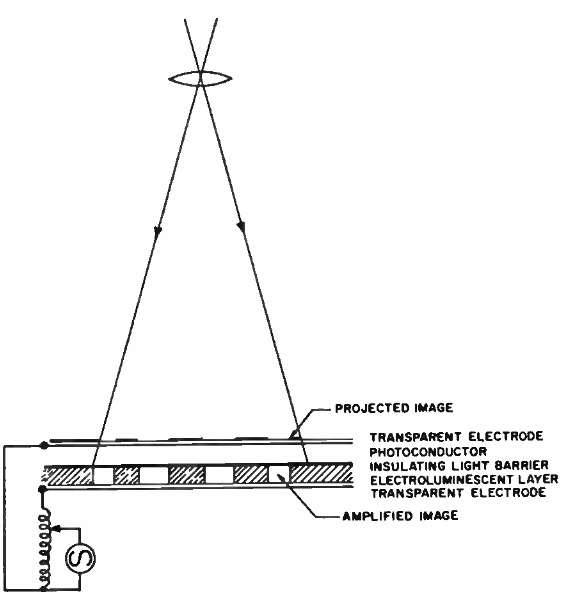

Fig. 19—Principle of the solid-state light amplifier.

Semiconductor Devices*

J. M. EARLY†, FELLOW, IRE

Summary—**The semiconductor art began early in the nineteenth century. Gradual advances in materials, techniques, and understanding followed. The decisive event in creation of the modern semiconductor device field was the invention of the transistor in December, 1947 by Bardeen and Brattain. Understanding of minority carrier injection, invention of the junction diode and transistor, and major advances in materials and techniques then came in rapid sequence. In the last decade the semiconductor devices have grown prodigiously in variety and complexity and in speed, power, and reliability. Further growth will be shaped by the semiconductor materials and the constraints which they impose on speed, power, and impedance. The transistor and allied single-crystal *p-n* junction devices will probably be the key tools of electronic circuitry for many years.**

Introduction

The TRANSISTOR and related single-crystal *p-n* junction devices are the first of the modern solid-state devices. At present, the probability seems high that, in the electronics of the future, they will play many of the roles which de Forest's audion and its offspring played in creating the field. This paper includes in successive sections a brief history of the semiconductor technology, a short assessment of its influence on both engineering and science, and a summary of the present state and future prospects of single-crystal *p-n* junction devices. Emphasis is put on the key steps in the creation of the technology and on the work of the handful of pioneers who made the essential discoveries. Of necessity, many contributions of very considerable importance are passed over without mention. Easily ten times the space available here would be required to do justice to all those who by notable contributions have brought this complex technology to its present level of sophistication.

The growth of the semiconductor technology and industry has shown a variety of patterns, many of which are common to the evolution of other technical fields. Important among those which flowed from invention of the transistor are the discovery of new properties of matter, a subsequent rapid growth derived in large part from a penetrating theoretical understanding of the new properties and the device possibilities inherent in them, an accompanying transformation of the field from a frontier province of science to a central area of engineering, and the practical possibility of forecasting the broad future shape of the field from the properties of the materials.

Of these events, the recognition of a new property of matter, the injection into semiconductors of excess mobile minority charge carriers of useful lifetime, was the key. This phenomenon is essential to the transistor and to the junction diode and effectively determines their properties. Once this phenomenon was understood the general character of subsequent growth was predictable. Transistor technology therefore depends for its existence on a material property whose existence was not even suspected 15 years ago.

History

The history of transistor devices resembles that of other device technologies, particularly those which have followed it in the development of the solid-state field. It began in the nineteenth century and moved slowly but with gathering speed until the time of the invention of the transistor. From that point, which made a radical break with the past, major steps in device concepts and process technology followed each other in swift succession. Preceding the invention of the transistor and essential to it were improvements which had been made in semiconductor materials throughout the preceding decade or more. The transistor and other device inventions which followed created powerful new stimuli for further improvements of the materials.

Semiconductors can be characterized by the increase in charge-carrier concentration which accompanies increase of temperature. This effect was first noticed as a decrease of resistance with rise of temperature in Faraday's experiments on silver sulphide. Rectification was observed some 40 years later, and the Hall effect was first seen in 1879. Various advances both in technology and understanding were made with the years. The discovery of the "cat's-whisker" detector for radio, and the later development of copper-oxide and selenium power rectifiers stimulated both scientific and engineering advances. This work, however, gave little, if any, hint of the revolution that was to come.

The improvements in materials which were to lay the foundation for the discovery of injected carrier action began with a new emphasis on silicon point-contact diodes as microwave radio detectors. Silicon and germanium were studied extensively at the Bell Telephone Laboratories and Purdue University, respectively. Study of germanium was stimulated by its similarity to silicon and its lower melting point. Nearly a decade of work in the purification of germanium and innumerable ingenious experiments preceded the invention of the transistor by Bardeen and Brattain in December, 1947.[1]

[1] J. Bardeen and W. H. Brattain, "The transistor, a semiconductor triode," *Phys. Rev.*, vol. 74, pp. 230–231, July 15, 1948; "Physical principles involved in transistor action," *Phys. Rev.*, vol. 75, pp. 203–231, July 15, 1949.

Their work was soon followed by the suggestion that excess charge carriers opposite in sign to those characterizing the material at thermal equilibrium could be injected into germanium and passed from electrode to electrode. The validity of this concept was underscored by the work of Shockley, Pearson, and Haynes, and will no doubt be demonstrated to coming generations of students by their study of and repetition of the classic Haynes-Shockley experiment.[2] This experiment determines clearly and quantitatively the mobility, lifetime, and effective sign of charge for the injected minority carriers.

Implicit in the new understanding was the fact that the charge-carrier densities could be characterized by a Fermi-Dirac distribution in energy and were described to good accuracy by the familiar Boltzmann distribution. This meant that the injected excess carrier densities increased by the factor e when the injection potential increased by kT/q. In theory, then, injected carrier densities and therefore currents could be increased by a factor of 10 for each increase of approximately 60 mv in injection voltage, thus allowing very large forward currents at low forward voltages.

Still other consequences of importance were implicit in these results. The two oppositely-charged types of carrier, the conduction electron and the hole, permitted most of the semiconductor bulk to remain electrically neutral and thereby circumvented significant space-charge limitation of current density. The carrier mobilities and large carrier concentrations obtainable led to the possibility of current densities of many thousands of amperes per square centimeter in materials with dielectric constants of 12 to 16. At the same time, the absence of need for a heated filament and the exponential dependence of current on voltage opened the opposite possibility of operation at minuscule currents and therefore powers. The subsequent history of transistor devices is the story of the realization of these marvelous possibilities.

Most of these possibilities were delineated explicitly or implicitly in Shockley's synthesis of device theory which closely followed the recognition of the existence of excess minority carriers.[3] From here, theory and experiment fed upon each other with steady improvement and with spectacular advance in the control of the properties of germanium and silicon leading the way. This work on crystals[1] by demonstrating dramatically the importance of purity and crystallinity in studies of solid materials, has probably made semiconductor technology's most important indirect contribution to scientific and technological progress.

A tremendously improved control of the composition and structure of the materials, and thereby of devices, is the essence of this advance. Perfection of crystal-pulling techniques,[4] the invention of zone-leveling,[5] plus a wide variety of supporting techniques in the preparation of raw materials and the subsequent handling of the purified ones reduced undesired constituents of the new single crystals by factors of 1000 or more. "High back-voltage germanium" with perhaps 10^{15} impurities per cubic centimeter was replaced by intrinsic germanium containing 10^{12} or fewer impurities per cubic centimeter. Control of crystallinity and of chemical-purity concentration was followed by techniques for similarly reducing the concentration of other defects, such as dislocations. Hand in hand with the perfection of means for removing or avoiding undesired chemical or physical defects came techniques for introducing many of these same impurities or defects in a highly controlled fashion. Substantially all of the present techniques for control of the form and characteristics of junctions are the outcome of such work.

The technological possibilities of the new materials and the transistor devices were obviously large, and the problems of development and manufacture soon accompanied those of research. Control and understanding of the structure and behavior of the junction surfaces lagged far behind the advances in bulk properties. Even today most changes in the behavior of diodes and transistors during normal use result from changes at the junction surfaces. A fully satisfying description of surface structure and behavior is still evolving, but in the most stable devices yet developed surface changes have been minimized by application of a simple rule for design and manufacture: "seal the junctions clean, dry, and very hot." The lesson to be learned in the advances made through refinement of materials has been repeated in this technique of improving reliability. Control of composition and structure is the common factor in these parallel developments.

The decade since measurements on junction diodes and junction transistors were first reported[6,7] has witnessed major advances in device concepts, process techniques, materials properties, and in the device performance sought through these improvements. The levels of performance reached in today's multitude of devices are surveyed in the closing section of this paper. Quite aside from the specifics of today's device realities and tomorrow's device possibilities are influences which the transistor and its technology have had on engineering and science. These are the subjects of the next section.

Impact on Technology and Science

The swift advance of semiconductor-device technology has had significant influence, both direct and indirect, on many technical fields. Particularly important for both technology and science have been the lessons taught concerning purification of materials and control of their composition and structure. Also of broad significance in many areas are the improvements in digital computers arising from the transistor work. The speed, power, reliability, cost, and size advantages of semiconductor devices have also modified innumerable other applications. Effects found in single-crystal junction devices have become in some cases important tools in studying the structure of solids. Finally, the highly rational theory of semiconductor devices has not only re-emphasized the importance of such theory but has stimulated development of unified theories covering devices of many types.

The close relation between materials improvements and the transistor technology showed the power of single-crystal studies and deliberate control of crystal composition. It stimulated attempts at purifying and controlling other crystalline solids, both directly by providing techniques, such as zone-refining, and indirectly by showing the advantage of such an approach. At the same time, the emphasis on purity and control was extended in the semiconductor technology from bulk properties to surface conditions. There can be little doubt that semiconductor successes have underlined most distinctly the importance of understanding and controlling the composition and therefore the properties of materials of many kinds.

Of the various semiconductor-device applications, use in computers will almost certainly have the widest influence on other areas of technology. Although the digital computer was already highly successful, the transistor brought increases in computer speed, complexity, and reliability which touched off an explosion in computer manufacture and use. Engineering and science, like the rest of our society, have felt only the beginnings of the changes which will result from the new machines. Other semiconductor-device applications range from dc clamp-on ammeters to low-noise microwave amplifiers. This applications revolution seems sure to grow in diversity and complexity. The new devices, until superseded by major new invention, seem certain to rule the electronics of the future.

The Esaki diode is an example of a new and useful junction device which is simultaneously a tool for the study of solids. Already used in several applications and under study for a variety of others, it provides a beautiful electronic instance of quantum-mechanical tunneling through a potential barrier. Careful study of the details of the voltage-current characteristic of this device, particularly at low temperatures, has given considerable data on phonon spectra in the electronic semiconductors.

Beginning with the publication of the first *p-n* junction paper, theory has charted much of the course in device development. Even the first junction transistors showed remarkable agreement with the predictions. This pattern has continued. Transistor theory has evolved in two directions, both towards more detailed understanding and prediction, and toward coarser and simpler pictures of transistor operation. The latter trend was instrumental in evoking the charge-control theory which describes in a common language[8] the fundamentals of devices so diverse as photoconductors, electron tubes, and the transistor. This generalization of device theory may be extended still further with the development of a gain-band product given by the reciprocal of relaxation time multiplied by the ratio of two energies.[9] Still another form of a gain-band product can be found as the quotient of a change in controlled power divided by the change in control energy. These unifications of viewpoint have been a welcome advance among, and byproduct of, increasing specialization. This is perhaps only an expression of the trend toward a more unified viewpoint in engineering which has accompanied the closer approach of engineering to the basic sciences.

Status and Future

Semiconductor technology has become the basis of a rapidly maturing industry making a wide variety of devices by use of many complex processes and techniques. The skills of the factory and the market are largely supplanting those of the research and development laboratories. Beyond these easy generalizations other directions of progress common to most device technologies can be seen. Present trends in materials, structures, performance, and function are rooted in the past and provide the raw material for an outline of the future.

Materials limit present devices and will determine those to come. Concepts of structure and techniques for achieving them must work within the limits set by nature. Pressure for improvement of devices is based on the insatiable demands of users for more speed, power, and reliability, and less cost. For the most part, even the search for lower noise is but the opposite face of the demand for greater power. At the same time, sharpened perception of applications needs and of device possibilities stimulates development of numerous new and specialized devices. This section discusses present and future prospects in materials, then surveys the present and future of some of the principal devices with regard to speed, power, and reliability, and ends with speculation on what lies still further beyond.

Among the materials, germanium and silicon have carved out major and secure uses and contend with each other and with some of the secondary materials for a

[8] E. O. Johnson and A. Rose, "Simple general analysis of amplifier devices with emitter, control, and collector functions," Proc. IRE, vol. 47, pp. 407–418; March, 1959.

[9] E. O. Johnson, private communication, September, 1960.

variety of special applications. Various of the 3-5 compounds have already proved their worth where some superior property offers a performance gain to balance the increased difficulty in material refining and device fabrication. To date germanium has been the usual first choice when cost per device was the prime consideration. Progress in silicon fabrication may change this balance. In low-frequency power transistors, germanium appears to have a permanent niche because of the relatively large currents—up to 100 amperes or more—achievable in rather simple devices. In diodes, gallium arsenide is finding uses based on its very high carrier mobilities and good high-temperature performance. Indium antimonide is the major choice for Hall effect devices, and gallium antimonide for low-noise Esaki tunnel diodes, again because of special characteristics. As technology evolves, these materials will become purer and cheaper, as have germanium and silicon. The 3-5's will become relatively more important, but the older materials seem certain to dominate the field.

Perhaps the chief factor insuring leadership for the elemental semiconductors is their relatively simple metallurgy. In formation of junctions in or contacts to the compound materials, reaction of the alloying metal with each of the elements of the compound material must be considered. This restricts the choice of alloying metals severely. In addition, virtually every 3-5 compound has a high vapor pressure, and crystal growth is thereby complicated. It is sometimes necessary to carry out alloying operations in pressure chambers for the same reason. By contrast, despite difficulties, the processing of germanium and silicon offers no problems.

Device structure, as well as materials, determines performance. Among the major performance characteristics, reliability tends to be the one most nearly the same for transistors and diodes. In both silicon and germanium devices, the first reliability goal, that of device parameters permanently stable during normal use in ambients near room temperature, appears to be in sight. Clean junctions, sealed vacuum-tight at high temperatures in the absence of water vapor, seem common to all successful processes so far developed, including the very important one of a surface oxide on silicon. The future will bring use of such techniques on ordinary as well as premium devices. A further goal is the raising of the temperatures at which the devices are permanently stable. These will probably go as high as the temperatures at which the devices are electrically useful—about 150°C for germanium and near 300°C for silicon.

Power and speed of devices are determined by the device material and structure and are to some degree mutually interdependent. The diode is the most fundamental of the new devices and shows the widest ranges in speed and power-handling ability. This superiority results almost directly from the simplicity of diode structure—in ideal principle all diode currents flow at right angles to the junction and none flow parallel. It is precisely the flow of base current parallel to the transistor junctions which allows the transistor to perform its complex functions and at the same time restricts its speed power because of power losses in lateral current flow through layers of substantial sheet resistance.

The power-handling ability of diodes and transistors is set by both thermal and electrical considerations. Use of diode-junction areas of a square centimeter or more, together with the provision of forced cooling, has resulted in units with peak current ratings measured in thousands of amperes. At the same time, use of very thick junctions fabricated of high-resistivity silicon has produced devices with peak voltage ratings of thousands of volts. Individual diodes rectify tens of kilowatts and rectifier combinations for conversion of a megawatt have been built. The very high rectification efficiencies obtainable with germanium and silicon rectifiers promise continued effort to raise the maximum ratings of such rectifier combinations as well as of the individual units. In contrast to these maximum powers, reverse currents of silicon diodes are frequently less than 10^{-10} amperes and gallium-arsenide diodes have shown reverse currents in the 10^{-13}-ampere range.

P-N junction devices are subject to the usual frequency-scaling laws of electronics and must be reduced in size as their speed is increased. The evolution of high-speed junction diodes brings them ever closer in gross form to the point-contact diodes which preceded them. This general parallelism of structure provides a fine example of the evolutionary principle that form tends to follow function, producing a convergence in general appearance between members of different evolutionary lines specializing to occupy similar ecological niches. Silicon-computer diodes (now operate in the nanosecond range) and still faster gallium arsenide diodes have been reported. Structures in the tenth-nanosecond class will almost certainly evolve.

The varactor diode, however, provides the present outer bounds in both speed and power of semiconductor device performance at high frequencies.[10] Cutoff frequencies ($Q=1$) above 200 Gc have been reached in germanium, silicon, and gallium arsenide. Gallium-arsenide devices operating at liquid-nitrogen temperature have given parametric amplification in the degenerate mode with noise temperatures as low as 30°K thus setting the lowest minimum so far in the power-handling ability of semiconductor devices. At the other end of the power spectrum, varactor diodes of larger area, used as harmonic multipliers, have produced output powers of a few watts at a few Gc.

Although the advance in diode speed and power will continue, increase of power at high frequency must encounter limitations imposed by frequency-scaling laws. If, in these devices, linear dimensions are made inversely proportional to operating frequency, device impedance

[10] This, of course, excludes the optical maser, which is not a *p-n* junction device.

at operating frequency[11] remains fixed, as does the device Q at operating frequency. However, the junction area then decreases inversely as the square of frequency and, because power per unit area is nearly an electrical design constant, power-handling ability at a fixed impedance level also varies as the inverse square of operating frequency. This limitation applies to diodes and transistors alike. The circumvention of its effects by development of successful means for operation at very low impedance levels and by series connection of units is a major challenge to the years to come.

Advances in the speed and power of transistors have paralleled those in diodes. Cutoff frequencies have increased from the few tens of megacycles seen in the first point-contact transistors and in early grown junction transistors to the several gigacycles of today's fastest diffused-base units. Major steps in this evolution to greater speed were the concept of the thin base-region, thick collector-barrier transistor, and the development of diffused-base technology to realize this structure.

Again, as in diodes, the primary tool in achieving increase of speed has been the reduction of dimensions. Minority-carrier transit distances were cut by diffusion fabrication of thin base layers. A wide variety of techniques have been developed for achieving small electrode areas. These range from ball-alloying through jet-plating plus alloying, and evaporation plus alloying to the use of photolithography.

As indicated previously, the power-handling ability of transistors has stayed well inside that of diodes and seems certain to do so in the future. The difficulties and challenges to the expansion of power and speed capabilities of transistors are closely similar to those in diodes. By way of comparison, transistors have controlled powers of several kilowatts at low frequencies, have given outputs of a few watts at a few hundred megacycles, and work is underway on units to provide a watt or more in the low gigacycle range.

The *p-n-p-n* diodes and triodes now appear to be the most important of the many devices related to the diode and transistor. Their major impact has been in the use of *p-n-p-n* triodes as controlled rectifiers and pulse generators. Devices switching tens of amperes at many hundreds of volts in a few nanoseconds have already been put into service. It appears that the *p-n-p-n* structures will remain intermediate in power capabilities between transistors and diodes and will be restricted to speeds lower than those of transistors.

The transistor art has spawned many other devices. Many of these have more limited design ranges in speed and power and justify their existence by utility in special applications. Various thermistors, Hall-effect devices, microwave protective limiters, and the field-effect transistor are other offshoots from the principal line of development. Many of these do not depend on excess injected minority carriers for their operation, but nonetheless are derived from transistor technology. The Esaki diode, for example, which depends for its operation on a quantum-mechanical tunneling effect not imagined in or relevant to the transistor theory, is a single-crystal *p-n* junction device built by transistor techniques from transistor techniques. It appears to have established a niche in low-noise amplification around 1 Gc, as well as in some level-setting and triggering applications. Despite difficulties, active study continues on Esaki units for computers, frequency conversion, and microwave-oscillator service.

The broad outlines of the future can be seen. The technology of the more complex and difficult compound semiconductors will gradually be mastered, and their importance will therefore increase. Germanium and silicon will almost surely remain the basic semiconductor materials. Reliability will increase, thus allowing higher device temperatures. Scaling laws of frequency, power, and impedance dictate the use of ever lower impedances and smaller dimensions in the evolution toward higher power and greater speed. Expression of these limitations in terms of specific powers and speeds seems dangerous. Forecasts of this kind have almost always been regarded as extravagant at the time and as ridiculously conservative a generation later.

Accompanying the growth in power, speed, and reliability will be an increase in device complexity. This includes not only the development of more refined designs for particular service and numerous specialized types of devices, but also the development and use of multiple devices and integrated circuits. The use of several diodes and several transistors in a single encapsulation provides economies of manufacture and use. Combining of these with passive components provides additional advantages in some instances. Multiple devices, integrated circuits, and individual semiconductor devices will all play important roles in the future of electronics.

In the far future, displacement of the diode, transistor, and allied components by now unimagined devices seems possible. However, such new devices will almost certainly find competition with diodes and transistors more difficult than these devices have found the competition with their high vacuum and gaseous predecessors. The requirements for effective competition can be seen in the limitations of the semiconductor devices. The diode and transistor, useful as they are, show objectionable temperature dependence. Breakdown fields and relatively low charge-carrier velocities restrict their powers and speeds. Any successful major competitor to semiconductor devices must almost certainly show marked advantage in one or more of these characteristics, and at the same time must equal or surpass them in simplicity and cost. Perfection of new solid-state triodes might bring an advantage in speed, but so far the trend in such devices has been away from the originally-conceived schemes and toward the transistor materials and structures, and therefore toward acceptance of their limitations.

Solid-State Devices Other than Semiconductors*

B. LAX† AND J. G. MAVROIDES†

Summary—**The solid-state properties of matter are of interest not only to the research scientist but also to the engineer who has translated the findings of basic research into endeavors of great technological significance. The research in ferromagnetism has led to the magnetic amplifier, which for certain applications is superior to amplifiers using vacuum tubes and to the development of new materials such as ferrites, which are now finding use at radio frequencies in pulse transformers, radio frequency inductors, antenna rods, magnetic core delay lines, computer elements, and magnetic recording media. Ferrites and antiferromagnetic materials are now also widely used at microwave frequencies and millimeter wavelengths as nonreciprocal phase shifters, load isolators, filters, ferrite switches, ferrod radiators, modulators and power limiters. Such phenomena as piezoelectricity, ferroelectricity and magnetostriction have resulted in the use of ultrasonic waves for the study of phonon-electron and phonon-spin interactions as well for such practical devices as the detection of imperfections and faults in solids, electromechanical transducers, resonators, filters, delay lines, computer memories, ultrasonic soldering, cleaning, drilling and cutting, and strain and acceleration gauges. Dielectric materials have found applications as prisms, polarizers, restrahlen plates and more recently in dielectric wave guides and fiber optics. Advances in low-temperature techniques have facilitated the study of resonance phenomena in paramagnetic materials, and this has led to such exciting new devices as the solid-state maser and the laser; from a study of superconductivity at these low temperatures there have emerged such new devices as the cryotron for computers, frictionless magnetic bearings for gyroscopes and other applications, and infrared detectors. The future promises many applications employing as yet unexploited phenomena in solids involving electrical, mechanical, magnetic and optical effects.**

HISTORICALLY, solid-state components are as old as technology itself. We may classify these devices in terms of the physical phenomena which are involved. Thus the phenomenon may be dielectric, optical, electrical, mechanical or magnetic, the latter of which in turn may be subdivided further into paramagnetic, ferromagnetic and ferrimagnetic. In this broad classification a variety of materials and their special properties may be included, and in some cases in more than one of the above categories. Thus, for example, we are not only interested in the dielectric properties of materials for their role in electrical circuits but in optical components as well. It is the latter property, indeed, that was one of the earliest uses of solid-state phenomena, namely, the spectrometer by Newton, the telescope by Galileo, and the microscope by Leuwenhoek. Another device, one as old if not older, is the magnetic compass. In this review, however, we shall not try to bridge the gap between early history and modern times, but shall restrict ourselves to the twentieth century, and particularly to the last 50 years. We shall emphasize the modern developments which exploit the complex properties of solid state materials involving piezoelectric, magnetostrictive, ferroelectric, superconducting, ferro- and ferrimagnetic, and resonance as well as optical phenomena. These have led to such devices as nonreciprocal circuit elements, computer components and such exciting new developments as microwave and optical masers.

Ferromagnetic Devices

Magnetic Amplifier

Magnetic amplifiers and related devices whose operation depends on magnetic saturation are among the oldest solid-state electronic devices [1]. They were first studied before the turn of the century. However, they did not become an important technological factor until fairly recent years when improved magnetic materials [2] with rectangular hysteresis loops such as super-malloy, mu-metal, hipersil, etc., and efficient solid-state rectifiers enabled them to compete successfully with vacuum tubes and rotating amplifiers in the performance of a wide variety of functions.

The basic principal of operation is shown in Fig. 1, where the flow of ac current in the output circuit is controlled by adjusting the dc current in the input which determines the degree of saturation of a magnetic core, as shown by the hysteresis loop in Fig. 2. When the core is saturated, all the ac voltage appears across the output. For nonsaturation, very little voltage appears; thus a small dc power can control a much larger ac output power—hence the term magnetic amplifier.

Magnetic amplifiers have been used primarily to control ac machinery and power supplies at 60 and 400 cycles. More recently, amplifiers have been used for controlling power from 10 to 100 Kc using metallic cores, and to 10 Mc using ferrite cores [3]. At the lower frequencies magnetic amplifiers can control powers ranging from a microwatt to over a million watts [4] and with an amplification factor in some cases much greater than 10^4.

High-Frequency Ferrite Components

As the frequency of electronic circuitry increased in many applications prior to World War II, it was necessary to make thin metallic ribbons and tapes for transformers and powdered iron for core material in order to

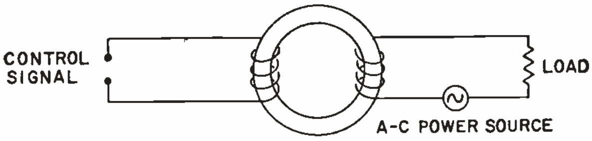

Fig. 1—Basic magnetic amplifier circuit. The direct current through the control winding determines the degree of saturation of the core. When the core is completely saturated, the full ac power appears across the load.

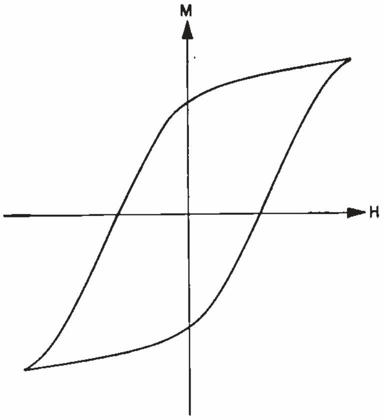

Fig. 2—Ferromagnetic hysteresis loop. Here *H* is the magnetic driving field and *M* is the resultant magnetization.

reduce the high-frequency eddy current losses. The solution to this problem was offered by the use of ferrite materials which are magnetic insulators with very high resistivity and therefore very low eddy current losses, which of course increase as the square of the frequency. The first proposal for high-frequency application was made in Germany in 1909 by Hilpert, who first synthesized such ferrites [5]. However, the practical development and exploration of these materials did not come about until Snoek [6] from the Phillips Laboratories in Holland carried out extensive investigations on the high-frequency properties of such materials as manganese and nickel ferrite well into the UHF region. Today we have a large variety of ferrites, often of mixed composition, with copper, magnesium, manganese, nickel, zinc, cobalt, as the divalent ion in the spinel structure for many of these applications. The specific applications which are of greatest practical interest are pulse transformers, television deflection transformers and yokes, radio frequency inductors of fixed and variable variety, ferrite antenna rods, and magnetic core delay lines.

Although the ferrites have smaller hysteresis losses than the magnetic metals, the saturation magnetization which ranges from about 3000 to 5000 gauss is much lower (by almost an order of magnitude), so that at lower frequencies the prohibitive size makes their use less desirable. Another property of ferrites which is utilized in the application of the antenna rod is their large permeability at radio frequencies, which may be of the order of 1000 or more. This permits the size of the antenna rod to be very small. Furthermore, the magnetic antenna has a better signal-to-noise response than the electrical counterpart since the electrical component of noise is usually larger than the magnetic.

Magnetic Recording

Perhaps one of the most popular applications of remanent or permanent magnetization of materials is in the tape recorder. Although most of us think of the tape recorder as a modern invention, of the postwar era, the original patent was obtained by Poulsen at the turn of the century [7]. However, it did not realize its full potential until relatively recently.

The basic phenomenon of remanent or permanent magnetization is of equal importance for commercial and military use of magnetic drums in computers. It is known that many magnetic materials possess hysteresis loops; this property permits them to be set in a permanently magnetized state by appropriate inducement. The amplitude of the magnetization will depend upon the strength of the magnetic induction, which may be applied by a current through a coil or by the poles of a small electromagnet. For example, tape moving past the recording head when a signal is applied is left in a magnetized state, with a remanent magnetization proportional to the signal (see the Schematic drawing in Fig. 3). The inverse process requires that the tape induce a weak signal, proportional to the magnetization found at any point on the tape, in a magnetic circuit, without seriously affecting the state of magnetization found in the tape. Usually there is a small loss of signal, although the fidelity is not affected by successive runs. The direction of magnetization of the tape may be longitudinal, *i.e.*, parallel to the direction of motion, perpendicular, *i.e.*, at right angles to the surface of the tape and to the direction of motion; or transverse, *i.e.*, parallel to the surface of the tape but perpendicular to its motion.

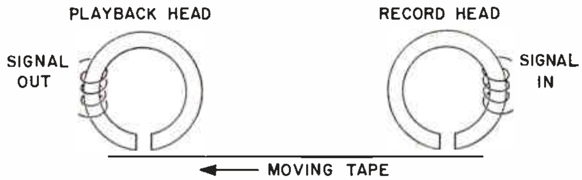

Fig. 3—Schematic representation of a magnetic recording and playback system.

The medium utilized for recording may have one of several geometric forms—wire, tape, or a rigid frame such as that in a magnetic drum. Metallic or nonmetallic material may be used. Metallic material in the form of a carbon steel wire was first used. Since then tungsten steel and stainless steel, whose magnetic properties are obtained by appropriately cold working and heat treatment, have been utilized [8]. The nonmetallic materials most commonly used are iron oxide powder, in small particles of a micron or less, incorporated in a nonmetallic binder. These particles are usually in the form of needles, which are often oriented by a magnetic field within the coating, usually flexible film of acetate or mylar. The most widely used oxide powders are γFe_2O_3 (red oxide) and, less extensively, Fe_3O_4 (magnetite or black oxide) [9]. The two properties that are important in the application for a recording medium are coercive force and magnetization.

For metallic materials the coercive force may range from about 40 to several hundred oersteds, and the remanent magnetization may be as high as 10 to 12 Kg, whereas for nonmetallic oxides the coercivity may have typical values of from 200 to 300 oersteds, and the remanence from 600 to 1200 gauss.

Fidelity of reproduction is one of the primary aims of recording. The nonlinearity of the magnetization curve however results in serious distortions. A linear transfer characteristic, and therefore, high-fidelity reproduction is achieved by mixing a high-frequency bias current with the signal to be recorded.

Electromechanical Devices

Propagation of mechanical waves in solids has been considered theoretically for well over a century, and has been the major topic of two volumes by Lord Raleigh [10]. From a fundamental viewpoint the existence of such waves, called *phonons*, is of interest to physicists because of their interaction with electrons in semiconductors and metals, or with magnetic spins in other solids. From a device viewpoint phonons acquired more practical interest when electro-mechanical interactions were observed as early as 1847 with Joule's discovery of magnetostriction [11], and in 1880 with the Curie brothers' discovery of piezoelectricity [12]. Today ultrasonic waves are used for a great many purposes in solids, including the detection of imperfections and faults in solids, and the composition of polycrystalline metals, as well as in more practical processes such as ultrasonic drilling and cutting, and in transducers, resonators, and filters [13].

Piezoelectricity

It has been found that when certain crystals are subjected to pressure, electrical charges appear on their faces; it has also been found, inversely, that voltages applied to the faces of a crystal produce corresponding changes in the sample dimensions. This phenomenon is called the piezoelectric effect. It exists only in crystalline materials which do not have a center of symmetry. Thus, when a stress is applied, the center of gravity of the positive and negative charges can be displaced relative to one another so that the permanent electric dipole moment is altered. There are a number of crystals which exhibit this property. Among the more common materials are quartz, rochelle salt, ammonium and potassium dihydrogen phosphate, and tourmaline.

Piezoelectricity is used as an electromechanical transducer in which electrical energy is converted to mechanical energy and vice versa, and also as a resonator for frequency control of oscillators, time standards and highly selective filters. In the latter application, which was introduced by Cady [14], the piezoelectric effect drives the crystal into mechanical vibration, which in turn reacts back to control the electrical impedance of the circuit. Quartz has been used almost exclusively as a resonator, since it is highly stable, has very low internal losses, and can be cut so that its properties are independent of temperature. In the laboratory, Q's as high as 6×10^6 have been measured.

However, it was as a transducer that this phenomenon first found use as a device. During World War I, in order to combat the submarine menace at the request of the French government, Langevin [15] began research which led to the development of a sonar system which employed quartz piezoelectric elements. Since then, this transducer action has been used for other devices such as phonograph pickups, ultrasonic delay lines, ultrasonic soldering and cleaning, and strain and acceleration gauges. In electromechanical transducers the maximum sound generation is obtained when the frequency of the applied electrical voltage coincides with one of the modes of vibration of the crystal element. In general, the smaller the dimensions of the element the higher the natural frequency ν. For example, for free-free thickness resonant vibrations of a slab, $\nu = nv/2t$ where v is the velocity of sound in the medium, t is the thickness of the slab, and $n=1, 2, 3$, etc. The dimensions thus set an upper limit to the highest frequency possible for sound generation. Using very thin slices of quartz fundamental frequencies just under 100 Mc are obtainable. With harmonic operation this technique sets an upper limit for ultrasonic wave generation of about 1000 Mc. More recently, new techniques for piezoelectric sound generation have been developed. Ultrasonic waves have been excited at the optically flat surface of quartz rods by placing the surface at the high electric field region of a microwave cavity [16]. These waves then propagate into the interior of the rod. The frequency of these waves has been extended to about 30 kMc, and it appears that the availability of electromagnetic driving fields now determines the highest frequency of ultrasound [17]. These microwave ultrasonic frequencies have been used in spin resonance experiments which have provided basic information on the spin-phonon interactions and selection rules in paramagnetic host crystals [18] such as MgO with Fe^{3+} and Mn^{2+} and ruby with Cr^{3+}. Another new type of generator employs semiconducting intermetallic compounds, such as InSb and GaAs, which have a zinc blende structure with no inversion symmetry and which are piezoelectric [19]. A junction is produced by depositing a thin metallic film on the semiconductor. The piezoelectric action takes place in the back-biased junction depletion area, which sustains all the applied voltage and behaves as a piezoelectric crystal. Since this depletion area is very thin, its frequency of operation is very high; by varying the back bias, the thickness of the depletion area and the resonant frequency of the transducer are varied accordingly. Depletion layers of the order of 0.1 μ, then, could provide an operating frequency which could exceed 10 kMc, with efficiencies about 100 times greater than any other known technique. At the present time a working model at Bell Telephone Laboratories operates at 600 Mc with a 5 per cent (30-Mc) bandwidth, which should provide storage of large amounts of information for computers [20].

Ferroelectricity

Ferroelectricity, the electrical analogue of ferromagnetism, involves the spontaneous alignment of electric dipole moments below the Curie point by material interaction. Ferroelectric materials are characterized by hysteresis loops such as that shown in Fig. 2, except in that the electric field E replaces the magnetic field H and the electric polarization P replaces the magnetic polarization M. Thus, by subjecting the material to an electric field a remanent polarization will persist, even after the removal of this field; and when thus polarized the substance exhibits piezoelectric behavior. Therefore, ferroelectric materials can be used as transducers and resonators in much the same way as piezoelectric crystals. Ferroelectric substances such as barium titanate have the highest known electromechanical coupling coefficients and are frequently used, consequently, as underwater sound transducers and other types of pickups and delay lines. However, because of the relatively large hysteresis losses, temperature variations and aging effects of ferroelectrics, piezoelectric materials are usually preferred for high-Q resonators. These ferroelectrics may be employed either as single crystals or as rugged ceramic material which may be cast in any desired shape for special applications. By using single crystal rather than polycrystalline ceramic ferroelectrics, the squareness of the corners of the hysteresis loop can be improved. Such square hysteresis loops have a potentially important use in information storage devices. Ferroelectricity was first discovered by Valasek [21] in 1921 in Rochelle salt, which is piezoelectric above its Curie point; however, the most important ferroelectric material today is barium titanate, which was discovered in 1942 and developed shortly thereafter at M.I.T. [22] for ferroelectric applications. Since then, other materials of the Perovskite structure and of other structures have been found to be ferroelectric [23].

More recent applications [24] of the electromechanical property of piezoelectric materials are the development of ferroelectric voltage transformers and ferroelectric electromechanical filters. The voltage transformer is a simple device in which the driver sets the ferroelectric specimen into vibration at one of its natural modes. The voltage output is taken off at the other end of the crystal, as shown in Fig. 4, at a lower current level but at a much higher voltage. The output voltage, which can be as large as 1000 volts rms and which can be generated with a bar of the order of 6 inches, is limited by the electrical breakdown or depolarization effects that are due to heating of the rod. These types of devices are much simpler and smaller than the more conventional high-voltage coil or magnetic transformers.

The other interesting device is the ferroelectric filter, which is essentially another use of the transformer element just discussed. The filtering action comes about from the high Q of the mechanical resonance required for transforming the input to an output signal. For many applications these filters may very likely replace large single crystals of quartz, since they are easily molded and fabricated. Additional flexibility is possible from composite filters made of both ferroelectric and magnetostrictive materials.

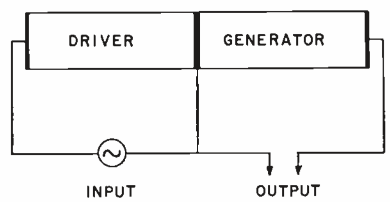

Fig. 4—Ferroelectric electromechanical voltage transformer. For maximum output voltage, the over-all length of the rod is made mechanically resonant at the electrical driving frequency.

Magnetostriction

Magnetostriction is a well-known phenomenon [11] in which the mechanical dimension of a magnetic material is altered as the magnetization is varied; and in which, conversely, the magnetization is altered as the dimension is changed. Thus, an alternating current applied through a coil wrapped around a specimen can induce mechanical vibrations in it; and, alternately, mechanical vibrations set up in such a specimen can transform the mechanical energy into electrical energy in a coil wound around it. The ideal material for such devices would have a large magnetostrictive constant, high permeability, low losses and a low Young's modulus. The material that fulfills these requirements most closely is nickel, which has been widely used for magnetostrictive transducers in applications very similar to those of piezoelectric devices. Ferrites also appear to have promise in this respect [25], although their electromechanical coupling is smaller; however, they are suitable for high-frequency filters in the Mc range, whereas nickel magnetostrictive devices operate best in the 20 to 50 kc range. A unique advantage of the magnetostrictive as well as ferroelectric mechanical filter is the characteristic (shown in Fig. 5) of remarkably steep sides with a flat top, which makes such filters superior for many applications to the quartz filter. The magnetostrictive properties of magnetic ma-

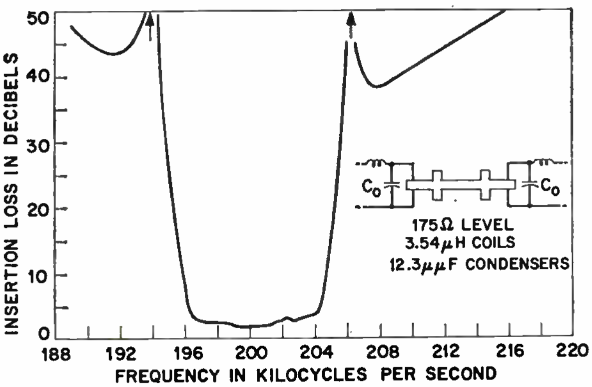

Fig. 5—Measured attenuation for a two-section mechanical filter made from barium titanate ceramic. [*After* W. P. Mason, "Physical Acoustics and the Properties of Solids," D. Van Nostrand Co., Inc., Princeton, N. J., p. 146; 1958.]

terials have also been used to construct delay lines, particularly for low-speed computer applications.

Dielectric Materials

Optical and Infrared Devices

The more conventional optical devices, such as lenses and prisms, are well known to most scientists. However, in recent years large single crystals of quartz and various alkali halides have provided selective dispersion in different regions of the infrared spectrum; for example, NaCl is most useful from 8 to 15 μ, KBr from about 12 to 24 μ and CsBr and CsI up to 40 or 50 μ, respectively. In the infrared spectrum, elementary semiconductors such as Ge and Si have been used as lenses and as polarizers, since at wavelengths corresponding to energies below the energy gap these materials behave as conventional low-loss dielectrics. Polarizers of such materials, with light incident at the Brewster angle, have been successfully used in the wavelength region from a few μ to 20 μ. Another useful effect in these materials is associated with the anomalies in the dielectric at long wavelengths well into the far-infrared region of the spectrum. These are the so-called restrahlen frequencies, which are associated with resonances of the vibrations of ions in the lattice. At these resonances the electromagnetic wave transmitted through a thin crystal shows a peak absorption. At a slightly different wavelength the reflection shows a relatively narrow peak known as the residual ray, or restrahl. This reflection peak is utilized as a selector for narrow-band radiation to permit selected far-infrared radiation from an incandescent source. Thus NaCl gives a peak reflection at 52 μ, KCl at 63 μ and KI at 94 μ, providing sources of "monochromatic radiation" in a very simple fashion; often several of these plates are used in series to narrow the bandwidth to perhaps 5 per cent. Such restrahlen plates are also used as filters for the far infrared.

Fiber Optics

Fiber optics is a very exciting development which utilizes the dielectric properties of glass. These fibers are essentially electromagnetic dielectric waveguides analogous to those found at microwave frequencies, except in that the electromagnetic radiation at optical frequencies is reflected internally by a well-known phenomenon in optics. The angle of incidence of the internally reflected wave is well below the critical angle, known as the Brewster angle, so that there is total internal reflection. It is possible to analyze the modes mathematically and to obtain the field configuration as a consequence. In practice, when light is transmitted through such fibers the mode configuration can be optically displayed as shown in Fig 6, and readily identified in terms of the mathematical analysis [26]. Optical fibers used in bundles are finding important applications as display devices, as a snooper scope, and for illuminating and examining the internal organs of patients. It is conceivable that fibers containing optically active impurities may lead to the development of traveling-wave optical masers.

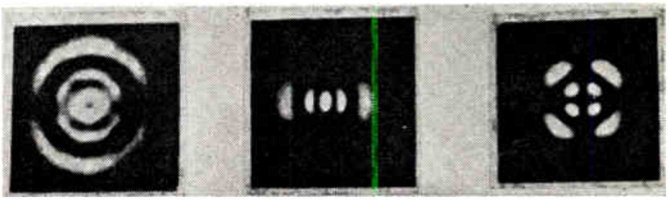

Fig. 6—Dielectric waveguide modes in the visible region. [*After* E. Snitzer, and A. Osterberg, "Observed dielectric waveguide modes in the visible spectrum," *JOSA*, vol. 51, pp. 499–505; May, 1961.

Of course, dielectric waveguides [27] are not unique to optical frequencies, but have been used at microwave and millimeter waves for some time. They operate on the principle that the electromagnetic energy is concentrated in the dielectric rod which acts as a waveguide, and that electromagnetic energy beyond the air-dielectric interface falls off exponentially. Thus the electromagnetic energy is confined within a small region surrounding the dielectric waveguide. This principle has been effectively used at millimeter wavelengths to build relatively low-loss components, including such devices as directional couplers [28].

Computer Elements

Magnetic Memories

The last decade has seen the advent of modern electronic computers, which are likely to reshape our modern technology perhaps more than any other single invention. At the heart of this modern computer lies a tiny ferrite core which serves as its memory element. The ferrite, as we have mentioned, is a magnetic insulator which in an appropriate composition possesses a rectangular hysteresis loop on magnetization. This makes it an excellent bistable magnetic memory element. A current I through a wire interleaving the memory core can magnetize it clockwise or counterclockwise, representing the binary digits 0 or 1, respectively. Usually this is done by two sets of wires which interleave a two-dimensional array of cores such as that shown in Fig. 7. Each wire carries a current $I/2$, thus magnetizing the core in one or the other direction when both wires are carrying this current in the same sense. This is known as current coincidence. In practice, a large number of these ferrite memories is utilized in a modern computer, exceeding a million in a few very large ones, such as the TX-2 Lincoln Laboratory computer and/or the IBM Stretch computer. Small cores of magnesium manganese ferrite have been engineered to give a minimum response time of 10^{-7} seconds, which is limited primarily by the domain wall motion. However, the random-access times of such systems range from 1 to 10 μsec. Therefore, in order to increase the time response and ultimately the capacity of modern computers, new memory and switching elements have been sought.

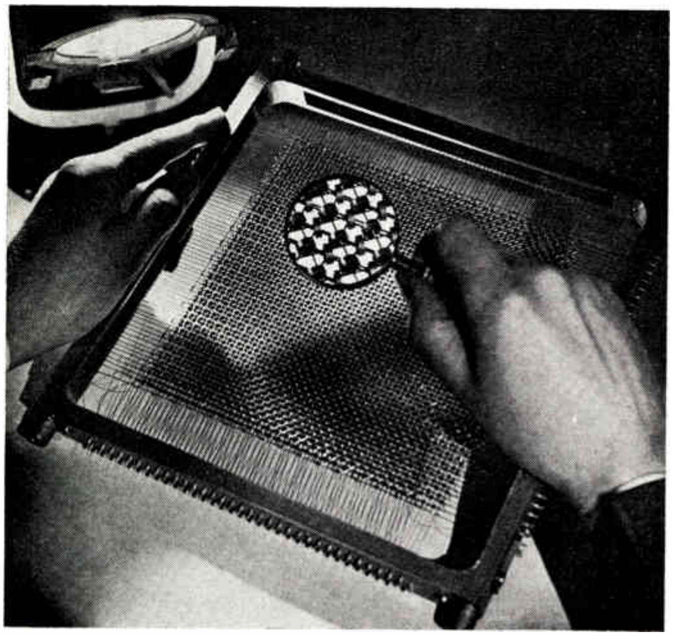

Fig. 7—Memory matrix of ferrite cores. [*After* W. N. Papian, M.I.T. Lincoln Laboratory, Lexington, Mass., private communication.]

Two approaches have been considered, one using thin magnetic films [29] and the other using cryogenic components such as the cryotron [30] and cryosar [31]. The principle of operation of thin magnetic films is quite different from that of the toroidal ferrite core, in which the two states of magnetization were in opposite directions in the toroidal plane. In the thin film, an internal uniaxial anisotropy is introduced by annealing in a magnetic field. The thin film of approximately 1000 Å is is deposited on a glass substrate. The material of 80–20 permalloy, which was first reported by Blois [32], showed a characteristic rectangular hysteresis loop. Following this work, these films have been fabricated with switching speeds of the order of mμsec, or 300 times faster than the ferrite cores in a comparable driving field of about 1 oersted. The magnetic film memories, such as that in Fig. 8, can be made as small or smaller

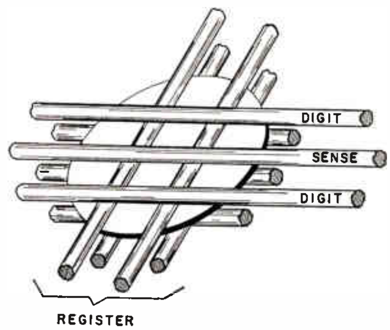

Fig. 8—Single magnetic film memory cell. The film which is supported on a glass substrate is about ¼ inch in diameter and 1000 Å thick. For high-speed switching drive lines, simulate transmission lines. [*After* J. I. Raffel, M.I.T. Lincoln Laboratory, Lexington, Mass., private communication.]

than the ferrite cores; furthermore, transmission-line techniques for magnetizing the films will permit higher-speed computers with access time well below the μsec range.

Cryogenic Elements

A superconducting switching element was first examined by de Haas and Casimir-Jonker [33] in 1935; however, it was not until 1955 that Buck demonstrated a practical device which he called the cryotron [30]. The basic principle of the cryotron depends on the existence of a critical magnetic field above which the superconducting metal becomes a normal conductor. The original cryotron utilized a small tantalum rod wound with a niobium wire. At liquid helium temperatures the tantalum wire has a critical field of the order of several hundred gauss, whereas that of niobium is of the order of 2000 gauss. Consequently, when the niobium wire is pulsed with a suitable current, the magnetic field that it creates is sufficient to destroy the superconductivity in the tantalum but not in itself. The current in the niobium wire can be smaller than that in the tantalum wire so that a small current can control a larger one, thus producing a current gain in the device. The more recent cryotron elements, such as that shown in Fig. 9, utilize small superconducting strips which cross one another and are separated by thin insulators (hundreds of angstroms thick) in which one superconducting strip controls the current in the other [34]. Usually the narrower film with the greater critical field controls a larger current in the thicker film. Cryotron loops performing the function of a memory can be made in very small configurations, possibly 100 to 1000 per cubic inch with extremely low power dissipation such that a network of a million cryotron loops would require about 1 watt of power. The switching time is now competitive with that of the thin magnetic films and is of the order of 10 mμsec. Although no computer as yet has been built utilizing the cryotron, the possibility in the near future looks promising.

Even though it is a semiconducting device, another computer element that should be mentioned in this context is the cryosar [31]. Germanium containing impurities can be made conducting at liquid helium temperatures by an avalanche process. Localized breakdown can be produced by very low fields of order of a few v/cm, permitting switching junctions of crossed conducting strips on either side of a thin germanium slab such that as many as 1000 per cm² can be fabricated on a thin wafer. Thus as many as 10^4 elements in a cubic centimeter are possible. The breakdown phenomenon is extremely fast and the time involved is shorter than that of other computing elements mentioned. A compound cryosar has been developed by McWhorter and Rediker which provides bistable elements in a coincident-voltage memory for computer applications.

At present, the difficulty with cryogenic computer elements involves the necessity of providing many leads from the low-temperature Dewar to the driving transistors at room temperature. The large number of wires required results in an undesirable heat leak. However, it appears that, in the future, low-gap semiconductors and semimetals may provide transistors and transistor-like devices [35] making it possible to contain the entire computer at liquid helium temperatures except for the output and input terminals.

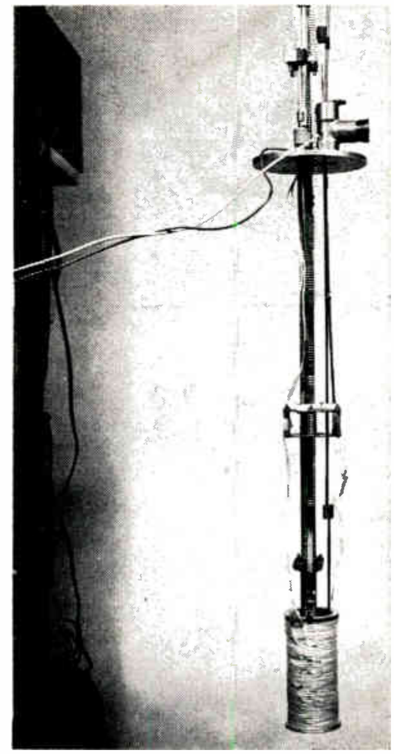

Fig. 10—Tunable *L*-band maser using superconducting solenoid to provide the magnetic field. This particular solenoid can supply up to 6500 gauss with a 1½-volt dry cell and a variable resistor. A closed superconducting circuit may be set up, after which a persistent current maintains the magnetic field and the dry cell may be removed. [*After* S. H. Autler, M.I.T. Lincoln Laboratory, Lexington, Mass., private communication.]

Other Superconducting Applications

That several other superconducting devices have been developed, in addition to the cryotron, makes this phenomenon more than an intellectual curiosity. Perhaps the superconducting magnet is the one that is likely to have the greatest technological impact. It is known that Onnes experimented with small coils of superconducting lead for making solenoids capable of producing a few hundred gauss [36]. A few years ago this idea was extended by Yntema [37], who made a coil of niobium wire to produce fields of the order of several thousand gauss. However, the first serious application was that of Autler [38], who used niobium to make superconducting magnets for use with microwave masers, as shown in Fig. 10. He wound wire which was stressed such that he was able to reach approximately 8 to 10 Kg, and took advantage of the persistent current to produce very stable fields by shorting out the battery supply. He also developed small electromagnets immersed in a helium Dewar in which the fringing field around the superconducting coils was below the critical value. However, the fields within the pole tips were about 25 Kg in a gap$\sim\frac{1}{4}$ inch. The major breakthrough was made very recently by Kunzler, *et al.* [39], at Bell Telephone Laboratories, when they fabricated niobium tin wires with critical fields in the vicinity of 200 Kg. Subsequently, niobium zirconium wires have been made by this group with smaller current capacity and critical fields of the order of 80 Kg and current densities of 10^4/cm². With appropriate technological developments it appears that superconducting magnets with fields of between 50–100 Kg should be feasible in the near future.

A number of devices based on the Meissner effect [40] and its related properties in superconductors are receiving serious consideration at this time. It is known that a superconductor below the critical magnetic field is essentially a perfect diamagnetic material; *i.e.*, the magnetic field does not penetrate the superconductor, which behaves as a magnetic mirror. Thus it is possible to suspend a magnet above a spherical lead mirror immersed in a liquid helium bath. Alternatively, a magnetic flux can be used to suspend a superconducting sphere or plate in space, thereby providing a frictionless bearing. This provides the basis for a superconducting gyroscope with possibilities for application in inertial guidance systems. Other possible applications which would utilize this type of phenomenon are superconducting motors and magnetic focusing for increasing the resolution of electron microscopes.

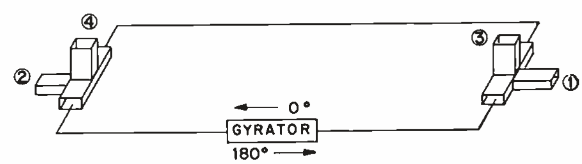
The bridge between fundamental theoretical discovery and its application to technology is beautifully illustrated by the tunneling phenomenon observed in superconductors. Approximately four years ago the far-infrared experiments of Tinkham and Glover [41] gave evidence of an energy gap in superconductors. At about that time a quantum theory of superconductivity developed by Bardeen, Cooper and Schrieffer [42] quantitatively predicted this energy gap. Perhaps the most elegant demonstration of the existence of the energy gap and the related details of the density of states was provided by experiments of Giavaer [43], in which the tunneling between superconductors separated by a thin insulating aluminum oxide film was observed. Undoubtably this phenomenon will be exploited for a number of practical devices. Already it has been suggested that such sandwiches can be utilized as sensitive photoconducting detectors in the far infrared [44].

Microwave Ferrites and Ferrimagnetics

Nonreciprocal and Reciprocal Devices

The last decade has seen a great many practical developments in solid state, but perhaps one of the most far reaching was that involving the microwave application of ferrites. A great stimulus for this work was the demonstration in 1952 by Hogan [45] of the microwave circulator utilizing the nonreciprocal Faraday rotation in a circular waveguide. Soon thereafter, Kales, Chait and Sakiotis observed nonreciprocal phase shift and loss in ferrite loaded rectangular waveguides [46]; this led to a number of devices, soon exploited commercially. The phenomenon involved in the rectangular waveguide nonreciprocal components is rather straightforward. It is known that an electromagnetic wave traveling in a rectangular waveguide possesses an RF magnetic field component which is circularly polarized at a point between the center and the side of the waveguide. The sense of circular polarization is opposite, depending on the direction of propagation. Consequently, if a ferrite specimen in the shape of a long flat bar magnetized transversely is inserted in this region of the waveguide, the polarization of the magnetic field within the ferrite remains circular. For one direction of propagation the spin dipoles of the ferrite precess in the same sense as the rotation of the RF magnetic field, thereby reacting strongly with the electromagnetic wave. For the opposite direction of propagation the precession is opposed to the rotation of the RF field, so that the interaction with the electromagnetic field is much weaker. Consequently, the phase shift is said to be nonreciprocal, since the change is much greater for the first direction of propagation then for the second. When the magnetic field is such that the frequency of spin precession differs substantially from the frequency of the electromagnetic wave, the interaction is essentially reactive. When the magnetic field is adjusted so that the frequency of precession is equal to that of the microwave frequency, then for the positive direction of propagation (i.e., when the rotation and precession are in the same sense), the ferrite absorbs the electromagnetic energy rather strongly. In the opposite direction the absorption is weak. This latter device is known as the resonance isolator.

The performance of these devices, when appropriately designed, in microwave circuits agrees well with the figure of merit predicted theoretically, based upon the loss properties of the ferrites [47]. The nonreciprocal phase shift can be used in a microwave circuit in which it forms one branch of a four-terminal network, which may consist of two magic T's as shown in Fig. 11(a). The ferrite phase shifter provides the same phase shift in the two arms for one direction of propagation but a difference of 180° for the other direction of propagation. If the microwave energy is then properly traced through such a circuit, it can be shown that it becomes a circulator such that if energy is fed into arm 1 it comes out in arm 2, if fed in arm 2 it comes out in arm 3, as indicated in the circuit symbol of Fig. 11(b). More recently, a



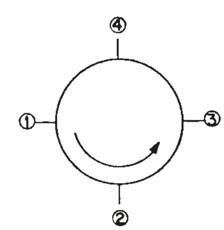


Fig. 11—Ferrite circulator. (a) Schematic representation indicating microwave circuit with either a nonreciprocal phase shifter or gyrator in one arm and magic T's in the other two arms. (b) Symbolic representation.

much simpler circulator known as the three-port or Y circulator has been developed. It is a planar junction with a 120° symmetry, and contains a ferrite rod or post at its center such that each arm is perfectly matched. It has been shown theoretically and demonstrated experimentally that under these conditions energy fed into arm 1 goes out arm 2, energy from arm 2 proceeds through arm 3, energy through arm 3 goes to arm 1, and so on. Circulators of the latter type have been constructed from the UHF frequencies of several hundred Mc well into the mm region as high as 150 kMc [48].

Isolators use a variety of ferrites, from substitutional low magnetization aluminates which are useful in the UHF region, to the barium ferrites or magneto-plumbites with high anisotropy which extend into the millimeter region to about 70kMc [49]. Beyond this range the isolators become impractical because the internal magnetic field of the highly anisotropic magneto-plumbite is inadequate to provide sufficiently high magnetic fields or resonance. This has been overcome by the use of antiferromagnetic materials at low temperatures, in which resonance occurs in internal fields of the order of 50,000 oersteds or more. Heller, *et al.*, using Cr_2O_3, have built a resonance isolator operable at 150 kMc [50].

Nonreciprocal ferrite devices have been engineered to handle high peak powers of Mw, as well as average power in the kilowatt range for use in communications and radar systems to isolate transmitters, and also receiving circuits, at low-power levels. A number of other nonreciprocal and reciprocal devices at microwave frequencies have been constructed in a variety of configurations. Dielectric-loaded coaxial line is used to reduce the size of the devices at lower frequencies [51]. The dielectric distorts the normal TEM mode and generates a longitudinal component of RF magnetic field to provide circular polarization for nonreciprocal devices. Similar techniques have permitted the use of ferrites in strip lines as well.

Another nonreciprocal device which has received a fair amount of attention is the field displacement isolator [52], which depends on the different electric field configurations which exist in the ferrite for the two opposing directions of propagation in a ferrite-loaded rectangular waveguide. When the parameters of the ferrite are suitably adjusted there is an electric field null at a ferrite-to-air interface for one direction of propagation, whereas a large field component exists for the other. By coating the interface with a lossy material a field displacement isolator with a large figure of merit can be obtained. These are usually low-power devices.

Applications using the reciprocal properties of ferrites and waveguides have also been developed. Among these perhaps the most important is the ferrite phase shifter located at the center of a rectangular waveguide and magnetized longitudinally as shown in the inset of Fig. 12. This device [53] operates on the principle that electromagnetic energy is concentrated primarily in the ferrite, due to its relatively large dielectric constant. The RF permeability is increased or altered substantially as the ferrite rod or slab is magnetized, thereby producing a large reciprocal phase shift. The principle of operation has been theoretically accounted for on this basis [54]. Another device that has been utilized in an analogous manner is a cavity resonator which can be used either as a filter or as a variable tuning device where frequency is altered by the application of an externally applied magnetic field which magnetizes the ferrite rod in the cavity [55].

Other passive microwave ferrite devices which have been developed are the single-sideband modulator, which utilizes the birefringant properties of a transversely magnetized ferrite; ferrite switches; ferrod radiators using ferrite rods often in an array [56]; and nonreciprocal isolating elements in traveling-wave tubes and traveling-wave masers.

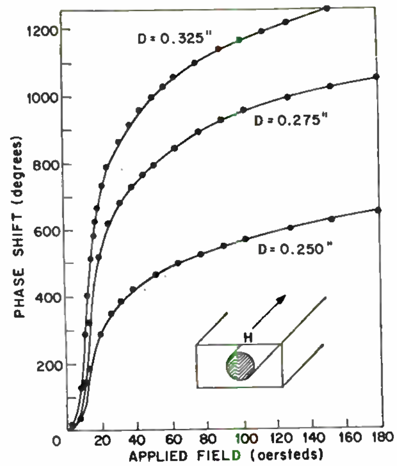

Fig. 12—Reciprocal phase shift for a longitudinally magnetized ferrite rod at the center of a rectangular waveguide as a function of applied dc magnetic field with rod diameter as a parameter. The phase shift increases sharply at the threshold thickness of 0.2 inch at *X*-band wavelength. [*After* F. Reggia and E. G. Spencer, "A new technique in ferrite phase shifting for beam scanning of microwave antennas," PROC. IRE, vol. 45, pp. 1510–1517; November, 1957.]

Nonlinear Devices

From theoretical considerations of the equation of motion of a magnetic dipole in a large RF magnetic field, it is evident that the motion exhibits a nonlinear behavior. The first exploitation of this phenomenon was by Ayres, Vartanian and Melchor [57], who designed a harmonic generator by simply driving a ferrite specimen with a large linear RF magnetic field transverse to the applied dc field. At the high-power levels obtained from a magnetron they were able to get quite effective frequency conversion which now has been extended into the mm region and capable of producing peak powers of the order of 50 watts at 150 kMc. This phenomenon obviously can be utilized as a nonlinear mixer as well.

Shortly after this development, the theoretical work of Suhl [58] on the nonlinear behavior of ferrimagnetic materials at high-power levels led him to propose a new device known as the ferromagnetic amplifier. This amplifier operates on the principle of a parametric device in which the spin system is pumped at the resonant frequency and the signal frequency is at a lower value such that it is equal to the pump frequency reduced by the idler frequency. In the original amplifier (shown in Fig. 13 constructed by Weiss [59], the idler and the signal frequencies corresponded to resonant modes of the microwave cavity and were operated with a pulsed signal. This is known as the electromagnetic mode of operation. Since then a variety of other combinations using different modes of resonance in the ferrites have been demonstrated [60]; however, the particular mode that proved to be most successful is the magnetostatic mode of operation which in addition used longitudinal pumping of the spin system. This device utilized an RF magnetic field at the pump frequency parallel to the dc magnetic field and equal to twice the ferromagnetic resonant frequency. The idler and the signal frequencies,

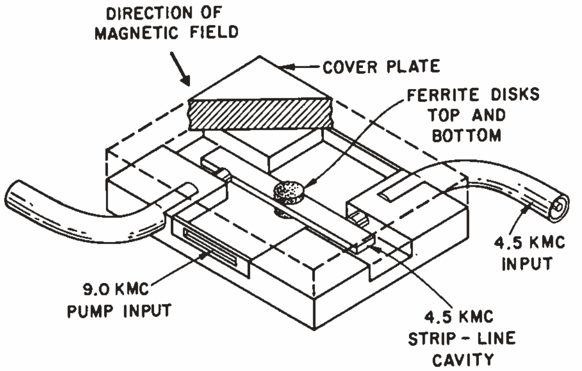

Fig. 13—Cavity configuration for microwave ferrite amplifier. [*After* M. T. Weiss, "A solid state microwave amplifier and oscillator using ferrites," *Phys. Rev.*, vol. 107, p. 317; July, 1957.]

straddled on either side of the ferromagnetic resonance, employed long wave length spin-wave modes of the ferrimagnet, fulfilling the frequency requirement of a parametric device. The amazing result was that the device developed by Denton [61] operated as a CW resonator and amplifier with a relatively low level of pump power of the order of 500 mw. The gain of the device was about 25 db, with a bandwidth of 100 kc and a noise figure of approximately 12 db.

Still another important application of the nonlinear behavior of spin systems in ferrimagnets is the microwave power limiter. According to Suhl, as the power into the spin system is increased, the ferrimagnet exhibits greater loss corresponding to the increased saturation of the spin system. Thus, a waveguide circuit containing such a ferrite can behave in a manner analogous to a gas T-R switch. Unfortunately, this high-power device exhibits a spike in the initial phases of the pulse which prohibits its use as an effective device for crystal protection in the receiving circuit. A low-power application, developed by DeGrasse [62], utilizing the narrow resonance line of yttrium iron garnet (YIG) takes advantage of the substantial decrease in susceptibility at relatively low threshold power in two transversely crossed microwave lines which become decoupled when the susceptibility of the garnet is reduced. Although the nonlinear properties were first discovered in ferrites at high microwave powers [63], the significant exploitation of these devices followed the discovery of the yttrium iron garnet whose resonance linewidth under suitable conditions was found to be one to two orders of magnitude narrower than that of ferrite crystals. In addition, the garnet materials provided an ideal medium for studying the fundamental properties of ferromagnetic resonance.

Masers

Microwave

The word *maser* was first coined by Gordon, Zeiger and Townes [64] to describe the microwave amplifier which operated by removing the energy from an inverted population of an electrically focused ammonia beam by stimulating the emission of these atoms from the excited to a lower energy state. The maser really became a much more practical device after Bloembergen [65] proposed the three-level scheme using the resonance phenomena in paramagnetic materials. He suggested that microwave energy from a source excites spins from the lowest energy level 1 to the highest energy level 3 such that at low temperatures and at relatively high microwave power the number of spins occupying state 3 would exceed considerably that at the intermediate level state 2. With an inverted population, if a microwave cavity were tuned to the frequency corresponding to the energy separation $\epsilon_{23}=h\nu_{23}$, then maser action would ensue at this frequency by stimulated emission. The device would oscillate if the total losses, including those of the cavity and of the internal circuits coupled to it, were exceeded by the energy stimulated within the crystal. However, if the stimulated energy is sufficient to overcome the losses of the cavity but not those of the total system, then the device operates as an amplifier. Indeed, such a maser was built at Bell Telephone Laboratories [66], and it demonstrated this principle unequivocally. Subsequently, using such materials as potassium chromicyanide [67] and ruby [68], microwave amplifiers with operation over a wide frequency range have been constructed. The dual frequency cavity for one of these masers is shown in Fig. 14. These masers were shown to have the low noise figure predicted theoretically [69], which is essentially equal to that of the crystal itself plus the losses encountered in the microwave circuitry associated with the maser. The initial noise figures corresponded to temperatures of the order of 20°K, but figures of the order of 17°K have been obtained subsequently [70]. These masers have since been used in radioastronomy for obtaining radar as well as radiometric signals from Venus and for the observation of the hydrogen line from external galactic systems [71]. Significant progress has also been made in the design and construction of traveling-wave masers, which has permitted the increase of the gain bandwidth product of such a device to the order of 13 db with a bandwidth of 67 Mc and tunable over a 350-Mc range with a pumping power of 100 mw at a frequency of about 19 kMc [72]. The three-level maser principle has now been extended by the group at Lincoln Laboratory [73] as far as 70 kMc, utilizing the levels of Fe^{3+} impurity in rutile TiO_3 such that the frequency range from 26 to 76 kMc can be achieved in two separate cavities. Because of the high dielectric constant of this material, many resonant modes of operation were obtained in this interval by merely rotating the magnetic field relative to the crystal axes. The pump power for the lower frequency range was obtained from a 4-mm klystron, whereas for the higher frequency range the pump was a 2-mm carcinatron, and both were at a power level of the order of about 5mw.

In addition to the three-level masers, a number of two-level devices have also been developed which

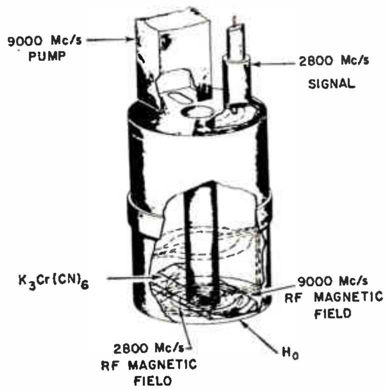

Fig. 14—Three-level maser cavity for 2.8 kMc operation with *X*-band pumping. [*After* A. L. McWhorter and J. W. Meyer, "Solid-state maser amplifiers," *Phys. Rev.*, vol. 109, pp. 312–318; January 15, 1958.]

operate on a pulse basis. The first of these two-level schemes [74] utilized adiabatic fast passage in Si, and although unsuccessful, it was actually the precursor of the first such successful solid-state maser which was operated by Feher, *et al.*, at Bell Telephone Laboratories [75]. Another maser employed a two-level electron-spin system in single crystals of quartz and magnesium oxide containing paramagnetic levels introduced by neutron irradiation, and was operated by the group at Westinghouse [76], who also obtained inversion of the electron population by adiabatic rapid passage in which the magnetic field was swept through resonance. A unique maser using pulse techniques was that developed by Foner [77], in which two sets of levels in ruby were inverted by pumping at 9 kMc, then pulsing a magnetic field in a period of the order of 100 μsec, a time which is short compared to that of the relaxation of the inverted spin system. By this technique the energy separation between two inverted levels made it possible to obtain stimulated emission as high as 70 kMc. Two interesting features of this system were that the signal frequency was higher than the pump frequency, and that energy was supplied not only by the pump power but also by the magnetic field.

Optical and Infrared Masers

Although the initial proposal of optical masers by Schawlow and Townes was centered around well-known spectral transitions in alkali vapors [78], the first optical maser was a solid-state device, developed by Maiman [79], who used a ruby rod containing 0.05 per cent trivalent Cr^{3+} impurities surrounded by a helical xenon flashtube which excited electrons into a band of levels as shown in Fig. 15. These electrons then quickly emptied into a lower set of doublet levels whose lifetime relative to the ground state was of the order of msec. During the pulse, which was of the order of about 100 μsec, it was possible to excite more than half the electrons from the ground state into the *R* levels, thus inverting the population momentarily. The silver-plated

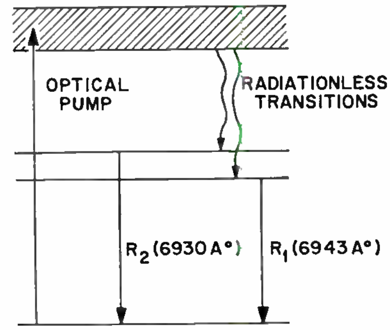

Fig. 15—Energy levels of dilute ruby (Cr^{3+} in Al_2O_3) utilized in the ruby *R*-line maser.

mirror ends of the rod provided an interferometer which acted as the resonant cavity of the microwave maser, thus producing stimulated emission from the *R* levels to the ground state, resulting in maser action at 6943 Å. Subsequently the coherence properties of the ruby maser were demonstrated by the Bell Telephone Laboratories group [80], who observed diffraction patterns produced by the beam of the maser. Masers similar to that of the ruby but effectively using four levels instead of three were developed by Sorokin and Stevenson, who initially employed uranium and then later samarium in CaF_2 host crystals [81]. These have the property that the ground state is split; therefore, at low temperatures the Boltzmann factor reduces the equilibrium population of the higher of the two pertinent ground states, thus requiring less energy for inverting the excited states relative to the higher ground state. Indeed, their maser required pumping power one order of magnitude below that of the ruby maser. The four-level optical maser appears more promising than the three-level as a candidate for CW operation, although it has not yet been achieved. The only CW device is the gas maser of Javan [82], which operates in the infrared at 2.1 μ. The red ruby maser emits lines at 6943 Å, but another ruby maser [83] with high concentration of impurities 0.7 per cent Cr^{3+} produces a splitting of the ground level into two satellite lines due to pairing of chromium ions so that emission at 7040 and 7010 Å has been observed at 77°K. One other solid-state maser that should be mentioned in this context is the cyclotron resonance maser [84], which is essentially a three-level device utilizing transitions of electrons from the quantized magnetic levels in the valence band to those of the conduction band of the same quantum number. Then cyclotron resonance transitions between neighboring levels within the valence band produce stimulated emission for maser action. Although this maser has yet not been built, theory indicates that it is feasible if an optical ruby maser or similar device with a pulse output well in excess of 100 watts is utilized and if magnetic fields of the order of 100,000 gauss are imposed at liquid helium temperatures on crystal wafers of Ge. This maser should be magnetically tunable in the far infrared and submillimeter region of the electromagnetic spectrum.

Conclusions

From the variety of applications discussed in this paper, it is apparent that solid state has become an extremely important technological field for the future. Areas of research in this science which were viewed as intellectual curiosities until recently have now become endeavors of great practical significance. Superconductivity is probably the most notable example. Just within the last two years it has emerged from the cocoon of basic physics to a practical prominence which may well revolutionize many electrical and electronic devices. Even semimetals, which are closely related to semiconductors, have future possibilities at low temperatures for electronic devices similar to those of the transistor and the tunnel diode.

The magnetic materials of the postwar era, ferrites and garnets, have already proved of extreme value for computer and microwave applications. In addition, ferrimagnetic materials and their related antiferrimagnetic counterparts show natural resonances in the submillimeter and far-infrared region which undoubtably will be exploited in a practical way when the technological art in this range of the frequency spectrum is sufficiently advanced. Such advances do not seem too far away. Masers, of one variety or another, should provide coherent monochromatic sources much more energetic and efficient than the black-body radiation or harmonic generators used at the present time. Low-temperature detectors using the solid-state phenomena of superconductivity or maser amplifiers combined with coherent sources should make this energy-starved region as fruitful for the future as the microwave region has been for the last two decades.

Without a doubt, unexploited phenomena in dielectrics, in alkali halides and in metals involving electrical, mechanical, magnetic and optical effects, which are today in the province of the research physicist tomorrow will become the bases of new inventions by the applied scientist.

Contributions of Materials Technology to Semiconductor Devices*

RICHARD L. PETRITZ†, SENIOR MEMBER, IRE

Summary—**Two basic disciplines underlying the design and development of solid-state electronic devices are: 1) the design and analysis of the device from the electron physics standpoint, and 2) the materials technology by which suitable structures in solids are prepared to fulfill the conditions specified in the device design. This article considers the second discipline, and reviews the basic steps of purification of materials, crystal growth, and processes such as diffusion and alloying for fabricating structures. Germanium, silicon, and compound semiconductors are discussed. An historical review is given, and directions of future developments are indicated.**

THERE are two basic disciplines underlying the design and development of solid-state electronic devices. One is the design and analysis of the device from the electron physics standpoint. This involves an understanding of the transport properties of electrons and holes in the presence of *p-n* junctions and other energy band structures, independent of the technique used to fabricate the device. The second, which we shall call materials technology, undertakes to make suitable structures in solids by various techniques to fulfill the conditions specified in the device design.

Within this materials technology article, we shall consider the basic steps of purification of materials, crystal growth, and processes such as diffusion and alloying for fabricating semiconductor devices.

Semiconductor technology progress can be divided in two broad categories. We group and review those contributions related to the purification and control of germanium and silicon single crystals and associated device technology in the first category. The second considers work related to compound semiconductors.

Materials Research on Germanium and Silicon

Research Prior to 1948 [1]–[3].

The history of semiconductor technology can mark its beginning with the crystal rectifier which was used as the detector in the early radio receivers. Typically, a detector was made by soldering or clamping a piece of the crystal in a receptacle, and a flexible wire "cat whisker" held in light contact with the crystal made the rectifying contact. This arrangement allowed good rectification only from "sensitive" spots on the crystal and with frequent adjustments of the contact point.

Until the 1940's the crystal rectifier served as a laboratory device to detect and monitor UHF power, since the thermionic tubes had replaced its utility in radio receivers. For this work the combination of a silicon crystal and a tungsten or molybdenum whisker was used because of the sensitive characteristic provided.

With the advent of radar in the late thirties, renewed attention was given to crystal rectifiers because mixer tubes did not perform well at radar frequencies. The first mixer crystals made by the British Thomson-Houston, Ltd., used commercial silicon of about 98 per cent purity. They exhibited the usual sensitive spots, but showed considerable variation in sensitivity. Similar results were obtained at the Radiation Laboratory of Massachusetts Institute of Technology. The General Electric Company, Ltd. of England took the first steps toward using silicon of higher purity than commercially available. Their crystals were obtained from melts of highly purified silicon powder with a fraction of a per-cent of aluminum and beryllium added.

The theory of semiconduction predicted that the conductivity and, hence, the rectifying properties of silicon would be affected by small amounts of impurities. This, together with the success of the General Electric Company, Ltd. rectifier process, stimulated research along similar lines in the United States.

F. Seitz of the University of Pennsylvania initiated a program in connection with E. I. duPont de Nemours & Company to develop a method to produce high purity silicon. Reduction of silicon tetrachloride with zinc yielded silicon with a spectroscopic purity better than 99.9 per cent. Other impurities not detectable by spectroscopic analysis, such as carbon, were present in larger amounts. Ingots made with this silicon, with an appropriate impurity added, had improved conductivity and rectifying properties over prior materials.

K. Lark-Horovitz of Purdue University recommended that the Eagle-Pitcher Company develop techniques to prepare high purity germanium. Their work led to the germanium oxide process for the preparation of high purity germanium.

J. H. Scaff and H. C. Theuerer at BTL investigated metallurgical methods for preparing ingots of silicon and germanium for use in point contact diode studies. A directional freezing technique was developed which produced polycrystalline ingots. Because of the segregation of impurities occuring between the liquid and solid phases, this process provided ingots of improved purity.

The role of Group III and V elements as *p*- and *n*-

type dopants respectively for germanium and silicon was studied during the World War II period. The Purdue group made systematic studies of various impurities added to germanium. A similar, but not as complete, study was made on silicon at the University of Pennsylvania. The similarity of effects of impurities in the two materials was recognized. In spite of these efforts, we note that even as late as 1948 rectifiers were made with tin-doped germanium which had very high back resistance for inverse voltages of the order of 100 volts, and it was thought that tin was the doping element. We now know that impurities in tin, probably antimony or arsenic, were responsible for this action and that tin itself does not affect germanium electrically. Thus, impurities in impurities led to confusion during the early forties. However, the research during 1940–1948 resulted in considerable progress in the purification of germanium and silicon and in the controlled addition of impurities to them.

The success of the silicon and germanium diodes developed during this period further stimulated scientists to seek methods for making an amplifying device from a solid. The discovery of the point contact transistor by Bardeen and Brattain [4] at BTL was made in 1948, giving impetus to the over-all program.

Germanium Materials Research—1948 to 1952

In the latter part of 1948 G. K. Teal and J. B. Little of BTL began experiments to grow germanium single crystals, selecting the pulling technique [5]. They succeeded in growing large single crystals [6] of germanium of high structural perfection (Fig. 1). They also improved the impurity of the material by repeated recrystalization methods. The advance in our understanding of basic semiconductor properties has come largely from experiments on single crystals. Furthermore, single crystal technology has become a cornerstone of the transistor industry.

In 1949, W. L. Shockley showed the possibility of obtaining both rectifying and transistor action using *p-n* junctions in bulk material [7]. This important theoretical step stimulated research toward preparing *p-n* junctions.

At BTL Teal, working with M. Sparks, devised a unique method for preparing *p-n* junctions by modifying his crystal-pulling apparatus (Fig. 2), to allow controlled addition of impurities during crystal growth. Using ingots they prepared single crystals containing *p-n* junctions [8], and soon afterward *n-p-n* grown-junction transistors [9] (Fig. 3) which had many of the properties predicted by Shockley [7]. Thus the BTL achieved both the theoretical prediction of junction transistors and the distinction of first solving the physical and metallurgical problems of fabricating a useful device. These transistors were first prepared in 1950, but their public announcement was not made until July, 1951 [9].

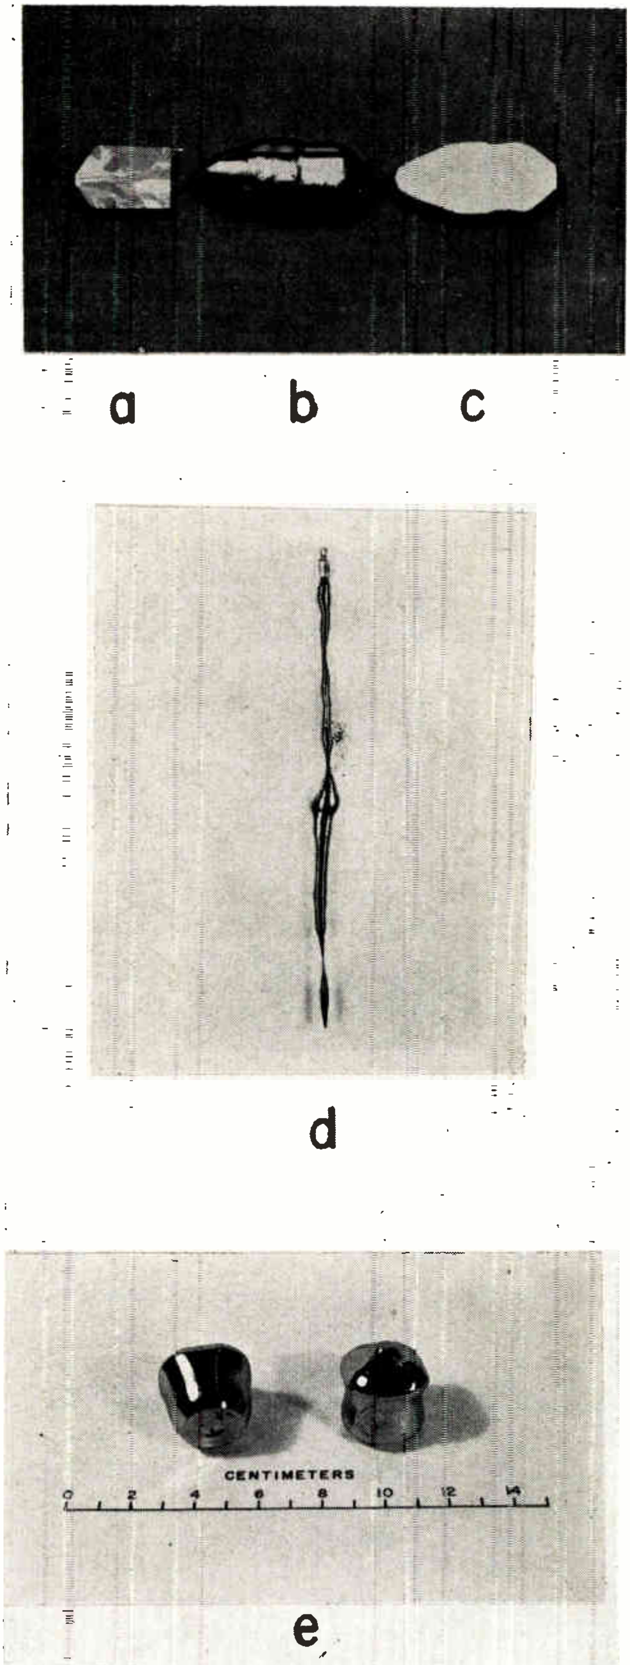

Fig. 1—Polycrystalline and single crystal germanium. A shows a cross section of a polycrystalline germanium ingot revealing a large number of grain boundaries. B shows a single crystal grown by the Teal-Little method. C is a cross section of such a crystal showing the absence of grain boundaries. D is one of the early germanium crystals grown by the Teal-Little technique, while E is a recent germanium single crystal grown by the same method.

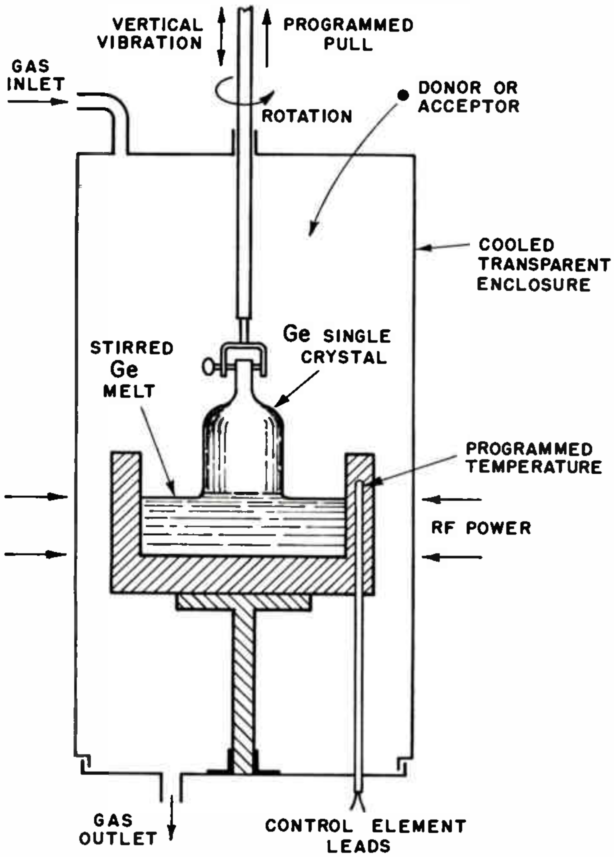

Fig. 2—Cross-section of germanium crystal pulling equipment for growing single crystals of controlled composition. (See Fig. 3 caption for a description of how this equipment is used in the preparation of *n-p-n* transistors.)

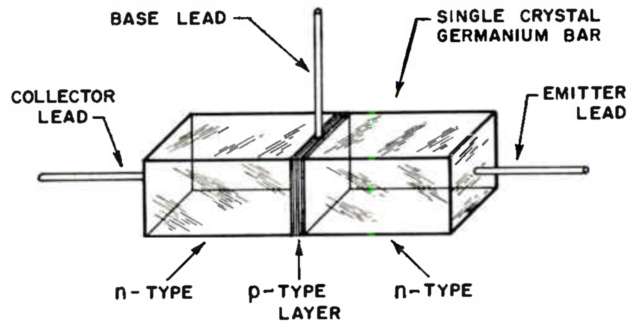

Fig. 3—The structure of an *n-p-n* germanium grown-junction transistor. Using the equipment of Fig. 2, a single crystal is drawn from an appropriately doped *n*-type melt (phosphorus or arsenic, typically), aided by a seed crystal, and the collector region is formed. At a suitable time, a *p*-type impurity such as boron or gallium is added to the melt to dope the base. Subsequently, an additional donor impurity is added to the melt to form the strongly doped *n*-type emitter. The crystal is then withdrawn, cut into bars, and leads attached. Several hundred transistors are obtained from a single crystal.

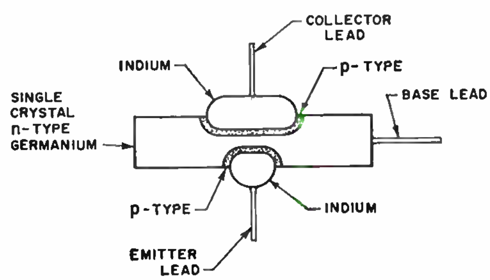

Fig. 4—A *p-n-p* alloyed germanium junction transistor. Two small dots of indium are alloyed into a single crystal *n*-type germanium wafer at a temperature of approximately 500°C. At each indium-germanium interface the surface of the germanium wafer dissolves as indicated in the drawing and upon cooling the assembly, the indium becomes supersaturated with germanium, and a recrystallization layer of germanium heavily doped with indium is formed upon the wafer. These recrystallized layers then form the emitter and the collector sections of a *p-n-p* junction transistor with the original *n*-type wafer playing the part of the base. The leads to the three sections are connected to the indium dots and to the base as shown.

succeeded in preparing single *p-n* junctions by an alloying technique [10]. Later J. S. Saby [11] prepared *p-n-p* transistors by the alloy technique (Fig. 4). It is interesting to note that *n-p-n* grown junction (Shockley, Sparks, and Teal) and *p-n-p* alloy transistors (Saby were discussed publicly for the first time at the same informal technical meeting [12].

Rapid developments soon followed in materials technology. W. G. Pfann [13] discovered a simple method for repeating the action of normal melting and freezing, which avoided handling the material between each operation (Fig. 5). This resulted in material of extremely high purity which was then grown into single crystals by the pulling technique. Pfann also developed the zone leveling technique, which distributes impurities uniformly through a rod. He grew single crystals in his zone leveling apparatus using seeding techniques. The combination of zone leveling and horizontal growth of single crystals has become the standard technique used in today's transistor manufacturing operations [14], [15].

In 1952 the Bell Telephone Laboratories released the technological details of the grown-junction transistor process to a large number of licensed manufacturers. At a historic symposium, details of the crystal growing and related experiments were disclosed, and a set of articles was written in the form of a two-volume publication

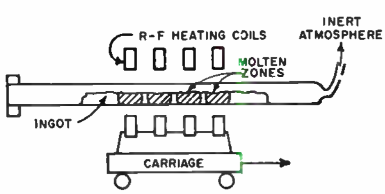

Fig. 5—Cross section of zone refining equipment. The RF heating coils cause melting to occur in the narrow zones. The zones are caused to move from one end of the semiconductor bar to the other by moving the carriage. Segregation at the liquid-solid interfaces causes impurities to move toward the ends of the bar. Several stages of recrystallization can be obtained without handling the material by using several zones and making repeated passes, so an extremely high degree of purification can be achieved.

[16] for the licensees, some 28 companies. Later they were made available to the public. A revised version has been published recently [17]. Fig. 6, a reproduction of page 4 of "Transistor Technology" shows the stages through which germanium materials technology had proceeded at BTL by 1952. The left side of the figure shows the early stages in which chemical purification (GeO_2) was used along with normal freezing (N.F.) of ingots to producer point contact varistor material. In the center of the figure the phase is shown where normal frozen ingots were used in the grown junction apparatus to produce single crystals, grown-junction transistors and diodes. The right side indicates that zone refining had replaced normal freezing for purification of the ingot and that the pulling technique was used for preparation of single crystals, diodes, and transistors. The dotted line shows the zone leveling single crystal technique as being under development.

The IRE provided a needed service by devoting an entire issue of PROCEEDINGS [18] to transistors. One of the many useful purposes this issue served was to disclose details of processes being used for transistor fabrication by a number of industrial concerns.

Silicon Materials Research—1951 to 1954

Large single crystals of silicon and silicon *p-n* junctions were prepared by Teal and Buehler [19] by an extension of the pulling technique developed for germanium. These crystals were used by G. L. Pearson [20] to prepare *p-n* junction diodes by the alloy method.

Silicon, while similar to germanium in many respects, presented certain problems which delayed the development of transistors for several years. Because it has a higher melting point and higher reactivity, a completely satisfactory crucible to hold a silicon melt has not been developed even today. The most satisfactory crucible material is fused quartz; however, it tends to be dissolved slowly by molten silicon. Impurities present in the crucible, such as boron, are transferred to the silicon. Also, oxygen dissolves in the melt and is subsequently incorporated into the growing crystal.

Horizontal zone refining of silicon is also complicated by the crucible problem. Because molten silicon wets the quartz boat, and since silicon and quartz have quite different coefficients of thermal expansion, cracking occurs on cooling. Because of the difficulty in applying zone refining to silicon, more reliance was placed on chemical purification methods [21].

Attempts to fabricate silicon transistors proceeded along the lines of grown-junction and alloy techniques. Control over alloying to the degree necessary to get effective transistor action proved difficult with the material available at that time, while the grown-junction technique was successfully used to fabricate silicon transistors [22], [23]. Relatively few industries adapted the grown-junction technique (even for germanium), and silicon transistors were produced commercially by a single company, Texas Instruments Incorporated, for several years.

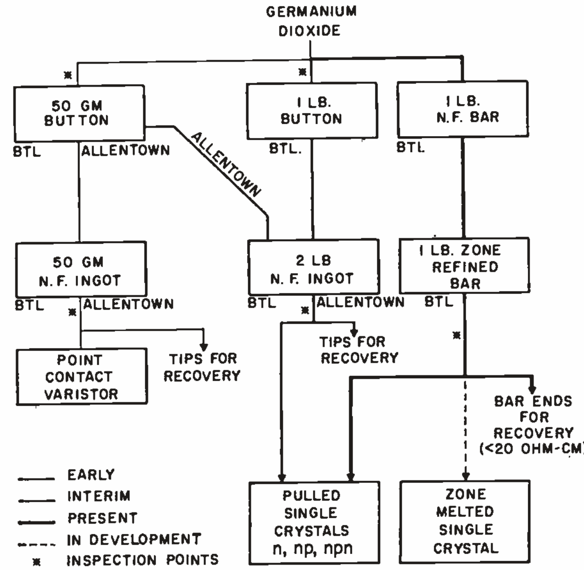

Fig. 6—Stages in the preparation of germanium for varistors and transistors at the Bell Telephone Labs. in 1952. The left side of the figures shows the early stages in which chemical purification (GeO_2) was used along with normal freezing (N.F.) of ingots to produce point contact varistors. The interim phase, where one goes from the normal frozen ingot to the grown-junction technique for production of transistors and diodes, is shown in the middle of the figure. The right side indicates how zone refining replaces normal freezing for the purification of the ingot, and how the pulled crystals are made for the transistors. In the dotted line, the zone leveling single crystal technique is also indicated as being under development.

An improved silicon purification technique was developed which produced material of sufficient quality that alloy silicon transistors could be fabricated with good yields. This was a novel variation of zone refining called "floating zone refining" developed by P. H. Keck [24] and independently by R. Emeis and H. C. Theurer [25]. This operation employs a vertical system and uses surface tension to support a stable liquid zone formed by induction heating. Hence, the crucible is completely eliminated. Silicon with thousands of ohm-cm resistivity and minority carrier lifetimes of greater than 100 μsec can be produced by this method. This material has been used to prepare silicon transistors by the alloy method. However, diffusion processes were developed about the same time, so that alloy techniques have been relatively less important for silicon than for germanium transistors.

Further Developments in Process Technology

While the grown-junction and alloy processes served to give the transistor industry two basic technologies with which practical devices could be manufactured, their inherent limitations were soon recognized. Chief of these were the inability to produce extremely narrow base regions, and to fabricate small area junctions, both of which were needed for performance above a few hundred kilocycles.

The double-doping technique of Teal did not have sufficient control to fabricate base regions narrower than about 0.5 mils. Hall's rate-growing technique [26] offered improvement and transistors of good performance at intermediate radio frequencies were manufactured at good yields.

The jet etching technique [27] was developed at the Philco Corporation to achieve narrow base regions (Fig. 7) and small area junctions; this produced improved high-frequency performance. When metal contacts are plated to both sides of the thin section [28], the surface barrier transistor (SBT) [29] is produced. The micro-alloy (MAT) [30] process developed as a result of forming alloyed junctions on each side of the etched region.

The next major advance in device technology was the diffusion process (Fig. 8). Research on the diffusion of III–V impurities into germanium and silicon by Fuller at the BTL, and by Dunlap at GE laid the foundation for transistor fabrication using diffusion as a key process step [31]. The BTL was the first to fully integrate these results into germanium and silicon transistors [32], [33].

Diffusion techniques have proved to be one of the best controlled methods for preparing *p-n* junctions (Fig. 8). Because the common doping impurities diffuse very slowly in semiconductors at rates which can be varied by adjusting temperatures, close control and reproducibility of the impurity distributions can be achieved. Hence, control over the electrical parameters of the resulting devices may be maintained. The ability to form base regions only a fraction of a micron thick allows very high-frequency transistors to be fabricated.

Diffusion technology, in addition to offering an entirely new technique for processing transistors, was adaptable to many existing processes [34]. The grown-junction technique was quickly modified to utilize diffusion. The result was the grown-diffused transistor [35] which had significantly improved high-frequency performance for both germanium and silicon transistors.

The built-in electrical field which results from a diffusion process was found to give higher-frequency performance for the basic alloy transistor, as predicted by Krömer [36]. This transistor, called a "drift transistor" by RCA has higher frequency response than the conventional alloy transistor (which has uniform doping in the base region).

The addition of a diffused base to the jet etching procedure has resulted in the Philco micro-alloy diffused transistor (MADT) [37], which has excellent high-frequency response, fast switching speeds, and low collector series resistance.

The diffusion technology was not only adapted to existing processes, but it also led to new device structures, the first of which was the mesa transistor (Fig. 9) [32], [33]. For germanium the base was formed by diffusion and the emitter by evaporation and alloying. Precise, small area emitters and narrow base regions

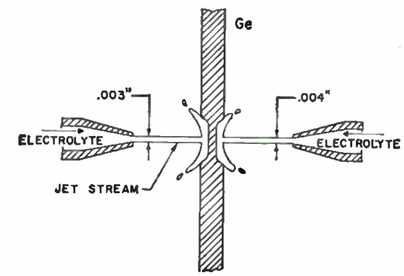

Fig. 7—Jet etching a germanium transistor blank. The wafer is jet etched from both sides until a relatively thin section remains. When metal contacts are plated [28] to both sides of the thin section, the surface barrier transistor (SBT) [29] is produced. If the structure is heated and the metals alloy to the semiconductor the microalloy transistor (MAT) [30] is formed.

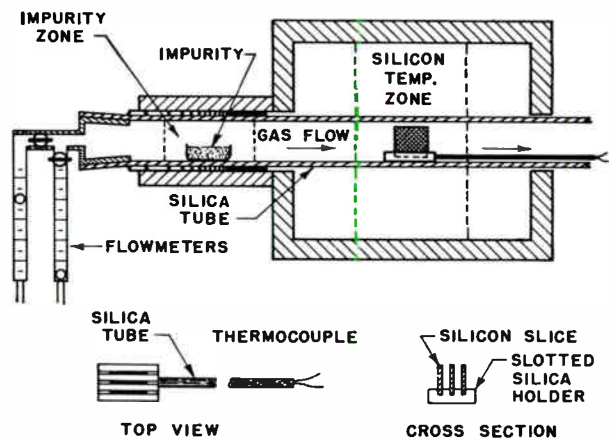

Fig. 8—Two-zone open-tube diffusion apparatus for silicon. The impurity zone temperature can be maintained independent of the silicon temperature to control the surface concentrations. An inert gas flow transfers the impurity to the silicon slices. Generally, the impurity sources are compounds—for example, P_2O_5 and BBr_3. A chemical reaction occurs on the silicon surface resulting in the phosphorus or boron being deposited on the silicon. Diffusion then occurs into the silicon. Other diffusion techniques include the closed tube, and the semi-closed tube (box) systems.

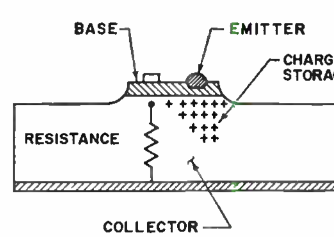

Fig. 9—Cross section of a diffused base, alloyed emitter, germanium mesa transistor. The starting material, which becomes the collector region, is *p*-type single crystal germanium with a typical resistivity of a few ohm-cm. An *n*-type impurity such as arsenic or antimony is diffused to form the base region and base-collector junction. The emitter is formed by evaporating and alloying a metal stripe containing a *p*-type impurity such as indium. An ohmic contact to the base region is similarly made using an *n*-type impurity in the stripe. Photomasking and chemical etching techniques form the mesas. The slice is scribed and broken into several hundred individual transistor wafers which are assembled onto headers.

were possible. Chemical etching was used to remove unwanted diffused material so that small area emitter and collector junctions were obtained. The frequency response of germanium was extended into hundreds of megacycles. These techniques allowed fabrication of hundreds of transistors on a single wafer. The chief limitations of this transistor are the high collector series resistance and charge storage in the collector.

A variation of the combination of alloy and diffusion processes is the alloy-diffused process [38], where the emitter is first alloyed and the base impurity diffused from the emitter region.

For silicon mesa transistors [33], both the base and emitter were formed by diffusion, and etching was again used to define a small collector area. These processes also allowed hundreds of transistors to be fabricated on a single slice, with performance far exceeding that achieved previously in silicon.

Another important technological advance in this period was the development of oxide masking for silicon by C. J. Frosch of BTL [39]. He observed that a thermally grown oxide on silicon impeded the diffusion of certain impurities, including boron and phosphorus. This technique, coupled with photographic masking against etching, provides a powerful tool for silicon processing, and will be illustrated by example in a later section.

Physical imperfections, such as dislocations, are also important in the physics and chemistry of solids, and in achieving good process control. W. C. Dash has made important contributions to this subject. First he decorated dislocations in silicon by precipitating copper and then observed them directly with an infrared imaging microscope [40]. He then developed methods for growing silicon single crystals with essentially no dislocations [41]. This technique has also been used to grow dislocation-free germanium single crystals, and the etch pit method for observing dislocations has been used to verify this.

Surface Technology

With the announcement of the grown-junction transistor in 1951, enthusiasm ran high for a device with performance determined principally by bulk properties. Unfortunately, this optimism was not justified because developments soon indicated that while the primary transistor action was a bulk phenomenon, the surface determined such important properties as leakage currents and over-all stability of the device.

Even today the surface remains a major technological problem. While progress has been slow in this field, there are encouraging signs that improved methods of stabilizing the surface are being developed.

Basic research in the field of surfaces has been oriented toward obtaining a fundamental understanding of surface states and how they are related to various chemical and physical processes [42]–[44]. A second, more empirical study has been to develop techniques for stabilizing the surface to achieve long-life, stable transistors. Stabilization techniques have been investigated ranging from the extreme of a bare transistor sealed in a hermetic can with a getter, to surfaces with various protecting agents put or grown on them.

Thermal oxidation is proving to be an important technique, and M. M. Atalla [45] of BTL has been a significant contributor. Much of this research has been directed toward growing the oxide on the device after fabrication. One difficulty is that high temperatures (1100–1200°C) must be used to grow good oxides on silicon; at these temperatures the impurity distributions will change because of diffusion. For diodes, where the *p-n* junction is deep in the material and its position is not critical, post oxide passivation [46] works well and devices are commercially available. For transistors, where the diffused junctions are near the surface and in close proximity to each other, the redistribution of impurities that occurs during growth of the oxide seriously degrades the device.

Another important approach to this problem is the planar process [47], where the oxide is grown on the silicon slice before the base and emitter diffusions are performed. The oxide serves as a mask in the diffusion processes and protects the *p-n* junctions which are formed under the oxide (Fig. 10). The over-all planar process is described in a later section. Silicon planar transistors have extremely low leakage currents (in the nanoampere range), improved current gain (β) at low currents, and generally good stability and reliability characteristics. Commercial devices made by this method were first introduced by the Fairchild Transistor Corporation.

Epitaxial Crystal Growth

Until 1960 the semiconductor industry followed a pattern of starting with a crystal as pure as needed in the initial stage, and each step added impurities in a controlled manner. In June, 1960, the Bell Telephone Laboratories [48] announced a new method of fabricating transistors using epitaxial single crystals grown from the gas phase with controlled impurity levels. This technique (Fig. 11) had been studied at a number of laboratories [49], but it was not until the 1960 announcement that the potential was fully grasped by the semiconductor industry. Its unique advantage is the ability to grow very thin regions of controlled purity.

The specific process employed by BTL for a germanium mesa transistor utilizes the epitaxial technique to grow a thin, high resistivity *p* collector region, on a low resistivity ($p+$) substrate crystal. The transistor is then fabricated by conventional diffusion and alloy techniques (Fig. 12) in the thin epitaxial layer. The device retains the advantages of the mesa structure, but undesirable aspects (high collector series resistance and minority carrier storage time) are appreciably reduced.

While the principal application to date of the epitaxial method has been to grow *n* regions on $n+$ silicon

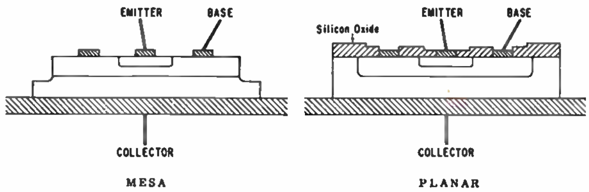

Fig. 10—Silicon mesa and planar transistors. On the left is a mesa transistor where the base-collector junction area is defined by the mesa etching process and the emitter-base junction by the oxide masking process (the oxide subsequently removed). In the planar structure at the right, both junctions are defined by the oxide masking process. The silicon oxide also serves to protect the junctions of planar devices. Further details of the mesa etching process and of the oxide masking process are given under Figs. 9 and 13, respectively.

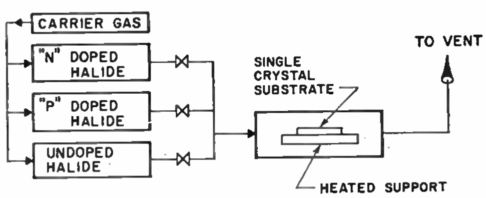

Fig. 11—Schematic of apparatus for epitaxial growth of single crystal semiconductors of controlled composition. A typical silicon process is as follows: The single crystal substrate slice of $n+$ material is placed on the support and heated to 1100°C. The undoped halide ($SiCl_4$) is carried to the silicon slice by a carrier gas (H_2). A chemical reaction occurs at the silicon surface

$$SiCl_4 + Si + 2H_2 \rightarrow Si + 4HCl$$

resulting in the growth of the crystal. Doping can be achieved by mixing n- or p-doped halides (BCl_3 or PCl_3) with the $SiCl_4$ by the valve system. The boron is deposited along with the silicon by the surface reaction

$$2BCl_3 + Si + 3H_2 \rightarrow \underbrace{2B + Si} + 6HCl.$$

The degree of doping is controlled by the gas mixtures and flow rates. Because of the high temperatures involved, diffusion of impurities occurs during the growing period, and account of this must be taken in the device process design.

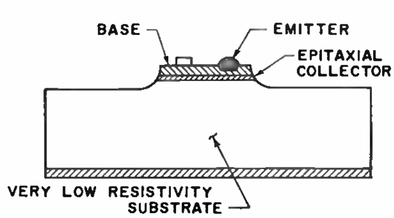

Fig. 12—Cross section of an epitaxial, diffused base, alloyed emitter mesa transistor. Typical fabrication steps for a p-n-p germanium transistor are similar to those described under Fig. 9, with the important difference being that the starting slice is one on which a high-resistivity p region has been epitaxially grown on a low-resistivity $p+$ slice. The fabrication steps of Fig. 9 then occur in the p region, the $p+$ region serving mainly as a mechanical support and a low-resistance electrical connection to the collector.

substrates, and p regions on $p+$ germanium substrates for use with mesa-planar transistors, its potential is much broader because of its flexibility. This technique may well be the most powerful yet developed for the semiconductor industry. A comprehensive review of this subject has not yet been written, but J. Sigler and S. V. Watelski [50] provided a good introduction.

Semiconductor Process Technology—1962

The resultant effect of semiconductor technology developments is the transistor industry, which daily works with crystals of chemical, physical, and structural perfection orders of magnitude better than in any other industry. The processes used for manufacturing devices are sophisticated combinations of diverse technologies. The successful manufacturers are those who have best integrated the various technologies to manufacture specific devices, with economies often being a deciding factor. The so-called "obsolete" technologies, grown) junction and alloy, in their modern version, still account for an appreciable share of the semiconductor market.

The silicon transistor of today combines many aspects of advanced technology and exemplifies the heights to which process technology has progressed. To give the reader an appreciation of these strides, we shall outline the steps in manufacturing the epitaxial, planar, double-diffused silicon transistor produced by most manufacturers today.

The discussion will refer to Fig. 13, where the key process steps are shown. Step a shows the starting slice, a single crystal of silicon of low resistivity ($n+$) 5–10 mils thick (figure not to scale). Step b is to grow an epitaxial layer of n-type material with a resistivity of a few ohm-cm and a thickness of a few tenths mil. Next (step c), an oxide layer a few microns thick is thermally grown on the surface. Then (step d), a photosensitive compound similar to that used in printed circuit technology is applied over the oxide. A suitable mask covers the defined regions for base diffusion, and the remainder is exposed to light. Chemical development removes the unexposed photomasking over the base area as shown in step e. The oxide over the base region is then removed by an acid such as HF, the photomasking not being attacked (step f). Next, the photomasking is removed by a suitable solvent (step g).

The base diffusion is performed using a boron compound and the oxide restricts diffusion to the exposed silicon surface (step h). The boron diffuses laterally under the oxide into the silicon as well as forward into the material, and an oxide is grown over the base region while the diffusion is in process. Note that the base collector junction is formed under the oxide, minimizing possibilities of contamination.

The emitter area is defined by a second photomasking and etching process (similar to d through f), resulting in step j. The emitter diffusion, using a phosphorus compound, is carried out with the oxide again masking

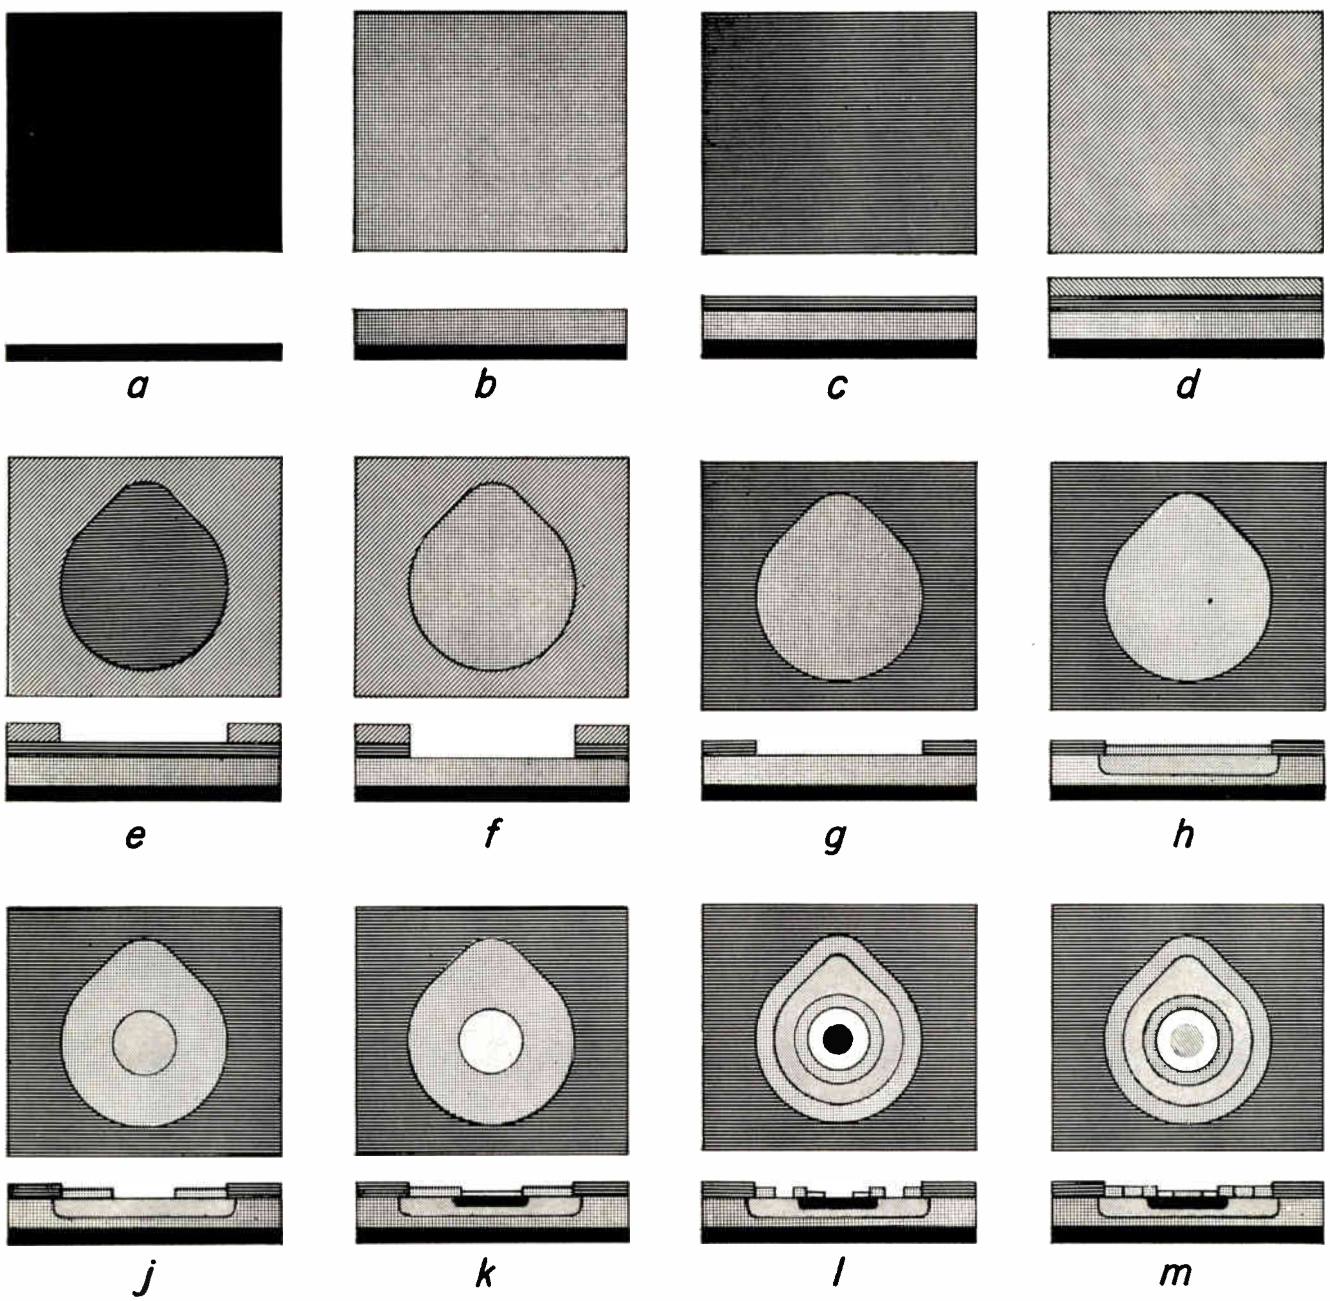

Fig. 13—Steps in fabricating a silicon epitaxial planar transistor. The operations are described in the text.

all but the desired region. The emitter-base junction is formed under the oxide, and another oxide is grown over the emitter region while the diffusion is in process (step k).

Another photomasking-etching operation defines the base and collector contact regions (step l). Aluminum or a similar contact material is evaporated over the slice and another photomasking step removes the aluminum from all but the base and emitter contact regions. The aluminum is alloyed to form a good ohmic contact to the silicon (step m).

Several hundred transistors are being formed in a single slice during these operations (Fig. 14). The slice is next scribed and cut into individual transistor wafers. These are assembled onto headers.

Hopefully, this illustration, while somewhat laborious, will give the reader some feeling for the subtleties and sophistication that the materials technology developments have brought into the semiconductor industry over the past twenty years. It is an achievement hardly envisioned in 1948, when there was little hope for single crystals ever becoming important in a practical sense, since it was generally thought that such a technique would be too expensive.

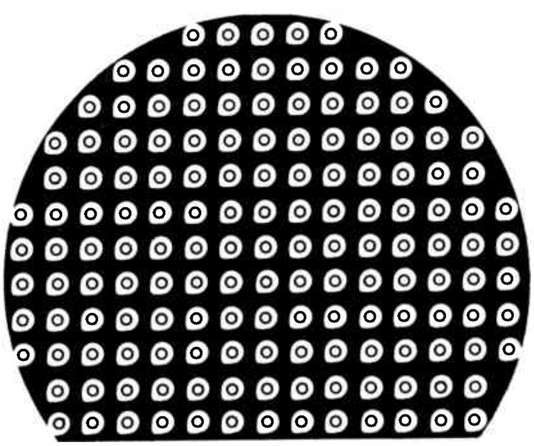

Fig. 14—Sketch showing a typical silicon planar transistor slice prior to scribing and breaking into individual units.

Compound Semiconductor Developments

New Compound Semiconductors and the Chemical Bond Theory

A second major development in the field of materials technology during the past 20 years was the discovery and classification of new compound semiconductors. Prior to 1940 there had been some research on naturally occurring compound semiconductors such as cadmium sulfide, zinc oxide, and others, but no systematic approach to the discovery of new compounds was made.

As early as 1925, E. Friederich [51] speculated that high electrical conductivity occurs in compounds in which not all of the valence electrons are involved in the bonding. He also noted the absence of an appreciable electronic conduction in molecular crystals. In 1944, W. Myer [52] considered electronic conduction in solid compounds and found that Friederich's basic question of the necessary and sufficient conditions for electronic conduction in compounds was still not rigorously answered. Systematizing the wealth of accumulated data from many investigations, Myer concluded the following:

1) The electrical conductivity of a solid compound is related to the electron configurations of the component atoms.
2) Semiconductors and insulators are normal valence compounds; compounds which do not adhere to the valence rules and compounds with compositions deviating from stoichiometry are good (metallic) conductors.

Myers' conclusions could very well have been a guidepost to search for new semiconducting materials. However, by the end of World War II, the scientists' attention was focused on the two Group IVB elements: germanium and silicon. The explosive growth of solid-state devices which followed the discovery of the transistor created a desire for new semiconducting materials suitable for various applications.

A major advance occurred in 1952 when H. Welker [53] recognized the isoelectronic similarity between the Group III-V compounds and the Group IVB (germanium, silicon, and gray tin) elements, and predicted that the former would also be semiconductors. Subsequent investigations verified Welker's prediction.

Welker reasoned that the eight electrons which make up the four covalent bonds for each atom in the diamond lattice (Fig. 15), would, in the case of a III–V compound such as gallium arsenide, be furnished by the five and three valence electrons of arsenic and gallium respectively. Thus Welker predicted a whole new class of semiconductors, which should have properties similar to, but distinct from those of the Group IVB elements. He predicted that they should have the zinc blende crystal structure, which is analogous to the diamond structure as shown in Fig. 15.

Welker went further and attempted to predict the electrical properties of the III-V compounds. For example, he argued that the bonding of the elemental semiconductors—germanium, silicon, and gray tin— is purely covalent, but that in the corresponding isoelectronic compounds—gallium arsenide, aluminum phosphide, and indium antimonide—the bonds should have an ionic as well as a covalent component. Resonance between the covalent and ionic structures leads to an increased bond strength; therefore, the band gaps of the compounds should be larger than those of the corresponding elements. Since higher bond strength lowers the amplitudes of thermal vibrations of the atoms, Welker predicted higher charge carrier mobilities for the compounds. Experiments verified some of these predictions for several of the III-V compounds. However, these arguments are not conclusive, and band structure

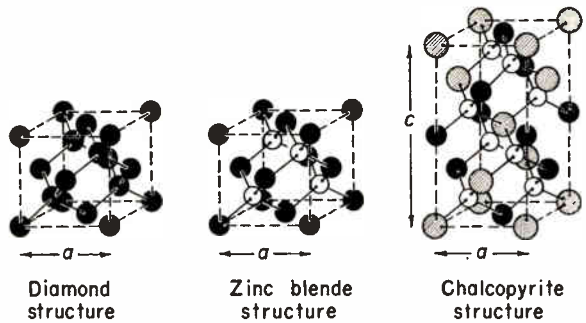

Fig. 15—Relationship between the crystal structures of some elemental and compound semiconductors. Elemental semiconductors such as silicon and germanium possess the diamond structure. Each atom is surrounded by four identical atoms arranged tetrahedrally. The zinc blende structure, characteristic of the III–V compounds such as gallium arsenide, is very similar. The atomic positions are unchanged; however, every atom is surrounded by four atoms of the opposite element. In the chalcopyrite structure, characteristic of compounds such as $ZnGeAs_2$, each atom is bonded to atoms of two different elements causing the tetrahedra to be distorted. Although the composition of these compounds differs, the similarity in structures and electronic configurations causes them all to be semiconductors.

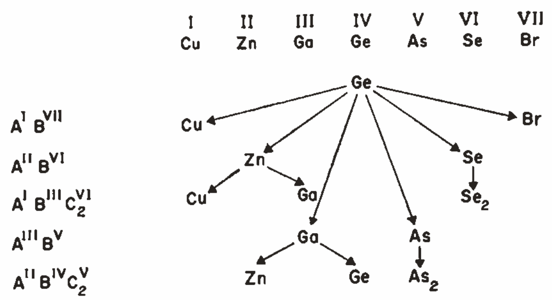

Fig. 16—Relation between some elemental and compound semiconductors. Examples of five types of semiconducting compounds related isoelectronically to germanium are shown. The lattice structure and properties are similar as shown in Fig. 15 and Table I.

TABLE I

LATTICE CONSTANTS OF SEMICONDUCTING COMPOUNDS OF COMPOSITION $A^{II}B^{IV}C_2^{V}$

$ZnSiP_2$	$a = 5.39_8$	$\frac{c}{a} = 1.93_4$
$ZnGeP_2$	$a = 5.46$	$\frac{c}{a} = 1.97$
$ZnGeAs_2$	$a = 5.67_0$	$\frac{c}{a} = 1.96_7$
$CdGeAs_2$	$a = 5.94_2$	$\frac{c}{a} = 1.88_9$
$CdSnAs_2$	$a = 6.09_2$	$\frac{c}{a} = 1.95_7$

calculations are needed for a more complete understanding of the transport properties.

Other classes of compound semiconductors were discovered using the isoelectronic argument (Fig. 16). C. H. L. Goodman and R. W. Douglas [54] predicted and found semiconducting properties in the chalcopyrites of composition $A^{I}B^{III}C_2^{VI}$, which crystallizes in a tetrahedrally distorted superlattice of the zinc blende structure (Fig. 15). O. G. Folberth and H. Pfister [55] later predicted the existence, the structure, and the semiconducting properties of the series of compounds with composition $A^{II}B^{IV}C_2^{V}$. Figs. 15 and 16 and Table I show some of the interesting correspondence in the properties of these three classes of isoelectronic semiconductors.

These discoveries led to the attempt to classify semiconductors in terms of a valence bond description analogous to L. Pauling's [56] work in the theory of the chemical bond. Basically, the difference between the metallic state and the semiconducting state is that the former is characterized by covalent bonds which lead to partial filling of the valence orbitals of the atoms. By sharing electrons in forming the bonds, all atoms in elemental semiconductors acquire filled valence subshells. Thus, the difference between the two types of electronic conductors—metals and semiconductors—is attributed to the difference in the degree of filling the valence shell of the component atoms.

The chemical bond theory is still in development; a current review is E. Mooser and W. B. Pearson [57]. It does afford a chemical criterion analogue to A. H. Wilson's [58] physical criterion of filled bands, permitting a distinction to be made between metals and semiconductors. However, only little progress has been made in predicting and calculating such fundamental properties as energy band gaps and charge carrier mobilities of semiconductors from this theory.

Energy band calculations [59] are a more powerful tool for predicting and understanding the detailed properties of a particular semiconductor. The complex band structure of germanium and silicon (Figs. 17 and 18) that has been revealed by cyclotron resonance [60] and other experiments indicates that transport properties depend in an intricate way upon the detailed structure of the conduction and valence bands [61]. Thus, it is doubtful that the chemical bond approach can predict the subtleties of the true electron band picture.

In the author's opinion, the chemical bond approach is valuable in predicting and classifying new compound semiconductor families, but band theory calculations are needed to predict the detailed properties of a particular semiconductor. Conversely, band theory calculations are too complex to be of much value in predicting and classifying new semiconductor compounds, and it is in this area that the chemical bond approach is especially important. The two approaches necessarily complement each other since they are different means of describing the same physical phenomena.

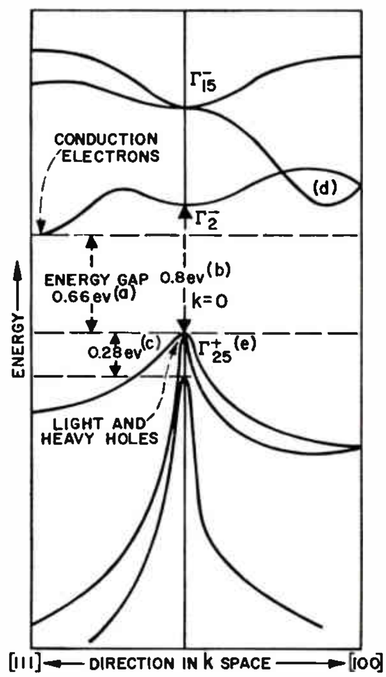

Fig. 17—Energy as a function of wave vector k for the [111] and [100] directions in germanium.

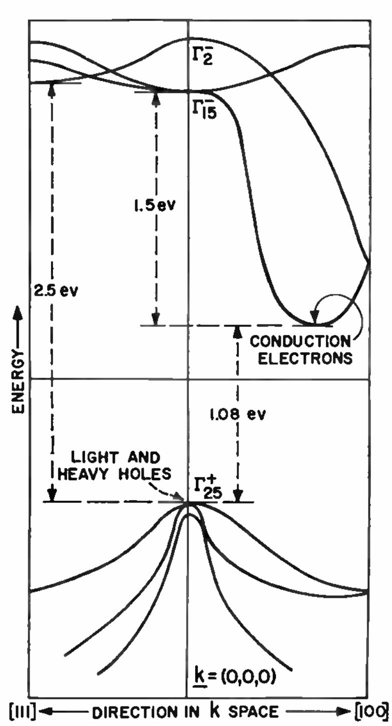

Fig. 18—Energy as a function of wave vector k for the [111] and [100] directions in silicon.

Technology of Compound Semiconductors

Technology problems of compound semiconductors are similar, but in general more complex than those discussed for germanium and silicon, and many techniques that have been developed for the elements are applicable. Progress has been relatively slow compared to germanium and silicon, one reason being that the wealth of materials has made a concentrated effort difficult. Another reason is the heavy concentration of industrial research and development on silicon and germanium. However, in certain areas considerable progress has been made. For example, indium antimonide [62] can be considered the third best-known semiconductor in terms of physical and chemical properties. Since both indium and antimony have rather low vapor pressures at the melting point, indium antimonide has proved relatively easy to prepare and purify by zone refining, and has received considerable study. This research has produced impurity concentrations of less than $10^{14}/cm^3$ and collision times sufficiently long that cyclotron resonance has revealed its band structure.

On the other hand, the arsenides and phosphides of the Group III elements have appreciable vapor pressures at the melting point, which complicates purification. It has been necessary, therefore, to construct sealed furnaces with heating arrangements to maintain the entire system at a high temperature to prevent condensation of the constituents. This requires control of the gas phase as well as the solid and liquid phases. However, progress is being made and application of chemical and metallurgical techniques is bringing better control of these new materials. Reviews of compound semiconductor physics and technology can be found in references [62]–[67].

Implications of Compound Semiconductors for Device Electronics

The discovery and systematic investigation of compound semiconductors afford the device electronics man an expanded degree of freedom for his work. For example, the properties of gallium arsenide make it interesting for transistors [68] (Table II and Fig. 19). This compound has potentially higher-frequency and higher-temperature performance than silicon or germanium. The latter property means better power handling capabilities for the same active area. Transistors have been constructed from gallium arsenide which demonstrate their feasibility [69]. Moreover, the improved electrical parameters expected from the physical properties can actually be realized.

New materials are also being sought in the field of thermoelectricity [70]. For a highly efficient thermoelectric generator or heat pump, a material with high electric conductivity, low thermal conductivity, and high thermoelectric power is needed. No simple semiconducting material satisfies all these requirements, so compounds are required. Using the chemical bond approach, the search for better materials is not so random

TABLE II
ELEMENTAL III-V COMPOUND SEMICONDUCTOR PROPERTIES

Semiconductor	Band Gap (ev)	Electron Mobility cm^2/v sec	Hole Mobility cm^2/v sec	Max. Temp. (Usable °C)
Ge	0.67	3,900	1,900	85–100
Si	1.11	1,500	500	150
C (diamond)	6.70	1,800	1,200	>1,000
InSb	0.18	85,000	3,000	−196
InAs	0.33	33,000	450	~30
InP	1.25	4,800	150	~300
GaAs	1.40	9,000	450	~400
GaP	2.25	>100	>20	~650
AlSb	1.52	460	460	~450

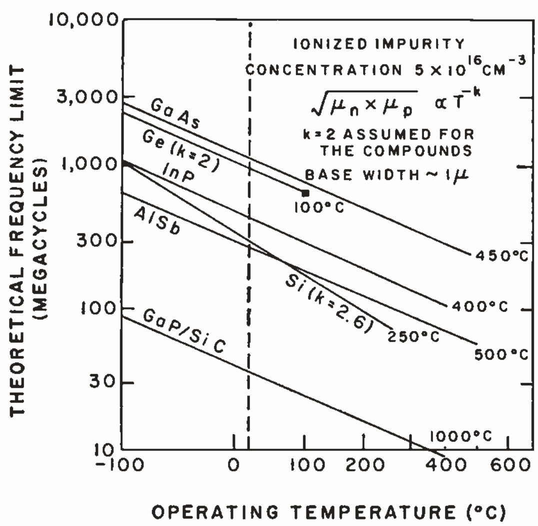

Fig. 19—Theoretical frequency limit vs operating temperature of bipolar compound semiconductor transistors.

as it might otherwise be. Materials may be tailored to achieve certain properties needed for specific devices. For example, alloying two similar materials such as bismuth telluride and bismuth selenide reduces thermal conductivity without materially affecting electrical conductivity.

Infrared detectors are another example of semiconductor devices which depend on new materials. For detectors to operate over a broad range of spectral response, materials with intrinsic energy gaps of different magnitudes, and/or extrinsic impurity energy levels of great variety, are needed. Indium antimonide is already of commercial importance because of its low intrinsic energy gap, which allows detection of infrared radiation to approximately 5 microns [71]. The lead sulfide, lead selenide, and lead telluride family of compounds yields spectral response from 2.7 to over 5 microns [72], [63]. Alloys of these materials allow response to any specified value in this range. Similarly, alloys of indium arsenide and indium antimonide can be used to adjust the spectral response between 3 and 5 microns.

Impurity levels in both elemental and compound semiconductors are important for infrared detectors. Already devices using the gold level in germanium [73] have been brought to the commercial stage, and more recently copper-doped germanium detectors with response to 20 microns have been developed. We thus see that the availability of a variety of impurities, along with a variety of host lattices, offers considerable flexibility to the approach to infrared detection [74].

The discovery of the Group III-V semiconductors along with the systematic development of the theory of the chemical bond for solids has brought forth many new compound semiconductors to be explored for a variety of device applications. No longer is the device man restricted to germanium and silicon, but he now has a broad, highly variable class of materials with which to work.

FUTURE TRENDS OF MATERIALS SCIENCE AND TECHNOLOGY

It is appropriate in an issue dedicated to the 50th Anniversary of the IRE to discuss trends in materials technology which may be expected to take place in the next 50 years.

Four areas will be of particular importance:

1) Improved materials and process technology of germanium and silicon for *p-n* junction-type devices.
2) Investigations of compound semiconductors for electronic devices.
3) New device principles which will require new materials technology for their implementation to a practical device.
4) The full development of the integrated circuit concept, based on a high degree of sophistication in materials and process technology.

The first is necessary to further improve the performance and reliability of *p-n* junction devices of germanium and silicon, as well as to improve manufacturing yields so that prices will be further reduced. New techniques will be discovered and the technologies discussed above will be further refined; surface studies can be expected to receive particular emphasis. New ways of using advanced technologies will result in devices which, while fundamentally of the *p-n* junction type, will have higher performance and reliability and lower cost than present devices.

More attention will be focused on the technology of compound semiconductors, and we can expect the universities to be instrumental in exploring the basic properties of these materials. Compound semiconductors will be especially important in developing new types of devices where some particular properties, not found optimum in germanium or silicon, are utilized.

Category three already contains several new solid-state devices which involve principles different from those of *p-n* junction devices, but which are limited by materials techniques. An example is the metal-oxide-metal tunneling [75], [76] device, where the device function depends on quantum-mechanical tunneling and hot electrons. While the theoretical understanding of this device is quite advanced, the practical development is lagging because of lack of technique in the field of thin films. This example illustrates the general point; namely, that new device principles will be discovered, which will in turn place new demands on the materials technologist in order for the device to reach a stage of practical development.

The last category will place the most stringent demands of all upon the materials technologist. One is attempting to make "devices" which perform complex functions, and the need for control of materials processes is obvious—if it is not obtained the cost of manufacturing such "devices" will not be brought low enough to compete with more conventional approaches, except in special areas. We are confident that the necessary advances will be made, and that integrated circuits will be extremely important in the future.

While the developments in solid-state electronics have already been of spectacular proportions, we believe that the field is still in its infancy; that many exciting developments will take place in the years ahead; and that materials technology will be a most important factor in this continued development. We highly recommend the field of solid-state electronics to our young engineers and scientists, and encourage them to fortify their challenging future with a concentrated study of chemistry, metallurgy, and physics.

Summary—**The development of digital computing machines is described and illustrated, from the mechanical devices of the seventeenth century to the electronic systems of today, in three chronological sets of sketches. Only a few typical ones of the modern systems are treated and not all early machines are discussed. A bibliography is appended.**

Introduction

IN APRIL, 1944, during the third year of the second World War, a huge electromechanical computing machine formally named the "IBM Automatic Sequence Controlled Calculator" and familiarly known as the "Mark I," was put in operation in the basement of Harvard University's Cruft Laboratory in Cambridge, 24 hours a day, 7 days a week. By the time it had been moved, late in 1946, to its permanent location in the Harvard Computation Laboratory, the Mark I had fairly revolutionized the calculation of mathematical tables.

During the same period, early in 1946, the eighteen-thousand-tube "Electronic Numerical Integrator and Computer"—called "ENIAC" for short—was put to work at the Moore School of the University of Pennsylvania in Philadelphia, to perform such tasks as the computation of ballistic tables. The ENIAC could compute the trajectory of a projectile in less than the time of flight of the projectile.

Thus, large-scale automatic computation began. A scant fifteen years later, automatic electronic computation had become a billion-dollar-a-year industry of unsurpassed vigor, supplying solutions to scientific problems of almost inconceivable complexity and performing data-processing tasks of almost unimaginable extent.

The purpose of this paper is to describe panoramically—in a chronological series of glimpses—the evolution of electronic digital computing machines from early con-

cepts of over three-hundred years ago, through a transitional period in the decade following World War II, to the present era of modern computing systems.[1] Only *digital* machines and systems are described; the important class of *analog* machines are not treated here.[2] (A digital computing machine is one in which numbers are represented by discrete symbols—discrete physical states of the machinery used—forming a definite number system. In an analog machine, numbers are represented by continuous physical entities, such as voltages.) Because of space limitations, only a few of the modern digital computing machines (and only some of the earlier ones) can be discussed. The mere identification of all the distinct digital machine types now in use would require more than the entire space allocated to this paper [142]. For the same reason, foreign modern machines are not explicitly mentioned. As the whole evolution of electronic digital computers must be covered in a paper of reasonable length, which should, as George Sarton said of his history of Hellenistic science, "enlighten the reader without overwhelming him," it is obvious that the authors cannot deal with every part of the subject.

In the sense in which the term is used here, an automatic computer is essentially an assemblage of units designed to recognize information (usually but not exclusively numerical) supplied at the computer input, store information (both to be used and to be supplied by the machine), perform arithmetic and other operations, form definite sequences of these operations under appropriate control, and supply the results of the computation to the computer output. A digital automatic computer is one in which numbers are represented in terms of a base (such as the base 10 of decimal numeration or the base 2 of binary numeration, etc.) as the discrete physical positions or states of the computing mechanism. For example, a wheel which can be driven to any one of ten discrete angular positions can represent a decimal digit 0 to 9; a two-tube toggle circuit, or *flip-flop*, in which only one or the other of the tubes is conducting, can represent a binary digit 0-1, and so on. The first digital computers, like the well-known hand adding machines, were entirely mechanical. Then electrical (solenoid or motor) actuation and sliding contacts appeared and digital computers became electromechanical. Later, electronic conducting states, as in the vacuum-tube or transistor flip-flop, were used to represent numbers. Of course, definite variations of these states could be, and were, used to perform operations on the numbers as well. Physical motion of parts was no longer an essential feature of a computer. And the action became so fast that it made no sense to build an electronic digital computer that was not also an automatic digital computer. So the word "automatic" was gradually dropped.

A mechanical digital computer can add two digits, for example the two decimal digits 5 and 8, by counting first up to 5 positions and then 8 positions more with a ten-position counting wheel, generating a carry of 1 into the next higher decimal *place* (also called *column*, or *stage*) as the wheel passes through 9. An electronic digital computer can add in the same manner with an electronic counter. Many adders based on this principle have been built, including most of the early and all of the mechanical ones. But, in electronic machines, it was soon found more economical and much faster to use various kinds of *logic circuits* which generate the sum digit and the carry digit directly from the given augend and addend digits (5 and 8 in our example) by means of the elementary operations of logic.[3]

Subtraction has often been performed by means of complementary numbers.[4] In electronic machines, more direct techniques have been used as well. Multiplication can be performed, of course, simply as repeated addition. The early digital computers (and some not-so-early ones) multiplied in just this manner. In some machines, multiplication was performed by means of a built-in multiplication table. This, however, required large amounts of "hardware"; more efficient techniques were developed later. Not all computers could divide explicitly. Division has usually been performed as a specially-designed combination of the other three operations; (many such combinations exist). For all four operations, specially-designed logic circuits, together with specially-designed number systems, have played a large part in the development of electronic digital computers. In some of them, the *parallel* computers, computation proceeds simultaneously with all digits of the given numbers, as in a desk calculator. In other machines, the *serial* computers, computation is performed one digit at a time, as with pencil and paper.

The automatic character of an automatic digital computer consists in its ability to perform definite sequences of arithmetic and other operations (such as finding square roots, looking up entries in a table, etc.) without manual intervention. The operations in such a sequence are specified by a corresponding sequence of computer *instructions*. In early machines, these instructions were communicated one at a time to a computer by means of punched cards or punched tape read by the machine as

[1] The chronology is based upon the dates at which the various machines were put in operation. However, since the operativeness of an evolving machine is difficult to define, many of the dates given are only approximate.

[2] See, G. A. Korn, "The impact of hybrid techniques on the analog computer art," Proc. IRE, this issue, pp. 1077–1086.

[3] These elementary operations of logic are usually defined as operations in Boolean Algebra (named for George Boole, English mathematician, 1815–1864). They include the operation of union (A or B or both), intersection (A and B simultaneously) and complementation (not A), in which A, B, etc., are sets of binary conditions or states.

[4] "The complement on ten of a number is that second number which must be added to the first in order to obtain a power of ten. This complement on ten may be read off from left to right by taking the complement on nine of each successive digit except the last on the right, of which the complement on ten must be taken." (Quoted from Aiken and Hopper [4].)

its work went on. Later, the whole *program* (as a set of computer instructions is called) was stored in the internal *memory* of the computer along with the numbers to be used in the computation. Today, most large digital computers (and many small ones) are "stored-program" machines which utilize this idea. Since each instruction usually includes one or more *addresses, i.e.*, storage locations in the memory, a stored-program machine can be instructed to perform calculations on the instructions themselves. For example, it can add a number to an address. In this manner, such a machine can modify its own original program. More precisely, the machine is able to make explicit those parts of its own program that it determines are needed as the computation proceeds. In this ability resides much of the tremendous power of the modern electronic digital computer.

Early Concepts

Some aids to computation, like the abacus, are quite ancient. However, the invention of the first mechanical device capable of addition and subtraction in a digital manner has been generally credited to Pascal, who built his first machine in 1642. This claim has been contested on the basis of letters sent to Kepler in 1623 and 1624 by Wilhelm Schickhardt of Tübingen, in which the latter describes the construction of a calculator [121]. Pascal, who at the age of 19 had wearied of adding long columns of figures in his father's tax office in Rouen, made a number of calculators, some of which are still preserved in museums. His machines had number wheels with parallel, horizontal axes. The positions of these wheels could be observed and sums read through windows in their covers. Numbers were entered by means of horizontal telephone-dial-like wheels which were coupled to the number wheels by pin gearing. Most of the number wheels were geared for decimal reckoning but the two wheels on the extreme right had twenty and twelve divisions, respectively for sous and deniers. A carry ratchet coupled each wheel to the next higher place. The stylus-operated pocket adding machines now widely used are descendents of Pascal's machine (Figs. 1 and 2).

In 1671, Leibniz proposed a machine which could multiply by rapid, repeated addition. One was built in 1694, but it was not reliable (Fig. 3). The first machine to perform all four basic arithmetic operations well enough for commercial manufacture was the Arithmometer of C. X. Thomas, built in 1820. However, only a small number of Thomas's machines were constructed; real commercial exploitation of mechanical calculators did not take place until the last two decades of the nineteenth century. Two further inventions deserve mention as forerunners of automatic calculators. The first is the Jacquard loom punched-card system devised to control the automatic weaving of complex patterns. Jacquard's loom, which came into wide use during the decade following 1804, was the first successful application of principles of punched tape and card control demonstrated originally between 1725 and 1745 by Bouchon, Falcon, and Jacques.

The second invention is the difference engine, a device for automatically calculating mathematical tables of functions whose higher-order differences are constant. Such a machine requires a register for each order of difference and a means for successively adding the contents of each register to those of the next lower-order register. The difference engine was conceived by Müller in 1786. Construction was first attempted by Charles Babbage,

Fig. 3—Leibnitz calculating machine (close-up of mechanism).

who, between 1812 and 1822, designed and built a small working model with three registers of six digits each [36] (Fig. 4). It was characteristic of the man that he immediately proposed to built the biggest difference engine that might ever be needed. It was to have seven 20-digit registers and printed output. With the backing of the Royal Society he obtained government support and began work in 1823. However, the engineering of the time was not up to such a machine and Babbage had to invent techniques for engineering drawing and for precision construction. The machine was only partially completed in 1833 when government support ended and work stopped. A five-register sixteen-digit machine was later built in Sweden by Scheutz and demonstrated in England in 1854 [1].

In 1833, Babbage conceived his analytical engine, the first design for a universal automatic calculator. He worked on it with his own money until his death in 1871. Babbage's design had all the elements of a modern general-purpose digital computer; namely: memory, control, arithmetic unit, and input/output. The memory was to hold 1000 words of 50 digits each, all in counting wheels. Control was to be by means of sequences of Jacquard punched cards. The very important ability to modify the course of a calculation according to the intermediate results obtained—now called conditional branching—was to be incorporated in the form of a procedure for skipping forward or backward a specified number of cards. As in modern computer practice, the branch was to be performed or not depending upon the algebraic sign of a designated number. The arithmetic unit, Babbage supposed, would perform addition or subtraction in one second while a 50×50 multiplication would take about one minute. Babbage spent many years developing a mechanical method of achieving simultaneous propagation of carries during addition to eliminate the need for fifty successive carry cycles. Input to the machine was to be by individual punched cards and manual setting of the memory counters; output was to be punched cards, printed copy, or stereotype molds. When random access to tables of functions—stored on cards—was required, the machine would ring a bell and display the identity of the card needed. Although Babbage prepared thousands of detailed drawings for his machine, only a few parts were ever completed (Fig. 6).

The description of Babbage's ideas would not be ade-

quate without a mention of Lady Ada Augusta, Countess of Lovelace, who was acquainted with Babbage and his work. Her writings have helped us to understand this work and contain the first descriptions of programming techniques.

Less than twenty years after Babbage's death, H. Hollerith conceived and developed the idea of machine-readable unit-record documents. He introduced electromechanical sensing means and apparatus for entering, classifying, distributing and recording data on punched cards. Hollerith's machines were used during the compilation of the 1890 Census reports. The development of many types of electromechanical accounting machines and early computers was based on Hollerith's inventions.

The development by J. W. Bryce and his associates of devices and circuitry which would transfer data between registers, or from registers to recording devices, was an important step in the evolution of electromechanical computers. One result was a machine developed by the International Business Machines Corporation for Columbia University during 1929 which solved mechanical problems that had thwarted Babbage. The inventions which had made this machine possible strongly influenced the development of the 600 series of IBM multiplying machines introduced in 1931 and were used later in the Mark I.

Another significant series of developments were the Bell Telephone Laboratories relay computers, which were based initially on the work of G. Stibitz in 1938. These biquinary (using both the base 2 and the base 5) and binary-coded decimal machines included paper tape input, program control, branching, self checking and many other features later incorporated in electronic computers. The Model II and III machines were built for the National Defense Research Council and were placed in operation in 1943 and 1944. Later, Model V was built for the National Advisory Committee on Aeronautics at Langley Field, Va., and for the Ballistic Research Laboratory at Aberdeen, Md. [10].

Transitional Machines

Mark I

Utilizing twentieth-century advances in mechanical and electrical engineering, the Automatic Sequence Controlled Calculator, or Mark I, brought Babbage's ideas into being, giving concrete existence to much more at the same time. The Mark I, an electromechanical calculator 51 feet long and 8 feet high, was built by the International Business Machines Corporation between 1939 and 1944, when it was formally presented to Harvard University by T. J. Watson, IBM's President. The Mark I was developed jointly by Howard Aiken, Professor of Applied Mathematics at Harvard, (later, also Commander, U.S.N.R.) and his staff, and by IBM engineers (Figs. 7 and 8).

The machine was a parallel, synchronous calculator, using a number length of 23 decimal digits plus alge-

Fig. 8—Howard Aiken and part of the Mark I calculator.

braic sign. Calculations could also be done with 46 digits. It could perform any specified sequence of five fundamental operations, addition, subtraction, multiplication, division and reference to tables of previously computed results. The operation of the entire calculator was governed by an automatic sequence mechanism. The machine consisted of 60 registers for constants, 72 adding storage registers, a central multiplying and dividing unit, means of computing the elementary transcendental functions $\log_{10} x$, 10^x and $\sin x$, and three interpolators reading functions coded in perforated paper tapes. The input was in the form of punched cards and switch positions. The output was either punched into cards or printed by electric typewriters.

Each of the 60 constant registers consisted of 24 ten-position switches (for the 23 digits and the sign). Each of the 72 adding storage registers was composed of 24 electromechanical counter wheels capable of adding numbers as well as storing them. Each of these was essentially a ten-position switch (with additional contacts for carries) actuated through a magnetic clutch. Subtraction was effected in the same counter wheels by means of complementary numbers. The multiply-divide unit multiplied by first forming and storing the 9 integer multiples of the multiplicand; then selecting the multiples indicated by each digit of the multiplier and shifting and adding them in the proper columnar position. The position of the decimal point was fixed and determined by a plugboard. Division was carried out with the same unit in much the same manner: the 9 integer multiples of the divisor were first formed and stored. These multiples were then compared with the dividend and the largest multiple smaller than the dividend was selected; it was subtracted from the dividend and a digit defining it was entered in the quotient register. Logarithms, antilogarithms and sines were calculated automatically by means of special registers and appropriate series expansions of the functions. Each of the three interpolators carried an endless function tape containing values of the function for equidistant arguments together with appropriate interpolation coefficients. The tape was first positioned by moving it automatically in the direction of shortest travel; then the function was read by the machine and the interpolated value was calculated.

The sequence mechanism consisted of a sprocket drum over which ran a perforated paper tape, the "control" tape. Each transverse line of the tape had space for 24 equidistant holes in three groups, A, B, and C, of 8 holes each. Each line of holes constituted the instruction: "Take the number out of unit A, deliver it to B, start operation C." The sequence and interpolator mechanisms and the counter wheels were all synchronized and driven by a gear-connected mechanical system and a 5-HP motor. The fundamental cycle was of 300 msec. A typical multiplication required about 3 sec [4], [8], [14].

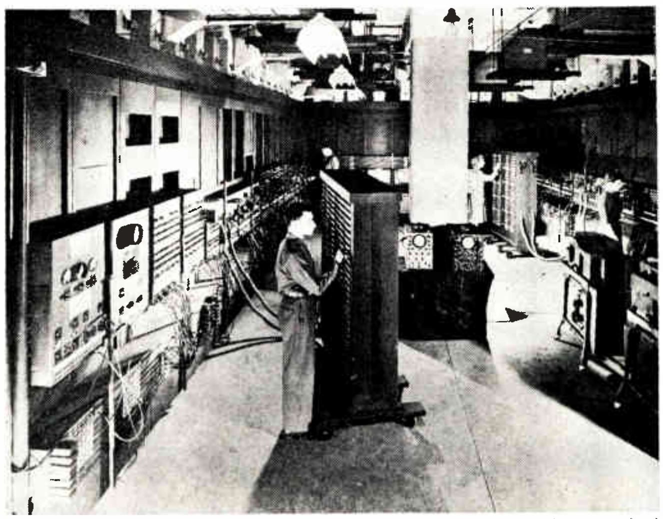
The Automatic Sequence Controlled Calculator was in operation for more than fifteen years. Results of its work are used in almost every computation laboratory.

ENIAC

The *ENIAC* was developed and built at the Moore School of Electrical Engineering of the University of Pennsylvania beginning in 1943, and was completed in 1946. As evidenced by its full name, "Electronic Numerical Integrator and Computer," it was not intended to be a general-purpose machine. Its principal objective was the computation of firing and ballistic tables for the Aberdeen Proving Ground of the U. S. Army Ordnance Department. This computation required the integration of a simple system of ordinary differential equations involving arbitrary functions.

Physically, the ENIAC was impressive. It consisted of 40 relay racks of equipment, arranged in a U-shaped assembly, with 4 relay racks forming a module, 4 modules on each side and 2 at the rear, as seen from the inside in Fig. 9. Half of the racks contained accumulators (registers with facilities for addition), one accumulator per rack, and the other half included the following:

1) Master programmer, cycling unit and initiating unit. These emitted the control impulses, cleared the machine to zero (4 racks),
2) Function-table panels (6 racks). These supplied on demand the functional values associated with a given argument. There were 3 such tables, mounted on heavy casters. The values were settable in advance on the rotary switches,
3) Divider and square root unit (2 racks),
4) Multiplier (3 racks),
5) Constant transmitter (3 racks),
6) Printer (2 racks).



(Remington Rand UNIVAC Division, Sperry Rand Corporation)

Fig. 9—The ENIAC.

This bulky equipment occupied a space 30×50 feet and contained 18,000 vacuum tubes. It required 130 kw of power. The computing elements consisted largely of decade rings, flip-flops and pentode gates. These were direct-coupled, requiring 18 power-supply voltages and consequent heater-cathode potential differences of over 100 volts. The input-output system consisted of modified IBM card readers and punches.

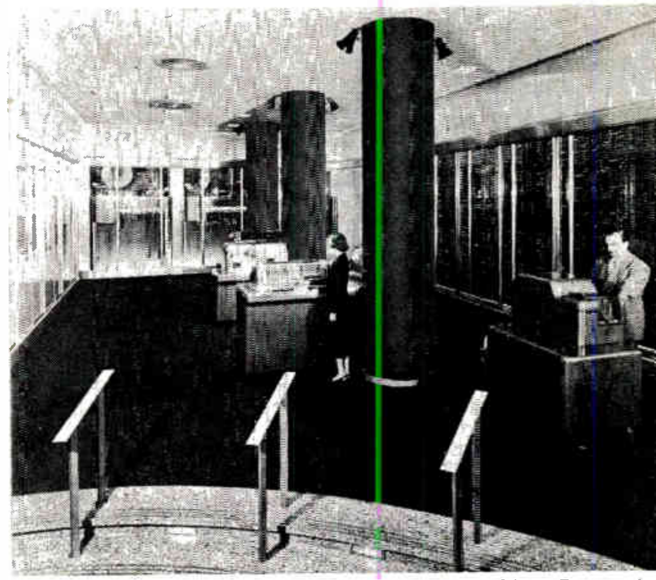
Numbers were of ten decimal digits, with negative numbers represented by complements. A basic pulse rate of 100 kilopulses per second was used. The machine carried out its calculations in the parallel mode by transmitting numbers additively or subtractively from one accumulator to another, with references to the multiplier and divider, table look-ups from the function tables and new numbers from the constant transmitter. Addition required 20 pulse times (0.2 msec) and multiplication required 14 addition times (2.8 msec). All this required elaborate preparation of the so-called background wiring of the machine. This wiring—plugged connections and switches—effected the cycling of addition, multiplication, etc., under control of the cycling unit. The connections required from 30 minutes to a full working day to set up and constituted a serious limitation on the flexibility of the system.

Even though it was not a serious obstacle to the calculation of ballistic and firing tables, this limitation was eased in the late 1940's when a more flexible wired programming system was devised as a result of suggestions of John von Neumann. The background wiring was made permanent and the function tables were used to store instructions rather than values of functions. This was made possible by extensive changes in the cycling unit and associated equipment. The instructions did not then constitute an internally-stored program, however, since they were manually set on the function-table switches [6], [7], [9], [11], [14].

The ENIAC is no longer a productive computer. The units composing it have been separated and given to museums and other institutions where they are accessible to the public. There, they serve as reminders of a pioneering effort in extending the scope of man's ability.

IBM 604 Electronic Calculator

The IBM 604 Electronic Calculator was a general-purpose electronic digital computer produced in quantity. Development began late in 1946 and the first deliveries took place at the end of 1948. This machine remained in production until 1960, and more than 4000 were built. The IBM 604, a descendent of the IBM 603 (a punched-card, six-digit electronic multiplier) employs miniature tubes in one-tube pluggable circuit packages for economy in assembly and maintenance. The 604 contains over 1400 tubes and operates at 50 kilopulses per second. The basic machine has a capacity of 60 program steps, which are set up on a plugboard. All steps,



(International Business Machines Corporation)

Fig. 10—The IBM Selective Sequence Electronic Calculator (SSEC), a 13,000-tube, 23,000-relay machine, went into operation at IBM New York Headquarters in December 1947, and was used until August, 1952. The SSEC was capable of conditional branching, permitting the selection of alternative program sequences according to intermediate results.

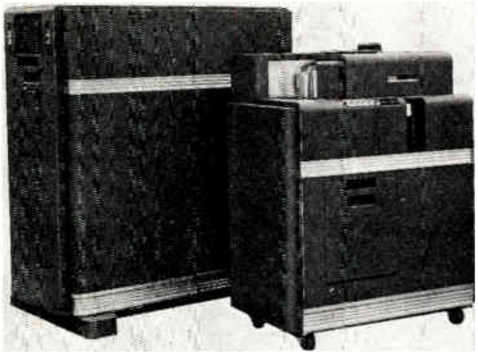
except those calling for multiplication or division, are executed in 0.5 msec (Fig. 11).

An important feature of the IBM 604 was the inclusion of a zero-test and a sign-test on the contents of the accumulator. These tests permitted a conditional program branch by allowing suppression of some steps of the normal program sequence. Additional flexibility was provided by the use of relay selectors. The calculator has a 13-decimal-digit accumulator and 37 digits of additional storage in vacuum-tube registers. Input and output are on punched cards. Marginal checking (*i.e.*, determination of performance margins) by clock frequency variation is provided [142].

IBM Card-Programmed Calculator (CPC)

The IBM Card-Programmed Calculator (CPC) line descended from the connection, made for Northrop Aviation in 1947–1948, of a multiplier to an accounting machine tabulator. First an IBM 601 Multiplier (mechanical) and then an IBM 603 Electronic Multiplier was connected to an IBM 405 Alphabetic Accounting Machine for solution of linear differential equations. In 1948–1949, an IBM group produced the models I and II Card-Programmed Calculator by connecting an IBM 604 to an IBM 402 Alphabetic Accounting Machine. This system provided a parallel printer and 80 digits of counter wheel storage. Sixteen additional ten-digit-plus-sign words could be stored in counter wheels in each of three separate IBM 941 Auxiliary Storage Units.[5] (Fig. 12.)

[5] A "word" is an ordered set of digits (or characters) used together.



(International Business Machines Corporation)

(International Business Machines Corporation)
Fig. 12—IBM Card-Programmed Electronic Calculator. *Left to right:* 941 auxiliary store, tabulator-printer, 605 computer, card reader-punch.

The Card-Programmed Calculator took its instructions from cards which could call for programs stored in a plugboard. Conditional branches were effected by switching to alternate sequences in the cards. The arithmetic speed of the IBM 604 System was lower than those of the large-scale machines then in operation and under construction, and its internal storage capacity was more limited. But access of the Calculator to an unlimited program on cards eliminated housekeeping operations (so time-consuming on the early stored-program machines) required to manipulate a stored program, and enabled the CPC's to outperform more sophisticated equipment in many applications. At one time about 200 Card-Programmed Calculators were simultaneously in use [142].

Electronic Discrete Variable Automatic Computer (EDVAC)

The Electronic Discrete Variable Automatic Computer, or EDVAC, was built at the Moore School (University of Pennsylvania) between 1947 and 1950 for the Ballistic Research Laboratory at the Aberdeen Proving Ground. It is a serial, synchronous machine in which all pulses are timed by a master clock operating at 1 megapulse per second. It contains some 5900 vacuum tubes, about 12,000 semi-conductor diodes and utilizes the binary number system with a word length of 44 binary digits (Fig. 13).

(Ballistic Research Laboratory)
Fig. 13—The EDVAC.

The EDVAC was built as a stored-program machine. The instructions, each of which consists of four ten-bit addresses and a four-bit operation code,[6] are stored in an internal memory together with the numbers to be used in the computation. This internal memory is composed of 128 thermostatically-controlled acoustic delay lines, each storing 384 bits (and accommodating 8 words) as sound waves in mercury. The information constantly circulates through the line. $128\times 8=1024$ words of rapid-access storage are thus available, with an access time of 48 to 384 μsec.

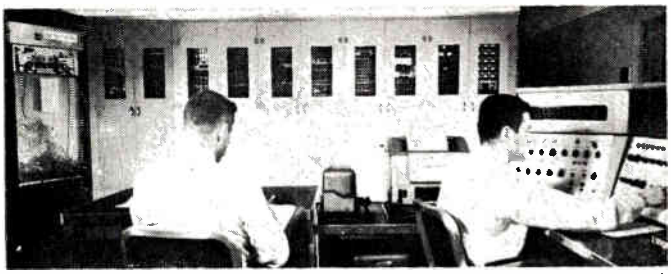
Twelve distinct operation codes are used, out of the possible sixteen, including double-precision operations (*i.e.*, with double-length numbers) and a branch instruction. Diode logic circuits are used. Subtraction is done directly, not through complements. The time required for the average addition is 864 μsec, for the average multiplication, 2900 μsec. Input-output means include paper tape, teletypewriter and punched cards. Equipment additions have been made to the machine from time to time, including particularly magnetic-drum and magnetic-tape storage.

Important features of the EDVAC have been used in other machines, notably the UNIVAC (built by Eckert and Mauchly) and the SEAC (National Bureau of Standards). The EDVAC was still in operation at Aberdeen at the time this paper was written [17], [142].

Standards Electronic Automatic Computer (SEAC)

The Standards Electronic Automatic Computer, or SEAC was built by the staff of the Electronic Computer Laboratory of the National Bureau of Standards. The design began in June, 1948 and the machine was put in operation in May, 1950. It was built under the sponsorship of the Office of the Air Comptroller, Department of the Air Force, principally to carry out mathematical investigations of techniques for solving large logistics programming problems (Fig. 14).

[6] "Bit" is a common abbreviation for "binary digit."



(*National Bureau of Standards*)

Fig. 14—The SEAC.

The SEAC was built as a stored-program computer. Its design was based upon that of the EDVAC. The SEAC is a serial, synchronous, binary, fixed-point machine operating at a one-megapulse-per-second rate with a word length of 44 bits plus sign. It was planned and constructed as a nucleus to which improvements and subassemblies could be added to increase its problem-solving capabilities. With some 750 tubes and 10,500 diodes, the original installation consisted mainly of the computing and control circuitry, a memory of 64 mercury acoustic delay lines providing for the storage of 512 forty-five bit words, a manual keyboard for direct input and a teletype printer for direct output. Punched paper tape was used to provide indirect operation. There were seven basic four-address instructions including "logical transfer" or branching.

Equipment additions have been made to the machine from time to time. One of the first was that of a cathode-ray-tube electrostatic memory of a type developed by Williams at the University of Manchester [18]. This electrostatic memory was later improved and enlarged and acoustic-delay-line memory capacity was doubled. The machine now has a memory capacity of 1024 words in acoustic delay lines and 1024 words in CR tubes. It contains some 2300 vacuum tubes and 24,000 germanium diodes. A "Flexowriter" (an electric typewriter punching paper tape) and magnetic tape are used for input and output as well as the original means. Facilities have been provided for the use of three-address instructions as an alternative to the four-address structure.

The National Bureau of Standards has operated the SEAC as one of its own facilities since January, 1954. The machine has been working nearly 12 years, not only solving innumerable problems for government agencies, but also permitting studies in the data processing field and providing means of developing and testing new computer components and devices [40], [44], [66], [142].

Whirlwind I

An assignment to build a real-time aircraft simulator was given in 1945 to the Digital Computer Laboratory of the Massachusetts Institute of Technology, at that time a part of the Servomechanisms Laboratory of M.I.T. Beginning in 1947, the major part of the effort was devoted to the design and construction of the electronic digital computer known as Whirlwind I. The project was sponsored by the Office of Naval Research and the United States Air Force. The machine was put in operation in March, 1951 (Fig. 15).

Whirlwind I was a parallel, synchronous, fixed-point computer utilizing a number length of 15 binary digits plus sign (16 binary digits in all). Physically, it was a large machine containing some 5000 vacuum tubes (mostly single pentodes) and some 11,000 semiconductor diodes. It consisted of an arithmetic "element" including three registers; a control element including central control, storage control, arithmetic control and input-output control; a program counter; a source of synchronizing pulses, or master clock, supplying 2 megapulses per second to the arithmetic element and 1 megapulse per second to the other circuits; an internal storage element, or memory; terminal equipment; and extensive test and marginal checking equipment.

The arithmetic element included three registers designated AC, A and B and a counter. The first register was a shifting accumulator, formed of an adding register and a carry register; it held the product during multiplication. The A register held the multiplicand during multiplication. The B register was a shifting register holding the multiplier. Special fast-carry circuits were provided for addition. Subtraction was by nine's complements and "end-around" carry.[7] Multiplication was by successive addition and division by successive subtraction. (In binary arithmetic, multiplication and division are carried out by addition, or subtraction, and shifting.) Complete addition required 3 μsec. The average multiplication required 16 μsec.

Whirlwind I was a stored-program computer. The instructions, each of which consisted of one ten-bit address and one five-bit operation code, were stored in the internal memory of the machine. There were 32 distinct operation codes, of which about 27 were assigned, including addition, subtraction, multiplication, division, shifting, transfer of all or parts of words, branching and conditional branching. There were terminal-equipment control instructions and also special instructions to facilitate double-length and floating-point operations.

The central control of Whirlwind I was arranged in the form of two "crystal matrices" or diode arrays (Fig. 16). The first of these was a 32 position control switch to decode the order part of the instruction while the second was an operation control matrix in which one horizontal selection made a large number of vertical selections. Both arrays were driven at a rate of one megapulse per second.

The memory of Whirlwind I consisted at first mainly of 16 specially-designed electrostatic storage tubes, each with an array of $32 \times 32 = 1024$ charged spots, providing 1024 registers of storage [20]. The M.I.T. electrostatic storage tube differed from the Williams CR storage tube

[7] From the highest to the lowest column of the machine.

Fig. 17—Coincident-current magnetic-core storage array of the Whirlwind I Computer.

developed at the University of Manchester [18] in that a second electron gun was used to maintain the charge, instead of cyclic replacement, and the storage depended on a change of the potential of the charged spot, rather than on a change of the geometry of the spot. Later, a coincident-current magnetic-core memory was used. The cores were made of a material possessing a rectangular hysteresis loop [30], [50]. Two banks, each of 32×32×17 cores were in operation in the machine in 1953 (Fig. 17). They provided 2048 registers of storage, each of 16 binary digits and a parity-check digit.[8]

The terminal equipment included:

1) A photoelectric paper tape reader,
2) Electromechanical paper tape readers and punches,
3) Electromechanical typewriters,
4) CR oscilloscope displays, including a computer-controlled scope camera,
5) Inputs from various analog equipments needed for control studies,
6) Outputs to analog equipment.

[8] A parity-check binary digit is used to make the number of binary "ones" of constant parity, either odd or even. Since a single error changes the parity, the parity check permits the detection of any single error.

Magnetic-tape units and magnetic drums were added later.

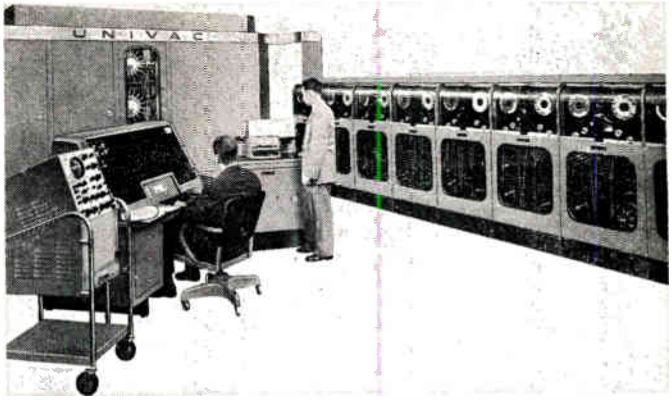
Preventive maintenance techniques called "marginal checking" were used on the Whirlwind I to establish the life expectancy of various components, particularly vacuum tubes and diodes, by determining performance margins. Variations of operating voltages and of pulse times were used, together with special pulse sources, to detect imminent failures. This was done automatically by means of telephone switching apparatus. The marginal checking of the whole computer, which could be carried out in 15 minutes, helped to bring its operational reliability to comparatively high levels [25].

Ideas embodied in the Whirlwind I are used in most of the modern digital computers [28], [33].

Universal Automatic Computer (UNIVAC)

The development of the Universal Automatic Computer, or UNIVAC was started about 1947 by Presper Eckert and John Mauchly who founded the Eckert-Mauchly Computer Corporation in December of that year. The first UNIVAC I was built for the U. S. Bureau of the Census and was put in operation in the Spring of 1951. (The Eckert-Mauchly Corporation later became a subsidiary of Remington Rand, forming the organization which is now the Remington Rand UNIVAC Division of the Sperry Rand Corporation.)

UNIVAC I was a direct descendent of the ENIAC and of the EDVAC, in the development of which Eckert and Mauchly had both had an important part at the University of Pennsylvania. It was a serial, synchronous machine operating at a rate of 2.25 megapulses per second. It contained some 5000 vacuum tubes and several times as many semi-conductor diodes in logic and clamp circuits. One-hundred mercury delay lines provided 1000 twelve-decimal-digit words of internal storage. Twelve additional delay lines were used as input-output registers. Aside from console switches and an electric typewriter providing small amounts of information, the input-output medium was metal-base magnetic tape. 48 UNIVAC I machines were built (Fig. 18).



(Remington Rand UNIVAC Division, Sperry Rand Corporation)

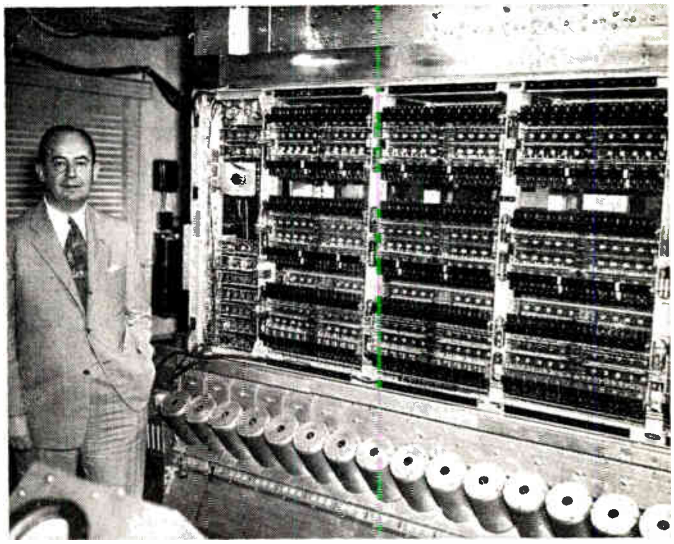
Fig. 18—UNIVAC I.

UNIVAC I was built as a stored-program machine. Through the use of a six-bit code, alphabetic characters, punctuation, control symbols, etc., could be handled by the machine as well as decimal digits. Within this binary-coded representation, decimal digits were represented in the "excess-three" code.[9] The code included a seventh bit for a parity check of every "alphanumerical" (and other) character. There were some 45 distinct instructions, including rounded and unrounded arithmetic, conditional transfers and input-output control. Each instruction consisted of a one-alphabetic-character operation code and of a three-decimal-digit address. There were two instructions per word. Subtraction was direct. Addition required 0.5 msec; about 2.5 msec were required for multiplication.

Not long after UNIVAC I was put in operation, "automatic programming" techniques were developed for the machine by its builders. These techniques consist essentially of means to instruct a computer to prepare that sequence of its own instructions which is needed to perform a given task. Sets of such means have become extensive programming languages that are important for the effective use of the modern digital computers[10] [27], [45], [142].

Institute for Advanced Study Computer

The design of the Institute for Advanced Study Computer was started in 1946 and the machine was completed in June, 1952, by a staff under the direction of Prof. John von Neumann, IAS. Its development and construction were initially sponsored by the Ordnance Corps, U. S. Army; later, the project was also sponsored by the ONR, the USAF and the AEC (Fig. 19).



(Institute for Advanced Study)

Fig. 19—John von Neumann (1903–1957) and the Institute for Advanced Study Computer.

The IAS Computer was an electronic, parallel, asynchronous, fixed-point machine using numbers consisting of a sign and 39 binary digits. It was of unusually small size, 2×8×8 feet (not including input-output equipment). It contained some 2300 vacuum tubes (mostly double triodes) and consisted essentially of 3 registers designated as RI, RII and RIII, a vacuum-tube parallel adder, a control unit and an electrostatic memory composed of 40 cathode-ray tubes. A magnetic drum was added to the machine later. Input and output utilized punched cards and teletype tape.

RI was an accumulator, a device capable of holding a number and of adding another number to it. It was a shifting register holding the augend and then the sum during addition. RII was called the "arithmetic register." It also was a shifting register and was designed to hold the multiplier and the least significant digits of the partial products during multiplication, and the quotient during division. RIII was a nonshifting "memory

[9] In the "excess-three" code each decimal digit is represented by the (four-bit) pure binary equivalent of the decimal digit plus three. In this code, binary complementation yields nines complements.

[10] See R. D. Elbourn and W. H. Ware, "The evolution of computing techniques and concepts," PROC. IRE, this issue, pp. 1059–1066.

register" associated with 40 complementing gates.[11] It contained the addend during addition, the multiplicand during multiplication and the divisor during division. The adder circuit contained 4 tubes (per digit) which propagated a carry to the next stage and which reduced the 8 possible inputs to 4 possible voltage levels. These 4 voltage levels were then resolved to 2 levels, representing a "1" or a "0," with additional circuitry. The control unit contained shift and address counters and other control devices. The electrostatic memory was of the type developed by Williams at the University of Manchester [18]. It had a capacity of 1024 forty-bit words and consisted of an array of $32\times32=1024$ charged spots on the phosphor surface of each of forty cathode-ray tubes.

Negative numbers were represented by complements. Multiplication was performed by successive addition and division by successive subtraction. The IAS computer was a stored-program machine, the instructions being stored in the CRT memory. Each instruction was composed of a ten-bit address and of a ten-bit operation code. There were thus a pair of instructions in each instruction word. The basic "machine language" or set of basic instructions, included: addition (or subtraction, executed in 62 μsec), multiplication (720 to 990 μsec), division (1100 μsec), left shift, right shift, load in RII, store from RI, input, output, unconditional transfer and conditional transfer (branching). This last instruction was executed when the number in the accumulator was positive, ignored when it was negative.

The IAS Computer was the prototype for various subsequent machine developments, including three for the AEC and one for the U. S. Army Ordnance Corps, Ballistic Research Laboratory, at the Aberdeen Proving Ground [5], [41].

IBM 701

The development of the IBM 701 Data Processing System began at the end of 1950. A model was operating late in 1951 and the first production machine was delivered at the end of 1952. The heart of the IBM 701 system was a 36-bit single-address, binary, parallel, synchronous processor employing vacuum-tube flip-flops and diode logic at a rate of one megapulse per second. Multitube pluggable circuit packages were used. The arithmetic registers employed a recirculating-pulse bit-storage circuit, developed for the NORC [67], in which a combination of diode gating and pulse delay made it possible to store, shift right, or shift left with one triode per bit. Computation was governed by a single-address stored program of two 18-bit instructions per 36-bit word (Fig. 20).

For the high-speed memory, a parallel-mode cathode-ray-tube system—patterned after the serial CRT store developed by Williams [18] was devised. Seventy-two CR tubes, storing 1024 bits each, provided a 2048-word memory with a 12-μsec memory cycle. Most instructions took 5 cycles, 3 of which were for regeneration of the CRT memory. Multiplication and division took 38 cycles, during which a reserve of regeneration cycles was built up that the succeeding 12 instructions could draw upon for faster operation.

Input to the processor was on punched cards; a 150-line-per-minute alphanumeric printer and a 100-card-per-minute card punch provided output. Magnetic-tape units using plastic tape operated at a rate of 7500 six-bit groups per second (100 bits per inch). Vacuum columns were used to buffer tape between the reels and the rapid start-stop pinch-roller capstan. Both clock-frequency and supply-voltage marginal checking were used. Nineteen IBM 701 Systems were completed [37], [42], [52], [142].

IBM 650

The IBM 650, an intermediate-size, vacuum-tube computer was considered a workhorse of the industry during the late 1950's. Development began in 1949 and the first installation was made late in 1954. Over a thousand 650's have been in service since then (Fig. 21).

The 650 operates serially by character on words of 10 decimal digits plus sign. A 2-out-of-5 decimal representation in storage is translated into a biquinary code in the operating registers, allowing a fixed-count check to detect the presence of more or less than 2 bits per character. The main store of the 650 is a 12,500-rpm, 2000-word magnetic drum. A two-address instruction format accommodates, as part of each instruction, the

(International Business Machines Corporation)

Fig. 21—IBM 650 (right, rear) with magnetic tape and ramac file.

[11] In computer terminology, a "gate" is a logic circuit designed to supply an output when and only when a specified set of conditions exist at its (several) inputs. See Ref. [75].

location of the next program step. This format allows the programmer to place instructions anywhere on the program drum, and makes it possible for him to minimize access times to successive instructions.

The 650 has a basic clock rate of 125 kilopulses per second, an 800-μsec add time, and a 24- to 200-msec multiply time. A three-triode latch—basically a double inverter with cathode-follower feedback—is employed for bit storage. Checking includes a character validity check and control timing ring start and stop. A buffer area on the drum allows simultaneous card input-output and processing. The original punched-card input-output devices are currently supplemented by paper tape, magnetic-tape units, a line printer, and remote inquiry stations. Additional supplementary equipment subsequently available for use with the 650 includes random-access disk files, a 60-word core memory, and the logic necessary for index registers, floating-point operations, and the handling of alphabetic characters using two digits per character [65], [142].

Modern Systems

The transitional machines differed markedly from each other, especially in the beginning. But modern electronic digital computers generally possess many attributes in common. They are usually built in several units, only one of which is a computer, or "processor." The other units are control, storage or input and output devices. Thus, the modern machine is more properly called a computing system than a computer. Most modern digital computing systems use semi-conductors (diodes and transistors) rather than tubes. Most include magnetic-core and magnetic-tape storage. Many contain circuits to perform floating-point arithmetic directly; and, in the later ones especially, sizes and amounts of equipment can be varied to meet specific needs.

The computers of modern digital systems are all stored-program machines and all include automatic checking. The modern systems nearly all provide alphabetic as well as numerical input and output. In many of them, especially the later ones, arithmetic is performed concurrently with other operations.

Since the engineering and other technical aspects of the modern digital computing systems are discussed in accompanying papers, we shall describe only the highlights of a few typical systems among the larger ones.

Air Defense Computers

Descendants of MIT's Whirlwind I and of the IBM 701, the AN/FSQ-7 air defense computers for the SAGE System began, in 1952, as a cooperative IBM-M.I.T. Lincoln Laboratories effort based upon previous studies and specifications by Lincoln Laboratories. SAGE, a real-time communication-based digital computer control system, accepts radar data over phone lines, processes, displays information for operator decisions and guides interception weapons. The first engineering model of the computer was delivered by IBM in 1955, and production deliveries began in June, 1956 (Figs. 22 and 23).

Each computer of this duplex system is a vacuum-tube and germanium-diode machine using diode and multigrid gate-tube logic, flip-flop bit storage, and pulses through pulse transformers for bit transmission. The computer originally incorporated an 8192-word core memory (6-μsec cycle), since increased to 69,632 words, and provides over 150,000 words of drum storage. The Q-7 is single-address, binary, parallel and synchronous. Words are 32 bits plus a parity bit in length. The arithmetic unit is "dual," *i.e.*, capable of operating simultaneously on two separate 16-bit numbers for efficiency in handling two-coordinate calculations. Other noteworthy features include instruction indexing, computation in parallel with input-output, high-speed multiplication (16.5-μsec total execution time for 16-bit factors), and buffer drums to couple the processor to many slow-speed inputs and outputs.

An extensive console system with keyboard inputs provides alphanumeric and pictorial display information to system operators. The processor, drums and tape

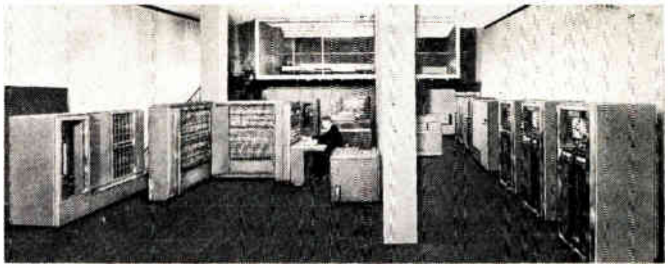
Fig. 23—AN/FSQ-7 SAGE Computer (computer frames).

units are duplexed for real-time reliability, while backup units are ready at all times to assume input-output and display functions. [72], [81], [142].

IBM 704, 709 and 7090

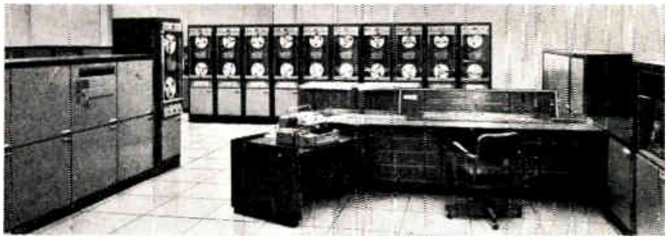
The development of the IBM 704, descended from the 701, began in November, 1953, and the first system was delivered in January, 1956. The 704 featured higher speed, magnetic-core memory, floating point and indexing (Fig. 24). It was followed in 1958 by the 709, featuring simultaneous read, write and compute by means of Data Synchronizer units that allowed the input-output channels to operate independently, as well as several special operations, including a table look-up instruction and indirect addressing. A 32,768-word core memory was installed on a 704 in April, 1957.

The IBM 7090, the first units of which were delivered in 1959, is a transistorized system compatible with the 709. About 5-times faster than the 709 on typical problems, the 7090 incorporates a 2.18-μsec core memory and improved magnetic-tape units [142].



(International Business Machines Corporation)

Fig. 24—IBM 704.



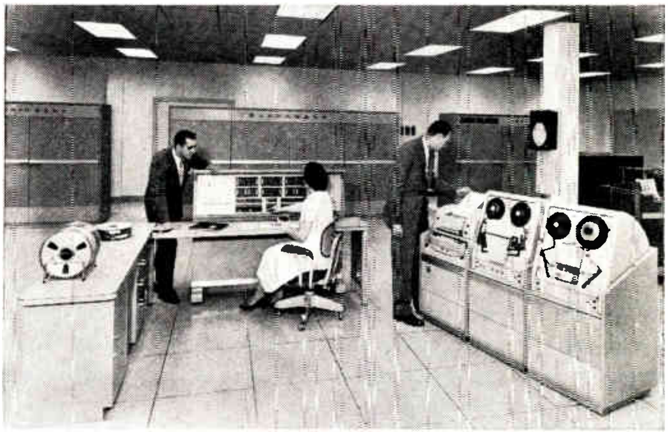
(Philco Corporation)

Fig. 25—Philco 2000 System.

Philco 2000

The Philco 2000 is an all-purpose data-processing system. The first installation was made in November, 1958. The machine's design is based upon direct-coupled, asynchronous logic circuits using surface barrier transistors (Fig. 25).

A typical Philco 2000 system contains 450 tubes, 1200 diodes and 56,000 transistors. The computer utilizes binary, binary-coded-decimal and alphanumeric internal number systems with a 48-bit word length. There are two 24-bit, one-address instructions per word; 59 of the 225 distinct instructions are floating-point instructions. As many as 32 index registers can be provided for instruction modification, relative addressing, etc. Arithmetic is performed in the parallel asynchronous mode concurrently with other operations. Addition requires 1.7 μsec, multiplication, 40.3 μsec. 4096 to 32,768 words of magnetic-core storage and 32,768 to 1,048, 576 words of magnetic-drum storage are provided. Input, output utilize punched cards, magnetic tape (up to 256 units) and a 900-lines-per-minute printer. Among the units available with the system is an input-output processor which connects 16 channels to the central computer, multiplexing any 4 channels [142].



(Burroughs Corporation)

Fig. 26—Burroughs 220.

Burroughs 220

The Burroughs 220 is a general-purpose data-processing system operating in the series-parallel mode (Fig. 26). The first installation was made in December, 1958.

The central processor contains 1800 vacuum tubes. The internal number system is binary-coded decimal, with a word length of 10 decimal digits plus sign. There are 93 instructions, each containing one four-decimal-digit address, a two-digit operation code and four "control digits" for instruction modification, relative addressing, etc. Arithmetic is performed in the serial, synchronous mode, with fixed or floating point. Addition requires 185 μsec, multiplication 2055 μsec. 10,000 words of magnetic-core storage are provided. Input-output equipment includes paper tape, punched cards, keyboard and monitor printer and up to 10 units of magnetic tape. Output includes a 1500-lines-per-minute printer [142].

National 304

The National 304, built by the National Cash Register Company, is a general-purpose data-processing system (Fig. 27). The first installation was made in November, 1959.

The central processor contains some 8000 diodes and 4000 transistors. The internal number system is binary-coded decimal. Word length is either of 10 alphanumeric characters or of 5 to 60 characters. 83 one-address "scientific" instructions or 37 three-address "business" instructions (with variations) can be used. Special opera-

(The National Cash Register Company)

Fig. 27—National 304.

tion codes, relative addressing and index registers are provided. Arithmetic is serial by word, parallel by character, with either floating point or fixed point and proceeds concurrently with other operations. With single-address instructions, addition requires 60 μsec, multiplication 1260 μsec. 2400 to 4800 ten-character words of magnetic-core storage can be used. Input-output equipment includes punched cards, punched paper tape and magnetic tape. Magnetic tape has no gaps between records. Up to 64 units can be used. Output also includes an 850–1200 lines-per-minute printer [142].

RCA 501

The RCA 501 is a general-purpose data-processing system using "building block" construction and completely variable word length (Fig. 28). The first installation was made in December, 1959.

The RCA 501 utilizes transistor and diode logic circuits. The internal number system is binary. A word consists of all the characters between special symbols defining its beginning and its end. Forty-nine two-address instructions are used, each including a one-character (six-bit) operation code, three characters for each of the two addresses and a one-character address modifier. This address modifier permits adding the contents of any one or two of seven memory locations or other registers to the instruction addresses. Arithmetic is performed with fixed point in the serial, synchronous mode concurrently with other operations. Typical addition requires 0.24 to 0.42 msec, typical multiplication 1.9 to 9.6 msec.

Up to 262,144 octal digits (base 8) of magnetic-core storage can be used. Decimal information is automatically stored as its octal equivalent. A magnetic drum storing 1.5 million characters is optional equipment. Input equipment includes keyboard, paper tape, punched cards and magnetic tape. (Up to 62 tape units can be connected on line. For accuracy, all information on magnetic tape is automatically recorded twice.) In addition to paper and magnetic tapes, output equipment includes a 900-lines-per-minute printer and a monitor typewriter [98], [142].

UNIVAC Solid State 80/90

The UNIVAC Solid State 80/90 was designed as a medium-size data-processing system. The term "solid-state" refers to the use of "Ferractor" magnetic amplifiers and transistors (Fig. 31). The system consists of a central processor, a read-punch unit, a 450 card-per-minute card reader and a 600-lines-per-minute printer. The card equipment can be obtained for either the 80-

(International Business Machines Corporation)

Fig. 33—IBM 1401 System.

column or the 90-column punched-card systems. The first installation was made in January, 1960.

The system contains 215 tubes, 900 transistors and 36,500 diodes. The internal number system is biquinary-coded decimal. Word length is 10 decimal digits plus sign. 53 two-address, ten-decimal-digit instructions are used; (first address, operand; second address, next instruction). Arithmetic is performed with fixed point, in the synchronous mode, serially by digit, in parallel by bit, concurrently with other operations. Addition requires 1.36 msec, multiplication 1.275 msec, including storage access. The internal memory of the machine consists of one or more magnetic drums providing for 4000 words of storage with 1.7 msec average access and 1000 words with 0.425 msec average access. Up to 10 units of magnetic tape are available. The card-punching printer provides the ability to punch a card and print on both sides of the same card [142].

CDC 1604

The CDC 1604 is a general-purpose data-processing system manufactured by the Control Data Corporation (Fig. 32). The first installation was made in January, 1960.

The entire system includes some 100,000 diodes and 25,000 transistors. The internal number system is the binary, with a word length of 48 bits. There are 62 24-bit one-address instructions (2 per word) each including a six-bit operation code, a three-bit index and 15 bits for the address. Indirect addressing is built-in and six index registers are provided. Arithmetic is performed with fixed or floating point in the parallel synchronous mode concurrently with other operations. Addition requires 4.8 to 9.6 μsec, multiplication 25.2 to 63.6 μsec, including storage access. 32,768 words of magnetic-core storage are provided. Input-output equipment includes paper-tape typewriter, punched cards, magnetic tape (up to 24 units) and a 667–1000 lines-per-minute printer [142].

IBM 1401

The IBM 1401, an intermediate-size system, was installed initially in September, 1960, upon completion of a 3-year development program (Fig. 33). Employing transistor-diode logic, and a serial-by-character core memory, the 1401 has an 11.5-μsec character cycle. A word-mark bit, additional to the 1401's six-bit-plus-parity-bit alphanumeric character code, allows variable length data and instruction words. Add-to-storage logic replaces the conventional accumulator. The 1401's card reader-punch reads 800 cards per minute and punches up to 200 cards per minute, while the system's chain printer delivers 600 lines per minute [142].

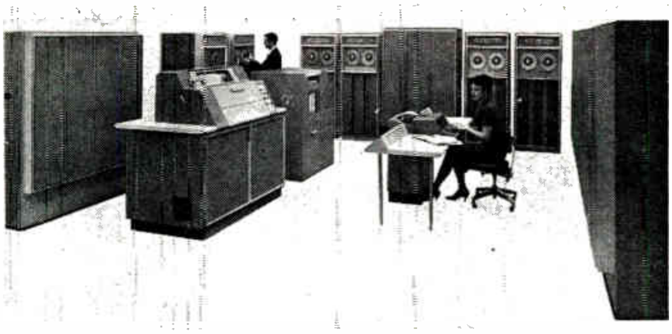
Honeywell 800

The Honeywell 800 is a general-purpose data-processing system capable of running as many as 8 distinct programs simultaneously without special instructions (Fig. 34). The first installation was made in December, 1960.

The system includes 30,000 diodes and 6000 transistors, excluding peripheral equipment. The internal number structure is binary and binary-coded decimal, with a word length of 48 bits, or 12 decimal digits. These 48 bits are assignable to numerical, alphanumerical or pure binary information. There are 59 basic instructions, each consisting of a twelve-bit operation code and 3 twelve-bit addresses. Eight index registers are available for each of the 8 programs which can be run concurrently. Other special-purpose registers are available. Arithmetic is performed in a synchronous parallel-serial-parallel mode, concurrently with other operations. Addition requires 24 μsec, multiplication 162 μsec, including storage access. Up to 32,000 words of magnetic-core storage can be used. Input-output equipment includes punched cards, paper tape and a 900 lines-per-minute printer. Up to 64 magnetic tape units can be connected to the system [142].

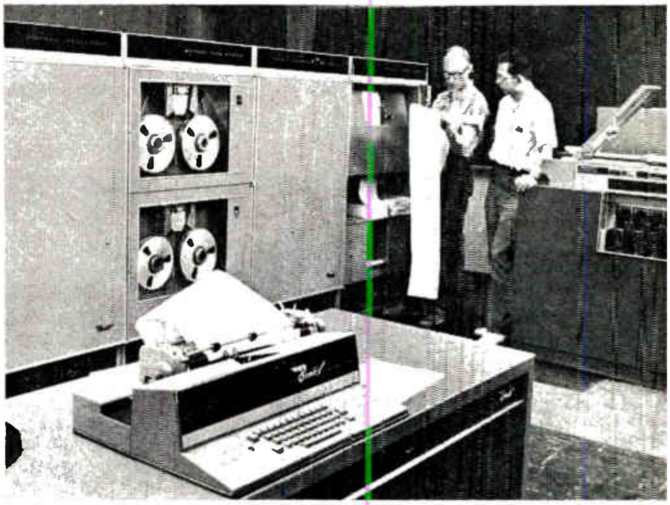
Bendix G-20

The Bendix G-20 is a general-purpose data-processing system of completely modular construction (Fig.



(Minneapolis Honeywell Regulator Company)

Fig. 34—Honeywell 800.



(Bendix Computer Division, Bendix Aviation Corporation)

Fig. 35—Bendix G-20 Computing System at Carnegie Institute of Technology.

35). The first installation was made in April, 1961, at the Humble Research Center, Houston, Tex., where the machine is used for oil-reservoir studies, including the solution of problems requiring eight to ten billion arithmetic operations.

The Bendix G-20 system typically contains 240 tubes, 38,000 diodes and 8900 transistors. The internal number system is binary, with a word length of 32 bits. One-address instructions are used, with provisions for indirect addressing. Arithmetic is performed with floating point in the parallel, synchronous mode, concurrently with other operations. Addition requires 13 μsec, multiplication, 56 μsec. 4096 to 32,768 words of magnetic-core storage are provided. Input-output is by paper tape, punched cards and magnetic tape (any number of units). Output includes also a 600-lines-per-minute printer [142].

Scribe

Digital computers primarily built to compute—to do common arithmetic—form a major part of the machinery used in the field. But there are rapidly increasing numbers of important digital data-processing machines that are not primarily "computers" in this sense. Examples are machine-tool control devices, such as those which control milling machines from information on tape; and "information-retrieval" machines, in which large files of indexed information (on magnetic tape or in some photographic form) can be systematically interrogated to supply designated subsets of the information stored. The Scribe test-scoring machines built in 1960 and 1961 by the Norden Division of United Aircraft Corporation for the Educational Testing Service form another example which is fairly typical of the class (Fig. 36).

(Norden Division, United Aircraft Corporation)

Fig. 36—The Scribe Scoring-Machine System.

The Scribe scoring-machine system consists of a paper handler in which pencil marks on $8\frac{1}{2}$ inch × 11 inch test "answer sheets" are sensed photoelectrically at the rate of 100 sheets per minute; a processor containing a magnetic-core memory, a magnetic drum and some 500 plug-in "cards" of transistor and diode circuits; and two output devices, an IBM type 514 card punch and an RCA type 581 magnetic-tape unit. The processing of up to 2280 coded marks, supplying up to 530 alphanumerical characters of several distinct kinds of information from each sheet, is performed serially, at a synchronous rate of 144 kilopulses per second, under the control of a program initially stored in the core memory. To score the "answers" on any one sheet, the machine can select as many as any six scoring "keys" from 24 such keys initially stored on the drum, supplying up to 54 part and total scores for each sheet. The system can modify its own program as may be required as the work proceeds [142].

Conclusion

Within the past fifteen years or so, digital computers have progressed from relays and rotating switches, as computing elements, to vacuum-tube and to semi-conductor logic circuits; from electromechanical, delay-line and cathode-ray-tube storage to magnetic-drum, magnetic-tape and magnetic-core storage. They have progressed from input-output speeds of one or two dozen characters per second to tens of thousands of characters per second; and from computation speeds of a few operations per second to thousands and tens of thousands of operations per second. Through the use of self-checking codes and by other means, they have reached high levels of reliability.

But the progress of the electronic computer art could not be so rapid if it did not concern more than machines. By programming its operation in some new way, almost every digital computer built has been found capable of doing more than it was originally designed to do. This has often led to significant improvements of the computing machinery. And then the process was repeated.

Early digital computers were built to solve a few important but relatively small scientific problems. Electronic digital computing machines and systems now at work

perform calculations for millions of pay checks,

bank accounts, insurance policies every day,

prepare weather forecasts,

solve scientific and engineering problems requiring from a few hundred to billions of arithmetic operations,

perform calculations for the design of almost every product of advanced technology,

translate English into Braille,

process data for the production, inventory control and transportation of millions of products,

perform the calculations needed in many diverse fields for the effective defense of the nation,

advance medical research by finding new patterns of diagnosis, by bringing new understanding,

make commercial airline passenger reservations,

perform calculations for satellite launching, orbiting and tracking,

keep records for billions of items of technical and patent information,

doing many other things as well, constantly accomplishing untold new tasks and demonstrating abundantly their usefulness to mankind.

The Evolution of Concepts and Languages of Computing*

R. D. ELBOURN†, MEMBER, IRE, AND W. H. WARE‡, FELLOW, IRE

Summary—**Digital computers are opening exciting new possibilities for progress in language translation, information retrieval, psychological modeling, problem solving and theorem proving. These have resulted not because of the microsecond arithmetic speed but because of the ability to manipulate symbols: to read, write, store, compare, and replace symbols and to follow different courses of action according to differences between symbols. Thus, language in a general sense is a common aspect of these new applications.**

Programmers have been extending the usefulness of computers through the evolutionary development of most artfully conceived languages. Recently, mathematicians and logicians have been proving theorems about formal languages, while linguists have been discovering laws that humans instinctively observe whenever they use natural language. Fruitful cross pollination among such endeavors now promises greatly accelerated progress in determining whether symbol manipulation is for information processing applications what numerical analysis is for arithmetic applications. This paper first reviews the evolution of programming languages from the early days when all programming was done in machine languages, through symbolic coding systems, interpreters, assemblers, generators, and compilers, to the recently developed list processing languages. Then the applications of these languages to game playing, problem solving, theorem proving, and behavior and biological modeling have been described briefly. Finally, in anticipation of extending the capability of computers to accept, use and generate natural languages, the paper concludes with an introduction to some of the contemporary work on formal language theory, including a discussion of six families of abstract languages and their practical implementation.

INTRODUCTION

CLASSICAL numerical analysis, as developed during the 19th century and the first half of the 20th century, replaces the infinite processes of the calculus by a finite, but very large, number of additions, subtractions, multiplications and divisions. It was for the purpose of making such large numbers of arithmetic operations practical that electronic computers were originally conceived. When the first stored-program computers were put into operation in about 1950, the evolutionary use of computers to mechanize quite different kinds of procedures began.

The drudgery of programming and the manifold opportunities for clerical blunders stimulated the development of automatic coding, which is a scheme to make the computer itself take over the drudgery. The successive development of symbolic assembly routines, interpreters, assemblers, generators, and compilers clearly demonstrated that one is not limited to the basic machine language. Suitable translating routines permit a variety of input and output languages to be used.

Experimenters who undertook to program a computer to play a game, to use heuristic procedures to solve problems, or to simulate human behavior found that such problems required specialized languages. Hence, the list-processing languages—IPL-V, LISP, FLPL and COMIT—were invented. For quite general purposes these free the programmer from machine language. More important, such list languages show the automatic computer in the role of a syntactic processor which, in addition to performing arithmetic, manipulates strings of symbols according to finite sets of rules.

Is there a science of symbol manipulation as numerical analysis is the science of arithmetic operations? We see the start of it in descriptive linguistics which is the science that searches for the laws which humans observe naturally as they use natural language. A few descriptive linguists, who also have a background in mathematical or symbolic logic, have formulated models of linguistic structure as abstract mathematical objects and have proved theorems about them. We find that much of natural language and also many artificial languages can be defined precisely by such formal grammars. We conjecture that the newly developing theory of abstract language models will be fundamental for both the applications and the logical design of computers. Therefore, we devote Section I of this paper to a brief review of the evolution of programming languages with an eye toward their description in abstract terms; in Section II we give a glimpse of the abstract theory of formal languages in the hope that readers will pursue further information in the literature.

I. EVOLUTION AND USES OF PROGRAMMING LANGUAGES

In the early days of the computer field, all programming was done in machine language.[1,2] This implies not only that the programmer was confined to only those kinds of instructions which the designers of the machine had built into its comprehension, but also that he had to work in the numeric symbology which the machine accepted. For example, the symbol "Add" was not an acceptable one to the machine. The machine would respond to only such numeric symbols as "010," the machine language equivalent of "Add". Furthermore, the store of the machine was regarded by the pro-

grammer as a collection of individual cells. He was completely responsible for assigning information to particular storage locations, and for being continuously cognizant of what information occupied each cell. The only way to find information in storage was to know the address of the cell which contained it. As an additional burden, the programmer used the same machine addresses in his instructions as the machine would later use to locate information for itself in the store. There was no means, for instance, to specify the location of one piece of information relative to the location of another piece.

The first relief from these problems came with symbolic coding. In such a programming language, the machine accepted such symbols as "Add" or "Multiply", or mnemonic abbreviations. The internal machine structure, however, did not change. With a simple table of correspondence, the machine could be used to transform one symbol into another ("Add" into "010"). Furthermore, the programmer no longer was bound to machine addresses. He could regard the store as divided into regions, each of which had its own set of addresses. If desired, positions within each region could be specified relative to the first location of the region. The first position in each region could also be specified in a symbolic form, rather than as an absolute machine address. A machine routine stated in such a pseudo-language must be translated into machine language prior to execution of the routine by the machine.

The routine which accepts a set of symbolically-coded instructions, translates them into machine language, and at the same time also assigns either symbolic or regional addresses to absolute machine addresses is generally called an *assembly routine*. Usually, the instructions with which an assembler deals are actual machine instructions although expressed in symbolic form. An assembler may allow for macro-instructions, which are kinds of instructions which the machine cannot directly execute but which must be expanded into a longer set of basic machine instructions. There may also be pseudo-instructions which are used to communicate information to the assembler about the routine on which it is operating. Thus, the assembler helps with the symbology problem confronting the programmer, expands the number of apparent operations available from the machine, and eases the chore of assigning storage locations.

An extension of the assembly technique is the *compiling routine*. Although terminology is not very precise, generally a compiler permits more complex macro-instructions than an assembler, and it often excludes machine instructions (even in symbolic form) from the language which it can accept. While the assembler generally deals with each instruction independently of all others, the compiler attempts to capitalize on the information which is contained in the structure or logic of the problem; the context in which each instruction is imbedded is important. Commonly, a compiler is language- or problem-oriented in the sense that it accepts as input the language and operations of a particular class of problems. A compiler usually eases the chore of arranging information in the store.

In the language which the compiler accepts, the programmer can refer to information by its name, rather than having to specify its location in storage. For example, the FORTRAN compiler accepts the symbology and the operations of ordinary algebra; the compiler can accept such symbols as ·, +, ( ), a superscript, a subscript, and letters designating algebraic variables. Sometimes it is possible to describe collectively a large class of routines and to embody this description in another routine called a *generator routine*. For example, a *sort generator* essentially contains a description of the process of sorting. Given information about the items to be sorted, the particular information on which the items are to be sorted, etc., the generator can construct a machine-language routine which will complete the sort.

Automatic Programming

The artificial languages represented by the assembler, compiler, and generator are really automatic coding languages, although they are commonly called automatic programming languages.[3] Building the translating routine for such a language is simply the problem of constructing a routine which makes a given physical sequential machine imitate the behavior of a nonexistent, but still sequential, machine whose language is the particular automatic coding language. The ideas from the theory of sequential machines and the associated theories of formal languages are becoming increasingly important in the construction of coding languages.

There are many coding languages (with their compilers) in existence. For example, FORTRAN[4] is a language for problems which can be stated in algebraic form. The symbols of the language are the symbols of algebra; the syntax of the language is the set of algebraic postulates and rules which leads to properly-written algebraic expressions. A more sophisticated language is ALGOL,[5] the international algorithmic language. COBOL[6] is a language for business problems; its symbols are the symbols of business transactions, and its syntax the set of rules which lead to well-formed expressions which describe business transactions. Other compilers, some of them related more or less to the

[3] The distinction between programming and coding is not always made. Often programming is considered to be that part of problem-solving which starts with formulation of the problem and exhibits the solution of a problem as an information flow diagram. Coding transforms the information flow diagram into a routine for the machine. For such problems as algebraic ones, the mathematical statement of the problem essentially describes the information flow process, and virtually no programming phase exists.

ALGOL language, carry such names as CLIP, JOVIAL, BIOR, MATHEMATIC, MYSTIC, SHADOW III, MADCAP, ALGO, FACT, and FLOWMATIC.[7]

Often the transition from the coding language to the machine language is made in two steps: first, an expansion of the original language to a sequence of machine operations but still in symbolic form; and second, the translation of the symbolic instructions into machine language. The intermediate language could, in principle be formulated in such a way that it would be machine-independent; only the translation from the intermediate language to machine language would depend on details of a particular machine. One proposal for a universal computer-oriented intermediate language is UNCOL.[8]

As the development of coding languages progresses, we can look forward to a large assortment of problem-oriented languages. A problem stated in any one of them will first be expanded into a corresponding statement in the intermediate language, from which a translation can be made to an appropriate machine language. Exchange of routines among users of the same kind of machine has long been practiced; we are beginning to see the exchange of routines (via the problem-oriented languages) among users of different kinds of machines.

List Languages[9,10]

In some very complex problems the allocation of storage space, even with sophisticated automatic coding languages, can be a major difficulty. Generally, this occurs because it is very difficult or impossible to foresee how much information will be produced or have to be stored at each phase of the routine. The concept of *list stores* and *list processing languages* was developed to surmount such difficulties.

"List" is used in the conventional sense to designate a linear sequence of pieces of information which, for some reason, are to be associated. One way to visualize a list store is to think of the individual cells of a conventional store as chained together; they need not be adjacent cells. For example, a given cell might contain not only an item of information, but also information which identifies the location of the next member on the list. Although no large list stores have been built to date, conventional stores can be programmed to behave as such. In a list store the location of information is in terms of the name of the list which contains it, but its position on the list may not be stated. The length of such a list is not necessarily fixed, which implies that there must exist a capability for inserting or deleting an entry anywhere along the list. Such a list is frequently called *push-down*, if the only entry point is at the top. An entry on a list may be the name of a *sublist*, the sublist in turn may reference another sublist, etc. Such a collection of lists and sublists is called a *list-structure*, and its name may itself be an entry on some different list.

List-processing languages permit such operations as the following: 1) insert an entry on a list, 2) delete an entry from a list, 3) create a list, 4) destroy a list, 5) coalesce two lists, and 6) search a list for a given symbol. The problems for which list-processing languages are powerful tend to involve the manipulation of symbols rather than calculation with arithmetic processes. Hence, list-processing languages are sometimes called *symbol-manipulating languages* and obviously must contain such operations as identify a symbol, compare two symbols, define a symbol.

List-processing languages include LISP,[11] FLPL,[12] and the family of Information Processing Languages (IPL-V being the best known).[13] Such languages facilitate storage allocation and give complete freedom for a subroutine to use itself one or more times in executing itself (i.e., recursively).

Artificial Intelligence[10,14]

A rapidly enlarging field of research is that of modeling the higher mental capabilities of man. One group of models, by means of a computer and an appropriate routine, successfully exhibit certain problem-solving abilities[15] which a man appears to use in such situations as proving mathematical theorems[16,17] or playing certain games (*e.g.*, chess).[18] Other models describe various aspects of human behavior and are useful for psychological research.

Routines which exhibit artificial intelligence or simulate natural intelligence are extremely complex; list languages have proved very useful in their construction. Generally speaking, these routines deal only with symbols or strings of symbols (expressions); they must recognize differences between symbols or between expressions, and usually contain a collection of methods for reducing such differences. For example, to prove a

theorem the routine assesses the difference between the beginning point and some intermediate or final step. By means of substitutions or by the application of already proved theorems, the routine attempts to reduce the difference. Problem-solving routines generally contain a collection of techniques for planning the attack on the problem and criteria for determining success. They often contain a form of learning-from-experience so that on future problems the routine will be more effective.

Other models simulate some aspect of the internal behavior of living systems.[19] For example, several models have been built which attempt to imitate the self-organizing ability of networks of neurons.[20] The research in various phases of modeling of intelligent behavior is perhaps the most exciting, challenging and significant work in the field of information-processing routines and machine development. This research may well suggest completely new kinds of machine organization and structure.

Natural Languages

There are many kinds of information-processing problems which are most appropriately stated in a natural language. For example, in a system whose purpose is to receive questions and attempt to answer them from a large file of information (the information-retrieval or library problem), it is most convenient for the user to frame the question in the natural language to which he is accustomed. Whether or not the internal file of information is structured in a natural language, the machine routine will have to deal with the letters, words and syntax of the language used to frame the question. One artificial language especially designed for processing a natural language is COMIT.[21]

Research in many kinds of machine processing of spoken or written language is in progress. The goals of such work include machine recognition of spoken[22] or written[23,24] statements, machine generation of properly formed spoken or written statements, machine translations of one natural language into another,[25] machine generation of abstracts,[26] and machine indexing[27] of files of information. Eventually, in conjunction with appropriate problem-solving routines, it is to be expected that machines will be able to fill the role of intelligent technicians.

II. Abstract Language Models[28]

Language, interpreted broadly to include artificial and formal languages, as well as natural languages and all their problems of definition, generation, recognition and translation, is the best framework we have found for understanding what an automatic computer is functionally and what it can do. In support of this thesis, the evolution of computer programming has been reviewed, beginning with the original basic machine languages and continuing through symbolic assembly systems; interpreters; assemblers; generators; compilers of algebraic, algorithmic, and business oriented languages such as FORTRAN, ALGOL, and COBOL; and the recently-developed list-processing languages LISP, FLPL, IPL-V and COMIT.

Next, the excitingly promising applications of these languages to game playing, problem solving, theorem proving, modeling of behavior for psychological research, and biological modeling have been surveyed. In practically all cases the function of the computer is fundamentally syntactic rather than arithmetic; it is manipulating lists or strings of symbols according to rules of structure. Its basic operations are reading, writing, storing, comparing and replacing symbols, and following different courses of action according to differences between symbols. Perhaps the ultimate achievement in this chain of development will be in providing the computer with the ability to accept, use, and generate natural language.

On this premise, therefore, a most important area of research for advancing the uses of computers is the study of language in the abstract, the inquiry into the forms that a language may take and the properties of formal models for the definition of a language, or the generation, recognition and translation of sentences of a language. Such a theory is now being constructed. It has foundation in the efforts of descriptive linguists to determine mechanically the syntactic structure within natural languages[29] and of mathematical logicians to create artificial languages for mathematics.[30,31] In the latter case, it borrows somewhat from recursive function theory.[32,33] Already the theorists are finding significant

problems within programming languages,[34] and programmers are borrowing techniques from the formal theories of languages and automata.[35] Because we confidently expect many more useful results to come out of this research, we have made the final section of this paper an introduction to some of the contemporary work on formal language theory.

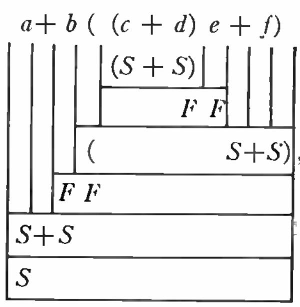
Simple Phrase-Structure Languages

The family called *simple phrase-structure languages* includes most systems of mathematical notation, most of the artificial languages used with computers, and quite possibly natural languages, so that it is not surprising that it has been the most extensively studied of the various abstract models of language.

Ordinary algebraic notation is a simple phrase-structure language. The algebraic expression

$$a + b((c + d)e + f)$$

can be analyzed into phrases as follows:



where F and S denote two kinds of phrases, "factor" and "sentence". Working from the bottom upward, each phrase can be regarded as produced by replacing a symbol F or S with other symbols according to one of six rewriting rules, called *productions:*

$$S \rightarrow S + S \qquad F \rightarrow (S + S)$$
$$S \rightarrow FF \qquad F \rightarrow FF$$
$$S \rightarrow x \qquad F \rightarrow x$$

where x denotes any variable $a, b, c \cdots$. It will be noted that beginning with the symbol S one can produce via these productions any correctly formed expression of this type, *i.e.*, any algebraic expression in which the operations of addition and multiplication are applied any number of times to any number of variables, and parentheses are inserted only where necessary for correct interpretation. Moreover, one cannot produce in this way any improperly formed expression such as $(a(b+)$. One can have the complete expression enclosed in explicit boundary markers $\# \cdots \#$, say for machine purposes, by starting with the production $B \rightarrow \#S\#$.

[34] S. Ginsburg and H. G. Rice, "Two Families of Languages Related to ALGOL," System Development Corp., Santa Monica, Calif., Tech. Memo. (TM Ser.) TM-578; January, 1961.

[35] E. T. Irons, "A syntax directed compiler for ALGOL 60," *Commun. ACM*, vol. 4, pp. 51–55; January, 1961.

These algebraic expressions are an example that satisfies the definition: a (formal) *language* is a distinguished (usually infinite) subset of all the possible finite *strings* (sequences of occurrences) of symbols from a set called the *alphabet.* If a string belongs to a language, we may call it a *sentence* of that language. A *grammar* of a language is a finite set of rules by which all and only the sentences of that language can be generated. *Simple phrase-structure grammars,* like the example given above, consist of the rules of the form $A \rightarrow \omega$, meaning rewrite the symbol A as the string ω.

The most general type of phrase-structure grammar may contain rules by which a symbol can be rewritten only if it occurs in a specified context, *i.e.*, $\zeta A \psi \rightarrow \zeta \omega \psi$ where ζ, ψ, and ω are specified strings. A symbol that can be rewritten under some rule is a *nonterminal* symbol; the other symbols in the alphabet are *terminal. A simple-phrase-structure language* is the set of all strings of terminal symbols that can be produced by starting with one specified nonterminal symbol and continuing to apply any applicable rule of a simple phrase-structure grammar to any occurrence of a nonterminal symbol until only terminal symbols remain. A *general phrase-structure language* is defined similarly using a phrase-structure grammar.

A sentence of a simple phrase-structure language can be produced in the normal left-to-right sequence as follows:

Output produced	Symbols in storage
	S
	$S + S$
$a +$	S
$a +$	$F\ F$
$a + b$	F
$a + b\ ($	$S + S\ )$
$a + b\ ($	$F\ F + S\ )$
$a + b\ (\ ($	$S + S\ )\ F + S\ )$,
⋮	
$a + b\ (\ (\ c + d\ )\ e + f\ )$	

where the convention is that at each step the left-most nonterminal symbol is rewritten.

Notice the properties of the storage used for nonterminal symbols. It behaves like the spring-supported stack of dishes in a cafeteria counter, which pushes down as dishes are added and pops up again when a dish is removed, so that the top dish is always accessible at the level of the counter top. A symbol storage with such properties is called a *push-down store.*

All of the list-processing languages employ push-down stores to hold the return address and the parameters used by a subroutine. If during the execution of a first subroutine a second subroutine is entered, the return address and parameters of the second are simply pushed down on top of those of the first. The latter are thus preserved and pop up again upon completion of the second routine and return to the first. If the push-down store has sufficient capacity, subroutines can be nested to any depth and one routine can even use itself as a subroutine any number of times. This fact corresponds exactly with the use of a push-down store in a simple phrase-structure language where phrases may be expanded within phrases to any depth.

In an application to natural language the various types of phrases denoted by the nonterminal symbols might be sentence, independent clause, noun phrase, verb phrase, singular particle, and so on, through a list of syntactic constituents of a sentence. The terminal symbols can be words or punctuation marks.

The idea that any nonterminal symbol can be considered the name of the set of strings (phrases) producible by starting with that symbol suggests an alternative way of defining simple phrase-structure languages. One can start with certain sets of symbols or strings that are finite sets or are otherwise effectively definable (which shall subsequently be defined precisely and called "decidable") and construct new sets according to the following two definitions in which A and B are any sets of strings:

Union: $A \cup B$, every string in A or in B.[36]

Concatenation: AB, every string $\zeta\psi$ where ζ is in A and ψ is in B. This alternative method would replace the six productions for the algebraic expressions by two equations:

$$S = x \cup FF \cup S + S$$
$$F = x \cup FF \cup (S + S).$$

The first equation means that a string of the set S is a single symbol of the set $a, b, c, \cdots$, or the concatenation of two strings from F, or a string from S followed by "+" followed by another string from S. This definition is constructive in that one initially assumes only the members of the alphabet x are in S and F; then one adds strings to S and to F by repeated use of the implicit defining equations.

The family of the sets that can be defined in this constructive sense by a system of simultaneous implicit equations in unions of concatenations has been shown to be exactly the simple phrase-structure languages.[29,34] ALGOL is thus a simple phrase-structure language, because its official definition[5] uses equations of just this kind; only the notation is slightly different.

A system of defining equations is rather more convenient to use (say, in a machine implementation) if it has the property that for each n the nth equation contains none but the first n variables. Such systems yield a proper subfamily called the *sequentially definable languages:*

$$A, B, C, \cdots \text{ are finite sets}$$
$$X = F_1(X, A, B, C \cdots)$$
$$Y = F_2(X, Y, A, B, C, \cdots)$$
$$Z = F_3(X, Y, Z, A, B, C, \cdots).$$

The identifiers and labels of ALGOL are sequentially definable, while the arithmetic expressions are not.

We will now introduce two more compositions of sets:

Power: $A^n = AA^{n-1}$, where $A^1 = A$ and A^0 is the set that contains only the string having no symbols.

Note that A^n is just A concatenated with itself n times. Power is introduced here only as a tool for the following definition:

Closure:

$$A^* = \bigcup_{n=0}^{\infty} A^n = A^0 \cup AA^*.$$

Closure is thus the first composition of finite sets that produces an infinite set. The two forms of definitions are equivalent, but the second exhibits its construction by iteration.

The structures of the identifiers I, unsigned integers N, and labels A in ALGOL are shown most clearly by the expressions

$$I = L(L \cup D)^*$$
$$N = DD^*$$
$$A = I \cup N = L(L \cup D)^* \cup DD^*$$

where L and D are finite sets of letters and digits, respectively. The meaning of the first equation is that an identifier may be any letter followed by any succession, including none at all, of letters and digits. The expressions that can be written using symbols denoting finite sets and indicating finite numbers of operations of concatenation, union, and closure are called *regular expressions:*

$$D^* = D^0 \cup DD^*$$
$$X^* = X^0 \cup (L \cup D)X^*$$
$$A = LX^* \cup DD^*.$$

The sets denoted by regular expressions are a subfamily of the sequentially definable sets, since each occurrence of the closure operation can be made the symbol for a set, say A^*, which is defined by an equation of the form $A^* = A^0 \cup AA^*$ as in the definition of closure.

Automata

Often an effective procedure for 1) generating the sentences of a language, 2) translating the sentences of one language into corresponding sentences in another, or 3) deciding whether or not any given string is a sentence of a given language can be defined by describing an automaton that will carry out the procedure.

[36] Other notations used are $A \vee B$ and $A + B$.

That is to say, an automaton may be a convenient form of either a *grammar*, a *translator*, or a *recognition grammar* for a language, as described in the following discussion.

Such an automaton can receive a sequence of symbols as input and responds by producing another sequence of symbols as output. This concept of an automaton thus includes all digital computers and switching circuits. The response of an automaton to a particular input symbol may be conditioned by the string of input symbols that preceded it. A state (of conditioning) of an automaton may be identified with a set of input strings that condition the automaton equivalently, which means that, no matter which string of the equivalent set is used to condition the automaton, its response to any particular subsequent string will not be changed. Each successive input symbol carries the automaton into the (next) state whose equivalence set contains the string formed by this symbol following the preceding string.

Abstractly, a finite automaton is a 5-tuple $(S, I, O, \Sigma, \Omega)$, where S (the states), I (the input alphabet), and O (the output alphabet) are finite sets, Σ is a (next-state) function, and Ω is an (output) function that, respectively, associate a member of S and a member of O with each member of the (concatenation) set SI.

A *finite-state language* has both generation and recognition grammar in the form of finite automata. The latter means there is a finite automaton with a designated (starting) state q and a designated subset F of (final) states such that a string is a sentence if and only if the effect of the whole string, applied as an input sequence, is to change the state of the automaton from q into a member of F. Kleene[37] proved that the finite-state languages are just the sets of strings denotable by regular expressions; thus the identifiers, unsigned integers and labels in ALGOL are finite-state languages. If all the productions of a simple phrase-structure grammar G are of the form $A \rightarrow Bx$, $A \rightarrow x$, or $A \rightarrow A^0$ (or $A \rightarrow xB$, $A \rightarrow x$, or $A \rightarrow A^0$) where A and B are nonterminal and x is terminal, then G is a (generative) grammar of a finite-state language.[38–40]

The Polish logician Jan Lukasiewicz discovered a simple way to eliminate the need for parentheses in expressions containing operators that have one, two, or any number of operands. Every operator symbol is simply written as a prefix (or as a suffix) to the sequence of its operands. Correspondence between the usual algebraic notation and the Polish suffix notation can be seen by verifying the equivalence of examples such as

$$a + b \text{ and } ab+$$

$$ab \text{ and } ab\cdot$$

$$ab + c \text{ and } ab\cdot c+$$

$$a(b + c) \text{ and } abc+\cdot.$$

In the last example, we see that a multiplies all the rest of the expression, so the multiplication sign implied appears at the end in Polish notation.

We shall now describe a simple automaton that can test any string to determine whether it is a sentence in this parenthesis language and, if it is, translate it into the equivalent sentence in Polish notation. This automaton cannot be finite state because for any fixed finite memory capacity there exist strings with parentheses nested so deeply that this capacity would be exceeded. Instead it is made of a four-state finite automaton combined with an (at least potentially) infinite push-down store used to remember previous states. The states, denoted 0, 1, 2 and 3, keep track of progress within a parenthetic expression as illustrated by

$$({}_0a_1b_1c_1 +_2 d_3e_3 +_2 f_3),$$

where the subscripts denote the state of the finite automaton after receipt of the subscripted symbol. Whenever the automaton receives a letter as input, it prints the letter as output and, if it was in states 1 or 3, then prints a "·". When the automaton receives a "(" it pushes down its former state into the push-down store, and when it receives a ")", which is proper only in state 3, it first prints "+" and then pops up the most recently stored state and prints "·" if that state is 1 or 3; otherwise, it changes state from 0 to 1 or 2 to 3.

The process of a translation is shown below:

Time step	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14
Input symbol	#	*a*	+	*b*	(	(	*c*	+	*d*	)	*e*	+	*f*	)	#
Output symbol	#	*a*		*b*			*c*		*d*	+	*e*·		*f*	+·	+#
Next state	0	1	2	3	0	0	1	2	3	1	1	2	3	3	0
Contents of Push-down					3	0 3	0 3	0 3	0 3	3	3	3	3		

A nonsentence will present an improper symbol in states 0, 1, or 2, or overdraw or underdraw from the push-down. This example is a very simplified illustration of the basic actions of the input scanner in a compiler for an algebraic language such as ALGOL, and it shows why a push-down store is usually programmed into such a routine.

Two recently designed machines, the Burroughs B-5000 and the English Electric KDF-9, have push-downs built into their hardware. The B-5000 also uses Polish suffix notation for its machine language and is said thereby to save one pass in algebraic compiling.

Recursively Enumerable Sets

Thus far we have discussed a series of families of languages beginning with the simple phrase-structure languages and progressing to smaller and smaller families, each contained in its predecessor. Now we shall investigate more general families.

Language theory can be related to recursive function theory through the device of numbering (assigning an integer to) each sentence of a language. A grammar then becomes a constructive procedure for generating a list of all the members of (*recursively enumerating*) a set of integers, and a recognition grammar is a procedure for deciding whether or not a given integer belongs to a given set. At least six quite different mathematical constructions have been defined[30,33,41–44] in efforts to make precise the notion of effective procedure in its widest possible sense. The striking result of these investigations is that each construction was found able to enumerate exactly the same family of sets, which are called the *recursively enumerable* (re) sets. The remarkable coincidence of capabilities of very different constructions lends great credence to Church's thesis[45] that no constructive procedure can ever be found to enumerate a set that is not re.

A basic result in recursive function theory is that there is a constructive procedure for numbering the re sets; indeed, they can even be placed in one-to-one correspondence with the integers. Define K to be the set of the integers that are numbers of re sets that contain their own numbers. K is re, but consider K', the set of all integers that are not members of K. Every re set contained in K' has a number that is also in K' but is not in the re set; hence K' is not re, which is to say that no constructive procedure can list exactly the members of K'. If the sentences of a language correspond to the members of K', that language can have no grammar; on the other hand, if they correspond to the numbers of K, then the language has a grammar but can have no recognition grammar. A language that has a recognition grammar is *decidable* and one that has not is *undecidable*.

The essential feature that introduces undecidability is the self-reference in the definition K. A language gains great power when it is made able to refer to itself, but it also acquires the power to state paradoxes and undecidable propositions. Most undecidable questions are in one way or another equivalent to questions about membership in K'.

Turing showed that any re set can be enumerated by a suitable (actually quite simple) finite automaton if it is augmented by a (potentially) infinite tape which it can move back and forth and on which it can read, erase, and write symbols. This combination is called a *Turing machine*. Certain Turing machines are universal in the sense that they can imitate any Turing machine if a finite portion of their tape is suitably pre-encoded; thus a universal Turing machine can enumerate any re set.

We have now described six families of languages. Each family is larger than and includes all after itself in the following sequence:

Turing machine (recursively enumerable)
Decidable (recursive)
Phrase structure
Simple phrase structure
Sequentially definable
Finite state (regular expressions).

Because a finite automaton alone suffices to generate or recognize the last family, while a finite automaton plus a tape can generate the first, it might appear that there is really little to choose between families in this hierarchy, but the theoretical power and probably also the complexity of practical implementation vary quite markedly according to the model chosen. Unfortunately, very little is known yet of general principles to guide one's choice. The essential distinction between them is in their memory requirements: *e.g.*, at the bottom, finite automaton; in the middle, finite automaton plus bottomless push-down; and at the top, finite automaton plus endless tape.

Development in High-Speed Switching Elements*

ARTHUR W. LO†, SENIOR MEMBER, IRE

Summary—**Recent developments in high-speed switching elements are outlined to indicate the trend of recent work and thoughts on physical implementation of high-speed digital data processing systems. Four outstanding switching elements, thin film cryotron, high-speed transistor, microwave parametric phase-locked oscillator, and tunnel diode, as well as some related circuit and fabrication techniques, are briefly described and commented on.**

The transistor remains as the predominant switching element for these systems, largely because of the vast experience with it. The other technologies are presenting an ever increasing challenge to the transistor in this area.

Introduction

THE phenomenal growth of the data processing science and industry in the past decade was both a cause and a result of the extensive research and development efforts on switching elements particularly suitable for high-speed digital operation. Major developments in this field centered on devices utilizing various solid-state phenomena, as well as the circuit and operation techniques associated with these devices. This paper is an attempt to outline the significant new developments which indicate the trend of effort in this area. Detailed description of specific devices and techniques will not be included, but the major technical approaches will be identified and commented upon. The coverage is limited to the basic, high-speed switching elements useful in handling digital information and excludes devices used for gating analog signals or controlling power in digital form.

Modern digital systems contain a great many (from a few hundred to tens of thousands) switching elements interconnected in complex ways. Such size and complexity, as well as the economics of design, manufacture and maintenance, demand a "building-block" approach, *i.e.*, the use of nominally identical components (of only a few types) and standardized signal waveforms throughout a system. As a basic requirement, switching elements must be able to function as designated in circuits with complex interconnections and under all forseeable combinatorial and sequential signal operating conditions and, at the same time, take into account the fundamental and practical aspects of component tolerance. Such considerations are reflected in the pertinent characteristics required in a basic switching element:

1) The element responds discriminatively to the discrete signals, and can restore deteriorated signals to their respective standard forms. The element must provide unidirectional information flow so that no ambiguity in control can occur through any spurious interaction. These requirements imply that the switching element has well-defined thresholds, discriminative gain and limiting characteristics, and adequate unilateral and isolation properties.
2) The element has high switching speed (considering both the delay time and the transition time in switching from one state to the other), and can operate at a high repetition rate.
3) The physical structure of the element lends itself to easy fabrication in large quantity within specified tolerance, and allows easy assembly and interconnection with associated circuit elements.

A switching element need not fulfill all these requirements to be useful since some of the deficiencies can be remedied, often, by some operation and circuit techniques and/or by incorporating some other components. Nevertheless, these basic requirements serve well as a yardstick for evaluating the various switching elements and help clarify the significance of new developments.

Switching Elements

Many electronic devices have been considered as basic switching elements for the handling of digital information. The various devices utilize widely different physical phenomena and operate in widely different manner. Viewing these devices as circuit elements, however, one can group them into three general categories. This cataloguing permits a systematic discussion of the operational characteristics of the devices and the implications of new developments.

Four-Terminal Devices

This group of devices has the general configuration of a two-terminal-pair network *not* sharing a common electrical node between the input and the output. Notable devices in this group are electromechanical relays, optoelectric devices and cryoelectric devices. The absence of a direct electrical connection between the input and output terminals in these devices allows flexible interconnecting configurations between elements, thus permitting the use of "relay logic" which is highly desirable in many applications. These devices have excellent unilateral action, apparently because their operation involves physical energy of more than one form, each of which can be easily discriminated from the other. [For example, in the Electroluminescent-Photoconductor (EL-PC) pair, the EL material produces light from electrical energy, but it is insensitive to light; while the PC material is electrically sensitive to light but does not

* Received by the IRE, July 5, 1961; revised manuscript received, January 2, 1962.

† Components Division, IBM Corp., Poughkeepsie, N. Y.

produce light.] Although many transducer-type devices have been suggested as possible switching elements, few have gain, especially gain at high operating speeds. Present optoelectric devices, using electroluminescent material or neon bulb as light source and photoconducting material or semiconductor devices as light detector, operate in the millisecond range. Significant improvement in speed awaits, it seems, a better understanding of optoelectronic mechanisms in solids. Recent developments in cryotron techniques, on the other hand, have improved the speed of the device so significantly that they merit consideration for practical applications.

Thin-Film Cryotron: The significant improvement in cryotron speed can be attributed to the evolution of constructing planar, thin-film cryotrons over an insulated superconductive ground plane. The operation of a basic thin-film cryotron circuit is illustrated in Fig. 1, where a constant current I flows, quiescently, in one of the two branches of the loop. An input current applied through control A causes the gate film under the control to switch to its normal (resistive) state. This operation is equivalent to inserting a resistance R into the superconductive loop of total inductance L to cause the steady current to switch to the other branch, in the form of a loop current: $i=I(1-\epsilon^{-R/L^t})$. At $t=2L/R$ approximately 90 per cent of the current I is switched from the left-hand branch to the right-hand branch; and this new division of current remains after the control current ceases, keeping the output gates a' and a resistive and superconductive, respectively. Improving the operating speed of a cryotron circuit is a matter of reducing the L/R time constant. The superconductive ground plane, only a fraction of a micron distant from the film cryotron, supplies an image current to any current in the cryotron. This action reduces the inductance of the cryotron several orders of magnitude below what it would be if the ground plane were not present. The ground plane has the additional effect of localizing the magnetic field produced by a current in its immediate proximity, thus allowing high-density packaging. The resistance R is determined by film thickness and penetration depth, as well as by the resistivity of the gate material. Some alloy gate materials have higher resistivity than the commonly used tin and indium and higher operable temperature, and they are the subject of extensive developmental effort at present. No energy is dissipated in a superconductive circuit in its steady state. For each switching, however, an amount of energy $\frac{1}{2}LI^2$ is dissipated in the form of heat. Because cryotron operation is inherently tied to the critical temperature of the gate material, a narrow operating temperature range must be maintained. Heat dissipation (in high-density packaging) is actually a more serious consideration than the L/R time constant for high-speed operation of cryotrons. Without the significant reduction of L through the use of the superconductive ground plane, the operation of a large-capacity, high-speed cryoton system would be impossible.

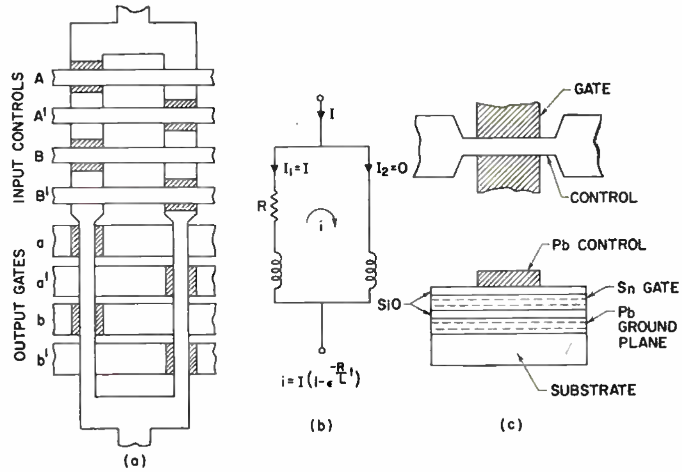

Fig. 1—Thin-film cryotron. (a) Basic cryotron logic circuit. (b) Switching time in terms of R/L time constant. (c) Cross-film cryotron structure.

Two forms of thin-film cryotron configurations have received extensive attention. In the cross-film configuration, the width of the control film is several times narrower than that of the gate film so that a small current in the control can switch the gate film to its normal state while in the absence of a control current the gate can carry a greater current and remain superconductive. Ideally, a current gain greater than unity is all that is required for one cryotron to drive others, but in practice a considerably greater current gain is desired to insure reliable operation against nonuniformity in cryotron units. For cross-film cryotrons of equal control and gate film width (a possible geometry for maximum packing density) and for in-line cryotrons (where the control film and the gate film run parallel in length to obtain a longer and thus higher resistance gate), the current gain is below unity. Operational current gain, however, can be realized by using a constant bias current applied through leads to the control film or through an extra superconductive film over the gate. With the bias arrangement, the amount of current switched is considerably smaller, effectively reducing the heating problem. The biased operation, however, imposes more severe requirements in the control of film dimensions and registrations, as well as of operating temperature. Controlling the thickness of the insulation layer has been a major consideration in the batch fabrication of thin-film cryotrons for high-speed operation.

Switching time of a few nanoseconds has been observed in experiments with a simple, biased in-line cryotron loop. Continuous operation of several interconnected cryotrons at frequencies up to 30 Mc has been reported, and the frequency limit was attributed to instrumentation difficulties in detecting the very weak voltage through the liquid helium dewar. Several hundreds of larger cryotrons (with tin gate film 500-microns wide and 0.5-micron thick, and lead control film 125-microns wide and 1-micron thick) have been batch fabricated on a single glass substrate. These elements have a uniformity of critical current within 5 per cent and operate at 4 Mc. While all the problems of producing a high-speed, high-capacity cryotron system, particularly in heat dissipation, are not solved, the technology is far enough advanced to justify serious consideration. The prospect of manufacturing superconducting systems (switching elements and all interconnections) with homogeneous, bulk-effect materials in an automated batch-fabrication process certainly makes the cryotron more attractive than many other switching elements for very large digital systems in the future.

Three-Terminal Devices

Vacuum tubes and transistors, which are the "work horses" in present-day digital systems, belong to this group. In these devices, there is adequate isolation between the input and output circuits, although they do share a common electrical node. Such an element functions well as a logical gate (conditional regeneration of signal), but it is not readily applicable, as are the four-terminal devices, as a transmission gate (conditional transmission of signal). The most significant progress in this area centers on the fabrication techniques for producing nanosecond bipolar transistors.

High-Speed Transistor: The high performance of recently developed transistors can be attributed to the precise structural geometry evolved from improved fabrication techniques. Early alloy junction transistors suffered in switching speed mainly because of the long transit time and minority-carrier storage time in the base region, since the alloying process was difficult to control in producing a very thin and well-defined base region. With a built-in potential gradient in the base region, the drift transistor offers some reduction in transit time; and at the expense of some circuit complexity, the storage time can be insignificant if the device is operated in the nonsaturating mode. The micro-alloy transistor on the other hand, is constructed by jet etching and surface alloying that produces a very thin base region for high-speed operation, but elaborate process control is required in manufacturing.

Recent development centers on diffusion techniques. Transistor fabrication is essentially a matter of transporting the right kind of impurity atoms over a well defined area on a high-purity semiconductor substrate, to the depth and concentration that form a prescribed impurity-distribution profile. The precise fabrication process is accomplished by a series of masking, photoengraving, and diffusion steps. In the present state of the art, base width in the neighborhood of one micron can be readily reproduced. With such small base width, transit and storage time in the base region is no longer a predominant factor in switching time. High-speed operation is essentially limited by the time required to charge and discharge transistor capacitances (the base diffusion capacitance, the emitter transition capacitance, and the collector transition capacitance). With the presently available thin base width, the diffusion capacitance is in the same order of magnitude as the emitter and collector capacitances. Base resistance is in the order of a hundred ohms because of the required geometry. Emitter and collector junction areas from 50 to 100 microns in diameter are presently feasible, and emitter or collector capacitance of a few picofarads is common. Using such units as an AND-INVERTER or OR-INVERTER basic logical gate with total fan-in and fan-out of five, a total switching time (delay time plus transition time) of 5 nsec is not unusual.

The carrier storage in the collector region has been a significant factor in operation speed. The recently developed epitaxial-growth technique offers a significant improvement. Over a low-resistivity single crystal wafer is grown epitaxially a thin high-resistivity layer, on which the collector junction is formed (Fig. 2). This composite collector structure retains the high collector-breakdown voltage, but effectively reduces storage, saturation voltage, and collector capacitance.

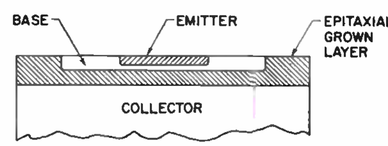

Fig. 2—A high-speed transistor structure (dimensions not drawn to scale).

Over the years hermetic sealing with can and header structure has been identified as the standard procedure in transistor manufacturing. Surface passivation methods, mostly with oxide and glass techniques, are now being developed for diodes and transistors. While thermal-compression bonding is the standard practice for attaching leads to semiconductor devices, various forms of metal-deposition process are being investigated for this purpose. Noteworthy is the growing interest in silicon in spite of its lower carrier mobility. The obvious advantage of higher operating temperature is often a secondary consideration. A significant property of silicon is that an oxide layer can be readily formed over its surface, and present photoengraving and diffusion processes can be readily applied. This is an example where fabrication techniques dictate the choice of a functioning material.

Microelectronics: With digital systems growing in speed and capacity, the task of assembling and interconnecting circuit components in a conventional manner, and meeting cost and performance (particularly speed) requirements, is becoming prohibitive. Developments centered on the idea of treating the assembly, interconnection, and packaging problems at the level of device fabrication have flourished in the past few years. These developments have been publicized under the general term *microelectronics*, although miniaturization is often a by-product of secondary consideration. Many approaches have been reported. The "printed-circuit" board is probably the first attempt. The various "micromodule" versions consist essentially of fabricating and attaching miniature components on suitable substrates with terminal contacts for easy interconnection. The "integrated circuit" or "semiconductor network" approaches are aimed at fabricating components and interconnections in successive steps on a single substrate to form a functional block. Since the commonly used components, such as transistors, diodes, resistors, and capacitors, can all be formulated by selectively controlled inhomogeneity in a semiconductor, the fabrication of a circuit unit consisting of several interconnected components is a task not unlike transistor fabrication, except in degree of complexity. Simple function blocks (such as multi-input logical gates and flip-flops) made in this manner are already commercially available. There is not sufficient evidence that some of the present structures show significant advantage in performance (particularly in speed and reliability) and cost, but the feasibility of this approach is certainly demonstrated. More ambitious approaches of batch fabricating an entire subsystem by physically transporting materials and chemically transforming materials on a molecular scale are currently being investigated in a number of laboratories.

Heat dissipation is a paramount problem in microelectronics. It is unfortunate that some microminiaturization proposals of packing 1,000 to 10,000 components in a cubic inch have not given adequate thought to the heat dissipation problem. Present high-speed transistor switching circuits consume tens to hundreds of milliwatts of power per stage. Noteworthy is the fact that although a transistor can be operated to perform switching at a power level of a fraction of a milliwatt, the high power level in practical circuits is a requirement dictated by component tolerance and operation speed. Component tolerance imposes an uncertainty in switching threshold, and thus a large excursion of signal voltage and/or current is required to insure reliable switching under adverse conditions (including noise). The presence of reactance (in components and interconnections) makes power dissipation a function of operation speed. While reactances themselves do not consume power, the switching of voltage or current level involves storing energy in and withdrawing energy from reactances through dissipative elements. Energy dissipation in this manner increases with switching repetition rate and even more so with switching speed. These considerations emphasize the need of low-level, minimum-reactance components that can be mass-produced to narrow tolerance. It seems apparent at this time that the high packing density of the order desired in microelectronics cannot be achieved simply by size reduction of neoconventional components and circuits.

Two-Terminal Devices

This category includes all the two-terminal devices, as well as devices which have more than two physical terminals, but where there is little or no isolation between the input and output circuits. In order to use such devices for information handling, some special circuit or operating techniques must be employed to provide directionality of information flow. Work in this area in the past few years has resulted in a number of fresh and interesting developments.

Nonlinear inductors and capacitors have long been investigated and used for amplification of relatively low-frequency signals, with a relatively high-frequency energizing source. A derivation of this type of operation, the ferroresonant flip-flop, has shown promise for digital operation at medium speed. It is, however, in the parametric phase-locked oscillator that we witness a fresh and inspiring approach for handling digital information at very high speed.

Parametric Phase-Locked Oscillator (PLO): While digital information is represented by discrete *amplitudes* of some physical quantity in almost all digital systems, the PLO system uses a *phase* script for representing a "0" or "1" signal by a sinusoid of constant amplitude and zero degrees or 180 degrees phase, respectively. When energized by a pump of frequency $2f$, a PLO tank circuit builds up a sustained oscillation of frequency f in either zero degrees or 180 degrees phase with respect to a reference maintained by the pump. The sustained oscillation is locked in phase, and is immune to input signals for the duration of pump energization. Control is executed by applying an input signal of roughly zero degrees or 180 degrees phase prior to or at the beginning of pump energization. This signal steers the oscillation buildup to the respective phase. On account of its perfect symmetry (with respect to the two discrete phases) the circuit has very high gain which is limited only by noise and the consideration of switching time. The pump supplies energy for building up oscillation to a constant amplitude, and simultaneously standardizes the signal by "pulling" the oscillation to one of the two standard phases.

The PLO by itself provides no directivity because the input and output signals share the same terminal. Unidirectional information flow is achieved through separation of input and output signals in *time*, rather than separation in *space* as in three- or four-terminal devices. A sequential pump-energizing scheme (illustrated in Fig. 3) is used to dictate the direction of information flow. It is to be noted that the three-pump scheme alone does not insure unilateral signal flow; the other factor is that the PLO is immune to input signals except for a short duration at the beginning of pump energization.

Logical operation is carried out by *majority logic*, which is essentially a linear summation of inputs (sinusoids of constant amplitude and zero degrees or 180 degrees phase) that allow the majority votes to determine the logical state. With one of the inputs a reference bias, AND and OR logical operation is straightforward. INVERSION is achieved simply by phase inversion through a transformer. An irony in PLO operation, however, is that while information is not represented by

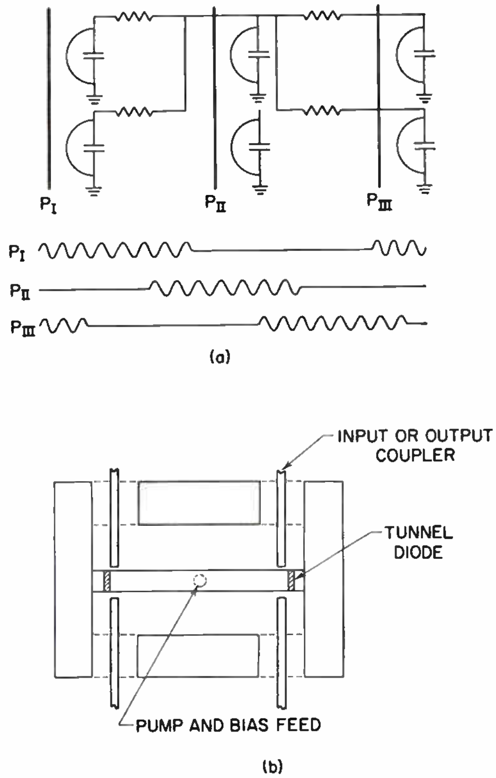

Fig. 3—Parametric phase-locked oscillator. (a) Sequential pumping system. (b) A microwave PLO structure.

amplitude, it is a necessity (and often a major problem in practical systems) to maintain a constant signal amplitude in order to perform majority logic.

The first PLO device was the Parametron using ferrite cores as nonlinear inductance. Practical systems have been built with this device for operation at an information rate of tens of kilocycles with a pump fre-frequency of several megacycles. This speed limit is a result of the heating of the ferrite at higher repetition rates; and attempts at using metallic magnetics have been reported.

Very high-speed operation of the PLO is currently achieved through the use of a semiconductor diode. The diode behaves as a high-Q nonlinear capacitor when slightly reverse biased. Diodes with very small junction area and low bulk resistance, encapsulated in a special, low loss, low capacitance package, offer a cutoff frequency of several hundred kilomegacycles. Using such units, a well-designed PLO circuit can reach a signal information rate of about 1 kMc with a pump frequency of around 30 kMc. Practical design of very high-speed PLO circuits hinges on microwave techniques. Microwave stripline and cavity structures have been explored extensively. An example is shown in Fig. 3, illustrating a two-diode balanced structure with pump and bias connection and input and output couplers. Simple PLO subsystems using symmetrical stripline structures interconnected with microwave transmission lines have been test-built to operate at information rates of several hundred megacycles; they use a pump frequency of 10 kMc.

The practicality of producing a microwave PLO system of usable size is yet to be established. Distribution of kilomegacycle pump power to a large number of circuit elements in proper amplitude and phase relation is a major problem. In microwave structures, geometrical configuration and dimensions dictate circuit behavior; whether this is a blessing or a handicap for building a practical system remains to be seen. These reservations aside, one cannot help but see in PLO an interesting and refreshing approach unlike conventional digital techniques.

Another group of two-terminal devices assume the role of switching elements through their storage and threshold properties. Ferroelectric and ferromagnetic materials characterized by a rectangular hysteresis loop have both been investigated. The ferrite core, in addition to its tremendous success in random access memory, has been used extensively in some logical systems. Although a core can have multiple windings, and turns-ratio can be used to advantage, any flux change in the core links both the input and output circuits. Because of the core's storage property, the output signal can be delivered at a later time than the application of the input signal. Nevertheless, some unidirectional coupling elements, usually diodes or transistors, are necessary in order to provide directivity of information flow. In recent years sophistication in device operation and circuit techniques has been incorporated in magnetic-core logical circuits that do not use unidirectional coupling elements. These developments include the use of multi-aperture cores (where flux transfer between various paths in the core allows the coupling between input and output circuits to be postponed in time), fast-and-slow switching (allowing higher or lower energy dissipation in coupling resistance) and partial switching (to take advantage of minor loop characteristics). Simple systems employing only ferrite cores and copper interconnecting wires have been demonstrated. The switching repetition rate of present ferrite cores is limited to around a megacycle; and metallic magnetics are currently being investigated for higher speed operation.

The conventional diode (which offers discriminative attenuation but no gain) has long been a major supporting switching element and has been used in large quantity in digital systems. Recent units, with shunt capacitance less than 1 pf and storage time measured in 1 nsec are indeed high-speed elements. Several types of negative-resistance diodes, utilizing a minority-carrier regeneration effect, suffer from a long recovery time in switching operation. The development of the tunnel diode now offers a device of very simple structure and extremely high switching speed, as well as well-defined thresholds and both voltage and current gain.

Tunnel Diode: The usefulness of this simple two-terminal device as a practical switching element depends largely on circuit techniques. Two basic modes of operation have been developed. The first mode consists of either bistable or monostable operation with a dc power supply (Fig. 4). In such operation, gain is realized by having the diode quiescently biased close to one of its thresholds so that a small input signal is sufficient to initiate switching in the negative-resistance region. Such operation imposes a severe demand on device uniformity (especially in the peak current of the diode) and the tolerances of other circuit components. These stringent requirements make practical design difficult. Unidirectional coupling elements also are required.

The second mode of operation employs a matched pair of diodes with pulse energization (Fig. 4). In many respects this operation is directly analogous to that of the PLO, permitting the same type of circuit and logic organization that is used in the PLO system. There are, however, some inherent differences between the two cases. The PLO has a natural, perfect symmetry immune to component variation; but the tunnel-diode pair is balanced artificially and requires a minimum input to offset any circuit asymmetry. (Matching diodes by pairs is, in practice, an easier task than that of demanding all diodes in a system to be uniform as in the first mode of operation.) On the other hand, while the information rate in the PLO system is only a fraction of the pump frequency, the tunnel diode switches at the rate of the energization pulse.

Since tunneling is a majority-carrier effect, the switching speed of a tunnel diode is primarily affected by the junction capacitance. As illustrated in Fig. 4, the voltage across the diode can switch only as fast as the condenser is being charged up. At the beginning of switching the condenser charging current is small, thus, the output waveform displays a longer delay time compared with the transition time. In order to reduce the long delay time, current overdrive of five to ten per cent over the peak current is required. Recently developed tunnel diodes of 5-ma peak current have capacitance in the order of 5 pfs and series resistance around 1 ohm. Individual logical gates of total fan-in and fan-out of two or three have been observed to switch in 1 nsec, and simple logic subsystems have been breadboarded to operate at 300 Mc. Although an all-tunnel-diode digital system is feasible, the advantages offered by the diode, including its speed capability, could be offset by the additional complexity in circuits and power supplies needed to operate this two-terminal device. The feasibility of three-terminal tunneling devices are being explored in several laboratories. At present, a promising approach is the transistor-tunnel diode combination, in which the transistor is used for isolation and current gain and the tunnel diode is used for its fast switching in discrete voltage level. Basic emitter-follow type gates have been built, showing a delay of 1 to 2 nsec per stage with fan-in of five and fan-out of four.

Conclusion

Recent developments in solid-state devices and circuit technology have inaugurated a number of high-speed switching elements, some approaching kilomegacycle rate, suitable for large-capacity digital data processing systems. The transistor remains the predominant switching element for these systems at present and probably will continue to be so for some years to come, largely because of the accumulated knowledge of how to build and use the element for performance and cost advantages. Undoubtedly, the progress of the other technologies cited above is posing an increasing challenge to the transistor as we know it today. When one or more of these competing technologies matures to economic practicability, we can expect more rapid advancement in data processing capability in speed, versatility, and reliability.

Acknowledgment

Recognition of the many individual contributions to the new developments covered in this article would require a bibliography several times the length of the text. It is, therefore, necessary to give a general acknowledgment to the contributors in this field. The author is also indebted to his colleagues at IBM for discussions and suggestions in preparing this paper.

New Concepts in Computing System Design*

GENE M. AMDAHL†, MEMBER, IRE

Summary—New system concepts are discussed within the framework of market requirements and the design goals which are to meet them. These goals are:

1) Programming and compiling aids for increased operating efficiency and flexibility,
2) Higher machine speeds for increased throughput and reduced job cost,
3) Multiprogramming (time sharing) and multiprocessing (load sharing) for greater concurrent utilization of system hardware,
4) System exchanges for greater flexibility in system hardware complement and allocation.

Introduction

THE SELECTION of items to be discussed in this abbreviated article depends upon the degree of association with areas recently having the greatest published activity in computing system design.

These design activities all appear to be focussed on rather general requirements in the market place. Market needs seem to be growing more rapidly in the direction of variety, within computing installations as well as among them. On any one machine it is very likely that: problem running times will be distributed over a range from several seconds to several hours; problem characteristics may vary from scientific computing to data processing to logical manipulation; compiling and debugging time may exceed production time; and real-time processing must be interspersed with scheduled processing. Also, as machine speeds increase, one finds that the communication between man and machine becomes more remote. In part this problem is alleviated by corresponding advances in software and hardware techniques which reduce requirements for "on-line" exchanges. However, not all of this communication can be replaced without serious loss in both man and machine effectiveness.

For purposes of exposition, principal design activities may roughly be categorized by four of the goals sought by the computing system designer. These four goals are:

1) Programming and compiling aids for increased operating efficiency and flexibility,
2) Higher machine speeds for increased throughput and reduced job costs,
3) Multiprogramming (time sharing) and multiprocessing (load sharing) for greater concurrent utilization of system hardware,
4) System exchanges for greater flexibility in system hardware complement and allocation.

Programming and Compiling Aids

Statistics obtained from a large number of computing installations indicate that programming costs have been running approximately 50 per cent of the total cost of the installation. Training programmers to prepare problems for computer solution is in itself an enormous task, and, with the growth of computer usage, the training programs have not been able to keep pace. Because of this, an increasingly larger percentage of problems are being written in a language more closely related to the problem than to the computer instruction set. These are then compiled by the computer into its own instruction set. Statistics relating to computer usage indicate that approximately 30 per cent of useful computer time is being used for compiling.

Because of these cost and manpower problems, more and more attention is being given to the area of reducing programming and compiling tasks for computer systems. In the past the most common way of attempting to reduce programming costs has been to design more sophisticated and larger sets of instruction codes in the computer. This approach may well reduce programming difficulty for writing a problem directly in machine language. However, the difficulty encountered by a compiling program in translating from a source language to a complex machine instruction set is much greater than that encountered in translating to a simple order structure.

Historically, the major emphasis in determining the speed of a computer was placed on raw arithmetic speed. In future systems the ability of a computer to perform the functions required by compiling, debugging and supervisory systems must be taken into account. Computers must be able to operate efficiently with variable sized fields, to scan data records, to search tables, to construct and use lists, to edit information for output, etc.

One approach to these functions is the use of an instruction set that is primitive in a computational sense. A primitive code is defined here as a set of operations in which the entire function of each is required whenever employed. The primitives should be selected for simplicity and generality so that required functional sequences can be efficiently constructed. It is of interest to note that the best programming systems use simple rather than complex coding techniques. A primitive instruction set has been employed in the Thompson

† IBM Corporation, Data Systems Division, Poughkeepsie, N. Y.

Ramo Wooldridge AN/UYK-1. This set concentrates on simplifying execution of macro and interpretative codes rather than reducing compiling difficulty.

An attempt to reduce compiling tasks by use of Polish notation during problem execution is encountered in the B-5000. In order to permit the use of Polish notation, the B-5000 employs a "pushdown" store. A "pushdown" store, in effect, retains operands, either from previous results or from loads, and automatically returns them to the arithmetic unit upon encountering an operation to be performed. The earliest hardware implementation of a "pushdown" store appears in the Aeronutronic Logic Evaluator, delivered in early 1961 to RADC. In this application Polish notation is not employed, but rather automatic translation from parenthetical algebraic notation to parenthesis-free Polish notation is performed during execution of the algebraic logic statement.

Another approach is to automate the task of storage allocation. This technique involves using a much larger memory for programming purposes than is actually available in high-speed random-access memory. This technique has been employed in the Ferranti Atlas. Backing up the large programmers' memory is a large drum memory. During program execution, requests for memory references go through an associative memory. The contents of the associative memory indicate whether the requested information is actually in high-speed memory and, if so, where. If the requested data is not in the high-speed memory, the supervisory program interrupts and calls for transfer of this data from the drum. In principle, the one for one relationship of large programming memory to backup drum storage is not required, for the supervisory system could determine the location of data in any of a number of peripheral media.

Related to the principle employed in the Atlas is the more generalized approach taken by the B-5000. For programming purposes one has, in effect, an almost unlimited pseudo-memory array addressed entirely symbolically. After compiling, the symbolic addresses have been replaced by entries to tables of arrays of actual addresses within the storage media. At execution time all memory references are executed indirectly through these tables set up by the compiling program.

In both the Atlas and B-5000 pseudo-memory approaches an indirect reference is required for all memory requests. This adds an extra memory cycle to each request. It is clear that these indirect references need not necessarily be performed every time, but only on condition that a reference to a previously unidentified block occurs.

Higher Speed

The principal reason for use of a higher-speed computer is that it generally provides more processing capability per dollar than a lower-speed computer. There is an empirical law—Grosch's law—which states that the speed of computers has increased generally as the square of the cost. We need not be concerned with the accuracy of this law, but only with the fact that the relationship between cost and speed does yield a lower cost per job the faster the computer.

A number of approaches to increasing the speed of computers have been employed or proposed in recent years.

Approaches of interest in the area of speeding up the arithmetic and control unit relative to memory-cycle time are *overlap* and *look-ahead.* These require a number of instructions to be in the process of execution at any given time within semi-independent functional units. In overlap the execution of a single instruction can normally be considered to take place in a fixed sequence progressing through these units. The sequencing is momentarily halted whenever a situation arises in which a given unit is busy, and this unit is required by a succeeding instruction. A machine which has developed overlap to a fairly high degree is the Remington Rand LARC. Look-ahead extends this philosophy in that a queue for the use of the functional unit is initiated, and other functions to be performed in the execution of the instruction continue if logically feasible. The IBM Stretch and the Bull Gamma 60 are two computers that make use of look-ahead.

To reduce the effective access time for data and instructions to less than the full memory-cycle time, a number of computing systems have employed multiple memory boxes operating in parallel. In some configurations, *e.g.*, Remington Rand LARC, the memories are available for accessing at separate phases of a clock which cycles in sequence through the core memories and makes a complete revolution every memory cycle. In other computing systems, *e.g.*, IBM Stretch, a clock is used purely for time sharing the memory buses. With this system any memory box may be referred to at any phase provided that the memory has completed its cycle from earlier references.

Another approach to speeding up computations involves reducing the number of references to large memory through the use of two types of high-speed stores. These stores may employ very-high-speed core or active registers. The two types of stores are FIFO (First In-First Out) and LIFO (Last In-First Out) (commonly called list structures) organizational structures. The FIFO store technique has been primarily considered for instruction storage. Instructions in a sequence being executed by the machine are simultaneously recorded in the FIFO store. When a transfer of control is encountered which transfers control back in the sequence a distance less than the capacity of the FIFO store, the instructions can be picked up from FIFO store for execution rather than requiring a lengthier access to the large memory. This technique was first used in the RCA BIZMAC I and was contemplated for, but not included in, the IBM Stretch. The FIFO store is in the Illinois Oddity and is planned for the CDC 6600.

The LIFO store (referred to earlier as "pushdown" store) is more commonly associated with the arithmetic unit and permits efficient automatic storage and return of intermediate results in a local portion of a computation. This technique has also been considered in program-control-sequence use for holding subroutine linkages. The LIFO store technique has been employed in the Aeronutronic Logic Evaluator, Burroughs B-5000, English Electric KDF-9, and Ferranti Atlas.

To take advantage of the higher performance attainable through the concurrent use of functional units and the reduced memory accesses with FIFO and LIFO stores, it is necessary that the arithmetic units in the computing system have a correspondingly reduced execution time.

Due to space limitations, the reader is referred to an excellent discussion of some high-speed arithmetic-unit techniques by MacSorley.[1]

Multiprogramming and Multiprocessing

In this paper *multiprogramming* will be defined to mean time sharing of a single CPU (Central Processing Unit) for a variety of tasks, while *multiprocessing* will refer to load sharing on one or more problems by more than one CPU. Primarily multiprogramming and/or multiprocessing have been concerned with the simultaneous handling of input-output buffering and computing. More recently, editing has also been executed simultaneously with internal computational tasks, as in the Remington Rand LARC.

Unless multiprogramming is restricted to jobs specifically planned to run concurrently and to programs that are "debugged," a minimum of five requirements must be provided for in hardware and/or in the programming system.

1) Memory protection—If all or portions of several programs are to be used concurrently in the high-speed memory, a given program cannot be permitted access to sections of the memory allocated to other programs. Further protection may be required if subroutines within the supervisory area are to be available upon request to all programs. The latter case may require that these areas can be read from, but not written into, by a program.
2) Program and data relocatability—Since the memory area available to a program and its data cannot be determined at compile time, a minimum need is for relocatability at load or reload (when a problem is dumped due to a high-priority job) time with a relocating load routine. Indirect addressing of some nature is required if the program and data are to be relocated independently.
3) Supervisory program—Since a problem program does not have full information about the status of the computing system, there must be a supervisory routine which handles storage and Input/Output allocation, controls I/O operations and processes interrupt signals.
4) Interrupt system—While the current trend is to provide a multiplicity of interrupt signals, a minimum of one—a timed return to the supervisory program—must be available. The timed return will permit the supervisory program to keep control of the computing system even if a problem program is in an endless loop or has executed a program halt.
5) Symbolic addressing of I/O—I/O units are similar to memory areas in that they cannot be allocated at compile time. The designation of a unit by the problem program must be replaced by an assigned number at loading or execution time, or else must transfer control to the supervisory routine for I/O execution.

This list is certainly not adequate for efficient multiprogramming and is not necessarily minimum if a multiprocessing system is considered. A number of things have been tried to improve the properties of a system for multiprogramming. One approach is the multiple program counters in the Minneapolis Honeywell 800 where one instruction of each of 8 programs is executed in a cyclical basis. Most of the concurrent programs for this system are related to I/O. Another approach is the MIT TX2 in which high-speed core registers hold the equivalent of a multiplicity of arithmetic-unit register sets. On an interrupt signal a given "arithmetic unit" is effectively brought into play until the next interrupt appears or a release is executed. Means are provided for returning to the previous "arithmetic unit" employed upon release by the current unit.

Approaches to multiprocessing include the Bull Gamma 60 which has a variety of independently-controlled functional units, some of which may be duplicated, such as a printer which executes its own program sequences (including limited editing functions), an arithmetic unit, a comparator unit, etc. Another approach is the TRW-400 where multiple computers may be switched between I/O units and communication channels via a real-time exchange (described under System Exchanges). The Remington Rand LARC has an I/O control and editing computer running simultaneously with a large-scale scientific computer. There are some examples of IBM 7090 and 1401 units linked together through tape units or 1301 disc files to compute and to perform I/O editing, respectively.

A special subgroup of requirements of multioperation includes memory protection, relocatability and symbolic addressing of peripheral equipment. In the B-5000 and Atlas computer these functions are performed by a

[1] O. L. MacSorley, "High-speed arithmetic in binary computers," Proc. IRE, vol. 49, pp. 67–91; January, 1961.

supervisory system implemented by combined program and hardware means. All memory references by the CPU are indirect through tables maintained by the supervisory system. These lists make available to a program only those areas of core storage belonging to that program. They also permit supervisory intervention to make available in high-speed storage that data which has been placed on backup storage due to internal space limitations. Since I/O is handled by the supervisory-system protection, relocation and symbolic addressing of I/O is achieved by programming. It is of interest to note that symbolic addressing of I/O is achieved in hardware in the TRW 400. A memory is provided which transforms the number used in the program to the proper I/O unit address.

Another approach to memory protection is the boundary registers in the IBM Stretch which cause an interrupt when memory access is attempted beyond these two limits. There are several versions of memory protection available on the IBM 7090, and one of the most interesting is the division of memory into blocks. Corresponding to each block is a bit in a memory-mask register. When access to memory is attempted, the bit corresponding to the block which contains the desired address can be interrogated to determine if this memory block has been assigned to the program controlling the CPU. In conjunction with this type of memory protection, a relocation register is provided to modify addresses generated in a program to the area assigned to that program and its associated data.

There is some question concerning the efficiency of multiple computers, for one cannot ignore the difficulties of making several computers appear like a single computer. If cooperating on a single task, coordination is necessary to ensure that computers do not get too far ahead or behind others in the system. If performing separate tasks, assignment, arbitration and monitoring functions for distributing work loads and peripheral equipment must be provided. There is also the problem of the amount of information that may have to be sent between the various units in the system. In general, two computers are less than twice as powerful as one computer, while doubling the equipment in a single computer usually results in much more than doubling the power of the resultant computer.

From a system-reliability viewpoint, there are advantages to a multicomputer system, provided that there are multiple units of each kind and that it is possible for one of these units to be disconnected from an active role in the system. A disconnected unit must make its internal register contents available to the system for recovery purposes. In such a system it may be possible to obtain graceful degradation in event of failure of a given unit. It would appear that the requirements for graceful degradation are probably greater than the requirements for multiprogramming or multiprocessing alone. Historically, the approach has been to have standby facilities in the event of failure of the operating facility. This method guarantees the minimum performance of the system without taking advantage of maximum computing capability available when all units are functioning properly.

System Exchanges

The computer system exchanges are considered to be the interconnection system between CPU's, memory boxes, peripheral storage and input/output units within an installation.

At present the most flexible computer exchange is in the RW-400 system. This exchange is fully electronic, being designed in both transfluxor and diode switching technologies. It is effectively a 16- by 64-channel rectangular cross-bar switch. CPU's and buffers, which are active controlling elements, are connected on the 16-channel side. On the 64-channel side the buffers again appear along with the array of peripheral storage and I/O devices. In addition, on one of these channels there is a small core memory which holds actual peripheral storage and I/O unit numbers assigned to each computer, addressed by symbolic unit numbers employed in each computing unit's operating program.

Of growing interest to the system designer is the handling of a large number of low-speed lines, where the communication network is a large or major portion of the system. These networks operate primarily under the control of devices other than the CPU, although in cases of traffic loads exceeding the capacity of the network the CPU can normally inhibit operation of any input unit. To bring such a large number of channels into a CPU economically, multiplexed (generally sequential scanning) I/O channels are used. In order to service requests for such a large number of I/O units, interrupt facilities must be provided which contain identification of unit and communication line. These systems require large transaction queue-buffer storage capacity, with essentially random access characteristics. Magnetic drums or disc files satisfy this requirement, but magnetic tapes must be precluded unless the system operation can be modified. In order to utilize magnetic tapes, the queues must be sorted before processing or retransmission rather than handling by input sequence alone. In addition, further backup random access storage is generally required to contain the large number of service routines which are likely to be needed for the variety of transactions. An early example of this is the SAGE system with its large number of telephone links with radar sites plus its large number of CRT displays. In the commercial area there is the SABRE system, in which up to 1000 agents' sets are connected into 7090's, 7080's or 7070's and where flight seat reservations are stored in disc files. The SABRE system requires large random access storage for file data but not too many routines for processing the data.

A third application is one in which a computer with large peripheral storage is used exclusively as a buffered communication exchange. Such a system has been designed, using the RCA 601, which handles 50 teletype or Kineplex input channels and 50 teletype or Kineplex output channels. These incoming messages contain priority and routing data along with the message. Messages are accepted by the central processor and stored in sequence in queues which are ordered by output line and priority. Provision is made to accommodate extremely long queues in the event of unusual communication loads on a very small number of output channels.

Similar systems are under consideration by some scientific computer users to simulate the operation of a multiplicity of small private computers. In this application terminal sets would be placed wherever convenient for the users of the system, and the terminal sets tied to a large CPU with its associated memory. The user would request service from his terminal set and, after the problem has been run, the output returned to the terminal set. Such a system is now undergoing limited tests at M.I.T. If its effectiveness meets expectations, the system may have considerable impact on the computing system designs of the future.

Conclusion

The new system-design concepts are aimed at making the computing system a more powerful, efficient, effective and flexible tool, in spite of the compounding complexity of hardware assemblies and the variety of applications. An adequate discussion cannot be presented in an article of reasonable length, or even by a single author. Furthermore, many of the new concepts are as yet unpublished. Even at this time so many of the computing machines and systems referred to in this article do not have nearly adequate descriptions published; therefore, the author feels compelled to omit all bibliographical material.

The Impact of Hybrid Analog-Digital Techniques on the Analog-Computer Art*

GRANINO A. KORN†

***Summary*—In a sense, many present-day analog computers exist in a gap left by the cost-speed characteristics of available digital computers. But even as digital computers improve, the all-parallel "live mathematical model" afforded by analog-type simulation remains indispensable to the system designer. As a result, new hybrid computing elements and systems combine analog and digital features, and analog computers are becoming faster. The techniques discussed include combination of conventional analog and digital computers, digital programming and checkout of analog computers, operational digital computing elements, new high-speed analog computers with memory and digital switching, true hybrid computing elements, and some hybrid computer systems.**

Introduction

MODERN electronic analog computers permit real-time and fast-time solution of the possibly formidable differential equations describing complex dynamic systems, such as space vehicles and chemical plants [1]. In such applications, analog computers have not merely filled a cost-speed gap left by existing digital computers; they serve as "live mathematical models" facilitating direct intercourse between system designer and simulated system, as well as the inclusion of actual hardware in real-time simulation. A system designer will tend to use the analog computer himself, while he may want to delegate digital-computer work to numerical analysts and computer programmers [2].

This situation is not static. The speed advantage of real-time analog computers is crowded not just by the increasing speeds of digital computers, but by their ability to work automatically-programmed night shifts. New compiler routines permit digital-computer setups directly from analog-computer-type block diagrams [3], [4]. At the same time, improved "operational" digital integrators, multipliers, and resolvers can replace analog components in some exacting applications and still preserve the direct-model all-parallel nature of the computation.

In the face of these developments, analog-computer designers have emphasized ever-higher computing speeds together with new devices and systems combining desirable features of both analog and digital computation. It is likely that the more expensive "analog" computers of the future will contain as many digital components as operational amplifiers.

Combined Analog-Digital Simulation

Real-time simulation problems requiring high computing accuracy (*e.g.*, trajectory computations with three-dimensional coordinate transformations) and simulation of digital system components have led naturally to combination of existing analog and digital computers in many of the larger simulation laboratories.

In the examples of Fig. 1 [5] a multipurpose digital computer is linked to a real-time analog computer through one of the conversion units now commercially available from several manufacturers [6]. The digital computer performs that part of the real-time computation for which it is most suited, namely, accurate coordinate conversions, trajectory computations, and the simulation of digital-control equipment. The analog computer simulates dynamic control functions requiring greater bandwidth and less accuracy. Another striking application of combined multipurpose computers is the postflight analysis of tape-recorded aircraft-maneuver flight-load histories [7].

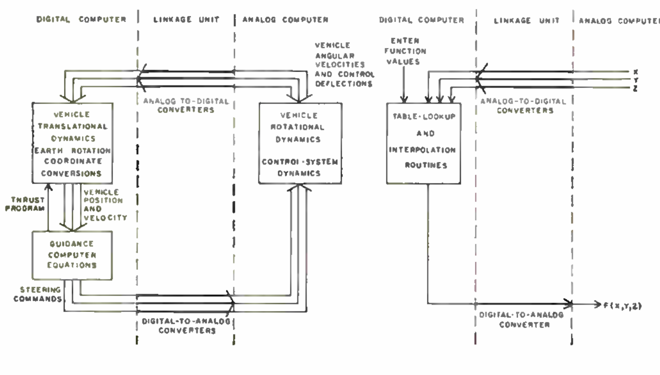

Fig. 1—Typical applications of combined general-purpose analog and digital computers [5]. (a) Combined real-time space-vehicle simulation. (b) Digital function generation.

The combined simulation technique was pioneered in the aerospace industry [5]–[7]. Painful experience seems to indicate that the provision of small multipurpose digital computers is greatly preferable to part-time utilization of large digital computers. In combined simulations requiring greater digital-computer speed, operational digital computing devices such as digital differential analyzers can supplement or replace the conventional digital computer.

Operational Digital Computation

In the author's opinion, the "operational" block-diagram structure of the analog computer, which closely parallels that of the system being simulated, will remain indispensable for system design. It is possible, however, to replace analog computing elements by digital computing elements capable of real-time operation. *Operational digital computers* represent variables basically by binary numbers, but unlike most general-purpose digital computers, they employ separate digital adders, multipliers, integrators, etc. in the manner of analog-computer setups. Such all-parallel operation permits relatively high computing speeds with a minimum of intermediate storage. The nuisance of transferring n-binary digits on parallel lines can often be avoided by *incremental computation* which transfers only changes ΔX of variables X between certain of the computing elements; during each clock period, ΔX is either 1, 0, or -1, so that, at most, two lines are required to transfer ΔX and its sign. An incremental computing element, then, represents the rate of change of the variable X by the repetition rate $\Delta X/\Delta t$ of the ΔX pulse train, and simple binary counters can generate the variable X itself wherever it is needed. Fig. 2 (next page) shows examples of simple operational digital computing elements employing binary and incremental representations [8], [9].

The best known operational digital computers are *all-parallel digital differential analyzers* which employ incremental integration and multiplication, together with digital function generators based on table-look-up and interpolation routines [8], [10]. A general-purpose computer of this type (Packard-Bell TRICE) can be patched just like an analog computer and uses 3-Mc digital circuits to produce 100,000 binary increments per second. Note that a given increment rate can buy either greater accuracy for slowly changing variables, or greater bandwidth with less accuracy [10]. TRICE permits all-digital real-time simulation of aircraft, but requires several hundred semiconductors for a single integrator. The resulting cost seems staggering when compared to that of dc analog integration. The author believes, however, that operational digital computation is still a relatively neglected field. In the future, costs are bound to be reduced through new arithmetic schemes, higher-order integration algorithms, new circuits and devices, and also through competition, mass-produced microcircuits, and amortization of development expenses.

Faster Analog Computers with Digital-Computer Features

In recent years the analog-computer industry has expanded its market to smaller design and research groups with small and medium-cost electronic analog computers which are likely to remain quite safe from digital competition. In view of the digital threat to a portion of their large-computer market, analog-computer manufacturers have attempted to increase the computing-speed advantage of their machines and to include automatic features which greatly simplify computer-setup and check-out procedures. At the same time, analog computers are acquiring a measure of the memory, decision-making ability and automatic programming abilities of digital computers.

Practically all large analog computers permit setup of coefficient potentiometers and function generators by digital keyboard control and punched-tape storage of coefficients and functions [11]. Such machines also per-

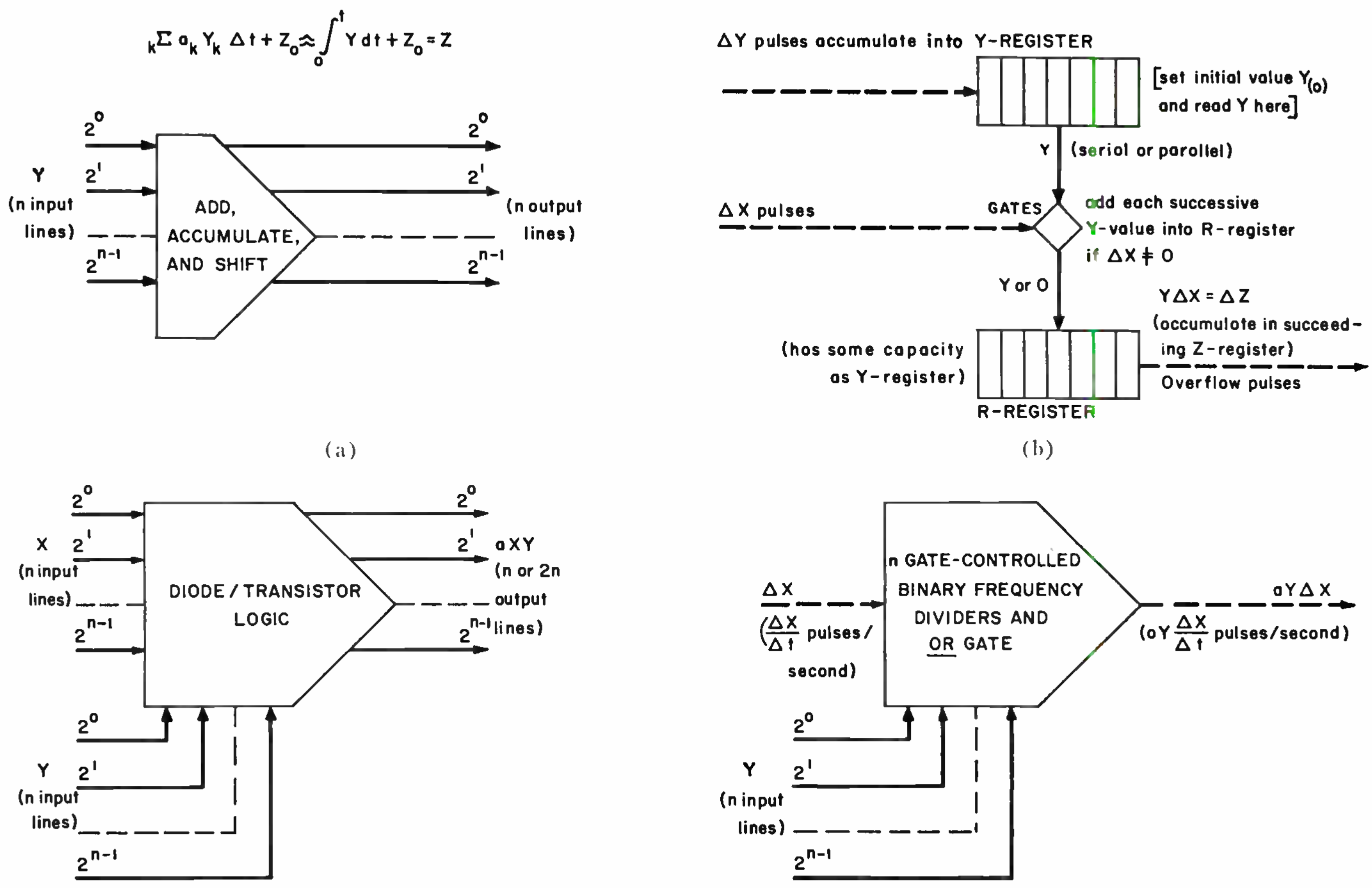

Fig. 2—Examples of simple operational digital computing elements capable of real-time operation. To simplify the representation, only operations on positive quantities are illustrated; in practice, a sign bit would be transmitted with, or coded into each variable. In the "incremental" computing elements *b*, *d*, the variables ΔX, ΔY, ΔZ represent pulses occurring at rates proportional to $\Delta X/\Delta t$, $\Delta Y/\Delta t$, $\Delta Z/\Delta t$. (a) Simple all-parallel integration in a digital computer. (b) Basic incremental integration in a digital differential analyzer. (c) All-parallel multiplier for multiplication of two binary numbers. (d) Multiplication of a pulse rate of a binary number.

mit digital printout of all initial conditions, thus speeding static setup checks [11].

The next step towards completely automatic programming of large electronic analog computers is to let a digital computer compile scale factors, potentiometer settings, and analog interconnection diagrams (setup sheets) directly from the given problem equations. Programming automation will be complete when the digital computer can actually accomplish analog-computer interconnections, say by means of a super-crossbar switch array, and proceeds to check out the analog-computer solution. Since the scaling-programming-checkout procedure for large analog computations is tedious and often consumes much more time than the computation itself, there is considerable interest in such complete programming automation [6], [37]. The very real difficulties inherent in switching a large number of analog-signal connections is simplified in some applications by various combinations of prepatching and automatic switching.

Wherever the inclusion of actual system hardware does not necessitate real-time operation, there is a universal trend towards *faster analog computation*. All-electronic multipliers, function generators, and resolvers are now more accurate as well as faster than computer servomechanisms. New diode function generators with a claimed static accuracy of 0.02 volts are available as sine-cosine generators [12] and for quarter-square multiplication [12]; they may well replace modulation-type multipliers if operating experience proves their reliability. The highest computing rates are afforded by repetitive and iterative analog computers which can implement vast parameter-optimization studies and statistical analyses at speeds impossible to duplicate by other means within the foreseeable future.

New Repetitive and Iterative Analog Computers

In conventional electronic differential analyzers, the integrator control relays cause each operational-amplifier integrator to follow an initial-condition (IC) input (RESET or TRACK mode), to integrate an input (COMPUTE mode), or to hold the last output value (HOLD mode) [11]. The use of high-speed relays or (preferably) *electronic integrator switching* permits accurate *repetitive operation* at between 5 and 1000 computer runs per second, so that the effects of parameter changes are readily seen on an oscilloscope presentation [2].

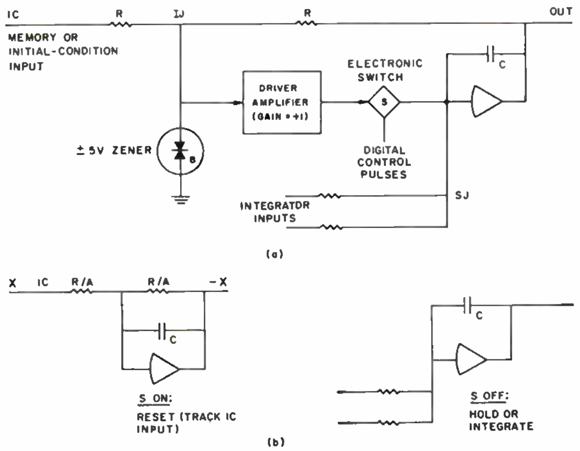

Fig. 3—The electronically-switched integrator is the key element of the modern analog computer and serves as an analog memory as well as a repetitive-computer integrator. With the electronic switch on (TRACK or RESET mode), the output will track the IC input. With the switch off (HOLD or COMPUTE mode), the output holds its last value or integrates an input sum. A typical unit can track a 20-v peak-to-peak sine wave at 50-kc and will hold within 0.1 v for 0.1 second with a 0.005-μf capacitor [14].

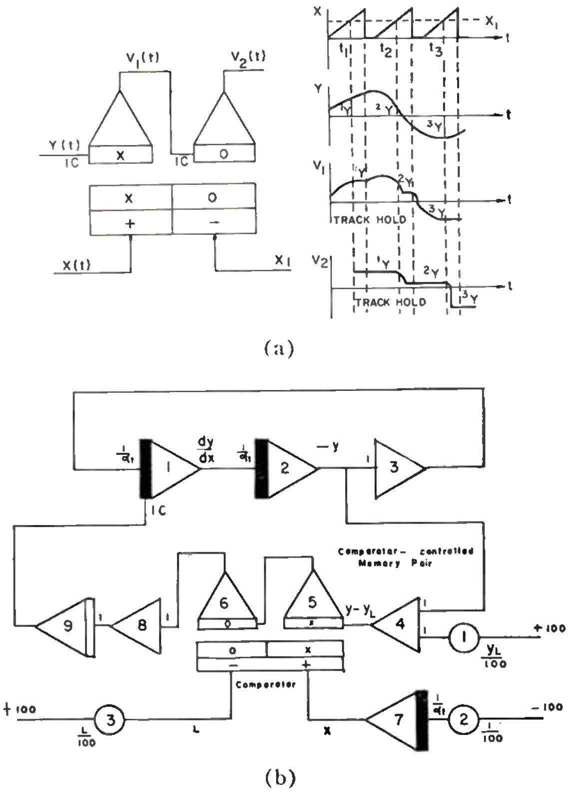

Fig. 4—(a) A comparator-controlled memory pair. Two electronically switched integrators alternate between TRACK and HOLD to permit solution of a wide variety of problems by finite-difference techniques. The comparator input voltage x can be any repetitively reset computer variable [16]. (b) A simple example of the iterative-differential-analyzer technique: iterative solution of the split-boundary-value problem

$$\frac{d^2y}{dx^2} = -y \quad \text{with} \quad \frac{dy}{dx} = 0 \quad \text{for} \quad x = 0,$$

$$y = y_L \quad \text{for} \quad x = L.$$

Darkened integrators are under rep-op control. x is represented by the computer time (real time) $\tau = a_t x$, so that $d/dx = a_t d/d\tau$. Amplifiers 1, 2, 3 constitute a differential-analyzer setup which solves the given differential equation repetitively about 10 times per second with the given initial condition $dy/dx = 0$ and the trial initial-condition change ${}^n\Delta y(0) = [{}^{n-1}y(L) - y_L]\Delta t$ for the nth computer run, where $y(0) = 0$. This trial initial-condition change is supplied by the comparator-controlled memory pair. Amplifier 5 tracks the output $y(x) - y_L$ of amplifier 4 from the start of each computer run until x reaches the value $x = L$ and trips the comparator. Amplifier 6 then acquires ${}^{n-1}y(L) - y_L$ and holds this value until x again reaches $x = L$ during the next cycle. The process converges rapidly to the desired solution.

Recent order-of-magnitude improvements in the speed and offset characteristics of electronic integrator switches [13]–[15] have not only improved repetitive computation but establish the electronically-switched integrator as a novel analog computing element which can serve as an *analog memory cell* as well as an integrator or summer. In the TRACK mode the new integrator can sample values of a variable applied to the IC terminal; in HOLD the integrator holds the last sample value and can introduce it into subsequent computer runs. Entirely new *sequential and iterative analog computing techniques* are thus made possible.

Fig. 3 shows an electronically-switched integrator and illustrates its modes of operation. Two such integrators are combined into a *comparator-controlled memory pair* [Fig. 4 (a)] which can sample fast computer solutions at sampling times determined either by a timing system or by any voltage in the computer. The step-wise output of the memory pair can be introduced iteratively into successive computer runs and may be said to simulate a digital-computer output. Fig. 4 (b) illustrates the iterative solution of a simple two-point boundary-value problem.

The repetitive-iterative differential analyzer with memory permits the introduction of "subroutines" obtained by fast repetitive analog computation into "slow" analog-computer setups [15], [19]. Examples of such applications include repetitive computation of the inner integral in a double integral [16], approximate solution of partial differential equations by difference-differential equations [16], and sequential solution of heat- and mass-balance equations at different points of a chemical reactor or distillation column [15]. Another significant application is automatic parameter determination or optimization by steepest-descent techniques [20]. The sequential optimization of, say, 40 parameters of a complex nonlinear system practically calls for high-speed repetitive operation; this need is even more acute when a *sample* of random-input computer runs must be taken for each combination of parameter values.

The repetitive-iterative analog-computation technique combines the operational model of the analog computer with the decision-making ability and memory of the digital computer. Because of the partially continuous and partially discrete nature of the computation, some of the new iterative techniques are not directly comparable to iterative digital-computer techniques. This is a fertile field for theoretical investigation.

Fast Analog Computers Incorporating Digital Logic

The availability of fast electronic switches, comparators, and sample-hold devices in the iterative differential analyzer has increased the utilization of these elements for direct simulation of control systems incorporating digital logic, sampled-data operations, and analog-to-digital conversion. Again, the switching elements have been operated at a sufficiently rapid rate to synthesize electronic time-division multipliers and electronic resolvers capable of operation with the slow portion of the analog computer, so that, in a sense, the "slow" portion of the iterative analog computer requires only linear computing elements, comparators and switched integrators. In the author's opinion, this type of operation is somewhat wasteful, since it simulates inexpensive digital flip-flops and digital switches by expensive chopper-stabilized operational amplifiers and accurate analog switches. It is suggested, therefore, that fast analog computers be equipped with a set of *digital modules*, such as Schmitt triggers, flip-flops, and diode gates, which can be operated together with switched integrators and analog switches to permit a new variety of simulation work as well as convenient synthesis of new hybrid analog-digital computing elements [21].

True Hybrid Computing Elements

The inclusion of digital computing elements in analog computers, or vice versa, brings us to the design of *true hybrid analog-digital computing elements*. It should be clear that the really basic transducers relating analog (continuous-variable) and digital (binary) operation are not complex analog-digital-analog converters but *comparators* (output changes state when the input sum goes through zero) and *analog switches* (analog voltage ON or OFF as dictated by a binary input). The development of accurate and fast components of this type, not an easy task, must be the basis of all hybrid-computer work [21]. Fig. 5 shows some currently used comparators and analog switches [13].

Repetitive operation and hybrid-computer techniques require *operational amplifiers* orders of magnitude faster than slow conventional analog computers. Fig. 6 shows a feedforward design yielding a chopper-stabilized amplifier capable of operation in the megacycle range.

Analog switches and fast comparators are combined in the well-known *binary-to-analog and analog-to-binary* converters shown in Fig. 7. Since the reference voltage in each of these circuits can be a variable, these circuits also permit *multiplication or division of analog and digital voltages*. The combination of both circuits has served as a hybrid multiplier-divider in both analog and digital systems [2], [24].

It is an intriguing fact that a pair of analog voltages each accurate within only 1 per cent can, in principle, represent a numerical variable to within 0.01 per cent. Although various vernier devices and two-speed servo-

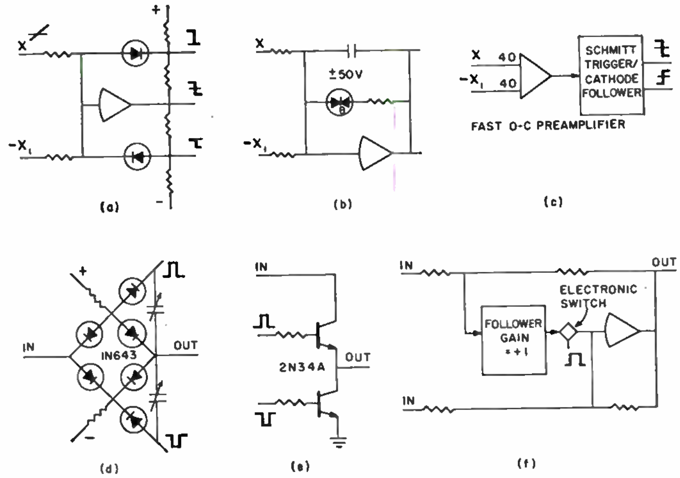

Fig. 5—Comparators [13] (a)–(c) and analog switches [13] (d)–(f) are the really basic analog-digital-analog conversion links. The basic comparators (a) and (b) yield 0.1-v accuracy at low frequencies (to 2 cps) and about 0.3-v accuracy at 100 cps. (c) shows a Schmitt-trigger comparator using a chopper-stabilized preamplifier to increase the static accuracy. This circuit is useful at 5–10 kc. The switching circuit (f) [15] can control ±100-v analog voltages with ±8-v pulses from transistorized digital modules.

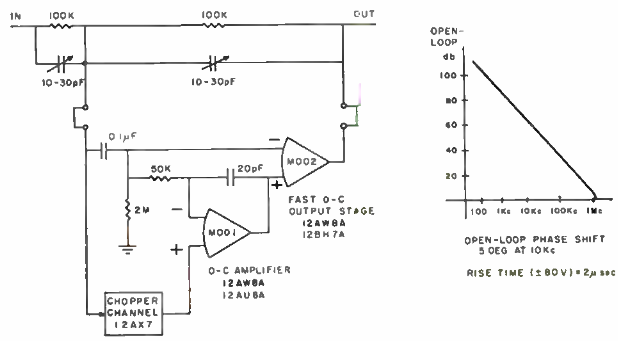

Fig. 6—Repetitive operation and hybrid techniques require operational amplifiers faster by orders of magnitude than "slow" conventional analog computers. The feedforward technique used in this ASTRAC amplifier yields 5° open-loop phase shift at 10 kc; the phase inverter shown is still useful at 1 Mc [21].

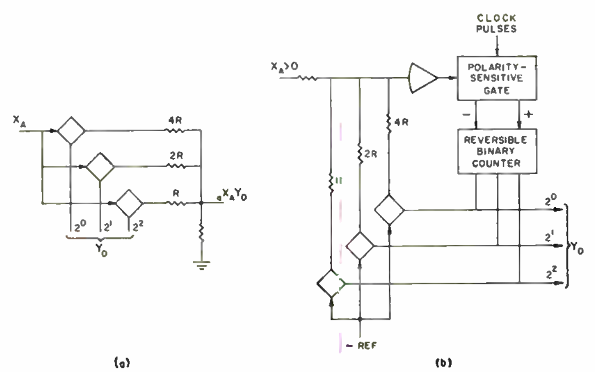

Fig. 7—Simple digital-to-analog converter (a) and analog-to-digital converter (b). In hybrid computers these circuits do not only serve for conversion but are used as relatively simple analog-digital multipliers, dividers, and scale changers (see also Fig. 9).

mechanisms and also perturbation methods for the analog solution of differential equations [25] can be considered as two-digit analog devices with two amplitude scales, this technique has not been tried to any extent.

On the other hand, a 3-digit binary number X_D (0 to 8) combined with an analog voltage X_A accurate to within 0.1 per cent can represent a numerical variable X to within 1/80 per cent. It should be possible, then, to combine simple 3-bit operational digital computing elements with analog devices so that the continuously-variable voltage X_A interpolates the less significant digits of X between the accurately computed coarse digital values X_D. Each hybrid computing element based on this principle will require interaction between its analog and digital components, including generation of *carry pulses.* Whenever the output voltage of an analog computing element exceeds a threshold corresponding to one digital unit, a *carry pulse* must be generated so as to add one unit to the binary output and subtract the threshold value from the analog output.

Fig. 8 shows a number of analog computing elements capable of generating a carry pulse whenever their analog outputs exceed set limits [26]–[28]. The carry pulse is then used to advance the digital output by one binary unit and to subtract a corresponding value from the analog output; the carry pulse may also serve as an increment pulse in an incremental computer. In each of the novel computing elements of Fig. 8 a transistor or bridge limiter senses when the threshold is exceeded and

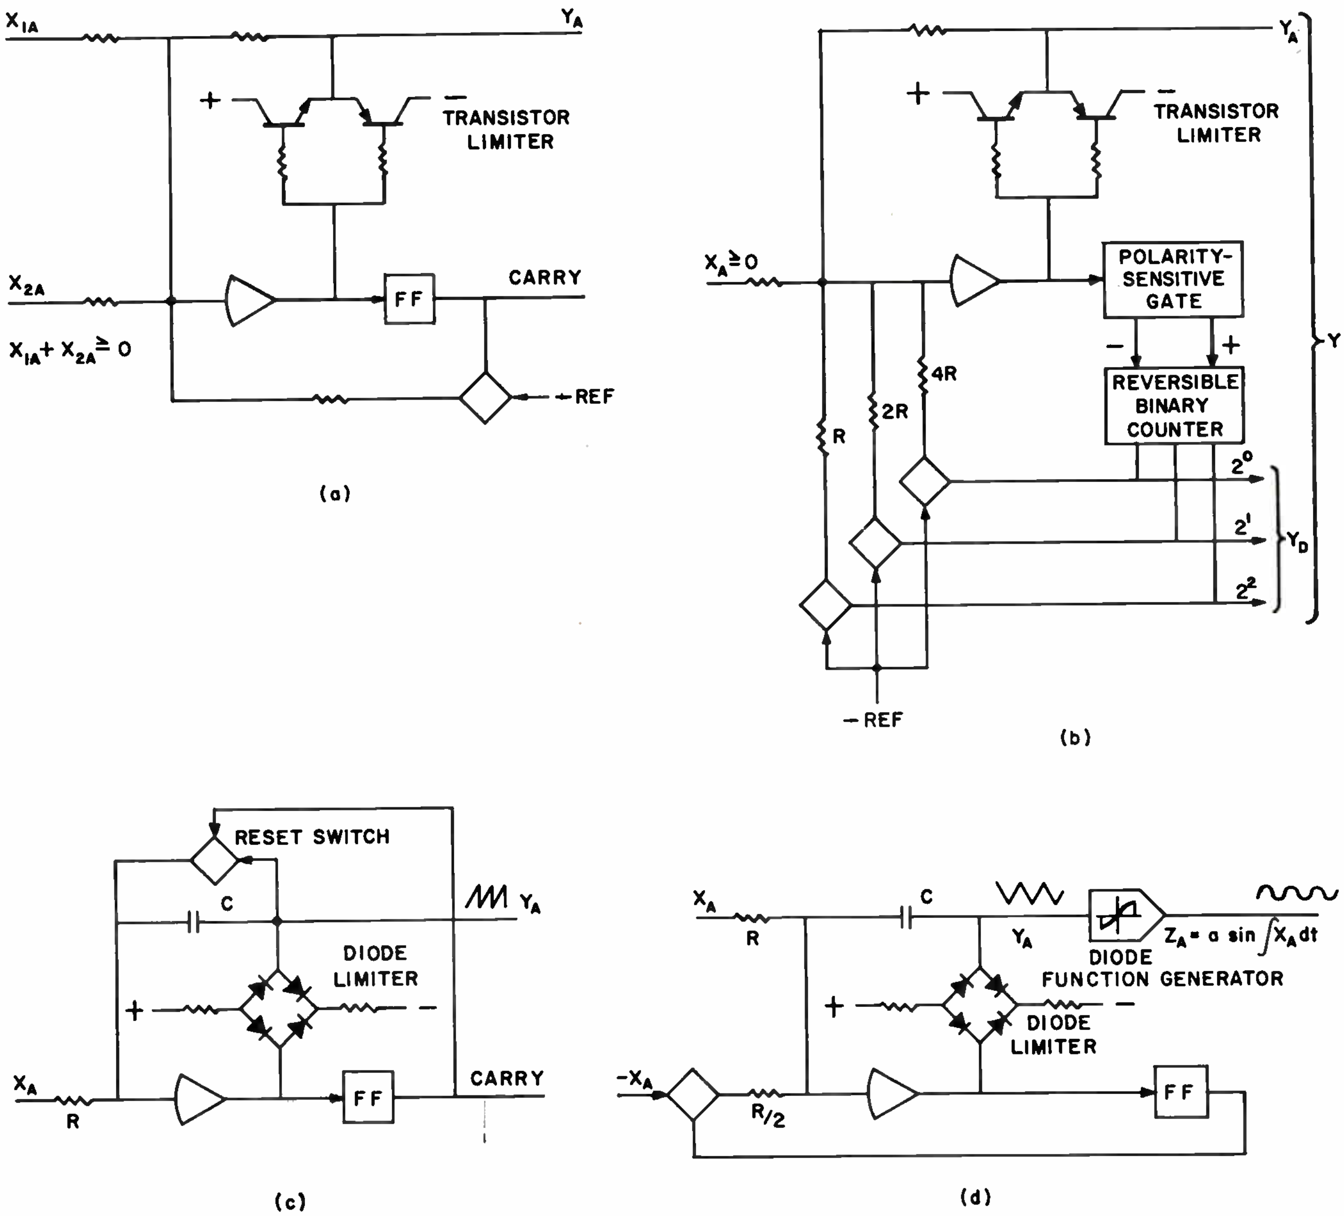

Fig. 8—Development of hybrid computing elements from operational amplifiers with built-in comparators: each circuit resets itself and generates a digital carry pulse whenever the analog output exceeds set limits. The circuits shown are (a) a summer-carry generator [28] (b) a partial analog-digital converter [26] (c) a self-limiting integrator-carry generator [27] and (d) a self-reversing integrator used in a scale-factor-free rate resolver [27].

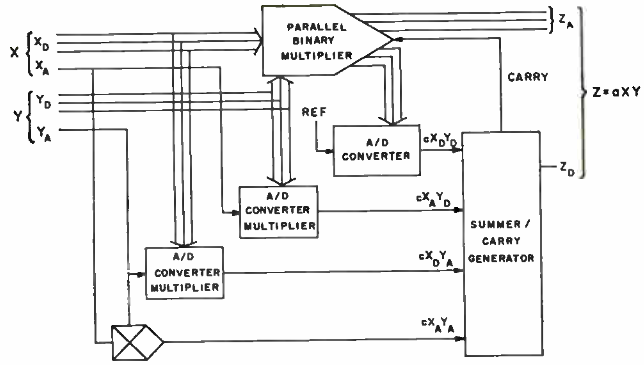
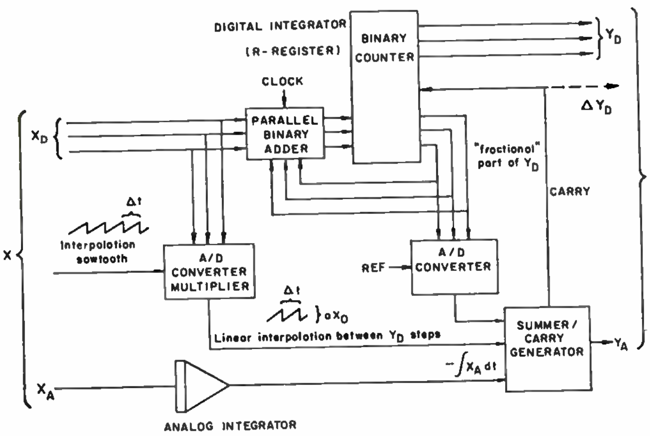


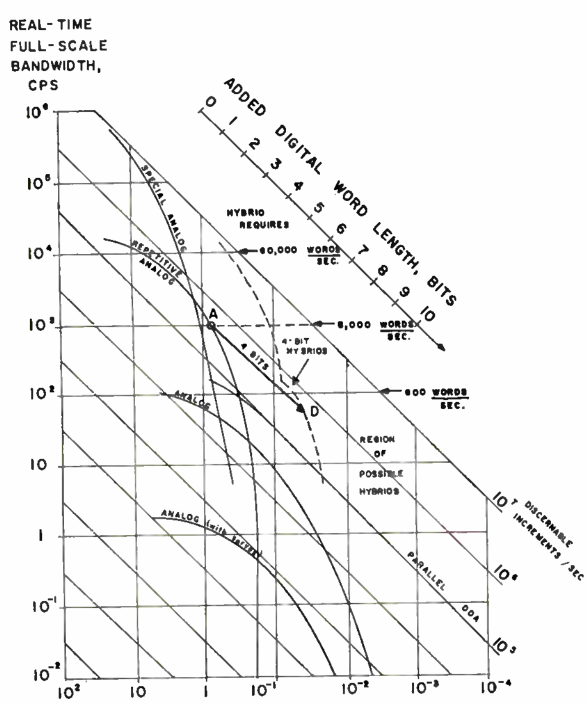
(a)

This true hybrid multiplier [29] combines circuits of the types illustrated in Figs. 2, 7, and 8. For simplicity only positive quantities are considered here. The product $XY=(X_D+X_A)(Y_D+Y_A) = X_DY_D+X_DY_A+X_AY_D+X_AY_A$ is generated by remarkably simple digital-digital, analog-digital, and analog-analog multipliers together with a summer-carry generator. Note that in this example the accuracy required of the analog-analog multiplier is only 1 per cent.



(b)

A true hybrid integrator. A simple 3-bit binary accumulator combines the digital integral with a carry generated when the analog part of the circuit reaches the value corresponding to 1 digital unit. The summer-carry generator analog inputs are 1) a sawtooth of amplitude X_D to interpolate between successive Y_D values; 2) a voltage corresponding to intermediate fractional values of the digital integral; and 3) the analog integral. Again only positive quantities are considered. The carry may be used to generate an incremental integrator output, if desired.



(c)

Gross accuracy-bandwidth relations for analog, digital, and NBS-type hybrid differential analyzers. The resolution-bandwidth product (discernible increments per second) for the DDA is constant, except for effects of increased truncation errors at low accuracies. Analog computers are limited by static accuracy and high-frequency phase shift. The vector AD exemplifies a practical hybrid using, for simplicity, only positive analog voltages (one-half analog full scale—simply add one extra digital bit for machines using negative as well as positive analog voltages). In this example, combination of a 1 kc, 1.5 per cent FS analog computer (point A) and a 4-bit 6000 words/second digital computer yields an over-all accuracy of 0.25 per cent FS with an over-all full-scale bandwidth of 60 cps (point D). Note that the bandwidths obtainable with NBS-type hybrids are limited by the state of the analog-computer art; and note the boundary of practical 4-bit hybrids.

Fig. 9.

interrupts an operational-amplifier feedback loop to produce the desired carry pulse.

The *complete hybrid computing elements* of Fig. 8 [28], [29] are developed from the simpler devices shown in Figs. 5–7. Each variable X is represented by an analog voltage X_A together with a binary number X_D expressing the most significant digits. In the *hybrid multiplier* of Fig. 9 (a) the digital components X_D, Y_D are multiplied in a parallel binary multiplier. Analog carries are introduced into the output of this multiplier to form the correct digital component of the product XY. An analog summer-carry generator accepts the three products $X_A Y_A$, $X_D Y_A$, $X_A Y_D$, which are generated, respectively, by a coarse analog multiplier and two digital-analog converter/multipliers [see also Fig. 7 (a)].

The *hybrid integrator* shown in Fig. 9(b) is the basic element of the National Bureau of Standards and Link hybrid differential analyzers [28], [29]. A digital integrator (binary adder-counter) integrates the digital input X_D with suitable modification through analog carries. A digital-analog converter-multiplier multiplies the output of a sawtooth generator common to all integrators of the machine by the input rate X_D of the output Y_D to interpolate between digital output values. The corresponding analog voltage is combined with an analog voltage corresponding to fractional values of the digital integrator output and with the integrated analog voltage in a summer-carry generator. The digital output Y_D can be transferred directly, or the carry pulses may be treated as increment pulses in the manner of a digital differential analyzer.

Hybrid Analog-Digital Computer Systems

Apart from their use in computing systems as such, hybrid analog-digital computing elements may have just the combination of accuracy and speed needed to save much digital equipment in many data-processing systems. This is especially true in instrumentation and control systems required to handle continuous-variable inputs, for it may be possible to build computing operations into the analog-digital conversion equipment.

Existing complete computer systems utilizing true hybrid computing elements are all of an experimental nature and will serve to indicate the possibilities of such systems rather than to indicate a definite trend.

The *National Bureau of Standards hybrid differential analyzer* [28] employs computing elements of the type illustrated in Fig. 8 with 5-digit digital components. Interest in such hybrid systems stems from the following features:

1) Digital components used need not be excessively fast and require a relatively low number of digits, so that all-parallel logic can be used at moderate cost.
2) Computing speed is determined by the relatively fast analog components.

Note, however, that in *every* computing system required to represent real-time phenomena over a given frequency spectrum *any increase in accuracy requires a proportionate bandwidth increase.* This is true simply because any increase in scale factors requires analog or digital data to change at greater rates.

Hybrid differential analyzers may bridge a speed-accuracy gap between analog and digital computers especially in fast trajectory computations (space-vehicle reentry, range-safety impact prediction). Such computers could conceivably be designed to serve as accessories to increase the speed of existing digital computers. Relatively little development work has been done on hybrid computing elements, and substantial improvements and simplifications are quite likely.

The *Arizona Statistical Repetitive Analog Computer* (ASTRAC) developed at the University of Arizona [21], [30], [31] is an all-electronic repetitive-iterative analog computer intended mainly for Monte-Carlo-type studies of control systems and communications systems [32], [33].

Random-input solutions of system differential equations are generated at rates between 10 and 100 cps; a flexible digital-control unit samples these solutions at push-button-controlled times for a preset number of 1000 to 10,000 computer runs. The sample values are read into a hybrid analog-digital statistics computer which computes probabilities [34] and sample averages of x, x^2, $x(t)\ y(t-\tau)$, etc., for nonstationary as well as stationary random processes. The repetitive computer contains digital multivibrator and diode-logic modules as well as analog memory units, switches and conventional analog computing elements. Random inputs as well as randomly-timed events are obtained from noise generators which generate random telegraph-wave or Gaussian outputs. ASTRAC memory-integrators can be comparator-controlled in the manner of Fig. 4; the all-digital control unit permits convenient control of iterative subroutines. Fig. 10 shows a block diagram of the ASTRAC system, and Fig. 11 illustrates the operation of a hybrid averaging unit in the statistics computer [21].

The possibility of *program storage* on magnetic tape or drums is an attractive feature of hybrid as well as digital computers. A hybrid differential analyzer proposed at M.I.T. as a real-time flight simulator for the U. S. Navy [13], [35] would represent each variable by a positive analog voltage, together with a digital word expressing sign and scale factor (floating-decimal-point position). The analog arithmetic unit comprises parallel analog integrators, but only one analog summer, one multiplier, and one divider, which are time-shared with the aid of electronically-switched sample-hold circuits. A relatively simple digital arithmetic unit performs the corresponding operations on the digital sign and scale words. Analog comparator circuits sense the magnitude of summer, multiplier, and divider output voltages and

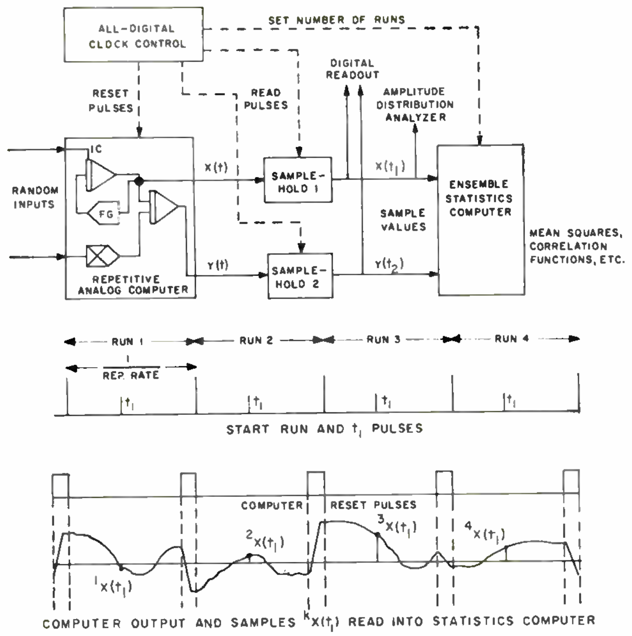


Fig. 10—ASTRAC implements Monte-Carlo techniques by simulating a random-input dynamic system 10 to 100 times per second. Digitally-controlled sample-hold units read out selected samples of dynamic variables $x(t)$, $y(t)$ at push-button selected times t_1, t_2 after the start of each computer run. The statistics computer averages functions of successive sample values to produce estimates of mean-square values, correlation functions, probabilities, etc., for nonstationary as well as stationary processes.

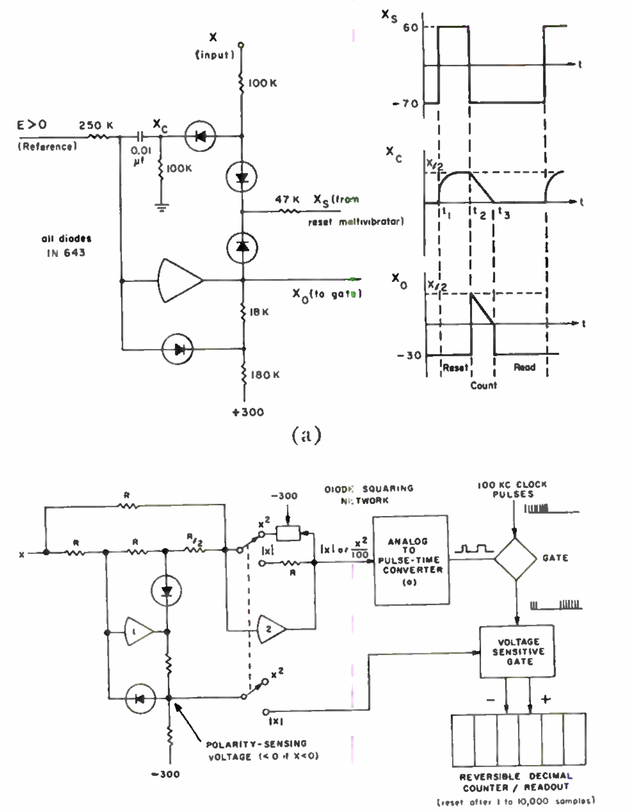

Fig. 11—(a) ASTRAC analog-to-pulse-time converter (b) Hybrid sample-averaging circuit. A precision absolute-value circuit (amplifiers 1 and 2) applies positive voltages $|X|$ or $X^2/100$ to the converter and, if X is to be averaged, reverses the counter input when X changes sign. The decimal readout counter accumulates readings for between 1 and 10,000 samples of X or $X^2/100$. Note that the average of a product $XY/100$ may be read out through alternate sampling of $(X+Y)^2/4$ and $-(X-Y)^2/4$.

automatically change the analog-circuit gain, together with the floating decimal point of the digital system, so that favorable scale factors are selected automatically. The digital arithmetic communicates with the analog arithmetic by gating scale-setting resistors into operational amplifiers.

A hybrid function generator employs digital circuitry, together with analog addition, multiplication, and division. Discrete values of functions of one, two, or more variables as well as values of constant coefficients are entered in digital form on a magnetic-memory drum. These digital data are decoded and entered into the analog-digital arithmetic unit which can perform suitable interpolations. The drum also controls the machine program by a sequence of command pulses which control the successive operations of the arithmetic elements through a switching matrix and a multiplicity of analog and digital gates. No information is entered on the drum during a computer run [13].

The final version of the M.I.T. hybrid computer omitted the floating-point hybrid arithmetic, since it was believed that digital bookkeeping on the exponents associated with each variable would be either too slow or too complicated [38]. The resulting system is, essentially, a very fast multiplexed analog arithmetic unit combined with analog integrators and a digital-control unit. The idea of automatically scaled hybrid representation is, nevertheless, interesting and might deserve more investigation, especially in connection with special-purpose computers.

Analog Variables Other Than Amplitude

Although analog voltages are easy to add and integrate, they are not easily stored on magnetic tape or drums. They are similarly difficult to transmit over long distances, and analog switching, which is required for all automatic programming schemes, requires relatively critical drift-free circuitry. These three disadvantages are readily overcome through analog representations of variables by *frequency modulation*, *pulse-width modulation*, or *pulse-position modulation* of pulse trains. These representations require merely the transmission of timing pulses, which are easily stored, transmitted and gated. Such modulation schemes also permit particularly simple conversion to digital representations with the aid of gated counters. The intriguing possibilities inherent in such a representation were demonstrated in a new and different flight simulator designed at the University of British Columbia, which uses pulse-time representation of data [36]. Although a complete set of new computing elements had to be designed for the simple operations of addition, multiplication, and integration, the simple gating and drum storage made possible by the new representation gives the machine unique automatic-programming capabilities. Methods of this type, possibly in conjunction with operational digital techniques, deserve continued attention in the future and may play a significant part in the continued impact of analog-digital techniques on the analog-computer art.

Conclusion

To summarize, many present-day analog computers exist, in a sense, in a gap left by the cost-speed characteristics of available digital computers. But even as digital computers improve, the all-parallel "live mathematical model" afforded by analog-type simulation remains indispensable to the system designer. As a result, new hybrid computing elements and systems combine analog and digital features, and analog computers are becoming faster. The trends discussed include combination of conventional analog and digital computers, digital programming and checkout of analog computers, operational digital computing elements, new high-speed analog computers with memory and digital switching, true hybrid computing elements, and some hybrid computer systems.

Mass Storage*

A. S. HOAGLAND†, SENIOR MEMBER, IRE

Summary—One key to expanding the applications potential for information processing systems is the economic availability of on-line memory of extremely large capacity to permit the automatic servicing of record files. Further, mounting emphasis on "management" decision making will accelerate the emergence of true file-centered systems. This paper reviews the evolution and future trends in the implicit "mass storage."

The term mass storage indicates a unit capacity ranging upward from one million characters. Such memory cannot currently be realized or projected with solid-state devices (*e.g.*, fabricated matrices of discrete, bit elements such as core arrays). Thus, continuous (and generally interchangeable) surfaces with associated coupling transducers are exploited.

The access time variability to memory locations, arising from the requisite mechanical motion, makes the structuring and organization of mass memory (software) of major significance to effective systems integration.

Magnetic recording, with its unlimited surface reusability, is the firmly entrenched mass storage technology. The last decade has seen almost two orders of magnitude improvement in storage density, with in excess of 25,000 bits/sq in already used in announced products. The major technical innovation to date has been in the air-floated head which, by permitting both high density and high surface speed, brought about the introduction of mass random access memory (disk array-1956).

Areas covered include systems perspectives and memory organization, memory modularity and mass storage structure, reliability and economic considerations, magnetic recording technology, and nonmagnetic media (including image storage).

For the forseeable future, magnetic recording will continue to be intensively exploited as a major factor influencing the growth of information processing with further major advances in storage density and mass storage performance capabilities developing rapidly.

I. Introduction

THE EXPANDING commercial applications for information processing systems are increasingly dependent upon the economic availability of on-line memory of extremely large capacity for the automatic servicing of sets of records (or files). Utility billing and airline reservations are two examples of file maintenance requiring "mass storage." The growing need in business operations to have masses of organized information readily available for effective management decision making will accelerate the emergence of true file-centered systems.

In the scientific field of data processing, the temporary storage of intermediate results dictates a mass store which can rapidly interchange data with main memory. In addition, the trend towards multiprogramming makes a large back-up store for high-speed reloads and dumps of internal memory (program shuffling) advantageous.

"Mass storage" is a term used here to imply a unit capacity in excess of one million alphanumeric characters (of the order of 10^7 bits). Certain existing mass storage units store more than a 100 million characters of information, and developments now under way will materially extend this figure.

Such memory is far beyond the present or projected economic feasibility of electronic devices. Solid-state memory is generally based on a matrix-like assembly of individual bit storage elements, (*e.g.*, magnetic core arrays) which are directly addressed and selected by a switching net [11]. This type of storage provides high-speed (microsecond) access to any memory location needed for accomplishing data and instruction manipulation within a central processor. In contrast, for mass memory, continuous (and generally interchangeable) storage surfaces with associated coupling transducers are exploited. The recording density (bits per square inch) is principally a function of the three-dimensional mechanical registration tolerances that can be realized between the storage film and the coupling transducer(s). Relative motion is required for access to memory locations. While very large capacities are practical, access times are in milliseconds to seconds, since mass storage involves mechanical movement. The access time variability to memory locations, arising from the requisite mechanical motion, makes the structuring and organization (software) of mass storage a key factor to effective systems utilization.

Modularity is an extremely important concept in mass storage. A module is an independently addressable block of memory, and a given memory system will, in general, consist of a number of such modules. In contrast to a core-type memory, a mass storage module can have a multiplicity of simultaneously addressed and operated access means. The most common attributes used to characterize a mass storage module are: capacity, access time (*i.e.*, the average access time for randomly located information), the instantaneous data rate on sequential information transfer, availability of storage member interchangeability, and hardware-imposed address location formats.

Systems-derived performance factors such as effective character rate and useful throughput (record processing rate) depend not only on the mass storage specifications but also on memory allocation (file layouts), per cent activity of a given file (ratio of records actually processed to total), number and availability of the data transfer channels servicing the memory (the maximum would be one per access mechanism), provisions for queuing and ordering of access requests, checking procedures, etc. The associated control logic is an integral facet of any mass storage appraisal.

* Received by the IRE, June 19, 1961; revised manuscript received, November 22, 1961.

† IBM Advanced Systems Development Division, San Jose, Calif.

The need for operational reliability of mass memory units, which involve the integration of complex mechanical and electronic assemblies, has been and still remains one of the major, even though less exciting, challenges faced in the further development of mass storage systems. The trend to communications-oriented multi-terminal systems with their inquiry requirements and emphasis on real-time response greatly magnifies the importance of "on-line" reliability.

To date, magnetic recording is the technology primarily used for the mass storage of digital information. Although it is only in recent years that magnetic recording has come into wide general use, its invention by the Danish engineer, Valdemar Poulsen, dates back to 1898. The paramount functional advantage of magnetic recording surfaces is their unlimited reusability. This property permits the direct modification of stored information (for digital information storage, binary coding with saturation recording is used). Additional advantages of magnetic recording for mass storage of data over other potential storage film media are: the simplicity of the recording transducer (a magnetic head); the flexibility in mechanical structure possible (and hence, choice of performance specifications) due to the ability to place the storage film on almost any supporting surface in conjunction with ease of mounting a magnetic head; the high bit storage densities and read-write transfer rate obtainable with magnetic recording; and great ruggedness with respect to handling and environmental conditions. Consequent from the above characteristics is extreme memory economy. Typical figures place on-line magnetic recording storage at a cost per bit of 1 per cent or less than that for magnetic core memory. The replaceability and off-line shelf storage potential (*e.g.*, tape reels) makes inactive mass memory less costly by even more orders of magnitude.

Magnetic recording represents the integration of several basic engineering fields and has been generally characterized by rapid progress achieved by evolutionary advances rather than dramatic innovation. The one "breakthrough" that can be identified with the computer field is the air-floated head. Otherwise, advances in the magnetic recording art have largely emanated from increasingly higher precision and quality in components. No technology that might challenge the position of magnetic recording now appears in sight. Thus, an increasing effort will continue to be placed on magnetic recording and associated mechanisms in spite of their already long period of exploitation.

Certain exploratory work has been carried out on photographic films for "read only" types of applications (for example, language translation and telephone exchange routing). In such uses, one can capitalize on an ability to carry out high-speed local searching with the effectively inertia-less optical beam transducer. However, for a large capacity requiring a great amount of surface area, mechanical positioning is required, and that is where the basic access limitations inherently arise in a mass store.

There is developing interest in image storage within the growing sphere of information processing. While concepts and techniques have yet to be generally established, it is in the storage of fixed images that films of photographic and thermoplastic materials have drawn most attention. Such materials permit optical or area-type transducers and hence, with simplicity, the ability to project, minify, magnify, etc. Thermoplastic materials do permit rewriting, and this feature distinguishes investigations into their potential role.

The body of the paper is divided into three major sections: historical evolution of mass storage, present state of the art, and future trends, with emphasis given to key problem areas faced in achieving further progress

II. Historical Growth

The work which ushered in mass data storage was firmly initiated by 1947. This activity was associated and concurrent with the explosive "take-off" of the digital computer field at that time. Since then, progress has paralleled the rapidly expanding growth of data processing. Early work was oriented to the scientific computer market. The initial mass memory device was the magnetic tape unit, to provide both auxiliary "back-up" storage to main memory and input-output (electromechanical terminals) buffering in large-scale systems. The later emergence of commercial data processing brought with it a wider variety of functional usages and mass storage hardware.

Commercial or business data processing, as it was evolving as a main facet of activity in the computer field in the early 1950's, gave a tremendous impetus to mass storage development and had a major impact on its direction. File storage for records maintenance was the central requirement. The volume of business records certainly justified the introduction of the descriptor "mass."

Magnetic tape was immediately exploited for mass records storage and to the present, almost all large-scale commercial data processing systems are tape based. Tape transports are inherently suited for sequential access to information, and conventional batch processing procedures (punched card methods) were therefore instituted. However, a major percentage of available machine time is then needed for the tape sorting of records preparatory to processing against a master tape file. For low file activity, tape devices are very inefficient, due to the constraint of sequential access. Further, effective file inquiry operations are not possible. To keep head and surface wear down to acceptable rates, tape speed is quite limited, representing a severe restriction on bit rate and access time.

The character of business data processing thus indicated the need for an entirely different type of mass storage. The desirability of storing large volumes of information with any record available rapidly gave stimulus to the development of a mass random access memory. A short access time is then necessary and a high-speed rotating surface provides this feature. The extremely high surface velocity then arising is only feasible by providing a slight separation or spacing between the magnetic head(s) and moving surface. This arrangement is categorized as noncontact magnetic recording.

The air bearing supported head (using an air cushion to control head-to-surface spacing) was the innovation which, combined with the above memory concept, brought about this entirely new hierarchy of mass storage, beginning in 1956. By this spacing technique, it was possible to develop a high-capacity rotating disk array since a head could closely follow the appreciable runout of large disks (the disk array permits a high recording surface area to volume ratio).

The first version (the IBM RAMAC 350) could store five million characters with an access time to any record of less than a second. Secondary technical features of note were the use of self-clocking and a wide erase narrow read-write head unit. These design approaches, combined with the use of an air-supported head, provided techniques that compensate for the head-to-track registeration tolerances of such a gross mechanical structure, and thus permitted the high track density and high bit density necessary for large capacity.

Since the introduction of mass random access memory there has been great activity in this type of mass storage and a number of units of rather widely varying configurations are now available. One other, uniquely different in form, is the NCR CRAM (1961), a randomly selectable magnetic card unit. This random access memory also features replaceable storage, formerly only available with magnetic tape. In terms of performance, a disk array has been announced (1960) with a capacity of approximately 90 million characters and an access time of less than 0.2 second.

As one perspective on the progress in digital magnetic recording over the last decade, consider storage density:

RR Uniservo I (tape), 1950—1400 bits/sq in
IBM RAMAC 350 (disk), 1956—2000 bits/sq in
Potter 906 (tape), 1960—24,000 bits/sq in
RR Randex drum file, 1960—30,000 bits/sq in
IBM 1301 (disk), 1961—25,000 bits/sq in.

These specifications are indicative of both the progress and emphasis placed on such storage in the last several years. The cost per bit of on-line mass memory has steadily dropped until now it is in the range of 0.1 to 0.01 cent per bit, a major factor for its increasing acceptance.

III. Present Status

There is such a wide diversity in mechanical configurations for mass storage that attention will be focused primarily on systems perspectives and technology. With respect to magnetic recording, four areas of technical development can be distinguished: the magnetic head, the magnetic recording surface, head-surface registration mechanics, and read-write electronics. Each of these will be briefly discussed in turn; then the present status of storage density, which involves the integrated performance from all these components, will be summarized.

A. Systems Features

Today, mass storage can essentially be distinguished as primarily sequential or random in character of access and, hence, mode of operation. For sequential record transfer, the effective character rate is less than the instantaneous rate due to hardware constraints on address location format. In tape, "interrecord gaps" define record groups for block transfer to main memory and are necessary to accommodate the consequent start-stop tape motion. Interrecord gaps, although much shorter, are also necessary on high-density disk or drum tracks to make feasible "single record" modification.

Magnetic tape has been the predominant means for mass storage, and its unique systems features result from the fact that a tape transport is a sequential access device. The only practical way to use tape is to address by record content. In updating a file, for example, the master and transaction tape reels are serially read (information is arranged and maintained in ordered sequence) and a "new" tape is created, on another transport, with the unmodified as well as the altered records being transferred. While this procedure is inefficient with low activity files, it is easy to make insertions and deletions as well as to handle variable length records, as physical sections of tape have no specific indentity. Further, a tape reel is relatively cheap and therefore low-cost, off-line, archival storage is feasible.

Random access memory involves addressing by physical location to a single record or a particular block of records (one track), which is then scanned. This addressing problem is acute since the "set of keys" (record identifiers) of a file will, in general, bear no direct relation to the closed set of machine addresses. Various randomizing techniques (key transformations) are used to convert scattered keys covering an extensive range to a dense and relatively uniform distribution of numbers to obtain automatic addressing capabilities. Another unique technique derived for random access memory is "chaining" or the linking of address locations (or records) by recording at a given address location the address of the desired succeeding location, etc. Chaining is a systems technique to overcome hardware constraints on "bucket size" but will generally incur the price of cascaded (multiple) access times. Certain hardware allows "selective" record length since intratrack sector addressing divisions are not mechanically imposed.

A disk array (noncontact recording) can easily read and write information at high instantaneous character rates. If the processor "compute" time is closely matched to this record transmission speed, there can arise a serious imbalance with the much longer mass memory access time for purely random access jobs. For this reason, continual cost reduction pressures exist to make more modularity of mass storage feasible, thereby effectively multiplying the number of possible channels that may concurrently service the total store and better mask the mechanical motion times inherent to mass storage accessing.

The high word rates with noncontact recording and multiple-head groups on a rotating unit have made such devices attractive for short-term high-speed main memory dumps and reloads even though this application involves a sequential transfer by its nature.

B. Magnetic Recording Technology

1) Magnetic Heads: Magnetic head design skills have advanced to the point where the principal concerns are to evolve fabrication techniques that will provide an improved and smaller precision assembly. Currently, head gaps as small as 20 microinches can be realized. When thin laminations (from ½ to 2 mils) or ferrite pole pieces are used, magnetic heads can yield considerably in excess of 5000 bits per inch *resolution* with frequency bandwidths extending considerably beyond one megacycle.

2) Magnetic Recording Surfaces: Higher quality, thinner recording surfaces is the mainstream effort in magnetic surface work rather than a search for improved magnetic properties. There is a broad range for the magnetic properties, within which performance is not noticeably affected.

Magnetic films in use today are oxide coatings formed from a dispersion of either Fe_3O_4 or $\gamma-Fe_2O_3$ in an organic binder, and Co-Ni platings. Oxide surfaces today can be coated to somewhat less than 100 microinches in thickness with a 2–5 microinch surface finish. The high quality achieved in magnetic coatings is extraordinary. Disk surfaces are made without any bit defects at 25,000 bits/sq in on a 24-inch diameter disk storing in excess of 5 million bits. The quality of high-performance magnetic tape is equal or superior to this.

Co-Ni platings require extremely good substrates, since for equivalent linear bit densities it is necessary to go to thinner layers than required with oxide surfaces. Co-Ni films have been made as thin as 20 microinches which have proven satisfactory. The unique advantages of metal films are their superior wear characteristics and their inherent suitability to the production of a thin layer.

3) Head-Surface Registration Mechanics: Spacing is the key bit density parameter. By using the boundary layer of air carried by the moving surface for a bearing, it has been possible to operate reliably at spacings down to 100 microinches while following several mils of surface runout. The development of the air bearing head, with its surface-following characteristic, represents the most significant technical breakthrough to date in mass storage.

4) Read-Write Electronics: Read-write electronics represents a development area where considerable future progress may be unpredictably realized since it is the one aspect affecting density least defined in terms of theoretical factors. From early work based on distinct output pulses and amplitude detection, we now see peak sensing and phase modulation techniques being exploited with a consequent capability to operate at higher densities where considerable pulse crowding occurs.

In digital recording, *each* bit must be read correctly (although simple parity checking can detect an error and cause a reread). For this reason, digital magnetic recording is the most demanding application of the art. Some digital recording standards call for less than one error per billion bits read, and the bit size may be less than one thousandth by twenty thousandths of an inch! Transient variations in head-to-surface spacing (*e.g.*, from dust particles) at high densities can cause large signal fluctuations and thereby multiple bit errors. Burst error correction codes and other sophisticated coding techniques now are attracting attention for such high-density digital magnetic recording.

5) Storage Density: Track densities up to 50 tracks per inch are now found in practice. Two criteria establish the limit on this figure: 1) signal-to-noise ratio (head output is proportional to track width); 2) mechanical ability to keep the head and track aligned. The IBM 1301 disk file stores data at 500 bpi[1] and 50tpi[1] while the Potter 906II tape unit records at 1500 bpi and 16 tpi (the low ratio of tpi to bpi on tape being typical).

C. Nonmagnetic Media

A photoscopic disk memory has been developed to serve as a dictionary for language translation. By its very nature, this information is "permanent." The model stores 30 million bits (2000 bpi, 700 tpi) with an access time of about 50 milliseconds. Optical sensing permits "servo tracking" (through an electron beam) with extreme sensitivity, allowing a much closer balance to be obtained between bit and track densities than in magnetic recording. A dictionary is an ordered file organized for rapid lookup. A search operation can be executed very efficiently with this device because of the speed of track-to-track repositioning with an electron beam readout mechanism. This application represents an excellent case where the advantages of a photographic material for a file are capitalized upon. Another such example is Minicard. The Minicard system is a document retrieval system in which photographic microimages (60:1 reduction) are placed on a card along with digital index information.

Thermoplastic tape as a medium for storage is a relatively recent innovation. It has limited reusability, but to date the mechanism must be kept in a vacuum, which limits design flexibility. An electron beam serves as the transducer. Compared to magnetic recording, writing is

[1] bpi = bits/in; tpi = tracks/in.

very slow and reading requires a relatively complex optical system, although its inherent compatibility with electron-optical transducers again leads to a high storage density potential.

IV. Future Trends

A. Systems Organization

Key systems problems, extending from applictions methodology and procedures to machine organization concepts, accompany the growing role of mass storage. Software will be as significant as hardware activities. We are at the beginning of the era of *file-oriented* data processing systems. "Real time" will become more meaningful in commercial information processing systems as there is more and more emphasis on management decision making. The evolution of low-cost random-access mass storage will bring about a file-oriented systems approach to all levels of business. Modularity of mass memory permitting continuous growth in capacity will be increasingly stressed.

The trend in the future will be on random plus sequential capabilities for mass storage. Consider a typical random access disk memory with an average access time of 100 msec, a character rate of 50 kc, and containing a file consisting of 100 character records. The effective record rate for sequential flow is nearly 500 per second, while for random access transfers, this figure would drop to 10. This wide differential highlights the desirability of planning around a random plus sequential (or batch) philosophy.

The control by programming of recorded format indicators will become standard, permitting dynamic masking and layout of memory space. The assignment of storage space for key-address combinations (index files) and their manipulation rather than record movement will be emphasized. Table lookup and cross-reference techniques must be improved by introducing special "rapid scan" features to optimize "built-in memory logic." Facilities will be introduced for address and record queues within the store with priority logic capabilities to maximize channel throughput. Sophisticated techniques and hardware combinations will be developed to provide for ready report generation without having to preplan for a desired correlation order. Communications-oriented processing systems will necessitate mass storage "buffer exchange" capabilities to handle record assembly and distribution traffic as multiterminal systems become commonplace.

A major problem in file-centered systems is establishing the proper balance in mass storage configurations. Hierarchies of memory modules (of widely varied performance parameter mixes) integrated to meet total systems requirements can best optimize over-all systems performance, recognizing that cost tends to be inversely related to access time for a given capacity. Mass storage control logic will eventually extend to the functional ability to readily rearrange records within the hierarchies of memory according to their activity, significantly improving access utilization. The concept of several processors working against a mass store will become established, radically changing the perspective of what is an "attachment" and what is the "mainframe."

For the immediate future, off-line storage must be used where possible for economy, but in time it should be possible to transfer increasingly inactive information successively to very cheap (and consequently long access) sections of storage until it truly becomes archival. In time, cost reductions will also permit a relatively high percentage of unassigned memory space. This fact will greatly simplify memory organization.

B. Mass Storage Structure

There will be continuous efforts at cost reduction to make larger mass storage with more modularity economic. On-line mass storage cost is a major barrier today to numerous applications susceptible to data processing, some proposed systems requiring the on-line storage of billions of characters. Manufacturing production techniques are rapidly improving the cost picture, indicating mass storage systems will also soon impact the conventional electromechanical accounting equipment area. Overlapped (read-compute-write), multichannel file operations will be conventional, giving an effective balance between access time, record transfer time, and process time to maximize throughput. Present systems configurations tend to be distorted in being dominantly either file limited or processor limited. The storage of interlaced (or multiplexed) data and/or the balancing of mechanical motions between surface and transducer movement will be introduced as a technique to control character rate independently while permitting the upgrading of capacity and access speed as technology progresses.

Looking to the future, there appear to be two unique approaches that will eventually characterize the principal on-line mass storage systems component. One is the disk array and the other is the magnetic strip file. The former offers a more economic access modularity, although this advantage is achieved through acceptance of a common disk drive (single shaft), and a low-cost "turntable" potential for smaller capacity storage modules. The tape strip memory basically uses a tape strip cartridge in the manner of a tape reel, emphasizing simplicity of interchangeability as well as high volumetric efficiency for extremely large capacity. For logging of journal-type data, tape still seems without a peer.

C. Reliability Considerations

A major problem which must be approached from a systems (as well as a technical) viewpoint is that of high reliability. Achieving extreme reliability in complex electromechanical assemblies, which are at the same time intimately integrated with high-speed, low signal level electronics, represents a challenging task. Increasing performance demands on technology coupled with increasing requirements for on-line "real time" file availability compound this problem.

Currently, in many random access memories, it is standard practice to provide automatically an address compare by recording the address of the physical location in the first section of the record located there. It is highly advantageous to make a readback check after writing to provide confirmation of proper data recording before the newly created or received information is eradicated from the transfer buffer area. While some tape transports provide immediate checking by means of a special dual element head unit, a separate read cycle has been required after writing in head positioning devices. Special head structures to provide this checking feature automatically as well as address compare without an access time penalty must evolve for all forms of mass storage. This capability will also bring about automatic data reallocation without system interruption when defective regions are detected.

Systems organization must provide for the requirements of operational reliability by suitably accommodating occasional hardware failures and maintenance needs. Replaceable storage concepts will be exploited since the storage member can then be placed on another mechanism to continue file processing during "down time."

D. Technology

Investigations made of a magnetic recording unit regarded as a communications channel will yield bit density gains by the acceptance of more sophisticated recording electronics. To date, progress has primarily been based on scaling down "geometry"; however, with no new storage technology warranting a redirection of activity, signal handling techniques must eventually draw major attention.

There has been and will be continuing exploratory research on novel transducers. However, no physical phenomena for a magnetic recording transducer appear competitive to the simplicity and flexibility of a magnetic head. Rather, the next major stage of progress in the transducer area will be automated head fabrication using thin film technology (rather than watchmaker-like assembly), resulting in cost reductions which will have an impact upon the hardware composition of mass storage mechanisms.

Reduced head-to-surface spacings, approaching theoretical limitations for air bearing heads of about 25 microinches, will bring about a large increase in noncontact bit density. The recording frequency bandwidth is inversely proportional to spacing (until this parameter is reduced to the order of the head gap and recording surface thickness). Track seeking and following servo access techniques, which can circumvent the track density limitations imposed by the buildup of cascaded mechanical dimension tolerances, will be applied to effect significant increases in this parameter. Within the next few years, one million bits/sq in (*e.g.*, approximately 5000 bpi, 200 tpi) will become the "state of the art" in digital magnetic recording.

There is continuing work looking toward the development of other, and hopefully better, film media for mass storage. There appears to be no evidence to suggest that a replacement can be anticipated for magnetic recording surfaces. Further, the upper bit density limit of magnetic surfaces is far in excess of present practice and laboratory studies, which are now set by achievable mechanical registration tolerances.

Prophesying the very long-range future course of mass storage, it is intuitively felt that eventually all such memory will not only be digital in form but also electronic in character. It seems evident that this latter "revolution" will not come about from further progress in the conventional matrix store as presently conceived and pursued. However, the studies gradually being initiated in, a) the field of neuron net simulation and the memory function, and b) microminiaturization, lead to the conjecture that one day these fields may merge and permit entirely new means and concepts to be applied to the problem of realizing mass memory of extended capability. For the foreseeable future, however, it is clear that mass storage based on magnetic recording has a vital and increasingly important role in information processing.

Eyes and Ears for Computers*

E. E. DAVID, JR.†, SENIOR MEMBER, IRE, AND O. G. SELFRIDGE‡

Summary—Attempts to mechanize character reading and speech recognition have greatly accelerated in the past decade. This increased interest was prompted by the promise of computer inputs more flexible in format than punched cards or magnetic tape. Research has shown that automatic sensing can be done reliably if the task is suitably delimited. Cleverly designed marks on standard forms can be both machine and man readable. A single type font or a few fixed ones are tractable if the print quality is controlled. Handprinting can be handled for careful writers, as can meticulous handwriting. Isolated spoken words taken from a small number of talkers and a limited vocabulary can be automatically recognized. Typical error rates for these machine-sensings run between 0.5 and 25 per cent. These results imply that reading unrestricted typestyles, handwritten scrawl, or recognizing conversational speech is beyond the reach of present methods.

From the engineering viewpoint, questions of values enter. Might it not be wiser to punch cards or tape while making copy rather than depend upon complex character recognition hardware? Is it useful to have voice input to a computer when a finger and typewriter are available? Answers to such questions will depend upon the specific application. Certainly, the utility of automatic sensing will depend upon what is to be done with the material after it enters the computer as well as the internal organization of the machine itself. Perhaps all would agree that we should have automatic inputs before the Russians, but it is not so clear that we need them soon as practical computer inputs.

As MAN RUSHES to build his replacements, he notices an interim requirement for man-machine communication. In the meantime at least, computers must be able to, but cannot, understand the writing and talking of men. We are protected from technological unemployment so long as we are buffered by punched cards, magnetic tapes, and on-line or off-line printers. But the day will come!

Current computer inputs are peculiarly inflexible in format, and inconvenient in use. To communicate with the machine by these means we almost invariably must employ an extra man or man-plus-machine, who transcribes our words into shaped holes exactly positioned or magnetic pulses precisely timed.

Men profess to be ill-suited to such menial labor. Though women seem more easily subjugated, they too tend to be expensive, slow, and inaccurate. Therefore, we are increasingly calling on computers to handle those highly variable input signals whose relevant features are not simply related to their physical properties.

In the early days of computers we all learned a congeries of theorems by Turing and von Neumann which told us (or so we thought) that a computer could do anything we told it. We would merely (!) have to specify sufficiently accurately just what it was we wanted the machine to do. And it is true that some highly variable input signals can be categorized by elaborate, exhaustive programs, but it is just not feasible thus to program recognition of printing, speech, handwriting, radar and sonar signals, and objects in photographs (clouds in satellite weather pictures, for example).

Such material can be converted to a standard format, of course, by a suitable scanner, microphone or other transducer whose output is amplitude-quantized samples. We are not much better off, because we then have the same excess of data in two forms, neither related to the classificatory representation we want in the end. Rather, for instance, from speech waveforms we ask a phonetic or literal transcription, from printing and handwriting a literal ("alphanumeric") transcription and not a TV raster, from radar a target inventory, and from weather pictures a cloud map. Such representations imply abstraction of raw data into more meaningful perceptual coordinates. Computers able to convert inputs to such forms will be much more flexibly, powerfully, and economically coupled to the real world.

Though such abstraction is difficult, we already have given some of our machines limited ability to read printing in certain type faces [1], [2]. But reading scratch-pad handwriting or transcribing conversational speech by machine is far beyond our ken. Also, it seems clear that, in any case, the computer needs much extra, expensive equipment to handle the patterned inputs we are discussing. Yet as computers get faster, and as we can program more sophisticatedly, input flexibility will become more crucial than it already is.

Computer engineers, in a spasm of interdisciplinary enthusiasm, are rediscovering that perception is hard to understand and even harder to simulate. Armed with the tautological knowledge that computers *can* do what we tell them to do, we tell them to perceive and then ask the psychologists to fill the gaps in our instructions. They don't know how to do it either, but *they've* known it longer. Pattern recognition, which refers to the actual categorization involved, the actual decision that some sound or sight is "mother," is learned by children at an early age. Computers are very young too and must learn pattern recognition; we do not say that pattern recognition must come full-blown from the machine unaided and untaught. Some men, at least, can construct and write pattern recognition programs. That is, men can do the learning and generalizing, and then

* Received by the IRE, August 11, 1961; revised manuscript received, January 8, 1962.
† Bell Telephone Laboratories, Murray Hill, N. J.

instruct the machine. But it does seem to us that in the long run the machine will have the ability to carry some of this burden itself and will, in fact, need to do so as it tackles subtler problems.

METHODS [3]

Automatic input (that is, without a man) is the classification of input signals (images or sounds) into categories. Basically, the objects or signals are presented one at a time to the input device which makes certain measurements on each. These measurements are inputs to a decision "logic" which assigns the input to one of the available categories [4]; that is, the machine measures and then decides.

What distinguishes the techniques we are discussing here from customary ones is that they concern recognition of complex variable patterns of many elements rather than detection of a few fixed elements. For instance, alphanumeric text from a typewriter comprises some 80 complex shapes. For machine recognition of a particular font, however, templates of these shapes can be prepared and input letters matched against these, reducing the recognition process to one of identity. Of course, the input letters must be (or must be transformed to be) the same size as the templates and must be properly oriented. *Template matching* then, involves samples or pieces of samples of actual or typical or ideal inputs in their original representations. The method gives accurate results for any finite alphabet of shapes each of whose examples are identical within the resolution of the processor.

Unfortunately handwritten or handprinted letters, spoken words and even some printed text typically show wide variations from any set of templates which can be prepared in advance. We might provide a metric to measure the degree of fit of the unknown to every template and also supply transformations to normalize the unknown input to reduce the variability. These measures do not rescue the situation. The greater the variability, the less successful template matching becomes. By human standards, very little variability may reduce performance to unacceptable levels.

We conclude from history that template matching in its pure form, or modified with a metric and normalization, is adequate perhaps only for printing and typewriting. It was evident (after some years) that in many cases people do not work with templates, but prefer to abstract features. Parallel lines, cusps, or totally-enclosed spaces, for example, are features that may aid in separating alphanumerics.

Characterizing shapes by their distinctive features or properties may ease the problem of variability. Such properties tend to be invariant over a far wider range of either hand- or machine-printed letters than can be accommodated by a like number of templates. A list of the properties of known samples can provide a basis for classifying unknown ones. This *property-list matching*, however, does not eliminate the variability problem but transfers it to another level. The "invariant" properties must be recognized regardless of their size and orientation, despite the variability inherent in human motor performance, despite our individual personal habits, and despite the "noise" in reproduction devices. Yet property or feature extraction is a step in the right direction and has proved to be less fallible than a "grand" transformation intended to reduce all inputs to one of a finite set of precise templates.

If the property list is appropriately designed, recognition need not hinge strongly on any one feature, and may incorporate correlated or dependent properties for correcting errors in feature extraction. That is, the property-list technique may work well enough to be useful in situations where template matching would not be useful.

In either case, recognition performance can be improved by using context. Most obviously, letters and sounds make words, but even knowing digram letter or syllable frequencies can improve decisions about letters or phonemes. We may be more sophisticated and use words, perhaps incorporating their syntactical and grammatical restrictions; we might even use semantics. We guess that using more context will mean using much more storage—the number of English words being vastly greater than the number of letters and the number of semantic possibilities overwhelmingly greater.

Again, both template and property-list methods can be supplemented by limited "learning" or "self-organizing" or "adapting." In effect, properties in a list or elements of a template are examined statistically for their relevance to particular categories by noting their influence in determining correct and incorrect classifications. Those leading to correct decisions are reinforced; that is, their influence is increased, and vice versa. The "adapting" can be programmed into the recognition system itself if so desired [5]. Thereby, the machine may vary its parameters to take advantage of "good" features—"good" features being those which make for correct classification. Further the machine may be able to make large-scale adjustment in its parameters adaptively. For example, guessing that a piece of text is in English rather than in French would call up different *a priori* letter digram and word frequencies. The flexibility of computer inputs can be increased in this way, but the method has been explored only scantily.

The ability to cope with new input patterns hinges upon the relevance of the features incorporated in the early stages of the recognizer, or upon the relevance of templates which can be formed from the available elements. Yet to be explored at all is any method, other than random combinations of available elements, for formulating new features to be tested for relevance.

Thus the crucial, often the least mentioned, aspect of recognition is the selection of suitable features. In many studies, particularly involving alphanumerics, experimenters have been guided by their intuition. Others have taken the exhaustive (and exhausting) approach. The accomplishments of these methods ride on *ad hoc* inspiration and dogged persistence. Still other researchers have consulted generating mechanisms for speech and handwriting, searching for constraints to confine the range of choices. Thus in speech recognition, studies of vocal tract acoustics and speech synthesis have established the vocal resonances as central features. Also at the contextual level, language and grammar reveal how phonemes and words are contrived to make phrases, clauses, and sentences. At its best, successful *synthesis* reveals a vocabulary of "atomic" features. These then provide the acid to attack verbal or literal compounds. At its worst, synthesis misleads the unwary to accept oversimplified, overspecialized elements which have no counterparts in the league of everyday usage.

Yet to the extent that it reveals the structure of words, letters, or sounds, synthesis is not to be ignored, and it provides a rationale beyond the helter-skelter of randomness. Studies of human perception and sensory mechanisms too, hold a promise of "features-to-come," but the meat is yet to be put on the table even though the aroma whets the appetite. Here also, bona fide knowledge of behavior and physiology can aid in avoiding naïveté.

Character-Recognition Devices

The goal here is to introduce alphanumeric, text into the computer, including *printed* text, handwriting, and handprinting. In the first the question of segmentation is usually not bothersome, since separate characters are completely isolated [6]. The characters are usually arrayed in horizontal lines, but subscripts and superscripts (as in reference notes and mathematical formulas) must be handled by any technique claiming to be complete. Fig. 1 shows a range of relatively easy to relatively challenging examples.

The first technical choice arises here: what range of fonts shall be admitted? There are many useful cases where just one font does suffice: an instructive example is that of the American Banking Association. Realizing that fonts intelligible to people are hard to make intelligible to computers, they settled on one that was intelligible to computers and only barely intelligible to people. (This example is also interesting because it is not a visual one for the machine. The font is printed in magnetic ink and scanned by magnetic sensors.)

If many fonts are to be recognized, we may suppose that they have been previously specified, and that successful recognition of the characters to some extent requires recognition of the font they come from. This case then must be distinguished from the most general one, when all fonts must be recognized, even those not met before—though perhaps we may exclude those like *The New York Times*, Fig. 1.

The next big choice is the extent to which variation

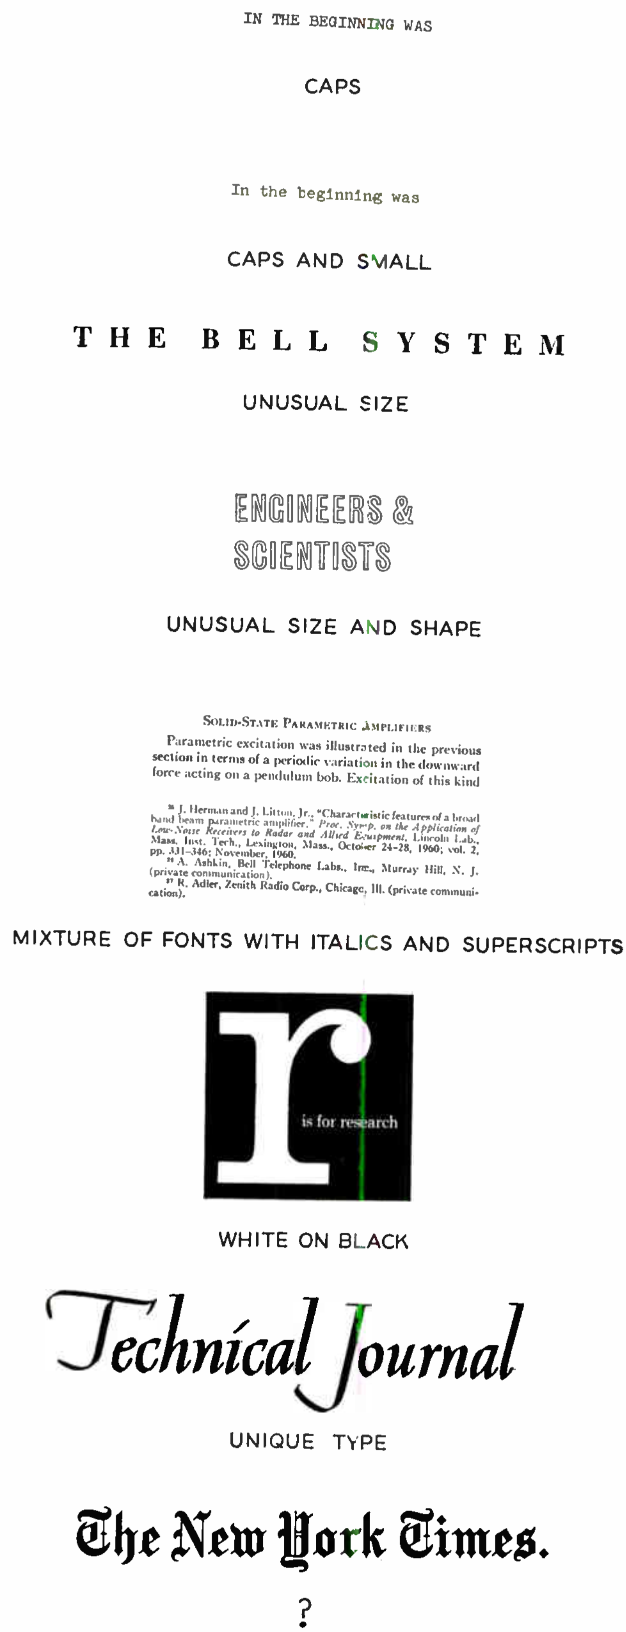

Fig. 1—Variations of type in common use complicate the automatic reading problem.

can be tolerated. We must expect a certain amount of additive or subtractive (or even multiplicative) noise, which should not (but usually does) seriously degrade performance. The noise is usually not independent from resolution cell to resolution cell, as has often been assumed for analytical purposes. In fact, noise comes in clusters like infections. There may be errors of registration, especially from typewriters, and occasionally errors of rotation. Probably the reasonable standard here is that errors from noise or misregistration should be no more frequent than typographical errors.

Now we reach the choice of techniques, as we described them above: template matching is well adapted to known fonts, especially when one can rely on good registration. Many commercial programs use what is essentially template matching. It cannot be said that these are entirely satisfactory, though some are interesting and ingenious.

Finally, there is a choice of mechanism. Though, of course, the critical element is some photosensitive material, it may be preceded by much or little optical processing, which can, in effect, do a large amount of parallel processing cheaply and fast. For example, in Fig. 2, two photosensitive elements can detect at once the degree of template matching of the image with a known character. Many people, however, have preferred scanning as a desirable compromise: here a vertical row of (typically 5 to 20) photocells sweeps horizontally along the line of type and the matching is done electronically. There are some advantages: misregistration in the optical example of Fig. 2 can scarcely be handled except by actual relative motion of the template and image, but electronically there are several plausible ways, for example, treating the lowest active channel as a base-line. Scanning does not restrict us to template matching but can extend fairly directly to property-list matching. The property list will naturally be biased by the fact of horizontal scanning, but should nevertheless be adequate. For either "matching," the stored patterns can be incorporated as logical circuitry. This acts as a "convoluted slot" through which the input pattern must pass. Further, extension to different fonts need not require physically new templates and one can, at least in principle, extend to completely new fonts.

There have been many character recognition experiments which illustrate these techniques and choices. Results from representative ones are listed in Table I [7]-[9].

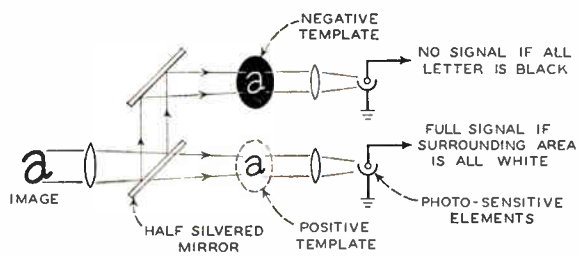

Fig. 2—Template matching is a useful technique where the type face can be specified in advance, but misregistration can reduce its effectiveness.

TABLE I

Investigator	Input Representation	Vocabulary	Number of Writers Tested	Approx. Error Rate	Additional Facts and Comment
Baran, Estrin	X-Y matrix	Machineprinted numerals	One machine over ribbon life	9 per cent	Maximize *a posteriori* probability (Bayes' Eqn.)
Highleyman	X-Y matrix	Machineprinted numerals	One machine, 50 heads	0.6 per cent	Cross-correlation against probability matrices
Bledsoe, Browning	X-Y matrix	Handprinted alphanumerics	1 person	22 per cent	Matching 2-tuples of matrix elements against table
Lewis	13 features	Machine and hand-printed letters	15 mixed people and machines	18 per cent	
Bomba	Local features	Handprinted alphanumerics	2 persons	0 per cent	Decision tree
Doyle	Local features	10 Handprinted letters	≈20 persons	12 per cent	Maximize *a posteriori* probability (Bayes' Eqn.)
Kamentsky	Presence or absence of intersections of character with scanning lines	Handprinted numerals	≈20 persons	1.7 per cent	Correlations of code lists which describe scan interactions
Sherman	Nodes describing line endings and junctions	9 Handprinted letters	≈20 persons	5 per cent	Connection matrix describing graph which joins nodes; tested against master matrices
Marill, Green	Distance of character from field edge along selected line segments	3 Handwritten letters	10 persons	3 per cent	Likelihood function assuming independent normal distribution of measures
Highleyman	X-Y matrix	Handprinted numerals	50 persons	6 per cent	Linear decision functions

Notwithstanding these possibilities, commercial ventures now are concentrating on optical and electronic template matching and hope to achieve speeds startlingly small compared with the easily attained 50,000 characters per second from modern tape units. It does not seem, though, that this limitation is inherent in the techniques themselves because photosensitive elements can certainly have better than a microsecond response time. But 50,000 characters per second is on the order of 18,000 words or some 30 pages per second, which is dangerously rapid for paper.

An interesting exception to the previous paragraph is the IBM 1418 [10]. A vertical line of 17 cells moves through 12 positions to blanket a character. The cells give binary responses (setting the thresholds is tricky) which are stepped into a 12×17 shift register. The character is thus normalized since at some stage it is centered; errors of rotation are not allowed for. The machine uses a large number of empirically derived features as inputs to a binary decision tree. It can recognize some, though not all, of the numerical printing of IBM printers, with a rejection rate as low as one in 10^5 or 10^6, but more typically one in 10^3 or 10^4. Extension to full alphanumeric coverage should be merely a matter of time and demand. The speed is 480 letters per second or about four Kennedys [7], [11]. (As many as 7 pieces of paper per second can be handled, though not necessarily processed.) The system's speed is thus about 20-db below available tape mechanisms, which can handle a full length novel every 6 seconds or so.

It is proper to ask who or what would want to read very many full length novels at 6 seconds each. The point is that to tie up a large digital computer at much slower speeds is expensive; thus, we conclude that probably for some time the print-reading device will include a buffer and will run essentially off-line.

This conclusion will limit for some time effective application of adaptation and learning. These have a depth of structure difficult to handle without a full general-purpose computer, which, as we have seen, we are reluctant to tie up while pages are slowly turned.

The acquisition of more general devices will, therefore, depend greatly on the need. Leaving aside the question of very high speed, who needs all-font capabilities and is willing to pay for it in computer time or extra equipment? The intelligence services might be expected to need something to read *Izvestia* and *Aviation Week*, but so long as the computer is acting as a mere transcriber or storer, the effective bottleneck is the man who must read the material to understand it. (And we are a long way, indeed, from a computer's understanding any but the *most primitive* English.)

If the reader, working with the electronic scanner, could show and identify samples of every letter for a piece of text, the scanner could then proceed without him. In reading *Izvestia*, at least, this could relieve the man's boredom by occasionally replacing one level of tedium with another, and would not necessitate complicated learning programs. But even this much would be a very large and complex piece of electronic equipment indeed, and even so, it would incorporate little of the sophisticated learning techniques many of us espouse as intellectual goals.

A hopeful sign is the increased emphasis on multiprogramming. If we can find ways of interleaving large programs, we may be able to use the computer to supply the sophistication for character recognition while it is performing unconnected computations most of the time. Were this possible, it would be more feasible to take advantage of context to correct character misrecognition or typographical errors [12].

One branch of character recognition where context is clearly essential is handwriting. The segmentation problem for characters is very difficult and that for words is hard enough. Handprinting has received some fair amount of attention (chiefly because it avoids the segmentation problem) though the applications are obviously limited. Representative results are listed in Table I [13]–[18]. An easy solution here seems tantalizingly out of reach: an IBM exhibit at the Western Joint Computer Conference in Los Angeles, in 1961, had a *small* machine to recognize handprinting of numerals only, but they had to satisfy a set of rules about which the illuminating comment was often heard, "Well, I could live with those rules, but I doubt if most people would."

Pure handwriting recognition is being studied at Bell Telephone Laboratories by Harmon and Frishkopf [19], and nowhere else that we know of. Actually, they treat not just the completed writing, but the dynamic formation of the strokes, and their technique is not easily extendible to previously written material. An interesting program by Eden and Halle [20] of the Research Laboratory of Electronics at Massachusetts Institute of Technology generates handwriting, but the constraints inherent in it have not as yet been applied to handwriting recognition.

Automatic Speech Input

Reduction of speech to machine-readable form is a problem of long standing. We do not know the origin of the idea and it is probably lost in antiquity. One early instrumentation of this notion was revealed by Paget [21], whose work in the 1920's on the basic nature of speech set the stage for much that followed. His contribution, among other important ones, demonstrated a correspondence between the individual phonetic symbols that represent a spoken language and the acoustic phenomena associated with the human voice. Thereby the voice-operated toy, "Radio Rex," became feasible. It consisted of a celluloid dog with an iron base held within its house by an electromagnet against the force of a spring. Current energizing the magnet flowed through a metal bar which was arranged to form a bridge with two supporting members. This bridge was sensitive to

500-cps acoustic energy which vibrated it, interrupting the current and releasing the dog. The energy around 500 cps contained in the vowel of the word "Rex" was sufficient to trigger the device when the dog's name was called. Modern speech recognizers utilize this same principle, elaborated and differently instrumented to be sure, but based upon similar phonetic-acoustic relations.

Such relations arise from the properties of the human vocal tract. In speaking, different positions of the tongue, lips, and jaw give the vocal tract diverse shapes. The shapes and gestures correspond to the various phonetic symbols. Each shape gives rise to a distinct frequency spectrum and each gesture to a spectral transition [22]. Acoustically, then, speech can be considered as a succession of spectral steady states and transitions. These features are in close correspondence with the phonetic content and we may see them clearly in a sound spectrogram which displays a "running short-time" speech spectrum, Fig. 3 [23]. Note that over most of the time scale, the spectrum contains three or four concentrations of energy, which arise from the natural modes of the vocal tract when it is excited by short pulses of air from the vocal cords. These energy concentrations are known as formants.

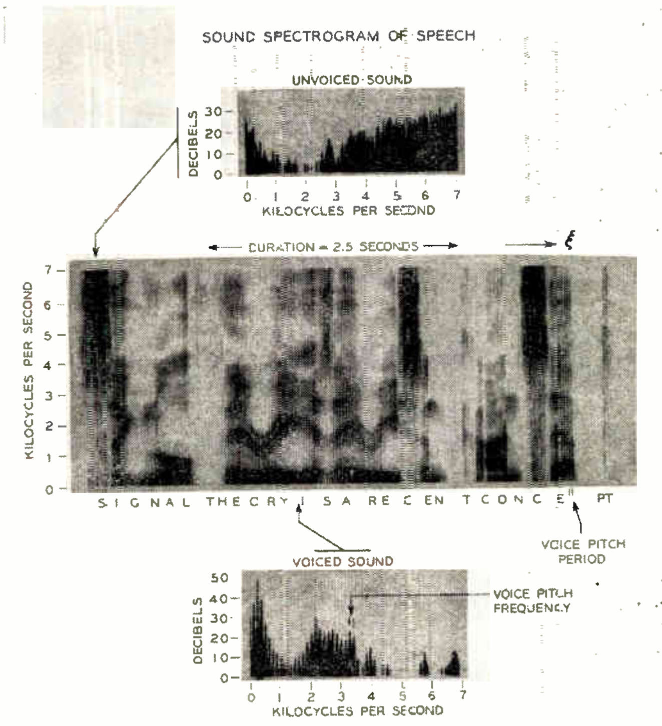

Fig. 3—Sound spectrograms of speech show spectral steady states and transitions which are intimately related to the phonetic content of the utterance.

At other times, the spectrogram contains no clearly-defined structure, but is noise-like. This characteristic arises when the vocal tract is excited with a random disturbance created by air-flow turbulence at a constriction in the vocal tract. An example is the final sound in the word *this*. Sounds with vocal cord excitation are known as *voiced;* those with turbulent excitation, as *unvoiced;* those with no excitation, as *silent.*

Speech spectrograms may be described quantitatively by dividing the time-frequency plane into rectangles $\Delta f \times \Delta t$ in size, and specifying numerically the energy in each. Intelligible speech can be recovered from such a matrix of numbers, and so in that sense it is a "complete" template representation [24]. Also complete, but more succinct, are abstract descriptions based upon time-dependent parameters, that is, properties such as formant locations, over-all intensity and voiced-unvoiced status. Sufficient resolution for the time-frequency matrix representation requires, *inter alia*, about 1000 degrees of freedom ($\Delta f \times \Delta t$ rectangles) per second of speech, while the parametric version has succeeded with as few as 300 per second. In terms of adequately quantized values, these numbers become 3000 and 1000 binary digits. Such representations achieve a great economy over a speech-time waveform which typically requires 10,000 degrees of freedom and 40,000 bits per second. In storing speech data for recognition, this feature is clearly of great importance, not only for efficient storage, but also because the spectrographic and parametric forms of speech-acoustic data are basic to phonetic interpretation. Most experimental speech recognition systems rest upon these fundamentals.

Typical recognition paradigms use either spectral templates or parametric property lists. Utterances to be identified are analyzed and represented in the same form, and then compared to the stored data. The closest fit, according to some metric (correlation or rms error, for instance) fixes the identity.

Schemes of this kind work less than perfectly. The same phonetic sound spoken by various talkers can give rise to spectrograms whose general features are qualitatively similar, but whose frequency-time matrices differ in detail. This fact is all too clear in Fig. 4. These differences reflect variations in vocal tract dimensions (which determine mean formant frequencies), the range of vocal pitch found among the population, the different gestures of articulation from person to person, the diverse timing and intensity patterns typical of the individual, and so on. Some of these factors are discounted in a parametric representation, but here too, any simple description taken over a number of talkers is far from invariant.

Another difficulty arises from the different dialects in common use. Here the same *words or phrases* spoken by different talkers will have different phonetic content. Thus transliteration from a sequence of phonetic elements to English words may involve complex linguistic structure.

Still another difficulty is that acoustically, speech is continuous in time, whereas its phonetic or literal representation consists of discrete symbols or words. How is a recognizer to reconcile or match a continuous acoustic

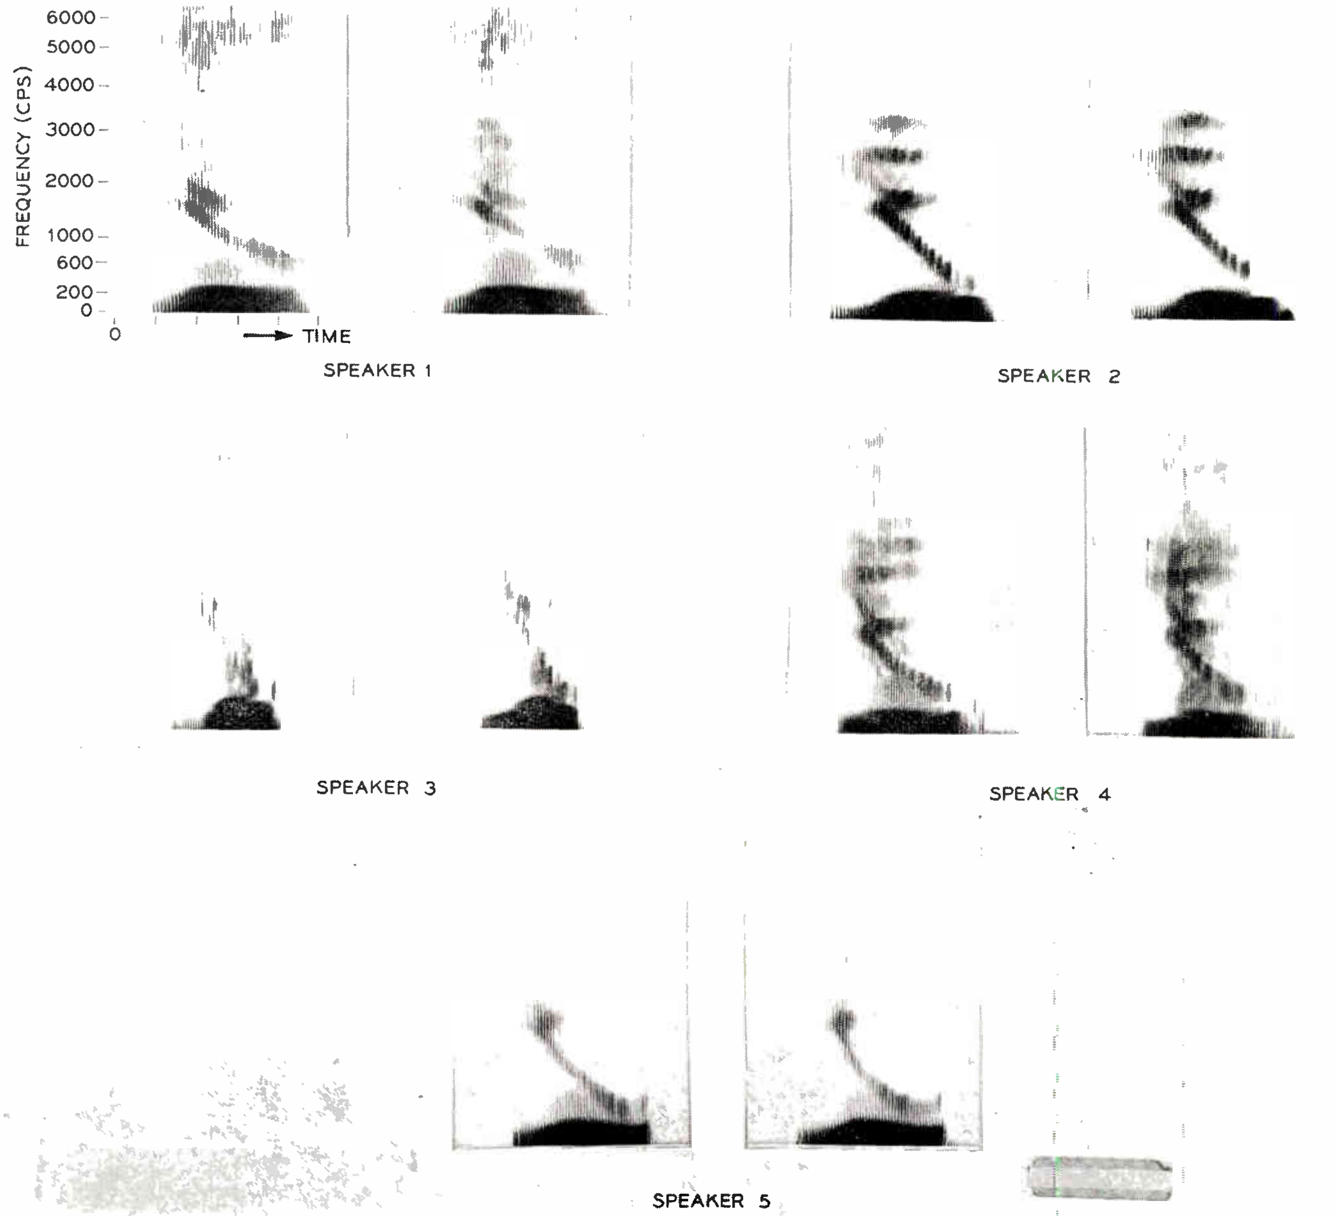

Fig. 4—Sound spectrograms of five talkers each pronouncing the word *you* twice, show that variations in spectral pattern from talker-to-talker are much greater than between successive utterances from the same talker.

flow at its input with the discrete acoustic segments in its memory?

These thorns have been avoided, rather than plucked out, in most speech recognition devices by imposing the following constraints:

1) The stored spectral-temporal patterns and the samples to be recognized are taken from the same talker, or a small number of talkers.
2) The recognition vocabulary is limited to a few words or sounds such as the 10 decimal digits.
3) Each word or sound must be spoken in acoustic isolation.

These crutches aid greatly in retrieving respectable performance from a difficult situation. Typical recognition results are listed in Table II [25]–[37]. Examination of this table shows that the rate of correct identification can approach 100 per cent when the input is protected from the rough and tumble of everyday talk.

As far as we know, no one has yet used such a scheme for practical computer input. Yet there seems no technical reason why speech recognition could not serve under constrained conditions like those where character readers have proved useful [38]. One obstacle lies in the amount and complexity of equipment required. Spectrographic analysis calls for an extensive bank of contiguous band-pass filters or their equivalents [39]. Their rectified and smoothed outputs may require further processing, normalization with respect to intensity and time for example, before being routed to the comparator.

TABLE II

Investigator	Speech Representation	Vocabulary	Number of Talkers Tested	Approx. Error Rate	Additional Facts and Comment
Kersta	Selected entries from Δf-Δt matrix (200 cps ×67 ms)	10 digits	9 men, 5 women	0.2 per cent	Spectrograms quantized into 2 levels
Davis, Biddulph, and Balashek	Formants 1 and 2 as a function of time	10 digits	1 talker	2.0 per cent	Correlation metric
Fry and Denes	Selected entries from Δf-Δt matrix	14 speech sounds in 139 words	1 talker	28.0 per cent (Sounds) 56.0 per cent (Words)	Phoneme digram frequencies used to supplement primitive recognition from acoustic data
Olson and Belar	Δf-Δt matrix	10 words or syllables	1 talker	2.0 per cent	
Dudley and Balashek	Δf-Δt matrix	10 digits	2 men	5 per cent	Temporal sequence disregarded
Mathews and Denes	Δf-Δt matrix	10 digits	6 men	6 per cent	Spectral pattern time and amplitude normalized
Hughes	Spectral features	11 sound categories in 100 words	4 men, 3 women	30 per cent	Feature selection based on linguistic analysis
Shultz	Spectral features	10 digits	25 men, 25 women	3 per cent	
Petrick and Willett	Δf-Δt matrix	10 digits	1 talker	<1.0 per cent	Spectral patterns time normalized
Forgie and Forgie	Spectral features	10 vowels	11 men, 10 women	7 per cent	
Keith-Smith and Klem	Δf-Δt matrix	10 vowels	11 men, 10 women	6 per cent	Statistical decision procedure used to select relevant spectral features
Sebestyen	Δf-Δt matrix	10 digits	10 speakers	<1 per cent	
Suzuki and Nakata	Formants 1 and 2	5 vowels in consonant contexts	5 speakers	≈20 per cent	Additional experiments on vowels in bisyllable words and short sentences yield higher error rates

For a parametric representation, this processing may include complex logic aimed at selecting significant spectral peaks, separating voiced from unvoiced speech and both from silence, etc. Time multiplexing may be convenient at some point in this chain to avoid multiple processors and comparators. Similar multiplexing must be adapted to read-out from the storage. If the stored data are to be adapted to different talkers or groups, then the equipment must operate in a "store" or "learning" mode in addition to the recognition mode. Suffice it to say, the engineering design problem for practical speech recognition is not simple.

Another unavoidable thorn is reliability. How is the performance implied in Table II affected by degradation of the input speech? One should not forget in practice that there are extraneous noises, like airplanes or other talkers or typewriters, and that people talk loudly or softly, holding the microphone close or far away, hoarsely or musically, and so on. We have barely started evaluating such difficulties; neither have we paid much attention to the permissible tolerances.

All these difficulties may well be eased by further research on speech and perception. More versatile speech recognizers may distinguish not only particular spectral features but particular dynamic transitions as well. Linguistic information concerning speaker dialects, intonation, stress, and timing may all aid in reconciling acoustic patterns with their literal counterparts. Surely the complexity of recognition paradigms will not decrease.

We should reiterate that mere extensions of the techniques in the works cited are almost certainly inadequate for handling conversational speech, which we believe to be much harder than handling isolated words.

We cannot easily predict the utility of speech recognition as a computer input. At present the amount of necessary hardware seems forbidding and the competition is simplicity itself, a keyboard and a finger, but the need for speed, for rapid feedback, for technological bravado surely dictate the availability, at least, of a speech typewriter in the next ten years. It will probably turn out that its utility will hinge on what is to be done with human utterances after they enter the machine.

Conclusion

We believe that progress towards useful and effective eyes and ears for computers has been slow, possibly slower than necessary (especially for print readers); partly because we seriously underestimated the difficulties; and there is an inherent question of values. What is the utility of a speech typewriter? Telephones now have dials instead of operators, and one big customer has vanished, alas! Why can't printing devices produce machine-readable tapes while they are printing? Present-day character readers provide a ponderous way of reading carefully-controlled print. All agree we should get these exotic sensors before the Russians, but we are not sure that we obviously need them soon as practical, useful, economical computer inputs. For most of us, contact with the computer is, as it were, by 24-hour mail;

telegraphy or teletype would be a bountiful improvement and telephones altogether too confusingly fast.

But in another vein, as these techniques appear, they will uncover their own applications just as computers themselves have. The commercial interest nowadays is largely a competitive one—successive advertising disclosures arouse successive new bursts of research activity. At some critical point the techniques will draw support from performance rather than promise, though we can at present only ill-describe such future performance.

Costs will be large. But remember that one reading input device can (potentially) replace hundreds of people reading onto keypunches. A real-time speech typewriter can replace 5 people if it works 24 hours a day; it will be a large piece of equipment that can be amortized on $20,000 a year.

The real difficulty then will be the input-input problem: given words thundering in, what do we do besides store them? The state-of-the-art of automatic indexing and abstracting is even more inadequate and as we said before, it will be a long time before we handle English in all its full meaningful glory. But we are a step ahead. The problems we discuss today are being solved. Here at least we can feel fairly sure that we have identified one of tomorrow's problems.

[38] Probably the real reason is economic: the marginal utility of a speech input adapted to just one talker, when he does not suffer from grippe or laryngitis, is just too small.

[39] There are only three computer installations that have gone as far as a real-time microphone-with-filter-bank input, we believe.

Section 13
ENGINEERING MANAGEMENT

Organized with the assistance of the IRE Professional Group on Engineering Management

The Art of Engineering Management*

HECTOR R. SKIFTER†, FELLOW, IRE

Summary—**Challenged by larger and more complex tasks, the engineering manager must place greater emphasis on the motivation and intellectual development of his people if he is to obtain the maximum creative effort from individual engineers.**

Management of the environment rather than the individual is suggested as the key to motivation—and to successful engineering management. Problems facing us in electronics will be easier to solve if managers build an environment characterized by sound organization, stimulating goals, economic rewards and, most important of all, freedom of initiative for the individual with maximum emphasis on self-direction and self-control.

Introduction

The need for excellence in engineering management has never been more urgent than it is today. With the exponential growth of science during the past few decades has come a vast change in the role and responsibility of those who manage technical personnel.

Management was not so difficult a generation ago when small groups of engineers could design and build most of our equipment. But today, in electronics, we are faced with tasks of unprecedented magnitude and complexity. The proposed lunar program, involving manned exploration of the moon before the end of the decade, will exceed in complexity and scope any of our previous technological enterprises. The skills of tens of thousands of engineers in government and industry will be required to achieve this step into space.

Today's manager faces vastly more difficult administrative and technical problems than his predecessor. He must not only coordinate the activities of large groups of engineers but also direct the application of highly advanced technology.

All this requires new management techniques and skills, and it has lent urgency to improvement in the art of engineering management. In fact, there are many today who believe that our technology has outstripped our management—that the biggest job we face is in learning how to motivate and lead effectively.

Today's manager has serious problems. One of these is the shortage of skilled technical manpower. The Engineering Manpower Commission has estimated that the present critical shortage of engineers in the United States will become even worse. By 1965 it is forecast that we will have only 32,000 new engineering graduates each year, in contrast to an average annual demand for more than double this figure. It will be more difficult than ever to build technically superior engineering groups. Even the oft-used, and usually unsuccessful, approach of subsituting "bodies for talent" will offer no solution, because the numbers simply will not be available.

Another problem is that of preventing the technical obsolescence of the engineering staff. In these days of scientific breakthrough and fast-moving, proliferating technology, an intensive and continuing effort is required by engineers at all levels, including the manager, to keep technically up to date.

Also, the manager is faced with balancing group needs against individual needs. On large, complex projects it is essential to maintain tight over-all direction and control in order to live within contract commitments. Yet, experience has shown that creative engineering activity cannot be programmed or closely supervised. The manager has responsibility not only for the group but also for the individual engineer. He must provide an environment in which the individual can reach his maximum potential.

Thus, it is appropriate that we give serious thought

* Received by the IRE, January 3, 1962.
† Airborne Instruments Laboratory, Deer Park, N. Y.

to the responsibilities of the engineering manager—and particularly to those functions which require emphasis at this time. To a large degree, the progress of our society will depend upon the skill with which we manage our scientific and technical resources.

This discussion will deal with engineering management in both large and small organizations. The ideas presented are undoubtedly influenced by the problems posed by extensive government-sponsored research and development programs. The type of engineering organization we discuss is engaged neither in pure research nor in routine design. It is, rather, typical of the groups involved today in the application of advanced technology to military and industrial problems. Its stock in trade is not only technical competence but imaginative leadership.

With this background, I would like to review the evolution of engineering management, the responsibilities of the manager, some approaches for the motivation and intellectual development of technical personnel, and some key problems of the future.

Evolution of Engineering Management

Engineering management, as we know it today, is relatively new. About the turn of the century several pioneers in management, such as Taylor, Gilbreth, and Gantt, made a profound contribution to modern production methods. In France, Fayol pointed the way to new techniques in administration.

During these early years, management techniques were developed and improved—primarily in manufacturing organizations. A body of experience and knowledge grew up during this period which made possible the establishment of large business enterprises. Management did not evolve into a science measured by the standards of modern technology, but it did become a well-established discipline. The problems of applying these production management principles to engineering management were first experienced by the managers of the small specialized engineering groups which grew up during World War I and characterized the early years of the radio and electrical industry.

World War II brought explosive growth to the research and development activity in electronics, nuclear physics, and allied fields. Organizations ranged in size from a single scientist and his staff to large groups such as Radiation Laboratory at M.I.T., Radio Research Laboratory at Harvard, and Airborne Instruments Laboratory at Columbia, operating under the Office of Scientific Research & Development. The Manhattan Project, of course, was the largest of them all. During the same period a number of commercial firms, such as American Telephone & Telegraph, General Electric, and Radio Corporation of America, organized large engineering staffs.

These groups were built with a minimum of formal organization. Work was organized around project engineers and department heads reporting to a director. Service and planning functions were accomplished on an *ad hoc* basis with a minimum of scheduling and paper work. Efficiency often suffered, because it was necessary to employ all available manpower, and many engineers were added without training or supervision. Still, these groups had able people and a variety of talent. No limits were placed upon the creative engineer, who maintained close liaison with the user.

Wartime pressures provided a motivating external environment that made these research groups highly effective, but this type of informal organization and management was not adequate for the long pull in peacetime. To obtain consistent results from an engineering group, it is essential to have planned objectives, sound organization, and carefully defined work assignments.

Several factors tended to bring about improvement in engineering management practices in the early postwar years. A number of groups "spun off" from the wartime research laboratories to form independent organizations. Many new companies were formed, and the larger commercial firms expanded their activities in defense electronics. As new enterprises proliferated and old ones expanded in a peacetime environment, management was forced to re-evaluate organization and engineering procedures. Managers found themselves answerable to employees, stockholders, and boards of directors. At the same time, their customers placed greater emphasis upon reliable systems and equipment, on-schedule delivery, and effective cost control.

Engineering management matured considerably during the first postwar decade. Engineers became more familiar with techniques that had been evolved over the years in industrial management. They participated in trade association seminars and management meetings. Most important, they learned on the firing line by successfully handling tasks of increased complexity.

During the period after the Korean War, important new lessons were learned. Many companies that had concentrated on research and development established production operations and experienced the problems of moving systems and equipment from research and development into production.

In recent years the emphasis in defense electronics has been on research and development. We have concentrated on the development and fabrication of a limited number of complex systems and equipment. We have had to anticipate the requirements of, and work with, newly created procurement organizations responsible for weapon systems. Within our companies we have had to create nearly autonomous project task forces; new organizations to handle schedule and cost control, reliability, and quality control; new groups to handle liaison between subcontractors and team members; new lines of communication within the organization and to the customer. To those of us who have participated in these electronic systems and space programs, this latter period has offered perhaps the greatest challenge to the imagination and capability of our engineering managers.

Responsibilities of the Engineering Manager

Today we are faced with a dilemma. On the one hand we must turn out vastly more complex systems and equipment within rigid cost and time schedules; this implies much greater "front office" direction and control. On the other hand, we must maintain the most favorable possible environment for creative engineering effort; this implies the maximum freedom of initiative for the individual engineer.

What does this mean to the engineering manager? His basic responsibilities remain the same. He is still charged with establishing goals, organizing, motivating and communicating, measuring performance, and developing the personnel in his organization. But he must shift emphasis to the most important elements of his job to meet changing conditions.

Who is this engineering manager? The president of the company? In many cases, yes. The working engineer? Certainly yes! The management principles, tools, and objectives outlined here apply throughout the organizational ladder. As Peter Drucker has so well stated, we are concerned with the management of managers. Each echelon of the management chain has a responsibility for the application of the appropriate techniques to the direction of the managers reporting to it. The objective can well be a team approach by all levels in the most effective management of the resources and capabilities of the organization toward clearly stated goals.

Obviously the engineering manager must be concerned with goals. They must be broad objectives which excite the imagination and give people something they want to work for, something they don't yet know how to do, something they can be proud of when they achieve it.

The engineering manager must also give careful thought to organization structure. As our engineering groups grow, it becomes increasingly difficult for the manager to pay detailed attention to the individual engineer's work accomplishments. The engineering activity must be subdivided into small enough groups for the individual engineer to achieve recognition and identity. Groups and section leaders must be selected who combine project engineering experience with leadership ability. And supporting engineering services must be provided to relieve the technical workforce of administrative and housekeeping details.

Performance evaluation is another of the manager's important responsibilities. In an engineering organization, intelligent measurement of performance requires that the manager demonstrate a personal interest in and technical understanding of the work being performed. The results of such an evaluation obviously are used for administrative purposes—for salary administration, promotion, and the transfer of employees. But, properly applied, performance evaluation results can provide the recognition which a group or individual deserves when a goal has been met or, conversely, the stimulant required when results are less than desired.

These functions—goal-setting, organizing, and performance measurement—are all important. But if today's engineering manager is going to face up to his really fundamental and most demanding tasks, he must place increasing emphasis on how he motivates and develops people. Effective motivation and development of technical personnel are so vital to successful engineering management, so related to working out a compromise between rigid management control and complete freedom of initiative, that this discussion will be devoted largely to these aspects of engineering management.

Motivation of Engineering Personnel

Managing the environment rather than the individual appears to be the most successful approach to the motivation of engineering personnel.

Experience has shown that the creative intellectual effort of the scientist or engineer cannot be programmed. The engineer's intellectual contribution cannot be obtained by giving orders or by the type of close supervision used in manufacturing operations. If the engineering manager places pressure on his people, indicating in detail what they can and cannot do, initiative and creativity are weakened or destroyed.

Those who study management believe that a revolution is taking place in management that is particularly applicable to the engineering organization. A long-standing concept of managerial control has held that it is necessary to impose direction and limitations on the individual in order to get him to perform the work for which he is hired. The trend is away from this toward recognition of the capacity of individuals to exercise self-direction and self-control in the service of objectives to which they have committed themselves. Management by objective and self-control will inevitably replace management by authority and externally imposed control.

This suggests that the engineering manager must adopt a new approach to establishing goals. He must continue to communicate and interpret the broad objectives of management. But he must give increasing personal attention to aiding, encouraging, and counselling his engineering groups—and individual engineers—to establish their own performance goals. These include not only time and cost objectives for the typical research, development, or production project but any number of goals that the individual engineering group can work toward in furtherance of the over-all corporate objectives—new technical areas that a group will investigate, new proprietary developments that the group will begin, new competence that the group will acquire through self-development or the addition of qualified personnel.

The important thing is that, with the encouragement and assistance of engineering management, these goals are self-determined. And the individual engineer, committed to objectives which he has helped to establish, develops an inner motivation and drive which he cannot possibly have if these goals are imposed upon him from above.

Before he can create a favorable environment for engineering work, the engineering manager must understand the values, interests, and expectations of technically trained personnel.

The typical scientist or engineer is keenly interested in exercising full use of his talents and training on the job. And he seeks recognition and the opportunity for development in his professional career. Thus, the engineering manager must keep alert to the nature of work assigned to individual engineers, the challenge involved in particular jobs, and the freedom which engineers have to carry out their responsibilities. The engineering manager must provide for recognition of status—both outside the company in the professional world and within the company. He must encourage publication of technical results and participation in the affairs of professional organizations. Within the company, the manager must provide the engineer with rewards and recognition for excellence; he must provide the engineer with the opportunity to advance up the "technical ladder" as well as up the administrative or managerial ladder.

There is growing recognition of the problem of providing opportunity for the talented engineer to advance. Even in a rapidly expanding organization, not everyone can become a vice president or department head. Many very competent engineers do not desire to switch from technical to administrative responsibilities. We need positions of prestige and challenge for these valuable individuals. Staff positions (such as that of consultant) have, in many cases, been filled or created for this purpose. Carefully chosen personnel can be very effective in such positions. If, on the other hand, these posts become a refuge for ineffective or incompetent personnel, great harm can result.

Financial incentives are a vital part of the environment which provides motivation. Though salary is not the primary incentive to peak performance, it must be competitive with what the engineer can obtain elsewhere; within the company, salaries must be fairly administered. The temptation to hire at salaries above those of comparable or superior persons already on the payroll must be controlled. The salary structure in the engineering organization must be set up so that the money an individual receives is fair relative to the market, economic conditions, importance of the job, and the individual's contribution. The company must also provide a fringe benefit program consisting of group insurance, medical insurance, and retirement benefits which are competitive and offer adequate protection to the employee.

Beyond this, it is essential to consider programs that provide increments of money, stock, or deferred income to provide incentive for and compensate different increments of risk taking and effort. In the intensely competitive electronics industry, incentive rewards must be provided for technically trained personnel who are making the basic risk-taking decisions that determine the future of the business. These rewards usually take the form of stock options, or, in a closely held enterprise, the opportunity for stock participation. The stock option is usually considered an incentive for future performance, not a reward for past efforts. It gives the valued employee a chance to build capital, to participate in ownership, and to identify personal with corporate goals. Many of us believe that a personal stake in the business is one of the best possible guarantees for extra effort on the part of key technical personnel.

Bonus plans are used to provide incentive reward to middle engineering management not directly involved in risk-taking decisions. The bonus offers a means of recognizing the work of individual performers throughout the organization who have made unusual contributions to over-all results.

Good communication is another essential element in an environment favorable to creative engineering. The establishment of objectives and financial rewards is meaningless unless both vertical and horizontal communication is effective throughout the engineering organization.

One of the most difficult problems facing the engineering manager is that of maintaining adequate communication as the organization grows. The typical engineering development group that has doubled or tripled in size over the past few years is no longer a happy little family. Whereas the department head previously knew all members of his staff personally, he now has two or three levels of command interposed between himself and his engineers. He must act through section leaders, group heads, and project engineers. He finds himself faced with the problem of managing managers rather than managing engineers. And he realizes that he must organize, delegate, and communicate in order to accomplish tasks that he previously handled directly with the responsible individual. This problem is acute because highly trained engineering personnel want a voice in policy—want to understand the total picture of what is going on.

The techniques of communication, and methods for improvement in such channels, are too involved to cover in this discussion. However, it should be emphasized that there is no substitute for informal face-to-face contact between the manager and his people. Meetings must take place often enough and last long enough for the manager to learn and, in turn, demonstrate his knowledge of and interest in the projects which are underway.

Some supervisors develop the facility of building strong personal friendships within their group. While avoiding any semblance of paternalism, improved communication and stability can be developed in a group in which personal friendships and common recreational interests help create mutual respect and understanding.

The engineering manager should be alert to a condition of unstable equilibrium that may develop in any organization. An interesting parallel with a collegiate football team can be pointed out. After a notably successful season, the cream of the crop of new players is attracted, resulting within a year or two in an unbeatable team. Subsequently a perturbation (a crushing defeat or change of coach) starts a decline that is just as spectacular as the earlier rise to fame. This is a thought to chill the heart of the engineering manager: the talented engineering organization is a potential victim of the same instability. The pinnacle of success is a mighty slippery perch. Intellectual challenge and strong motivation help provide the stability so important to the environment in which the engineer works.

Managing the environment by encouraging self-determination of goals and by providing adequate economic incentives and good communication thus appears to be the best way to direct engineering groups involved in tasks of increasing complexity. This does not mean that management shifts responsibility for over-all planning, organization, and direction to lower levels in the organization; this kind of responsibility cannot be delegated. But it does mean obtaining the maximum participation from highly trained technical personnel in every phase of the operation of an engineering enterprise.

Intellectual Development

In a period of rapidly advancing technology, such as now exists, technical obsolescence of the individual engineer—or of the entire organization, for that matter—is a real threat to the growth and effectiveness of the company. Maintaining an environment favorable to intellectual development is one of the engineering manager's most difficult and challenging tasks.

The task is difficult because there are so many intangibles among the factors which stimulate intellectual development on the part of an engineer. We know engineers who have kept up to date through an intense curiosity about their own and other disciplines. And we know others who have fallen behind and are no longer equipped to make technical decisions in their own fields, let alone embark upon new areas. The reasons for this difference are hard to understand. Intellectual capacity and drive certainly account for a good deal; yet, there are other elements. In industry there is growing recognition that we must do more to create an environment favorable to self-development.

Several points of view have been expressed about advanced training for scientific and technical personnel. Some consider such educational programs part of fringe benefits—something done to attract and hold young engineers and to remain competitive with other companies. Others claim that if a company is fortunate enough to have talented personnel, it has an obligation to society and to itself to encourage their self-development.

I would not argue with these concepts. But I believe there are other urgent reasons for attempting to develop our technical personnel. First is the recognition that technical specialists require scientific training beyond that received in the normal college program. The creative engineer must be able to apply the most advanced techniques to the problems that confront him. His perspective must be broad so that he can work in new fields required by the demands of dynamic technology.

Second is the problem of sheer technical obsolescence faced by engineers who have been out of school for a number of years. Much too large a proportion of our senior personnel have not kept current with fast-moving and complex developments in fields such as space technology, communications, computers and data processing, materials technology, energy sources, and industrial automation. Many lack the technical base and flexibility to meet the challenges that lie ahead.

The problem of technical obsolescence is related to the responsibility of engineering management to protect the assets of a business. Toward this end, we maintain physical equipment and set up depreciation reserves on plant and machinery. In much the same way, we have the obligation to protect and enhance our investment in people, the most valuable asset in the technically oriented business.

Fortunately, there is growing concern in the electronics industry over this problem. A number of companies have recognized the need to provide advanced training for newly hired engineers. One company has organized a program of graduate study in communications engineering and related sciences, conducted during working hours, which leads to a master's degree at the end of the second year. A number of companies have two- or three-year programs for newly hired engineers which emphasize advanced study in technical fields related to the engineer's future work. Other companies make it possible for newly hired personnel to take advanced work at nearby educational institutions. These are indications that progress is being made on the problem of advanced training for newly hired personnel.

The problem of advanced training for senior engineers appears to be more difficult to solve. Because of demands on the time of these responsible engineers, it is difficult to set aside time for advanced work during working hours; nevertheless, one large company recently established a program under which more than 100 engineers are enrolled each year at colleges and universities for resident work leading to advanced degrees. This company found early in the program that participation had become identified with status, that many participants were more interested in personal advancement than in advanced training. They discovered that a number of men were not adequately prepared in languages and mathematics to embark upon doctoral work and that refresher courses would be essential prior to sending such men for advanced work. With modifications, the program is being continued and expanded.

Despite cost and the impact upon the organization of the temporary loss of key personnel, other companies will no doubt establish programs involving resident college work for senior engineering personnel. Some will move ahead with out-of-hours educational classes, lectures, seminars, and other methods for providing advanced training. However, until such formal steps are taken, the engineering manager has an obligation—and an opportunity—to train both newly hired and senior engineers. Within his group, he must create an atmosphere favorable to self-development. By example, support, and counsel, he must influence his people toward placing effort upon self-development in areas vital to the individual and the company. He must encourage use of reference material already available within the company; many companies have discovered the desirability of providing extensive library services and facilities for engineering personnel. Beyond this, he must provide opportunities for the cross-fertilization of ideas; must permit wide dissemination of information on work in progress in different areas; must provide recognition to those who have taken advanced training, with or without company assistance; and must cultivate a spirit of competitiveness with respect to intellectual achievement.

Steps such as these should at least accelerate self-improvement on the part of engineering personnel and contribute toward greater capability and better utilization of existing scientific and technical talent. There is room for considerable imagination and experimentation in this area.

In the long term, I believe a change of philosophy will be required to accomplish all we need to do. Engineering management must recognize the benefits from educational programs and be willing to underwrite their cost. At the same time, the new generation of engineers must develop a realization that their careers will be divided between work and advanced study and that only through exposure to new disciplines and new technology can they hope to obtain advancement and the full realization of their potential.

Key Problems Facing Us

Of the many problems that face engineering management today, it appears to me that three deserve particular attention: planning our technical future, staffing and organizing to handle the increasingly complex systems jobs, and reducing the cost of engineering work.

Careful planning as to the technical areas in which an enterprise will concentrate is more essential now than ever before because military and industrial requirements are constantly changing. Emphasis today is on advanced equipment, larger and more complex systems. Even the largest companies cannot keep pace in all areas of technology. Hence, it becomes vital to be selective and to develop outstanding capability in specific technical areas.

The spadework necessary to make sound decisions on corporate technical direction is an important task for engineering management working in cooperation with finance, marketing, production, and other elements of the organization.

Many approaches to providing technical direction have been adopted. Some companies have established a planning organization within the engineering or marketing groups with clearly defined responsibilities for long-range planning. Others have established planning groups at a top corporate staff level whose job it is to initiate and coordinate forward-looking thinking throughout the organization. Several of the large companies have set up "think" groups of highly trained scientists and engineers who are completely separated from the day-to-day operations of the company. Each of these methods has advantages and disadvantages.

The planning groups within engineering may become too engrossed with technical factors, with the result that the needs of customers receive second priority. Those within marketing may place too great emphasis upon customer needs and market expectations, not enough emphasis upon technical aspects. Both types of groups, however, can make progress, if they have well-defined responsibilities.

The corporate-level planning staff may be too far removed from current technical and marketing operations to provide sound guidance. This is particularly true of the planning group whose members do not maintain sufficient personal contact with key staff members and potential customers. On the other hand, this type of planning organization enjoys the advantage of an over-all picture of the company's operations. Properly run, it can make a valuable contribution.

The most controversial of the planning mechanisms is the so-called "think" group of highly trained technical personnel, who often are completely separated from the rest of the organization, organizationally and geographically. Such groups may tend to concentrate to such an extent on long-term factors that they lose touch with intermediate-term factors. Some planning organizations of this type have been known to disassociate themselves from realistic corporate objectives. Others have lost sight of their original charter and have turned their efforts from planning to proposal effort and the handling of certain types of government contracts. On the positive side, such a group can be highly creative and look well into the future without being distracted by day-to-day considerations.

What is important is not where the planning function is located within the corporate structure, but that somewhere all the elements of effective planning are performed. This means that the engineering manager, regardless of the level at which he works, must accept planning as one of his crucial responsibilities. He must set up the mechanism for looking ahead regardless of whether the group for which he is responsible is a division, a department, or a section. He must block out time to participate in, provide liaison with, and feed information to the planning group, which may be operating elsewhere in the company. And the manager must create an atmosphere in his group that encourages looking ahead.

Staffing and organizing to handle the increasingly complex systems job may turn out to be the most difficult problem of all for the engineering manager. During the past decade we have had the challenge of gearing up for large, complex tasks. But this is only the beginning. In space technology and other areas we will be faced with tasks beyond anything we have accomplished to date.

The trend toward larger, more complex systems has several implications for the engineering manager. Internally it means that all of a company's related capabilities must be brought to bear on proposal effort that may lead to participation in systems work—and in the performance of these complex jobs after the proposal has been accepted. No longer can we afford the luxury of individual groups who draw aside from the mainstream of company effort and are not interested in joining the commitment for large tasks. These artificial barriers must be broken down; the specialized groups who see their particular challenge in highly creative engineering and advancing the state of the art must be made part of the total effort that individual companies bring to bear in obtaining and handling systems work.

Furthermore, we must place greater emphasis on joint bidding, which implies closer prime-subcontractor relationships, team efforts, and joint ventures with other companies. No one company, not even the largest contractors, can hope to accumulate the array of talent and resources necessary to handle the very large systems. Industry must take the initiative in evolving effective techniques so that the best qualified organizations in specialized technical areas can pool their capability to handle the very large systems jobs. Companies must join forces earlier and communicate more effectively during the precontractual stage. Once contracts have been awarded for major systems, steps must be taken to improve the working relationships between the companies involved, to improve cost and schedule control, and to speed the integration of subsystems into the over-all system.

Within individual companies, engineering management is faced with the problem of how to organize in order to handle participation, whether as a prime contractor or a subcontractor, in these large tasks. We have learned that supervision of these large projects is vastly different from the engineering work we have accomplished in the past. Program management groups are needed to coordinate and assume responsibility for all aspects of the job—cost, schedule, manpower, material, and other requirements. They subcontract to other elements within the company and establish relationships with team members or subcontractors outside. They visualize the task in its entirety, shift to meet changing technical, schedule, and budget requirements, and focus the collective energies of groups inside and outside the company on the accomplishment of the task.

Engineering management must face up to certain realities with respect to systems work. First, the management of these projects at all levels requires a unique combination of administrative and technical skill. Personnel selected for these positions must be people who are challenged by the rewards of creative management as well as those of creative engineering. Second, the maximum possible degree of permanence must be built into program management personnel assignments. The insecurity which has characterized the lot of engineers on many large systems jobs can be eliminated if the company builds program management groups permanently into the organization structure. This, of course, implies a commitment by the company to make systems work a permanent part of its activity. Beyond this, it means establishing the type of program management or task force type of operation that can be self-perpetuating. Such groups must not only keep on top of the work at hand, but must participate in planning and proposal effort that will find new fields to conquer and new applications for techniques, systems, and equipment already developed. When a major task has been completed, key personnel in the group are shifted to the business-getting function.

Finally, more effective tools must be developed for the direction and control of our systems work. At frequent intervals today we measure progress and arrive at estimates of time, cost, manpower, material, and other requirements needed to complete the task. On major systems this is a difficult and time-consuming undertaking. Engineering management must develop new review techniques and make greater use of computers and data-processing equipment, to speed and increase the accuracy of such controls. Engineering management needs more accurate and timely information during the progress of the work which can be used to remove bottlenecks, correct mistakes, adjust to changes—in short, to maximize performance on the job.

Reducing the cost of engineering work is another of the significant problems facing engineering management. By and large the electronics industry has done a creditable job of developing and producing complex systems and equipment during the postwar years. But from the controller's standpoint some of our efforts have been extravagant. We hear it said by members of Congress and special committees that defense research and engineering has become the greatest luxury the country has ever known. Our customers among the armed services tell us that greater emphasis must be placed upon financial management and cost control.

We in electronics realize that cost control will be essential if the major government programs ahead are to be carried out within the limits of funds available. It is already apparent that only the able and efficient contractors will survive in the long run.

For the engineering manager this means greater emphasis on accurate cost estimating, particularly on cost-plus-fixed-fee development programs. And it will require intensified and continuous effort to live up to our obligation to deliver complex systems within the original estimates of time and cost.

In carrying out his functions—planning, organizing, motivating, evaluating performance, and developing people—the engineering manager must be keenly alert to cost factors. He must develop within his organization an awareness of cost and the methods necessary for effective cost control. Still he must recognize that, in evaluating the performance of a research and development group, efficiency is not a simple ratio of output per unit of input. Often a creative engineering approach can substantially reduce the cost of a system or equipment under development.

It is the engineering manager's task to encourage this kind of creative approach, to make certain that costs are under control, and to obtain the cooperation of all project personnel in working toward cost reduction. If these steps are accomplished, the engineering manager will have gone a long way toward ensuring the success of the complex and difficult projects that lie ahead.

Conclusion

Technical personnel engaged in programs vital to government and industry must be strongly motivated and working at maximum potential if our society is to progress.

To achieve this result, today's engineering manager must place increasing emphasis on how he motivates and develops people. By effective motivation and intellectual development, the manager can arrive at a sound compromise between too rigid control and a "laissez-faire" approach to engineering management.

Faced with projects of greatly increased complexity, the engineering manager might be tempted to increase top-level direction and control. But we have learned that much more effective leadership is provided by managing the environment rather than by managing the engineer. We must create an environment favorable to creative engineering with all that this implies—good organization and communication, stimulating goals, economic rewards and, most important of all, freedom of initiative for the individual with maximum emphasis on self-control and self-direction.

The difficult problems facing us today—such as reducing costs, planning the technical future, and organizing to handle increasingly complex systems—become easier to solve if engineering managers create the kind of environment that encourages participation by technical personnel in every phase of the operation. Such an environment will also stimulate and accelerate intellectual development, which has become essential because of the danger of obsolescence of our knowledge in the midst of rapidly advancing technology.

In the long run, I am confident that emphasis on individual creativity, initiative, and self-expression will prove more effective in producing results than the closely directed and controlled systems of management that have sometimes been used. Engineering organizations that impose direction solely from above will never match the achievement of those who make self-direction and inner motivation driving forces. To create the kind of engineering groups in which free men cooperate and achieve the fullness of personal development is the challenge ahead for engineering management.

Section 14
ENGINEERING WRITING AND SPEECH

Organized with the assistance of the IRE Professional Group on Engineering Writing and Speech

Growth and Importance of Engineering Publication*

KEITH HENNEY†, FELLOW, IRE

Summary—**The pages of past issues of the PROCEEDINGS provide an interesting and accurate picture of how the electronics art and science has developed over the years. A few examples of early writings are given which reflect prior stages of the art, and some observations are made on the place of technical publishing in the electronics industry.**

BY ITS VERY Charter and Constitution the Institute of Radio Engineers has always had as one of its objects "the publication of papers." Among the evidences of distinction recognized by the Constitution in its qualifications for Senior Member is the "publication of important original engineering or scientific papers, books or inventions" and at least one Fellow had this honor bestowed on him because the Board of Directors felt that his editorial work had "served to advance the progress substantially" in the fields in which the Institute serves.

In all scientific, and most technical disciplines, it is well recognized that the publication of papers is a vital part of one's job. Radio engineers have not been backward in this respect. Even a casual glance through the pages of early issues of the PROCEEDINGS shows not only who was doing what and when but gives an excellent picture of how the electronic art and science has developed.

A casual glance, however, is impossible for any reader old enough to have had some contact with the early days. The casual glance is apt to consume hours because these early days constitute a fascinating panorama of what is now so well known (or forgotten) but what was then a complete puzzle or undreamed of. It is certain that a young engineer who never heard of Austin or Cohen or Morecroft or Arnold or of a quenched gap or a carborundum detector will come away from a reading of the PROCEEDINGS of the 1920's with a feeling of awe that engineers of those days accomplished so much with so little knowledge. It is also fairly certain that young engineers of today will discover that what seems so new now may really be rather ancient.

Thus Marconi (Fellow, 1916, Medal of Honor, 1920) writing in 1922 says,[1] "it should be possible to design apparatus by means of which a ship could radiate or project a divergent beam . . . in any desired direction, which rays, if come across a metallic object . . . would be reflected back to a receiver . . . on the sending ship, and thereby . . . reveal the presence and bearing of the (object) in fog or thick wheather."

Or, Moorhead and Lange in 1921[2] who lament that "in spite of wide applications of the tube, in spite of its being in daily use all over the world, no satisfactory solution of a mathematical theory has been given." Or, Alexanderson (Fellow, 1915, Medal of Honor, 1920) speculating[3] on how it is that radio will carry over such extraordinary distances on a quiet night or, in fact, how radio goes anywhere at all.

Between 1899 when Marconi made possible the first newspaper published at sea (Fig. 1) and 1962, the whole of radio and electronics has unfolded, at first slowly

THE TRANSATLANTIC TIMES.

VOLUME I. NUMBER I.

THE TRANSATLANTIC TIMES

Published on board the "*ST PAUL*," at Sea, *en route* for England, November 15th, 1899.

One Dollar per Copy in aid of the Seamen's Fund.

Mr. W W Bradfield, Editor in-Chief. Mr T Bowden, Assistant Editor. Miss J B Holman, Treasurer. Mr H H McClure, Managing Editor.

Through the courtesy of Mr G Marconi, the passengers on board the "St Paul," are accorded a rare privilege, that of receiving news several hours before landing. Mr Marconi and his assistants have arranged for work the apparatus used in reporting the Yacht Race in New York, and are now receiving dispatches from their station at the Needles. War news from South Africa and home messages from London and Paris are being received.

The most important dispatches are published on the opposite page. As all know, this is the first time that such a venture as this has been undertaken. A Newspaper published at Sea with Wireless Telegraph messages received and printed on a ship going twenty knots an hour!

This is the 52nd voyage eastward of the "St Paul." There are 375 passengers on board, counting the distinguished and extinguished

The days' runs have been as follows ;—

Nov. 9th	435
,, 10th	436
,, 11th	425
,, 12th	424
,, 13th	431
,, 14th	414
,, 15th	412

97 miles to Needles at 12 o'clock, Nov. 15th.

BULLETINS

1.50 p m. . . . . — . First Signal received, 66 miles from Needles

2-40 "Was that you "St. Paul"? 50 miles from Needles.

2-50 Hurrah! Welcome Home! Where are you?

3-30 40 miles, Ladysmith, Kimberley and Mafeking holding out well. No big battle. 15,000 men recently landed.

3-40 "At Ladysmith no more killed. Bombardment at Kimberley effected the destruction of ONE TIN POT. It was auctioned for £200 It is felt that period of anxiety and strain is over, and that our turn has come."

4.00 Sorry to say the U. S. A. Cruiser "Charleston" is lost. All hands saved

The thanks of the Editors are given to Captain Jamison, who grants us the privelege of this issue

Fig. 1—"The Transatlantic Times," courtesy of the Harvard College Library.

and then with great rapidity, but all the steps are to be found described in the pages of the PROCEEDINGS and in the pages of other radio publications of the times. The whole history is there, the editorial pages giving the concepts, the theory, the experimental methods and results, the advertising pages giving the components, devices and systems which resulted. For later-day patent lawyers, the advertising sections of the early publications have proved to be gold mines of information on the dates when certain matters entered the art.

Whatever the purpose of technical publishing today, there is no doubt that early engineers wrote papers to be read.

Any engineer of that time or this can easily get past the first page and more without giving up, and the proof of high readership lies in the extended discussions of individual papers which appeared in later issues. No one can read Lee deForest's (Fellow, 1918, Medal of Honor, 1922)[4] discussion of Roy Weagant's (Fellow, 1915, Morris Liebmann Memorial Prize, 1920)[5] antistatic inventions without visualizing the scene, the researcher-inventor setting forth what he has accomplished, the critics stuggling to understand or to deny.

Not all of the papers of the time were actually published—a situation which differs not at all from the present day. The writer remembers with great vividness an evening in Massachusetts spent with G. W. Pickard (Fellow, 1915, Medal of Honor, 1926) and Henry S. Shaw (Fellow, 1935). Pickard was then in the midst of his famous nightly recording of the strengths of signals from WENR in Chicago and the writer was sent to gather material for a report on this research. He broke into a rather hilarious session consisting in the reading of a paper by George Lewis (Fellow, 1951) on a proposed method of rating signal strength. This was a matter that was not very well standardized at the time. Signals were to be rated, according to the Lewis method, somewhat as follows:

1) Audible with the headphones tightly clamped to the head.
2) Audible with the headphones on the table.
3) Audible with the headphones in the next room.
4) Audible with the phones in the next room and the door shut.
5) Very loud signals.
6) Signals loud as hell.

For the record, and for the benefit of modern engineers, it is worth noting that Pickard's homemade comparison oscillator sat on the floor in the middle of a copper wash boiler (where can one buy such an instrument today?) and that this original research did not require a lush government contract to be revealing and effective. As the needle of Pickard's microammeter gave the instantaneous vagaries of WENR's signals, this young editor began to glimpse what the Appleton (Fellow, 1931, Vice-President, 1932, Medal of Honor, 1962) and Kennelly (Fellow, 1928, Medal of Honor, 1932) layers in the ionosphere were all about.

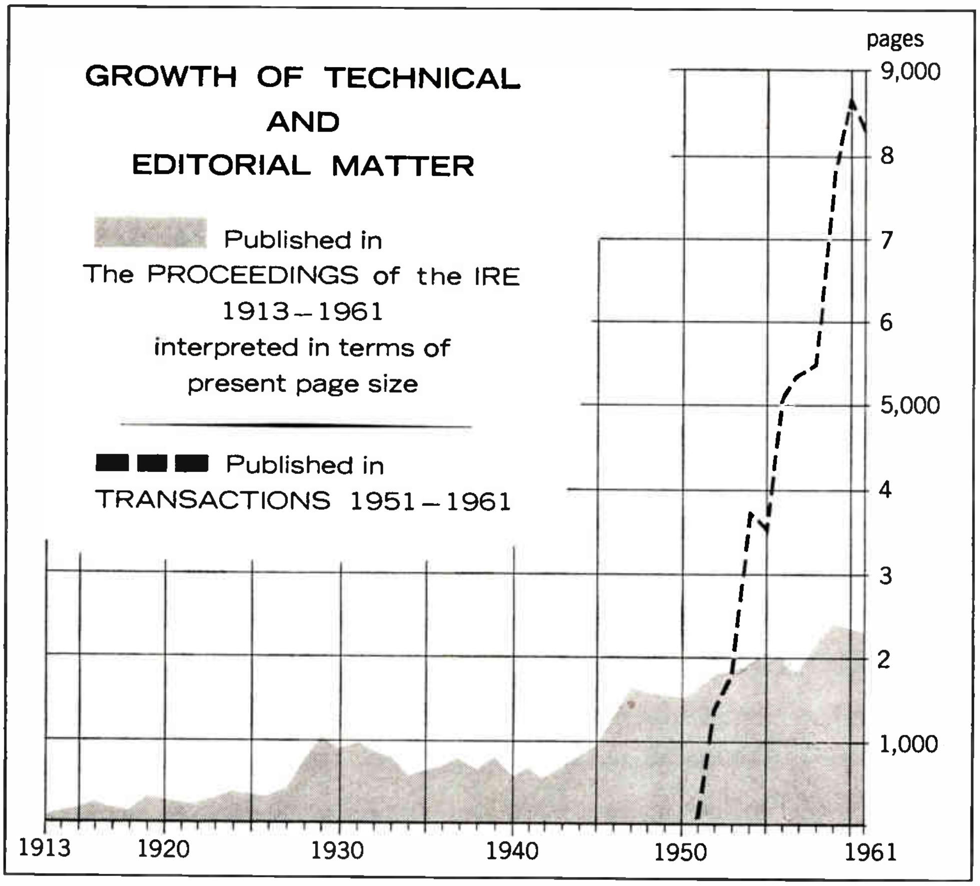

Fig. 2—Volume of technical and editorial matter published in the PROCEEDINGS and the TRANSACTIONS. The figures do not include advertising pages.

Many of the early papers were descriptive and not highly analytical. They dealt with important but broad subjects; they interested and concerned the whole field. All were readable.

Among other matters discussed in the PROCEEDINGS was a report by WJZ covering the period May 15, 1923 to May 1, 1924. In that time WJZ, then on top of the Aeolian Building, New York, and operating on 455 meters, broadcast 4325 events. Among them were the following:

Alto solos	3
Baritone solos	165
Bass solos	32
Contralto solos	104
Soprano solos	505
Tenor solos	159.

It is easy to see why engineers soon invented soprano killers which led, quite naturally, to the modern blab-off which makes television pleasant for many and possible for some.

It must not be supposed that all matters discussed in the PROCEEDINGS culminated in great advances; or that subjects once covered disappeared. Crystal detectors were in disfavor only to come into the limelight again after many years.

Whatever the eventual result, the work had to be done; something had to be studied, dissected, analyzed, reported, accepted or rejected. Even at this date, who is bold enough to say that the articles were not worth the paper to print them on?

The extraordinary growth of the Institute has, of course, occasioned or paralleled an equally great growth in the publication activities of the industry. While the nation as a whole was doubling in population (1910 to 1960) the Institute increased its membership by a factor of 40. For the first ten years IRE and its 2000-odd members produced approximately 300 pages per year. When the real and sustained rise in membership began in 1940, the 5000 members had nearly 600 pages per year to digest. Prior to this time, the pages of the PROCEEDINGS were small, constituting approximately 40 per cent of the word content of the present standard format.

The great leap in membership took place within the last ten years, attaining nearly 90,000 by the end of 1960. In the same period the publishing burden assumed by the Institute rose correspondingly (Fig. 2). In 1959 some 18,000 pages of text and advertising were written, edited, typeset, proofread and published. Over half of the editorial pages appeared in the TRANSACTIONS of the various 28 Professional Groups. Established in 1953, the STUDENT QUARTERLY contributed over 200 pages per year of readable and forward-looking articles.

From its very earliest days, the PROCEEDINGS under the editorial guidance of Alfred Goldsmith (IRE Founder, 1912, Fellow, 1915, Medal of Honor, 1941) educated its membership in the very forefront of the advancing art. Its standards were high; many papers probably written more for the benefit of the author than for the edification of the reader never saw the printed page. As the fledgling radio-electronics field grew from a purely empirical science to a highly sophisticated and analytical one, other journals more "practical" in nature found a niche and not only told their audiences what to do but how to do it. Few still exist, *Wireless Age*, *Radio Broadcast*, *Popular Radio*, *Radio Engineering* and others enjoyed editorially successful careers even if they were not too fortunate financially. Of the ancients, *Radio News*, *Wireless World* and *QST* continue, the latter being the *vade mecum* of the amateur and the engineer alike for many years and constituting the repository of numerous highly important articles, the results of experiments which proved more than once that all the technical brains are not bottled up in the great laboratories.

Although the audiences of the early journals were enthusiastic and often large, the publishing economics were not highly favorable. One journal, *Electronics*, begun in 1930 swam in tepid water for years and its editors, O. H. Caldwell (Fellow, 1944) and K. Henney (Fellow, 1943) were called on the carpet annually to explain why the magazine should not be thrown out the window. Yet they both saw the day (1956) when this journal published more pages of advertising than any other monthly magazine in the world.

The place of technical publishing in any industry as fluid, technically, as electronics is important and secure as a way of recording current events. What the historian of 50 years hence will think as he reads the pages of today lies completely in the realm of speculation; only one endowed with an excess of temerity would say today that much of what is printed is not worth the paper it is impressed on. In scientific circles, time has its own way of teaching the future-tellers to be careful.

Communication: A Responsibility and A Challenge*

ELEANOR M. McELWEE†, SENIOR MEMBER, IRE

Summary—**Throughout his career, an engineer has a responsibility to communicate the results of his work to four major audiences: his management, his colleagues, students or trainees, and the lay public. He must, therefore, be proficient in various forms of oral and written communication, ranging from simple conversations to formal reports and articles. To transmit information effectively, an engineer must have a complete understanding of his audience, his subject and his language. The Professional Group on Engineering Writing and Speech sponsors publications, meetings and workshops to help IRE members meet this communication challenge successfully.**

THE PROFESSIONAL responsibility of an engineer goes far beyond the mere obligation to keep himself informed of current developments in the industry which may affect his work. As his competence in his particular field increases, so too does his responsibility to make his own contribution to the body of knowledge which makes it possible for others to be informed. Thus, the successful engineer finds himself spending an increasing amount of time communicating what he has learned to the many audiences who have a right to expect to hear from him. Furthermore, he finds that his ability to express himself effectively—orally or in written form—becomes ever more important to his continued professional growth.

This paper, which is sponsored by the Professional Group on Engineering Writing and Speech (PGEWS), discusses the four major audiences with whom the engineer must communicate: management, his colleagues, students or trainees, and the lay public. It also describes the various methods or forms of communication which may be used for each audience, and outlines some of the activities of PGEWS which are designed to help engineers write and speak more effectively.

Reports to Management

An engineer's best and most interested audience is usually his own management. In today's rapidly expanding electronics industry, management has a vital

* Received by the IRE, January 5, 1962.
† Radio Corporation of America, Electron Tube Division, Harrison, N. J.

need to know and understand the results of research and development projects in many diversified areas. Because of the growing size and complexity of most companies, a manager generally must depend on his engineers to supply him with whatever information he needs. The reporting of such information is not only a fundamental responsibility of the engineer, but also a valuable opportunity to demonstrate the advancing status of his work, his understanding of its place in the company's over-all activities, and his ability to state things simply, clearly, and concisely.

Reports to management take many forms, ranging from simple conversation at one extreme, through conferences, memos, and letters, to formal engineering reports at the other extreme. Much of the reporting is oral, and most of it is rather informal. However, the formal engineering report deserves special mention here, if for no other reason than that it is used so much less than it should be.

The company that pays an engineer's salary certainly has the right to a written record of whatever results his work produces. All too often, however, valuable know-how is passed on from one generation of engineers to another by word-of-mouth only, with inevitable distortion and losses. The written report, when properly prepared, preserves engineering information in a useful, permanent reference source, and eliminates wasteful duplication of effort.

Professional Papers

The communications in which the engineer himself is usually most interested are the ones intended for his colleagues—for other equally experienced engineers working in his own or allied fields. In general, this category of communications is also the one of major concern to IRE because it encompasses the technical papers presented at the various national and local meetings and the articles published in the Proceedings, the Professional Group Transactions, and many of the Section publications.

Such professional papers enhance the reputation and prestige of the companies which employ engineers, as well as the status of the engineers themselves. In fact, in contributing such a paper an engineer discharges many responsibilities at once: to his company, to his professional society, to his colleagues, and to himself.

Education or Training

One of the most important communication responsibilities of the engineer is toward the engineering trainee or student. The electronics industry is advancing so rapidly in so many areas that information on the multitude of new developments can be made generally available only with the help of engineers closely associated with the actual work.

The engineer has a wide range of opportunities to discharge this obligation to trainees and students. The most immediate is, of course, the opportunity to train less experienced engineers working under his own direction. In many cases, the management of his company also makes it possible for him to participate in more formal training programs for engineers working in other activities. In addition, professional societies have a continuing need for qualified engineers to take part in lecture series, to talk to student chapters, and/or to write tutorial articles. Colleges, too, are in need of guest lecturers and of instructors for special courses.

Engineers can make a permanent contribution to the educational field by writing books. The "technical" departments of many of the large book publishing companies have long lists of subjects which they feel have not yet been adequately covered in book form. In most cases, they are more than willing to discuss prospective books with engineer-authors and work out a mutually satisfactory outline. This area of communication is perhaps the most rewarding to the engineer—personally, professionally, and financially.

Speaking to the Public

The most difficult, and consequently the most ignored, field of engineering communication is that addressed to the lay public, *i.e.*, the nontechnical audience. Too often this field is left entirely to "public relations" specialists whose technical knowledge may be inadequate to fill the need for complete, reliable, accurate, and easy-to-understand information. Newspaper reporters and magazine writers make a valiant attempt to serve as "middle men" between the engineer and the public, but their numbers are few and their information is necessarily limited by their separation from the actual work.

Engineers have a professional responsibility to promote understanding, and to prevent misunderstanding, of both their individual work and the profession itself. Particularly in the present "electronic age," it is increasingly important for the engineer to do his part to extend public knowledge of new developments and of engineering in general.

Opportunities for this type of communication may not be immediately apparent, but usually just the faintest indication of interest and availability brings forth invitations from various local civic, church, and business groups. Organizations such as the P.T.A., the Lions Club, the League of Women Voters, the Ladies Aid Society, and the Merchants Association are constantly looking for interesting speakers for their meetings. The engineer who takes advantage of such opportunities to communicate with his nontechnical neighbors performs an invaluable service to both his community and his profession.

Forms or Methods of Communication

The engineer who wishes to communicate with all these various audiences will, of course, use many different methods. In some cases, the communication will be oral, consisting of simple conversation with one or two others, conferences, panel discussions, informal talks to small groups, or formal lectures to large audiences. In other cases, the communications will be written, informally in letters or memos, or formally in reports, articles, or books.

Whether oral or written, however, the main purpose of engineering communications is to inform, not to impress. Some engineers mistakenly believe that formal papers call for long and unusual words, complex sentences and paragraphs, and a large quota of mathematical equations. Perhaps an engineer's simplest guide to what a good paper should be is his own reaction to those he hears or reads. An effective paper may well impress the audience, but the effect results from the engineer's achievements, not his vocabulary.

In all his communications, the engineer faces the challenge of transmitting knowledge from his own mind to those of his audience with minimum loss and distortion. To answer this challenge successfully, he must have a complete understanding of three important factors in the communication process: his audience, his subject, and his language.

An effective speaker or writer is always aware of his particular audience, and speaks to them on the basis of *their* knowledge and experience, as well as his own. He lets *their* interests and needs govern the length of his discussion, the amount of theory or detail he presents, and the language he uses.

To communicate effectively to any audience, the engineer must also know his subject thoroughly. In many cases, the actual preparation of a talk or article forces an engineer to take a broad, over-all view of his work—to place it in the proper perspective with regard to other developments, to organize his thoughts logically, and to do whatever additional work may be necessary to fill in gaps in his story.

An effective communicator is also thoroughly familiar with his language. His vocabulary is adequate to express even the most complex concepts simply, directly, concisely, and clearly. He uses language so skillfully that his audience is never aware of his individual words or sentences, but only of the information that they convey.

Well-prepared communications reflect the thought processes that are basic to both good engineering and objective reporting. When an engineer's thought processes are logical and disciplined, his comments are organized, accurate, factual, forceful, and clear. His communications are complete, but concise; thorough, but coherent; detailed, but understandable.

PGEWS

IRE took special notice of the engineer's responsibility to communicate just five years ago this month, when it approved the formation of a Professional Group on Engineering Writing and Speech (PGEWS). This Group was organized in the hope of improving the effectiveness, that is, the readability and the "listenability," of IRE publications and convention sessions. To date it has attempted to attain this goal by three types of activities: publications, meetings, and workshops.

Publications of the Group include a *Newsletter* which serves as an internal communication medium, TRANSACTIONS which include articles and book reviews, and *Symposium Proceedings* which contain all papers presented at national PGEWS meetings. The Los Angeles Chapter of the Group has also prepared a small eight-page booklet entitled "Techniques for Better Talks" which is distributed by IRE to all scheduled speakers for the Annual International Convention. Publication plans for the future include at least one new area of effort, the preparation of detailed instructional monographs which will cover various phases of the writing and speaking processes, as well as special aspects of various specific jobs.

PGEWS also sponsors its own national symposia, sessions at IRE national meetings, and local Chapter meetings. These meetings cover a wide variety of topics, ranging from basic principles of writing, editing, or speaking, to theoretical discussions on such subjects as information retrieval and automatic abstracting. Various formats are also used, including lectures, panel discussions, and formal debates.

Perhaps the most directly useful activity of PGEWS is the workshop type of program conducted by local Chapters. Because writing and speaking are skills to be mastered, rather than sciences to be learned from a book, both practice and criticism are essential parts of any training or improvement program. Local workship programs give all members of PGEWS an opportunity to increase their proficiency in oral, written, and graphic expression.

CONCLUSION

In the future, as in the past, the engineers who leave their mark on the profession will be those who recognize and accept their responsibility to share their accumulated knowledge with others; those who, having something to say, are willing to devote the necessary time and effort to saying it well to the right audience.

Section 15

HUMAN FACTORS

Organized with the assistance of the IRE Professional Group on Human Factors in Electronics

Human Factors in Electronics—Historical Sketch*

HENRY P. BIRMINGHAM†, SENIOR MEMBER, IRE

***Summary*—The growth of the new science dealing with man-machine relationships is traced from the first organized efforts during World War II to the present. The current rapid growth is underlined by the organization of professional societies, the largest of which is the IRE Professional Group on Human Factors in Electronics. The discussion includes reference to the several government, university and industrial laboratories which have pioneered in this field.**

ENGINEERS HAVE BEEN designing machines for human use since the start of civilization, and in doing this they have had to look closely at the man. In some instances only his physical structure and kinetic properties had to be considered, as was the case in the design of the screwdriver, the axe and the hand-saw. But often, as for example in the design of the automobile and the airplane, it was necessary to take into account more subtle properties. In these cases the engineer was required to consider not only the amount of force a man could apply, but also how quickly he could sense changes in energy and the way in which he responded to them.

However, during World War II, as the development of highly complex man-machine systems became commonplace, the need emerged for specialists in man-machine relationships. This has culminated in the start of an interdisciplinary science called variously biomechanics, engineering psychology, human engineering or human factors engineering. "Human factors engineering" has been popularly shortened to "human factors" and is the term generally applied to the science which is concerned with the characteristics of the human which are important in the design of systems.

* Received by the IRE, November 6, 1961.
† U. S. Naval Research Laboratory, Washington, D. C.

The new field has developed rapidly in the seventeen or eighteen years of its existence, and its importance has been recognized by the establishment of human factors groups within several of the older and larger professional societies including the American Society of Mechanical Engineers and the American Psychological Association. In 1956, a separate society, devoted to the new science, and called the Human Factors Society, was established.

In 1958, the Professional Group on Human Factors in Electronics was organized within the IRE with an administrative committee consisting of engineers who have been leaders in the new discipline. Assuming the continuance of existing growth curves, PGHFE, at the time of this publication, is the largest of these human factors groups. It is currently publishing Transactions on a semi-annual basis and has sponsored three annual human factors conventions.

The "human factors" approach to man-machine relationships emphasizes modification of the equipment to acheive man-machine compatibility, in contrast to the "selection and training" approach which attempts to fit the man to the machine. It was during World War II that such modifications of machine design was first applied on a large scale by people who became specialists in these relationships. Of particular significance during this early period was the work conducted under the National Defense Research Committee, exemplified by research on problems in anti-aircraft fire control at NDRC—project N-111 under Dr. William Kappauf. At the same time, in Great Britian and in Germany work was beginning on similar problems. It is of interest to observe that whereas in the United States and Great Britain this work was carried on primarily by engineers and psychologists, in Germany it developed under the Medical profession.

In the period immediately following World War II, growth of the young science continued in the Military and Industrial areas and in the Universities. In 1945, a human engineering group was established at the U. S. Naval Research Laboratory in Washington, D. C. by Dr. Robert M. Page. The group was headed by the late Dr. Franklin V. Taylor. At about the same time, a group at the U. S. Air Force Aeromedical Laboratory in Dayton, Ohio, also began work in research and design under Dr. Paul M. Fitts. It was not until a few years later that groups dealing in the new science were established in industrial laboratories. Early industrial groups formed include one under Dr. John Karlin at the Bell Telephone Laboratories, Murray Hill, New Jersey, and another under Dr. Stanley Roscoe at the Hughes Aircraft Company, Culver City, California.

Today, there is hardly a large industrial concern which does not boast at least one human factors group. Some, such as General Electric, have several. There are many in the various laboratories of the Department of Defense, and there is little reason to believe that the new scientific area has reached the end of its growth.

For the near future, a greater increase is seen in the interest of engineers, physicists and mathematicians in human factors engineering. Increasing numbers of young graduates in these fields are taking positions in human factors organizations with the intention of making this field their career.

It is expected that problems and approaches in the future will be largely in the systems area, and will call for knowledge of engineering, physics, mathematics and psychology on the part of all its workers, regardless of their primary field of education.

The Man-Machine System Concept*

D. T. McRUER†, SENIOR MEMBER, IRE, AND E. S. KRENDEL‡, SENIOR MEMBER, IRE

Summary—**The man-machine concept as developed in this paper refers to a closed-loop control system comprising a machine and an actively participating human operator. The human component attributes are described with both general and specific engineering models. Particular emphasis is placed on the human adaptive characteristics which make for an unusual control system.**

Predictive behavior is discussed in terms of actual-physical and conceptual-effective display organizations resulting in compensatory, pursuit, and precognitive system organizations. Adaptive-operator transfer characteristics are presented, and applications of the adaptive model for random-input compensatory system design are listed. As an example, the model is used to estimate operator and system characteristics for a specific system, and the estimates are compared with experimental results derived from associated empirical data. In a discussion of performance assessment, the basic attributes which any criterion for system performance should possess are reviewed, and a *modus operandi* for manual control system performance assessment is proposed.

Introduction

IN THE BROADEST sense, the man-machine system concept encompasses all the interactions between human and mechanistic elements when these elements are united into a system. However, as treated here, the concept refers to a system comprising a machine and an actively participating individual man. Central to the man-machine system concept in this context is the specification of human skills under circumstances where man's mechanical outputs serve as machine inputs, and machine outputs are among the inputs to the human. Historically, descriptions of human skills evolved by engineers were reflections of the then current state of technology. Early man-machine systems used man primarily as a power source, and descriptions of man were couched in such terms as "engine efficiency" and "duty cycle." With the rising importance of control devices, the language and techniques of control engineering have become increasingly appropriate for describing human skills. As the coupling of men with data-processing devices becomes increasingly critical for effective man-computer symbioses, perhaps even more effective communications and computer engineering descriptions of man will evolve.

Those human contributions to a control system which make manned control systems most desirable are unfortunately the very contributions most difficult to describe in conventional engineering terms. Such human component attributes as judgment, multimode capability, and adaptability make for a remarkable control system. Of these, human adaptability is the attribute which can most nearly be described in engineering terms. Within the confines of the physical constraints

* Received by the IRE, July 5, 1961; revised manuscript received, November 24, 1961.

† Systems Technology, Inc., Inglewood, Calif.
‡ The Franklin Institute Labs. for Research and Development, Philadelphia, Pa.

present in a given application, human adaptability includes:

1) Organization of the system structure.
   a) Selection and use, as feedback quantities, of those sensible machine outputs best suited for control purposes.
   b) Setup of an internal organization (equivalent to the construction of several signal-processing paths within the human) which effects highly efficient use of any coherence in the presented stimuli (system forcing function and feedbacks).
2) Adjustment, within the system structure as organized, of transfer characteristics to forms appropriate for control.

The attributes of judgment, multimode behavior, and adaptability in a control system component allow the design of systems of great reliability and versatility. By using judgment, the man can evolve and modify performance criteria, select relevant inputs, decide between programmed and impromptu responses, and so forth. A multimode capacity enables the man to implement different modes of behavior and thus to effect the diverse requirements which judgment may dictate. To design such control systems, engineering descriptions of the critical component, man, are needed.

As descriptions of man improve, at least three desirable effects will result: the synthesis of better man-machine systems will be possible; fruitful new insights into the mechanistic inner-working of man will evolve; and, since man is the archtype adaptive controller, potent analogical insights for new automatic adaptive controllers will emerge.

Implementation of the Man-Machine System Concept

Implementing the man-machine system concept implies that the techniques and data necessary to synthesize a desirable system are available in a convenient form. The generalized model of Fig. 1, which illustrates the variety of human adaptability listed above, defies description in terms of present-day analytic techniques. Perhaps the only means for describing the contents of Fig. 1 in a quasi-analytic sense would be to generate an elaborate catalog of cause-and-effect relationships. Science and engineering make progress, however, by simplifying their object of study so that a succinct catalog of cause-and-effect relationships is feasible, and then expanding this kernel of knowledge by successive elaborations. Thus, if the system is restricted by design to include only the path indicated by the heaviest line in Fig. 1 (redrawn as Fig. 2), the result is a rudimentary system which is fundamental to many man-machine applications, convenient for measuring a large amount of human dynamics data, and suitable for subsequent elaboration. In this compensatory system, the forcing function and controlled-element are fixed. The human's internal organizing ability is suppressed by providing Gaussian or otherwise random-appearing inputs, thus making the organization of both the physical and the effective system structures identical. Within this fixed system, the human is characterized by a describing function and remnant[1] achieved by measuring a smoothed-over view of the control process via cross- and power-spectral densities.[2,3] Generalization beyond the fixed parameters is accomplished by empirically determining analytical models and adjustment rules for Y_p and Φ_{nn} as functions of the constraints imposed by the other system elements.

As an alternative to the describing function technique, the experimenter can pit his skill as a computer specialist against the problem.[4–6] This results in the selection of useful analog computer mechanizations to simulate the human operator in a constrained control task. The criterion for goodness of simulation can be visual, for a point-to-point correspondence; best in a mean-square sense; or best according to other tests for goodness of fit. The analog model is more difficult to generalize for other system situations than analytical approximations to the describing function plus remnant data. However, human time-dependent effects and such nonlinearities as can be generated on an analog computer are more easily measured directly using simulation methods, although these effects are implicitly contained in describing function and remnant measurements.

As in most nonlinear system studies, an intermix of describing function and computer simulation models is appropriate. Their application is somewhat unconventional, because any description of human control dynamics requires that the measurements generated include the gross variability inherent in sampling human behavior. Such variability imposed by the nature of the human subject can be minimized by the nature of the task, as well as by stratifying the subjects according to levels of skill, experience, or other criteria.

Engineering Models of Human Behavior

The most complete engineering model for human behavior has been developed for the compensatory, random-appearing forcing function situation described by Fig. 2. When averaged data generated by different experimenters are brought together and generalized, a

model for human dynamics consisting of two essential elements emerges:[7–9]

1) A generalized describing function form.
2) A series of "adjustment rules" which specify how to "set" the parameters in the generalized describing function to form an approximate model of pilot behavior for the particular situation considered.

Fig. 3 illustrates a detailed model of this generalized describing function; some nonlinear and internal feedback features are not included, and no effort has been made to describe neural conduction in physiological detail. This detailed model is based not only upon spectral measurements of the form noted in Fig. 2, but it also reflects data from psychological and physiological experiments on various human "subsystems." The block diagram components do not necessarily correspond to physical elements within the human, but the structure shown is the minimum required to exhibit equivalent behavior on even a quasi-linear basis over the frequency range from zero to 5 cps.

This model applies only when the operator cannot effectively restructure the physical system. Consequently, while providing simplicity of analysis, the measurement situation of Fig. 2 also obscures the extent to which the human can take advantage of the coherence and predictability which may be present in the forcing function. For predictable aspects of the forcing function to be detected, the forcing function must be readily distinguishable from the control responses which the operator makes. Furthermore, for predictive behavior to be most effective, the human must have a preview of the forcing function so that he may prepare his response in advance. As an analogy, consider the steering of an automobile over a winding road. The speed of the vehicle and the bends in the road define a system forcing function. When visibility is clear and the road is flat, it is possible to predict the steering actions well in advance, and to proceed for intervals of time in an essentially open-loop fashion. Were the road hilly and the visibility poor, the driver would be able to predict the curves for only a short distance, and he would have to maintain closer control of his vehicle. Finally, if a dense fog closed in on the driver, so limiting his visibility that he could only see his hood ornament and the white center line of the road a few feet ahead of his vehicle, prediction would be extremely difficult, and the driver would be tracking an essentially compensatory display (as presented in Fig. 2). These three conditions, which merge at the boundaries, can be idealized in the precognitive, pursuit, and compensatory organizations subsumed by Fig. 1.

The compensatory, pursuit, and precognitive "displays" given physical meaning above can also be thought of as effective system organizations which result when the human learns to distinguish and to act upon predictable elements in the forcing function.[10] It is this ability to construct a succession of conceptual displays, which are effectively equivalent to more elaborate and often unfeasible physical displays, which constitutes adaptation to the input. These successive organizations of perception in terms of effective displays provide a model for the learning of motor skills and give the design engineer an upper limit for possible human performance in a tracking task.

[7] A complete summary, interpretation, and correlation of all data available to 1957 appears in D. T. McRuer and E. S. Krendel, "Dynamic Response of Human Operators," Flight Control and Aeromedical Labs., Wright-Patterson AFB, Dayton, Ohio, WADC TR 56-524; October, 1957.

A condensed version is given by these authors in "The human operator as a servo system element," *J. Franklin Inst.*, vol. 267, pp. 381–403, May, and pp. 511–536, June, 1959.

[8] Data generated after 1957 are presented in the same context as above in D. T. McRuer, I. L. Ashkenas and C. L. Guerre, "A Systems Analysis View of Longitudinal Flying Qualities," Flight Control Lab., Wright-Patterson AFB, Dayton, Ohio, WADD TR 60-43; January, 1960.

[9] A summary of quasi-linear operator models developed prior to 1956, with emphasis on psychological aspects, is J. C. R. Licklider, "Quasi-linear operator models in the study of manual tracking," in "Developments in Mathematical Psychology," R. D. Luce, Ed., Free Press of Glencoe, Ill., pp. 169–279; 1960.

[10] E. S. Krendel and D. T. McRuer, "A servomechanisms approach to skill development," *J. Franklin Inst.*, vol. 269, pp. 24–42; January, 1960.

Human adaptation to a control task may also occur by the selection of the most effective feedback paths (Fig. 1). Although this form of adaptation has not been submitted to as extensive a measurement program as has adaptation to controlled-element or adaptation to the input, it nonetheless holds great promise for future research in that it may define a clear-cut engineering basis for the design of complex displays.

Performance Assessment

The choice of criterion is the essential problem in the assessment of any control system. However, in a man-machine system the human component adds a new dimension to the evaluation of system performance, since the human is both an adaptive-operational device and a measuring device.

The basic attributes which any criterion for system performance should possess are reliability, ready applicability, and selectivity; and for control systems with deterministic inputs, criterion forms which possess each of these characteristics to a sufficient extent can readily be selected.[11] However, when Gaussian random inputs are used, "optimum" linear systems based upon minimization of the mean-squared-error are substantially the same as "optimum" systems derived by using non-mean-squared-error criteria.[12] Time-weighting and other devices to improve selectivity are usually not applicable, and such criteria as time-on-target are difficult to relate to system and forcing function characteristics. For these and other reasons, the performance measures ordinarily used for assessment of continuously operating man-machine systems are $\overline{\epsilon^2}$ or the closely related $\overline{|\epsilon|}$.

Unfortunately, for constant forcing function characteristics, human adaptability renders the mean-squared-error particularly unselective as a system performance measure. The human tends to maintain a fairly constant mean-squared-error by modifying his dynamics to compensate for changes in the controlled-element dynamics. Ideally, man-machine system assessments would combine two features: system performance, as measured by an average such as $\overline{\epsilon^2}$, and insight into how this performance is achieved by the system. When detailed measurements of describing functions are possible, they can serve the second purpose. An alternate procedure is the use of expert evaluations, as in pilot opinion ratings, to give a single, over-all measure. When tightly constrained situations are imposed upon the human controller, and several competing systems are to be compared, such expert ratings exhibit far less variability and unreliability than might be expected from common experience with routine opinion polls. Indeed, recent work has shown that the basically subjective expert ratings can give surprisingly objective indications of both over-all system performance and the operator describing function generated; this work has also shown that the man can rank, in a highly reproducible and valid manner, the system he controls in terms of these objective characteristics.[8] Thus, either human response measurements or expert operator differential ratings which are highly selective, are useful adjuncts to the more conventional, but less selective, average performance measures.

Applications of Human Behavior Models

All the ramifications of the general model in Fig. 1 have been used for design purposes; the simplest to illustrate in analytical application is the specialized model (Fig. 3) which applies only to compensatory situations. For most system studies, a simpler form (Fig. 4) is adequate to describe the system low-frequency (0–1.5 cps) characteristics. Here the adaptive features—the human's prime virtue as a system component—are separated from the relatively unalterable characteristics. Prominent among the latter is the reaction-time delay τ, which is ordinarily the dominant human-con-

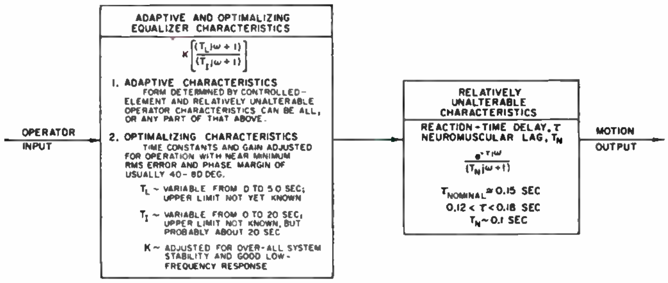

Fig. 4—Condensed version of human operator model for compensatory operation.

tributed liability in a manual control system. To estimate operator behavior in a given task, the adaptive equalizer characteristics are adjusted to values similar to those a servoengineer would select if he had the equalization $K(T_L j\omega+1)/(T_I j\omega+1)$ available to compensate for and close the loop about process dynamics comprising the unalterable operator characteristics in series with the controlled-element transfer function. When the resulting gain crossover frequency ω_c is greater than the effective system forcing function bandwidth ω_i, and when any dominant closed-loop system quadratic mode has a damping ratio ζ_{CL} greater than 0.35, these estimated operator transfer characteristics will be a reasonable approximation to experimentally obtained values. If either $\omega_i > \omega_c$ or $\zeta_{CL} < 0.35$ result, the actual operator describing function form will differ from the model characteristics; the operator will generate higher-order leads (in a generally unsuccessful attempt to make $\omega_c > \omega_i$), and will exhibit erratic nonlinear behavior.

The adaptive model for random-input compensatory systems described above is useful for many different an-

[11] D. Graham and R. C. Lathrop, "The synthesis of 'optimum' transient response: Criteria and standard forms," *Trans. AIEE*, vol. 72, pt. 2, pp. 278–288; 1953.

[12] S. Sherman, "Non-mean square-error criteria," IRE Trans. on Information Theory, vol. IT-4, pp. 125–126; September, 1958.

alytical purposes in manual control design. For example, it has been used to:

1) Estimate human and over-all man-machine system response and performance when the system forcing function and controlled-element dynamics are known.[7,8,13]
2) Determine the barely uncontrollable controlled-element dynamics and controllability boundaries.[8,13,14]
3) Find the maximum forcing function bandwidth compatible with reasonable control action on the part of the human.
4) Indicate the type of additional system equalization (to be achieved via the display, in the control system, or by controlled-element modifications) desirable to achieve best manual control in the sense of minimum operator-equalization requirements.[15,16]
5) Determine desirable machine outputs (for multi-degree-of-freedom machines) for feedback to the display.
6) Delineate those features of the machine dynamics which are most important from a vehicle-handling-quality standpoint.[8,13,14]

The analysis of compensatory manual control systems can be approached in much the same way as that for ordinary automatic-feedback systems. As a simple example, typical system performance predictions based upon the adaptive-operator model will be illustrated for the control system shown in Fig. 5. The operator-adapted describing function for control of the pure gain controlled-element will be

$$Y_p \approx \frac{K_p e^{-j\omega\tau}(T_L j\omega + 1)}{(T_I j\omega + 1)(T_N j\omega + 1)} \approx \frac{K_p e^{-0.15 j\omega}}{(T_I j\omega + 1)}. \quad (1)$$

In (1), the lag time constant T_I will be much greater than the lead time constant T_L to achieve good low-frequency closed-loop system response; and T_L will be adjusted to approximately cancel the neuromuscular lag T_N. With the simplified form of (1), the phase margin ϕ_M is

$$\phi_M = \pi - \tan^{-1} T_I\omega_c - \tau\omega_c. \quad (2)$$

[13] I. L. Ashkenas and D. T. McRuer, "The Determination of Lateral Handling Quality Requirements from Airframe Human-Pilot Systems Studies," Flight Control Lab., Wright-Patterson AFB, Dayton, Ohio, WADC TR 59-135; June, 1959.

[16] H. P. Birmingham and F. V. Taylor, "A design philosophy for man-machine control systems," Proc. IRE, vol. 42, pp. 1748–1758; December, 1954.

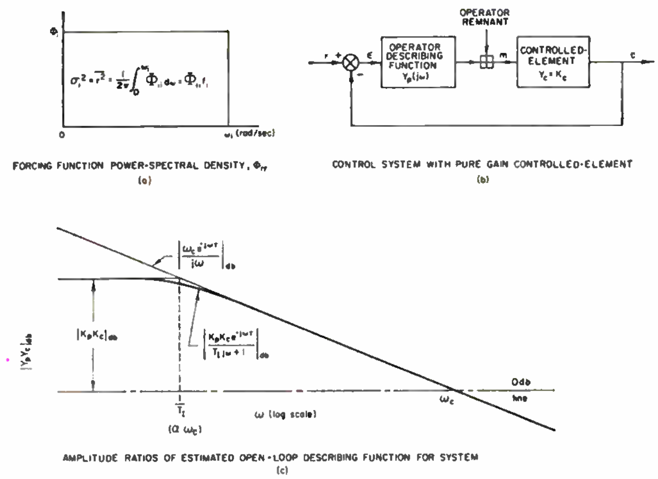

Fig. 5—Given and estimated characteristics for manual control system with $Y_c = K_c$.

Since $\omega_c \gg 1/T_I$ for good closed-loop system response, (2) becomes, approximately,

$$\phi_M \approx \pi - \left(\frac{\pi}{2} - \frac{1}{T_I\omega_c}\right) - \tau\omega_c.$$

Letting $\alpha = 1/T_I\omega_c$,

$$\omega_c \approx \frac{1}{\tau}\left[\frac{\pi}{2} + \alpha - \phi_M\right] \quad (3)$$

This relationship is shown in Fig. 6 for a phase margin of 40 degrees. Three values of τ are used to bound this parameter, or alternatively, to take into account slight phase margin shifts, for a nominal τ value, from the 40 degrees assumed. Any value of α less than 0.1 is compatible with good closed-loop system response, so an $\alpha = 0.1$-line provides the final boundary of a probable crossover frequency region. Using the middle of the region, the estimated crossover frequency will be approximately 6 rad/sec. This estimated crossover will remain approximately the same for all forcing function bandwidths less than 6 rad/sec. When the forcing function bandwidth exceeds 6 rad/sec, the describing function form will be modified drastically from that of (1) to one exhibiting far more lead, and the system low-frequency closed-loop response will be poor. Thus, the estimated crossover frequency is not only an important system response parameter for $\omega_i < \omega_c$, but it also gives the maximum forcing function bandwidth compatible with reasonably good system response.

As long as $\omega_c \gg 1/T_I$, an open-loop system describing function given by

$$Y_pY_c \approx \frac{\omega_c e^{-j\omega\tau}}{j\omega} \quad (4)$$

is suitable to estimate closed-loop system characteristics with little error. If operator remnant is ignored, the

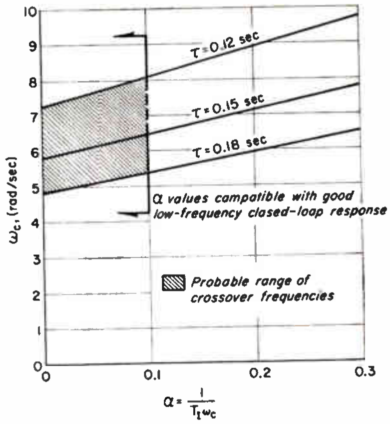

Fig. 6—Crossover frequencies for 40 degrees phase margin.

mean-squared-error, using this simplified form, will be

$$\overline{\epsilon^2} = \frac{1}{2\pi}\int_0^{\omega_i} \Phi_{\epsilon\epsilon}(\omega)d\omega$$

$$= \frac{\Phi_{ii}}{2\pi}\int_0^{\omega_i} \frac{\omega^2}{\omega^2 - 2\omega\omega_c \sin \omega\tau + \omega_c^2} d\omega. \quad (5)$$

Since $\sin \omega\tau \approx \omega\tau$ for $\omega < \omega_i$, the relative mean-squared-error becomes

$$\frac{\overline{\epsilon^2}}{\sigma_i^2} \approx \frac{1}{(1-2\omega_c\tau)}\left[1 - \frac{\omega_c/\omega_i}{\sqrt{1-2\omega_c\tau}} \tan^{-1}\frac{\omega_i}{\omega_c}\sqrt{1-2\omega_c\tau}\right] \quad (6)$$

or

$$\frac{\overline{\epsilon^2}}{\sigma_i^2} \approx \frac{1}{3}\left(\frac{\omega_i}{\omega_c}\right)^2 \quad (7)$$

if the arctangent is carried only to the third term in its expansion.

The various operator and system characteristics estimated above are compared in Fig. 7 and Table I with experimental results derived from data originally obtained by Elkind.[17] The major difference between the analytical and experimental operator models is the experimentally observed variation of T_I with ω_i. This is significant for fine-grained operator descriptions (for example, the observed T_I, ω_i variation gives credence to a more refined version of the model in Fig. 3 containing nonlinear elements enclosed by an internal feedback structure), but it is not extremely important for preliminary design calculations.

This elementary example illustrates pragmatically the major conclusion of this paper: that man, acting as a control system component, *can be* described in useful engineering terms.

Communication Between Man and Machine*

J. E. KARLIN†, MEMBER, IRE, AND S. N. ALEXANDER‡, FELLOW, IRE

Summary—**The inclusion of computer-based assemblies into man-machine complexes has enhanced the relevance of characteristics of the human link in the system. In particular, the virtues and limitations for transmission of information among the physical subsystems through a human channel is an important consideration in systems design. The current status of the supporting research for this area is briefly summarized. The related but more recondite area covering communication between man and computer is also important to the effectiveness of man-machine complexes. However, supporting research for this area is meager and most of it is contained in engineering psychology studies pertinent to the needs of specific systems. Research facilities more appropriate for the exploratory needs of both areas are becoming available and these presage the broad intensive programs needed to provide research guidance to the systems design of man-machine complexes.**

Introduction

THIS PAPER will consider two basic aspects of communication between men and machines:

Part I: Man as a transmission channel with short-term information storage properties, and

Part II: The relation between man and computer.

We will discuss basic problems and principles rather than summarize design information. The latter is quite voluminous and is readily available.[1-5]

Part I: Properties of the Human Transmission Channel

The general problem, diagrammed in Fig. 1, concerns the transmission of information between two points in a physical system via the human channel. Three aspects of the human channel will be considered: input, output and input-output compatibility. The principal discussion will be of the input.[6]

Input and Output

What are the important properties of man's input (sensory end organs) and output (motor end organs) which determine the design of the machine input (display) and output (control) for optimum information transmission?

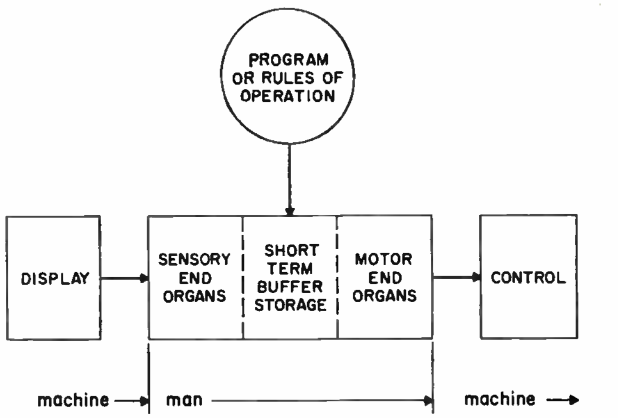

Fig. 1—Man programmed through rules of operation for "one to one" transmission where output and input information should be identical if transmission is perfect.

Input-Output Compatibility

In certain cases optimum matching of devices or circuits to man's input and output characteristics depends on a particular compatibility relationship between the two.

The discussion of these three aspects will be restricted on two scores: 1) to simple "one-to-one" information transmission and processing situations which involve only man's short-term buffer storage properties—long-term storage and information transformation are taken up in the next section on computers, and 2) to open-loop situations where man's output is not fed back to modify signals to his input. The feedback problem is taken up in a companion paper in this issue.[7]

Input Properties

Unidimensional Displays (for a single signal)

In a man-machine system the input to the man is often a single light or a sound, chosen from an ensemble of lights or sounds and invariant over its duration and spaced at relatively long intervals, where there is no premium on his speed. Where the signals in the ensemble differ only in one dimension, like frequency or amplitude, the capacity of the human channel for transmitting information is very limited—of the order of two to three bits. For example, as shown in Fig. 2, untrained

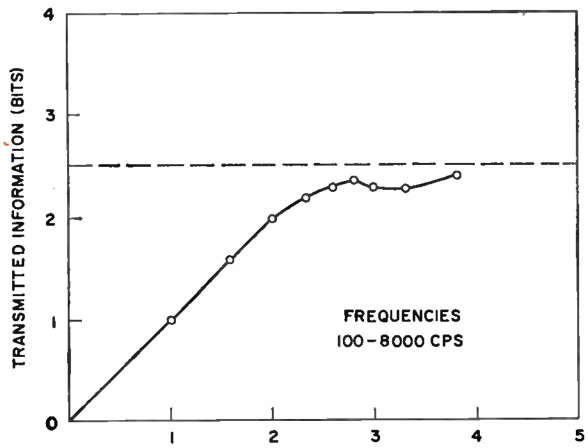

Fig. 2—As the amount of input information per signal is increased by increasing from 2 to 14 the number of different frequencies to be identified, the amount of transmitted information approaches, as its upper limit a channel capacity of about 2.5 bits per judgment.

man can no longer identify a single pure tone accurately if it can assume more than about six values of frequency over the audio range. The same limitation on "absolute" discrimination holds for intensity of tone, visual position of a pointer on a line and color hues.[8] This small number of bits tends to be constant for all of man's sensory inputs for signals presented singly and differing only in a single dimension.

It is evident in everyday situations that the human channel can transmit considerably more than this handful of bits. Three variables have been studied experimentally to provide better understanding of the problem of increasing such transmission of information: more complex single signals (multidimensional displays), sequence bursts of signals and multiple sensory inputs.

Multidimensional Displays (for a single signal)

A two-dimensional display normally results in the human channel transmitting more information than from a one-dimensional display but typically less than the sum of the information in both dimensions. For example, a tone with 2.5 bits of pitch information and 2.3 bits of loudness information results in only 3.1 bits being transmitted through the human channel; similarly a dot in a square gives 4.6 bits rather than twice the 3.5 bits from a dot on a line. In general, as Fig. 3 shows,[8] the proportionate gain in human channel capacity diminishes as the number of display dimensions increases; the upper limit to this kind of single signal transmission still appears to be small, something less than 10 bits. Furthermore, the human being requires more and more training to benefit as the dimensionality is increased.

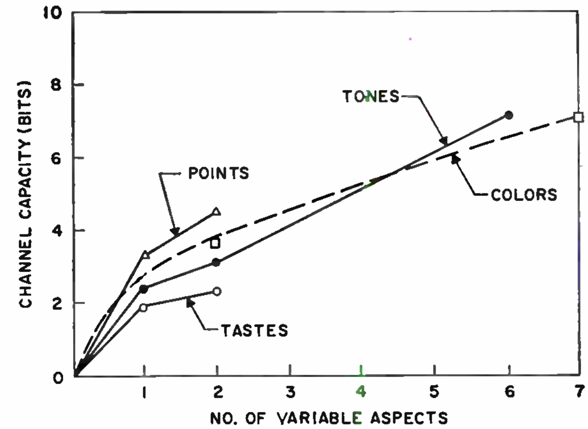

Fig. 3—The general form of the relation between channel capacity and the number of independently variable attributes of the signal.

Sequential Displays

Transmission through the human channel can be increased by the use of a signal burst input. The limit to such an increase depends primarily on the time elements involved and the decay properties of the human buffer storage.

How much information can be transmitted by the human channel in a signal burst? In classical psychology this limit has been linked with the span of immediate memory. As Fig. 4 shows, it turns out that almost regardless of the code or information content of each signal this limit remains in the region of 5 to 9 signals.[8] It can be seen that after looking at or listening to a sequence of letters or digits or words the average man can call back only about seven. Although this number of signals tends to be invariant, the amount of information transmitted through the human channel depends on the code and increases as the information content of each signal increases.

The limitation in information transmission for a burst does not appear to be imposed by the sensory input of the human channel but rather by the decay properties of the buffer storage and possibly the interference set up by the motor output action. It has been demonstrated, for example, that when a random sequence of 18 letters is presented to the human channel almost all 18 (between 70 and 80 bits) enter the channel even though only the 6 or 7 (about 30 bits) permitted by the memory span can be called back.[9] The rest are presumed lost through decay in his buffer storage while he is calling back the letters; this decrement is shown to occur within one second, as shown in Fig. 5. In this technique the man is exposed to the 18 letters (6 groups of 3) for 0.05 sec and then calls out one group of three consecutive letters where the group is identified at random immediately *after* the termination of the signal. The number of letters read out correctly is mul-

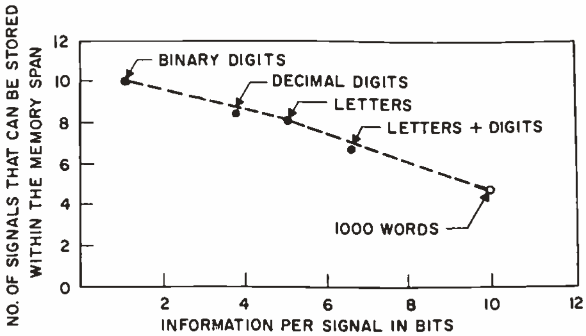

Fig. 4.

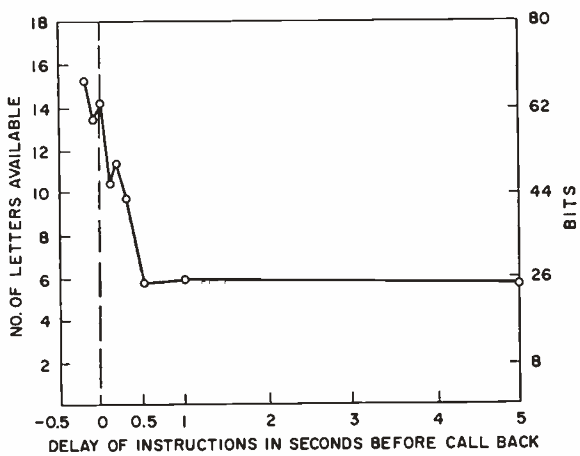

Fig. 5.

tiplied by 6 and this estimate, on the average, represents the information reaching the buffer store.

How fast can information be transmitted by the human channel? This is difficult to measure. In the preceding experiment it would appear that about 70 bits reached the input short-term store as a result of the 0.05-sec signal and that any part of this information is available to the human channel for immediate readout. However, the amount available decreases to an asymptotic value of less than 30 bits within a second.

Output and Input-Output Compatibility Properties

Data on man's output properties and the effect of input-output compatibility[10] are still quite meager. The references cited in this article summarize the information available. The most efficient form of output is probably speech rather than hand movement both because vocal movements are more rapid[11] and accurate and because speech signals are very familiar and contain a large number of bits per signal. However, the availability of machines responsive to voice signals is still very limited.

Multiple Sensory Inputs

Attempts to increase information flow through the human channel by using multiple sensory inputs have not been very fruitful. Optimizing transmission through a single input has shown better results. Perhaps of more importance to systems designers is the situation where the human channel is forced to respond to two message sources in parallel. In such cases some help can be obtained by having the sources feed different sensory inputs.[6]

Over-all Human Channel Capacity

What is the upper bound to human channel capacity? It was pointed out above that 70 bits of visual information presented for 50 msec to the eye are immediately available for readout. This suggests that the storage rate of the input may be considerably above 70 bits per second. However, it was also pointed out that this availability diminishes considerably within one second and, indeed, most measures of the output rate have shown a figure between 10 and 40 bits per second.[12] The highest rates have been in connection with the reading of words.[13] The limitation is apparently in the processing of the input information rather than because of mechanical output speed. For sustained communication beyond a few seconds the practicable rates for most human activities have been closer to 10 bits per second than to 40.[12] What happens when the human channel is overloaded has been studied in a number of experiments.[14]

Finally, the human channel has highly developed properties for resolving differences between signals. Two signals presented within a fraction of a second of each other can be discriminated with 1 per cent or less of the difference required for identification when presented singly under the same conditions.[6] Transmission through the human channel should be improved very considerably if ways could be found to use such "relative" information in displays.

Part II. The Relation Between Man and Computer

The foregoing summary of current information about human channel capacity in the simple communication chain shown in Fig. 1 must be interpreted carefully in shifting from laboratory environments to operating man-machine systems. While the theoretical measure of the information being transmitted during experiments may be held fixed, the way in which the human transforms the format of this information can not be disre-

garded in an operational environment. His ability to filter out or abstract the designated information from a rich sensory pattern is dependent upon prior conditioning or learning. In terms of the model of Fig. 1, a significant element of "programmed response" is employed in filtering and converting the input sensory pattern into the format for an output response. This provides opportunity for subtle inclusion of prior information derived from his long-term memory which is associated with the "programmed response." This effect may distort the communication experiment, but often it is the source of enhanced operational performance that justifies use of a human link in the communication chain. An example is the way in which subjects cope with occasional informational overload.[14,15]

Man-Machine Communication: Programming

Thus far, only the characteristics of the human link as a combined information filter and format converter have been considered. Other characteristics of this link are brought into play when the man-machine communication involves an interchange of data and systems-status information as part of their joint performance of a unitary task. This broadened "communication" can take the form of a coherent set of instructions for the computer, known as programming. Since this quickly becomes a demanding form of communication, a succession of synthetic languages for improving such communication is evolving and these are the subject of a companion paper.[16]

The way programming is presently being accomplished, the concept of "reaction time" is inapplicable, but it does have meaning for the "real-time" interchanges of information that can occur between man and machine after the programs are in the computer. The scanty literature that is available conveys the unjustified impression that effective real-time interchange has been realized. This overstates the current situation, and the level of accomplishment is better characterized as "mechanically extended man."[17] Current efforts to introduce automation into air traffic control tend to follow this pattern, as did earlier studies for applying radar aids.[2]

There are a few instances in which the intent is to use the man more as a systems monitor and decision maker and less as a conventional systems operator. The first serious effort along these lines appeared in the man-computer communication features of the Air Defense System.[18] As this trend grows, so will the appetite for research results that bear on how to better accomplish man-machine communications. The journal literature presently offers limited resources to meet such demands.[19] To date research information is sparse and it is usually imbedded in informal documents intended to report on the over-all performance of a particular system.

General vs Specific Systems Research

The potential yield from engineering psychology investigations that are independent of particular systems have been handicapped both by the lack of sufficient theory to guide the research and by the inadequacy of tools for conducting such research.[20] With respect to the latter, appropriate research facilities are beginning to make their appearance.[21,22] However, most of the contributions will continue to flow from the experience with specific man-machine complexes in which different distributions of the functions between the man and the machine are attempted. In this connection, Licklider has pointed up some thought-provoking extrapolations for enhancing the power of such man-machine combinations.[17]

An Example: Key Sort and Code Sort Systems

By comparison with the complexities of air defense and traffic control systems, schemes for automating the sorting of letter mail[23,24] show a far simpler pattern of man-machine relationships. Consequently, the human factors considerations can be more readily related to reported research results. Benjamin Franklin did the original human factors studies for the manual sorting system which is only just now being challenged by two approaches called Key Sort and Code Sort.

Key Sort is an example of "mechanically extended man" in that it removes the limitation of the manual system of giving efficient access to only 80 sorting bins and extends it to well over 300 bins. These systems require that the operator memorize the sorting scheme relationships which define the way in which the address on the letter determines the distribution into the bins. However, the operator of a Key Sort System must memorize a larger fraction of the relationships for the total scheme if this mechanical extension is to be effective.

The man-machine communication in Key Sort con-

forms partly to the model in Fig. 1. It departs from the model in that the operator is required to perform a conversion of the information content perceived in the address on the mechanically displayed letter before his handkeying operation conveys this converted information to the sorting machine. The conversion uses the scheme knowledge stored in the operator's long-term memory, and this "programmed response" serves a purpose similar to that of looking up a number in a telephone directory. Although some relevant psychological investigations have been reported, these now need to be supplemented by more specific investigations.

The Code Sort approach provides the assistance of an electronic directory that relieves the operator of the need to memorize any part of the sorting scheme. He initiates a lookup in the electronic directory for use by the sorting machine through keying in an abbreviated form of the perceived address. His long-term memory is called upon only to supply an appropriate abbreviation rule rather than to recall scheme relationships. Because the time and effort required to think through abbreviation rules are greater than the time and effort required to remember frequently used abbreviations, the operator will tend to memorize frequently occurring ones. Since the operator can always revert to the abbreviation process whenever presented with an unfamiliar address, the proportions of the two modes of action will depend on the extent of the operator's training and the occurrence of familiar addresses among the letters.

Doubtless there are other versions of the automatic electronic directory which might benefit from the contributions to engineering psychology that will result from code-sort experimentation. In line with comments above, this knowledge will initially have to be gleaned from systems reports on the automation of mail sorting.

Conclusions

The study of communication between man and machine is still in its infancy. Available methods and models for information transmission are as yet restricted to very simple communication situations, so that solutions to problems in everyday complicated communications such as radarscope search or air traffic control are still approached through realistic experiments. One principal impediment to model building is the difficulty in determining and quantifying the information content of complicated signals; a bit of information transmitted by man in distinguishing between two dissimilar signals can not meaningfully be compared with a bit for almost identical signals. The problem is, however, becoming increasingly acute and the study effort needs to be strengthened appreciably.

INDUSTRIAL ELECTRONICS

Organized with the assistance of the IRE Professional Group on Industrial Electronics

Early History of Industrial Electronics*

W. C. WHITE†, FELLOW, IRE

Summary—**Industrial electronics is the phrase usually employed to cover the use of vacuum tubes in fields outside of communication. The term was originally applied to the Tungar Rectifier (about 1915) and the use of phototubes (about 1927).**

By 1930 Industrial Electronics became a growing business. However, its early growth was slow, because there was a general mistrust about the dependability of tubes. Wider use of thyratrons that could handle currents in amperes was an important contribution; the development of ignitron tubes, and the use of steel envelopes for them, were considerable factors; also, such new applications as high frequency for induction and dielectric heating helped in the advancement.

THE TERM INDUSTRIAL ELECTRONICS is generally accepted as the use of electron-tube devices in the control and operation of machines employed in industry. This involves such fundamental applications as: photoelectric relays; Tungar Rectifiers for battery charging; railway signaling; high-voltage rectifiers; motor control; and induction and dielectric heating for the control of spot and seam welders.

Introduction

During the years of World War I and up through the early years of broadcasting, the demand for new types of tubes for applications to radio were urgent. As a result, not too much attention was paid, except in a few cases, to the use of tubes for industrial applications.

There were a few early non-radio uses for tubes, such as Tungar battery-charging bulbs and high-voltage kenotrons for cable testing and dust precipitation. As of January 1, 1930, there were some drastic changes in the picture as regards the future and the business outlook for industrial tubes. Three factors, all occurring at about the same time, contributed to this situation:

1) As of that date RCA took over from General Electric and Westinghouse the manufacture of all radio receiving tubes and some small transmitting tubes. They also had the right to take over the remaining transmitting tubes as soon as they were in a position to do so.
2) The big depression of the 30's had started and the demand for tubes, along with all other products, started to drop alarmingly.
3) It had been decided that development, design, engineering and manufacture of vacuum tubes had now grown to a point where they could be divorced from a laboratory.

It is hard to imagine a more inauspicious combination of circumstances for General Electric and Westinghouse. In order for them to exist it became absolutely necessary to develop new tube applications and new types of tubes to take the place of production transferred to RCA. A great deal was accomplished because of this urge.

The philosophy of tube work in industrial electronics had to be quite different than that in radio. In the latter case, advances in radio communication were largely based upon new and improved tubes and it was not too difficult to "sell" ideas and products. In industrial electronics, however, the situation was just reversed. In the field of power equipment and control, highly satisfactory methods and devices had been pretty fully developed and there was no great urge to substitute tubes. It was soon found that the best approach to this problem was developing applications that could not be done satisfactorily in any other way. Examples of this were high-speed spot and seam welding, motor control (dc motors from an ac supply line) and railway signaling, and elevator control and the electrocardiograph. There

was a common saying at that time that General Electric was not in competition with any other company but rather with the old way of doing things.

The Tungar Rectifier

It is interesting to review this development for two reasons. Not only is it the first application of a gas-filled, hot-cathode tube, but it is also very typical of the sort of procedure that seems to have been involved in several early, highly successful projects. Also like several other successful tube accomplishments, it was a by-product of lamp work.

During the spring and summer of 1912, Dr. Irving Langmuir of General Electric became interested and active in the development of the gas-filled, tungsten-filament, incandescent lamp. These early laboratory lamps were constructed with heavy-coiled tungsten-spiral filaments that operated at low voltage. The bulb space around the filament was relatively small so that it would operate at high temperature and a few drops of mercury were placed in the bulb. There was usually another portion of the bulb where the mercury vapor condensed and ran back into the filament portion.

These lamps were frequently tested by operation from a 110 v dc line through a series resistance. As one of the objects of these tests was to study the life and characteristics of the lamp at very high temperatures, there were frequent filament burnouts. It was noticed that, when the filament sometimes burned out during operation, an arc formed at the break.

In all of this early work, the primary interest was in the arc as a source of light and apparently no tests on the arc as a rectifier were made at that time. However, one of the men sketched a tube with a hot filament and a separate anode plus liquid mercury.

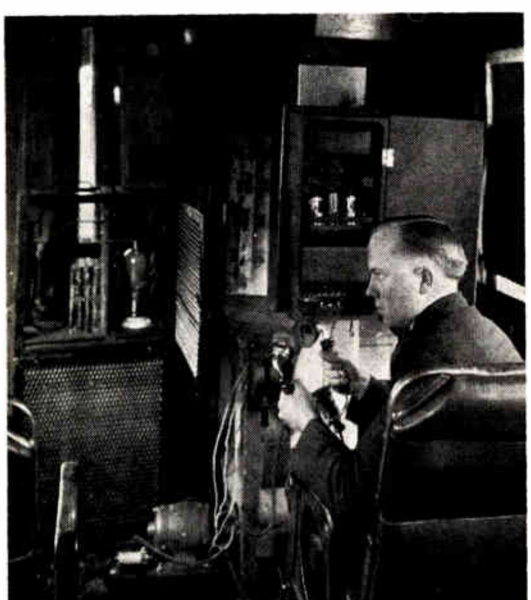

Fig. 1—Early carrier current equipment installed in a trolley car (1927).

In the early part of 1915 the possible need for a garage battery charger was considered and during 1916 it became a going business.

The Story on Early Phototube Work

Photoelectric effects in a voltaic cell were observed over 100 years ago. The phenomenon of photoelectric emission of electrons from the alkali metals (such as potassium and sodium), which forms the basis of modern phototubes, was first noticed over 50 years ago. Such tubes, custom built, could be bought at a high price from foreign scientific apparatus makers abroad. The U. S.-made tubes were really not commercially available until about 1928.

During the early years, work on photoelectric tubes was sporadic, largely because there was no apparent important demand for the use of such tubes. A few were made and used for incandescent lamp photometric work. Although the principle of the photoelectric relay was demonstrated to many persons between 1920 and 1928, no one seemed to envision the industrial uses for such a device.

The factor which really activated the quantity manufacture and use of phototubes was the development of talking motion pictures. Several methods for making such pictures were proposed. One involved the use of a black and white sound track on the film. This idea was the one that finally won out and it was demonstrated in a theatre in September, 1927. It used a phototube that picked up light variations from a film track and transformed them into audio currents for the sound effects. During 1928 a program of phototube development was started to meet the RCA demand for their photophone talking motion picture projectors.

Up to this time all phototubes had been made by distilling the light-sensitive electron-emitting surface of the alkali metal (at that time usually potassium) on the inside of the glass bulb, leaving an opening of clear glass for the light beam to enter. This type proved to be difficult to make in a factory using lamp or vacuum tube making techniques. In 1928 the idea of distilling the light-sensitive layer of alkali metal on a sheet metal electrode mounted on a stem inside the bulb was originated. This idea we accepted at once. In that same year, the American Standards Association adopted the word "phototube" to replace photoelectric tube to designate devices in which the electron emission resulting from exposure to light was the operating principle. A phototube, called the UX-868, was used by RCA Photophone for several years in practically all of their production of projectors for talking motion pictures. About this time cesium came into general use for the light-sensitive cathode surface since its spectral response is greater and more similar to that of the human eye than is potassium. In the fall of 1928 experiments were conducted on transmitting voice and music over a light beam using, of course, a phototube for a pick-up device.

By the new agreement with RCA, effective January 1, 1930, the manufacture of phototubes and their sale for television and motion picture use were transferred to that company. The only field left to General Electric and Westinghouse was that for industrial applications. Work was renewed on such applications during 1930, but, as in other industrial electronic applications, commercialization was hard, slow work. During 1929 a practical photoelectric relay unit was developed and during 1930 commercialization was underway.

Production of phototubes dropped to nearly nothing during the next few years because the industrial field was slow in developing; however, by the middle of 1931, business had picked up to a rate of a few thousand tubes a year. In 1932 added research work resulted in increased phototube sensitivity.

One interesting development was an automatic bean sorter that was put into commercial operation in 1931. In this device each dried bean was picked up and "looked at" by a phototube. If it were discolored, it was automatically rejected. Banks of these machines sorted beans at the rate of many thousands a minute.

Although new types of phototubes were developed and new uses found for them, high manufacturing costs further restricted the small market and, for a number of years following the outbreak of World War II, very little progress was made in this work.

Vacuum Tubes for Railway Signaling

Although business in tubes for train control was a very small percentage of the volume of tube business, it is significant as the first really successful wide scale industrial tube application. For over 25 years an average of several thousand tubes a year went into this service.

In 1916 the Union Switch and Signal Company of Swissvale, Pa., became greatly interested in GE's idea for a method of transferring the green-orange-red block signals from the trackside into the cab of the locomotive in front of the engineer.

If this could be done, not only would the danger of lower visibility due to fog, smoke, rain and snow be eliminated but automatic slowing down or stopping of the train if a signal was "passed" could be accomplished in a practical way.

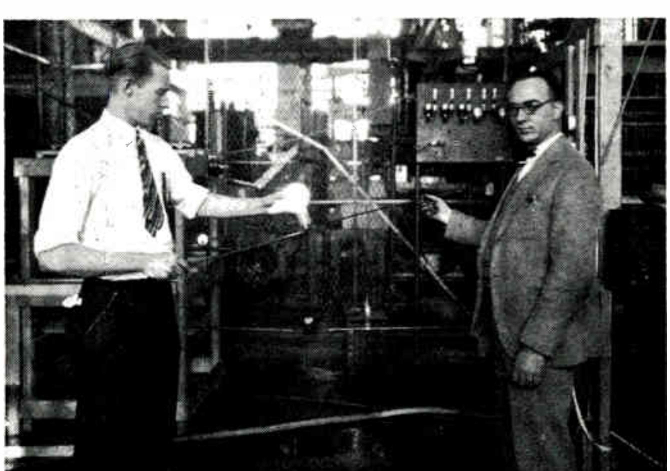

Fig. 2—10-kw 50-Mc oscillator with which artificial fever was first studied (1927).

To gain the broad objective there had to be a method of picking up, on the locomotive, a voltage or current of useful value proportional to the values of current in the rail used to activate the conventional trackside signals. The amplifying property of the vacuum tube provided a means of doing this from coils on the locomotive frame located a few inches above the rails.

Remember that it was 1916, five years before broadcasting, when vacuum tubes were considered expensive, frail, glass bottles used chiefly by a small group of somewhat eccentric individuals known as radio engineers and radio amateurs. The idea of putting them on a locomotive for a vital safety device seemed a little preposterous even to the early enthusiasts in the field of what was later known as electronics.

Progress was meager and slow until 1922 when the start of broadcasting necessitated a real tube manufacturing set-up. Two types of tubes were developed: a high-mu triode for voltage amplification, type TC-3 (later PJ-2), and a power amplifier tube, type TC-4 (later PJ-4).

During 1923 the General Railway Signal Company also became interested in GE's tubes. By June of that year a few locomotives and a short section of a Pennsylvania Railroad branch line near Sudbury, Pa., were equipped by Union Switch and Signal and put into regular scheduled operation. In 1924 installations were underway for the Santa Fe, Nickel Plate and New Haven Railroads and by the end of the year the tube demand was nearly 500 a month.

Much of the credit for the successful development of this electronic system of continuous automatic train control must be given to L. V. Lewis, an engineer of the Union Switch and Signal Company, whose vision, persistence and resourcefulness brought this development to a successful conclusion.

High-Voltage Kenotrons and Their Applications

The Field of Application

For a number of years there have been a few uses for high-voltage (up to millions of volts) dc for which only a few milliamperes or amperes were necessary:

1) For electrostatic precipitation of smokes, dusts and suspended air particles. (Active work in this field began about 1910 using a mechanical type rectifier and this business grew and has continued to the present.)
2) For a voltage supply for X-ray tubes where for certain applications dc is preferable to ac.
3) Testing of power transmission and distribution cables. (Due to the capacity between the conductor and the sheath, a very large kva rating of ac test equipment is required; therefore, dc is preferable.)

4) For test equipment to simulate the lightning of nature.
5) To supply voltages up to 20 kv for the plate supply of high-power radio transmitters. (This use disappeared after the development of the hot-cathode mercury-vapor tube in about 1928.)

High-Voltage Kenotrons

Before the work on the high-vacuum electron tube began in 1913, high voltages could not be employed with tubes having a hot cathode because of gas ionization troubles. However, the GE Research Laboratory developed techniques that made such tubes possible and practical. That same year Dr. Coolidge applied these methods to the making of a greatly improved X-ray tube. Tests using high-vacuum rectifier tubes for smoke precipitation were made in 1917.

Due largely to commercial reasons, progress in using high-vacuum rectifier tubes for smoke precipitation made little or no progress for many years.

Thyratrons

The present-day thyratron represents a combination of several pioneer developments:

1) In 1914 Dr. Langmuir first suggested a method of controlling the arc in a mercury-pool tube by means of a grid. He showed how a grid voltage could be used to control the starting of the main arc in each rectifying cycle. Thus, the average arc current through the tube was controlled when an ac anode voltage was used.

   In 1922 Toulon, a French scientist, improved on this method of control by varying the phase of the grid voltage with respect to the anode voltage rather than to its amplitude. Thus, the arc could be made to start at any point in the anode voltage cycle and this resulted in a very practical and convenient method of controlling the average value of a rectified anode current.

   Here then were the necessary tools for a whole new chapter in the progress of electronics. But they were somewhat ahead of their time and their value and applicability were not at once appreciated.
2) In 1936 Dr. A. W. Hull developed the idea of operating a hot-cathode diode in a low pressure of an inert gas or vapor. As a result, the space-charge effect was eliminated and the voltage drop of the discharge dropped to a low and more or less constant value of 5 to 10 volts. At this low arc drop voltage, the positive-ion bombardment of the cathode is not destructive. There results, therefore, a highly efficient rectifier.
3) Due to the elimination of space charge, the cathode could almost be surrounded by a heat reflecting and heat conserving shield. Only a few small holes are necessary for the conducting ionized vapor. Thus, the current-carrying capacity of the cathode for a given amount of heating power is enormously increased. An electron-emitting filament in space may give an emission of only about 50 ma/w whereas in a heat-shielded cathode in a well-designed gas-filled tube the figure may approach one ampere per watt.
4) In 1931 came the shielded-grid thyratron, the principle of which is incorporated in most modern thyratrons, even if the lead to the added electrode is not brought out to a base pin or other external connection. The function of the "shield" is to minimize the current and power required to activate the thyratron control grid.

The thyratron was announced in May, 1928 and the word first appeared in print in July, 1928. Actually hot-cathode mercury-vapor diodes were made available for use before the thyratron was brought out. There was a ready market for these rectifier tubes in the radio industry, particularly for rectifiers for the high-voltage plate supply of transmitters. By the end of 1928 such tubes were in regular use in several stations. Soon the hot-cathode mercury-vapor type completely superseded the high-vacuum type.

Thyratrons, however, found no early ready market in the radio field and to develop their use in industry took some time and much promotional work. During 1929 a line of thyratrons was developed which included the use of an inert gas as well as mercury vapor. These ranged in current ratings between a fraction of an ampere up to $12\frac{1}{2}$ amperes. Three types of shielded-grid thyratrons were made available early in 1933.

The first real commercial application of thyratons in

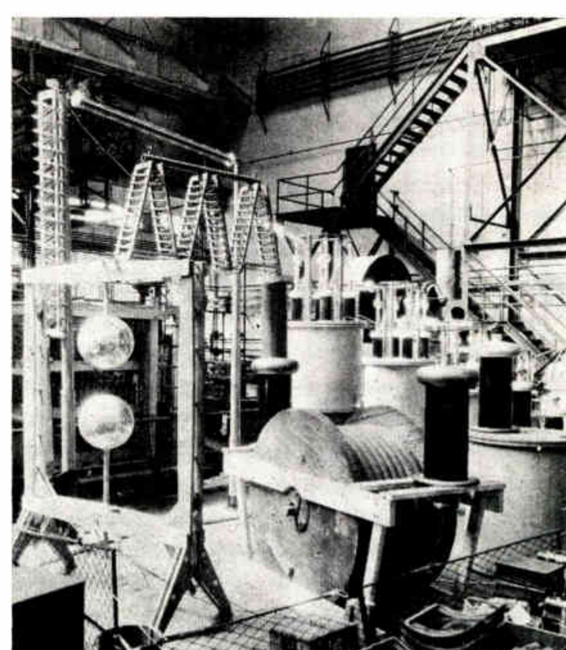

Fig. 3—High voltage, high vacuum tube rectifier for cable testing rated at 4,000,000 volts (1931).

appreciable numbers was made in the illumination control equipment for the then new Chicago Civic Opera House. This included about 250 small thyratrons in combination with saturation reactors to dim the lights in the many circuits of that large theatre. The theatre was officially opened in November, 1929, and the thyratron installation was highly successful. For its time, it was a very ambitious undertaking in the new science of industrial electronic control. A few other relatively large installations of illumination control were made.

In 1930 active engineering started on the use of thyratrons for the control of resistance welding (spot and seam). During the next year or two, a number of installations were made. The first large installation, and the forerunner of the wide use of electronic welding control in the automobile industry, came from the Ford Company in 1932 and numbered 12 equipments. These not only used small control thyratrons in the timing circuits but also $12\frac{1}{2}$ ampere tubes in the main-welding current-power supply circuit. Ignitrons were not known or available for the next few years. As soon as they were available they were substituted in place of thyratrons for the power supply control, but thyratrons continued to be used for the accurate timing and control circuits. Year by year such timing circuits have become more highly developed and complicated. Their accuracy of timing and flexibility of control were unobtainable except by electronics.

As early as 1930, an installation of a generator voltage regulator using thyratrons was made. This worked quite well and a few other installations followed, but it took many years for this field to develop. Before 1933 trial installations of thyratrons for synchronous motor exciters, railway signals, telegraph circuits, X-ray tube circuit control, and motor control were also made.

Fig. 4—Photoelectrically controlled drinking fountain (1931).

During 1931 active work started on a system of fire control for the directing of large guns on U. S. naval vessels. This system employed thyratrons for supplying dc to the motor for moving the gun mountings. It was fully developed and installed on a number of large ships. At the time it represented quite a business for thyratrons.

Building up the thyratron business was slow, hard work during the first ten years. Unlike transmitting tubes, there was no active business corresponding to radio broadcasting awaiting them and engineers in industry had not yet accepted electronic devices. There was little competition between makers of thyratrons; the real and serious competitor was "the old way of doing things."

Most of the initial successes were in applications, like welding control, where results were obtained which just could not be done in any other way and, therefore, expensive equipment was justified.

Sealed Steel Ignitron Tubes

Early Work on Pool Tubes

Work on mercury-arc phenomena was started by Cooper-Hewitt about the turn of the century.

There was a more or less steady increase in the use of sealed glass bulb rectifiers in the U.S.A. during the first quarter of the century. These were used largely for series arc street lighting and battery charging for electric vehicles. The increasing use of incandescent lamps for street lighting, the improvements in gasoline powered automobiles and the development of Tungar battary chargers have largely replaced glass bulb mercury-arc rectifier tubes in the U.S.A.

The Ignitron

In 1933 the Westinghouse Company announced its Ignitron. Its potential value was at once recognized and an active developmental program soon commercialized it extensively. Progress in making and applying Ignitrons was rapid. By the end of 1934 a welding control unit using glass Ignitrons was installed in a customer's shop.

The Sealed Steel Envelope

About the time of the Westinghouse Ignitron announcement, General Electric was well along on its program for making sealed steel envelope vacuum tubes of various kinds and types. This latter development was made possible by two other new techniques: fernico alloy for making heavy current seals with glass, and electronically controlled vacuum-tight resistance seam welding.

In February, 1936, the first successful sample of an all-steel envelope water-cooled ignitron with fernico seals was built. These all-steel ignitrons soon largely superseded the glass tubes.

As regards the power rectifier field, during 1936 the American Gas and Electric ordered for installation at Fostoria, Ohio, a sealed steel tube rectifier of about 150-kw rating for the excitation of a large (30,000 kva) synchronous condenser. By the end of 1936, this was in successful operation. Thus, the start was made in what proved to be an active field of application.

The Early Use of High-Frequency Induction Heating

Early Work

The production of heat by induced currents was recognized as early as 1880. The heating of transformer cores due to eddy currents was, of course, understood at an early date. Probably the real engineering and developmental pioneer in induction heating with frequencies above the power range was Professor E. F. Northrup of Princeton University. In 1918 he built practical "furnaces" for frequencies above 10,000 cycles and powers as high as 60 kw using a spark gap oscillator.

Largely as a result of the work on radio transmitting tubes, circuits and their components during World War I, it was possible in 1919 to produce, in a practical way, outputs of several kilowatts up to about 1-Mc frequency from vacuum tubes.

Not much further progress was made until 1921 when work became active in developing the UV-199 receiving tube for the new but fast growing broadcasting industry. This was before the ac heater type of tube was available and the low filament current of the UV-199 (60 ma) made it a popular type much in demand for battery operated receivers (even at a price of $6.50 each). Due to the very small filament, the outgassing of the anode by electron bombardmentheatingduring manufacture was impractical. High-frequency induction heating of the electrodes proved to be the only practical method. This at once created a demand for high-frequency heating equipment. During the next few years, the use of induction heating increased in the tube manufacturing industry and has continued to this day to be a widely employed technique.

Fig. 5—Photoelectric door opener in a restaurant (1931).

High-Frequency Dielectric Heating and its Application to Therapeutics

Prior Work

During the early years of the century when "wireless" was being developed, the problem of overheating the dielectric material of the transmitting condensers was a common one. For many years such heating was chiefly a nuisance rather than an interesting phenomenon leading to a possible business.

Actually much of the very early experimental work was on living things. In 1925 a Dr. Petroff of the Trudeau Sanitorium at Saranac Lake visited Dr. Coolidge of the GE Research Laboratory with an interesting story. At an earlier date, W. K. Kearsley of the GE Research Laboratory (now retired) had made up and given to Dr. Petroff a 2-meter oscillator of possibly 10 to 15 watts output. Dr. Petroff told Dr. Coolidge that small tadpoles had been killed when placed near the coil of this oscillator.

Except for a successful and lethal test conducted a little later on a cockroach discovered prowling near a short-wave oscillator in a laboratory, little work was done on this subject until about 1926.

In 1926 electrostatic heating tests were run on mice and flies. For flies it was found that, for the field strength available, a frequency above about 75 Mc was necessary for a lethal dose. About that time an egg was also cooked by high-frequency heating.

Later in 1926, Dr. Whitney of General Electric became much interested in this subject and began experimenting on mice in both electrostatic and electromagnetic fields. His tests covered long periods of exposure in fields not strong enough to kill or disable the mouse.

Two of his 1927 test results were of interest. The mouse was enclosed in a large diameter glass cylindrical tube in a horizontal position with the ends screened. The coil or condenser plates for heating were at one end of the tube. For some of the tests, this enclosure was put outdoors on fairly cold days. The mouse would soon learn to adjust its position just near enough to the electrode end of the cylinder to keep comfortably warm. Also after long exposure, during which time the mouse acted normally, its tail dried, withered and finally fell off. However, the mouse lived on. This latter test received considerable publicity.

The next step took place late in 1927 while tests were being run by E. D. McArthur of the GE Research Laboratory on a high-power (5 to 15 kw) radio transmitting tube under development. The men near the circuits while making these tests noticed a peculiar sensation and some complained of headaches. A doctor found an increase in bodily temperature (fever) of these men. Dr. Whitney was much interested as he knew of the promising work of others on certain diseases when the patient was given an artificial fever with drugs.

Equipment was soon constructed to heat parts or most of the human body between two large parallel plates at frequencies around 50 Mc. By the fall of that year, low-power equipments had been sent to Albany Medical College, Mayo Bros. Clinic and Johns Hopkins Medical School.

In the summer of 1929 a 400-Mc oscillator using a small split-anode oscillating magnetron was supplied to the Woods Hole Laboratory for some biological experiments. This was probably one of the earliest uses of the oscillating magnetron that was to become such a useful tool in the radar of World War II.

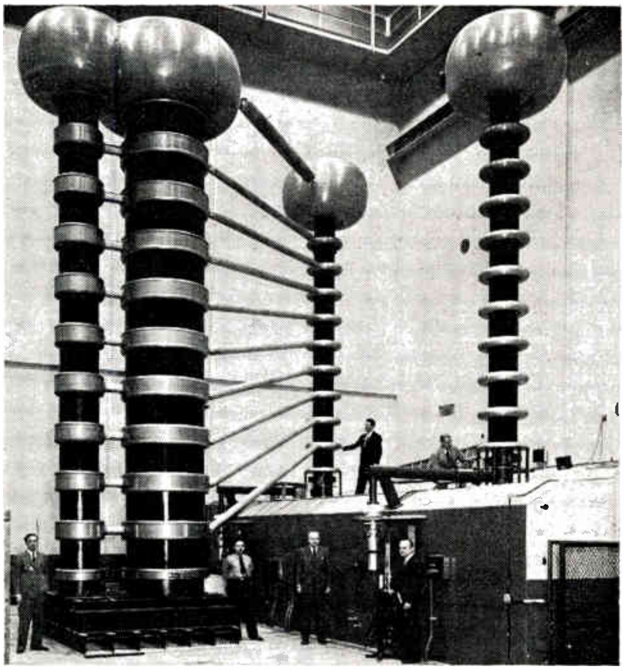

Fig. 6—X-Ray equipment 1.4 million volts (1941).

In 1930 the Cudahy Packing Company became interested in using this phenomenon for sterilizing and precooking meat. Tests were also made on foods, fruits, fruit juices, hot dogs, vegetables, eggs, nuts, etc., as well as on the drying of wet materials, including laundry.

There was publicity on some of these tests, with their frequencies up in the many megacycles. As to be expected, some manufacturers of medical equipment and publicity-seeking doctors saw an opportunity. Early in 1931 a New York City doctor coined the name "Radiothermy" and this helped to encourage commercialization. By the end of 1933 a model was in manufacture. By 1935 a number of manufacturers were active and equipments were in use by doctors, clinics and hospitals (and some by rental in homes) treating various aches and pains.

Except for cooking there was little interest or activity outside the field of therapeutics. Some tests were made on foods, golf-ball cores, gluing laminated wood for tennis racket frames and rayon drying, but, no applications resulted at that time. In fact, commercial industrial use of dielectric heating did not evolve until 1940 when a firm in Richmond, Va., developed the technique for the quick hardening of the bonding cement used in making plywood. Pilot plant operation was carried on in a mill on the West Coast.

Shortly thereafter the use of this method of heating was started in the manufacture of plastic articles for very quickly preheating the raw material pellets to soften them just before they were placed in the mold.

Active work was also started in several places on the rapid thawing and cooking of frozen foods.

In therapeutics the high hopes of some of its proponents that here was a general curative agent have not been realized, but it shows usefulness in alleviating the pain and stiffness accompanying some ailments of joints and muscles.

Industrial Electronic Developments in the Last Two Decades and a Glimpse into the Future*

WALTHER RICHTER†, FELLOW, IRE

Summary—**During the past two decades significant improvements have been made in all types of electron tubes. Small tubes became still smaller, and the output of large tubes has been increased. Greater reliability has been achieved, and frequency limits have been extended upward. Hydrogen thyratrons have been developed, providing high power for pulse work. Ignitron ratings have been increased significantly. The problem of shutting off gas tubes by grid control has received attention and has led to two new types of tubes which at this time have, however, only limited output.**

To the list of photosensitive devices have been added the lead-sulfide and similar cells, providing means of detecting infrared radiation of long wave length.

A host of ingenious transducers has extended the use of electron tubes in the measurement and control field; smaller magnitudes of physical quantities, such as distance, pressure and magnetic field intensity can be observed and recorded. On the other end of the scale, tubes have provided HF power for induction and dielectric heating.

But by far the most outstanding development of the last 15 years has been in the field of solid state or semiconductor devices. Here the transistor, announced in 1948, occupies first place, and improvements in its characteristics are coming at a breath-taking pace. In 1957 the silicon-controlled rectifier, aptly called a solid-state thyratron, joined the march. These two devices are giving industrial electronics a tremendous new drive.

About fifty years ago a witty observer remarked that the dividing line between the two then existing branches of electrical engineering was the decimal point. To the left of the decimal point was the power branch of the profession, with kilowatts, hundreds of volts and amperes, whereas the region to the right, with milliamperes, microwatts, etc., was the domain of the communication branch. Where should the electrical engineer specializing in electronics be placed in this picture? If Lee De Forest's invention, which is without doubt the most important milestone in the history of electronics, is considered as the starting point, then electronics for almost two decades operated essentially on the right side of the decimal point. After all, his "Audion" was an almost exclusive possession of the communication branch. However, mercury-arc rectifiers are decidedly electronic devices, and some of them were in operation as battery-charging equipment on that November day in 1906 when De Forest placed a grid between the cathode and anode of his experimental tube and thus became the "father of radio" and of a large part of electronics in general as well. The industrial electronic engineer of 1962 can definitely not be relegated to one or the other side of the decimal point; he has to jump nimbly from one side to the other (unless he chooses to confine himself to one side or the other). As a matter of fact, the two decades since the beginning of the Second World War have continued a trend already established in the two preceding decades; the number of digits to either side of the decimal point has been increasing for him, a development which should not be too great a surprise.

The list of tools that the industrial electronic engineer had at his disposal when entering the war is well known. The list included a great variety of vacuum tubes of the receiving type, high-power vacuum tubes as used for broadcasting which began to serve industry in applications to be discussed later in this paper, thyratrons and mercury-pool-type tubes, of which the controlled type, the ignitron, assumed a dominant position, and photosensitive devices. That improvements were made in all of these should, of course, be no great a surprise, but space limitations here do not permit the enumeration of more than a few of the changes that have taken place.

In the field of the receiving-type tubes—and these are also the workhorses for the industrial electronic engineer when he operates on the right side of the decimal point—metal tubes have given way to glass tubes again, but they are a good deal smaller than their predecessors. They were called miniature tubes when they appeared commercially, but they are already beginning to look like giants compared to what is just around the corner (more about this later). Triggered by an alarming failure rate when receiving type tubes began to be used in business machines and were operated for long periods under cutoff conditions, considerable work was done on cathodes, with the result that we now have much better cathodes. Reliability, which in industrial applications is, of course, of immeasurably greater importance than for a hi-fi set, has been the subject of intense study and many apparently small changes have contributed to making these tubes much more reliable than they were 20 years ago. Disk-seal-type tubes, a structure which shows minimum lead inductance, have increased the frequency capabilities of tubes. As far as the most recent developments in tubes are concerned, it may be suspected that the appearance of the transistor has brought on, or has at least hastened, the development of tubes of very small size. Thus, there have been developments of

* Received by the IRE, October 11, 1961.
† Consulting Electrical Engineer, 8575 N. Hawthorne Rd., Milwaukee, Wis.

stacked ceramic tubes, using ceramic washers not only as insulators, but also as the walls of the tube. RCA's Nuvistor uses cylindrical parts instead of washers. At the time of this writing the smallest tube is probably General Electric's microminiature heaterless tube. It consists of a coated cathode disk, a perforated grid disk and a solid anode disk, all of them made of titanium, which turned out to possess some properties just made to order in tube design. Two ceramic disks, hermetically sealed to the three metal disks complete the structure. Such a tube is about $\frac{1}{4}$ inch in diameter and less than $\frac{1}{8}$ inch high with a spacing of .01 inch between the electrodes. It gives a transistor of comparable power handling ability quite some competition. For such a tube to operate, the cathode must, of course, be brought up to a temperature sufficient to cause emission from its coating. In this case the tube, together with resistors, capacitors and inductances is placed in a heat insulated enclosure which is heated to 580°C. Naturally, resistors and capacitors must be able to operate under this condition also, but the circuit loss in the resistors can be utilized to keep the temperature of the enclosure at the desired point. The life expectancy of these tubes is about 100 times as great as that of regular tubes. These developments show that tubes are by no means ready to abdicate to transistors.

High-power vacuum tubes might be considered mostly of interest to the communication engineer where radar especially requires very high-power outputs. But high-power vacuum tubes are also serving industry as we shall see in the discussion of applications. Here significant changes in the design and utilization of new materials, especially ceramics, have resulted in much higher power as well as more rugged and reliable construction. Thus, a recently developed "super-power tube" can deliver 500 kw at 75 Mc. The tube operates with a plate voltage of 20 kv with a dc plate input of 1000 kw. Magnetron and klystron tubes have also seen spectacular advances but will not be discussed here.

As the communication engineer can claim the high-power vacuum tube as his own, so can the industrial electronic engineer claim the gas tube, and especially the mercury-pool cathode-type tube as his own. The workhorse for him was, and still is, the ignitron which served him well during the war years. The series of these tubes has been extended upward; the latest ignitron (7151) can switch 4800 kva (two tubes in back-to-back connection) at potentials of 250 to 600 volts.

In contrast to heated cathode type of gas-filled tubes (thyratrons) the ignitron is not controlled by a grid, but the arc is initiated by a relatively large current flow, fortunately of very short duration, through an ignitor rod. A successful attempt to combine the advantages of the mercury-pool-type cathode (its tremendous overload capacity) with a grid control is represented by the "Excitron" developed by the Allis-Chalmers Manufacturing Co. This tube appeared on the maket just about at the beginning of the war. In it a "keep-alive" dc arc provides an emitting spot on the surface of the mercury at all times. In a way we have here a heated-cathode-type tube, but the heating is accomplished by an arc instead of a filament. The tube has been used in similar applications as ignitrons. In the low-power field, the year 1941 saw the introduction of the type 2050 gas-filled thyratron which became one of the most useful tools in control circuits. In this tube an inert gas replaced the previously used mercury vapor, making the control characteristics of the tube independent of temperature.

The de-ionization time of both types of tubes just discussed is in the order of tens or hundreds of microseconds which is a serious drawback when the tube is to be used in pulse work. In 1946 the Sylvania Company placed on the market the first hydrogen thyratron, and this type of tube has become the standard in pulse work involving high power. Recent tubes of this type are capable of controlling discharges of pulse networks of nearly 50 Mw, and development work on tubes of even higher power is in progress.

However, the mercury-pool-type tube has also been the subject of further development work. From the RCA laboratories came the "Empretron" which is capable of operation in the kilocycle range. In this tube the arc is not started by an ignitor dipping in the mercury pool as in the ignitron, but by a spark from a starter electrode. This principle is not new, but in the new tube the starter is a small pot of mercury with an orifice at the bottom; a drop of mercury clinging to the orifice forms the starter electrode. Since the electrode thus renews itself, the problem of electrode consumption is avoided.

As is well known, the control element in a gaseous tube, be it a grid as in the thyratron or an ignitor as in the ignitron, can control only the start of the arc, but cannot shut the current off again. To accomplish this the anode circuit must be interrupted, or the anode must be made negative for a time about equal to the de-ionization time. This is a serious shortcoming of the tube, and has received the attention of research workers. Again from the RCA laboratories came two approaches to the problem; in 1951 the Plasmatron, a hot-cathode helium-filled diode capable of controlling a current of about one ampere continuously at a low voltage (6 volts) and in 1954 the Tacitron, a low-noise thyratron capable of current interruption by grid action. While these tubes are evidently low-power devices, their development shows that the value of a gaseous tube that can be turned off is well recognized.

In the field of light-sensitive devices, the war years added the lead-sulfide cell, soon followed by the cadmium-selenium and tellurium-sulfide cells; these types of cells extend the range deep into the infrared part of the spectrum, and found application in the solution of problems dealing with radiant heat.

Industry also profited from spectacular developments in the field of X-ray tubes. In 1941 industry was offered the first one-million volt completely packaged industrial radiographic unit; by 1946 the Betatron had emerged from the developmental stage and was providing 20-million volt X-rays. Within the last five years the amplification or intensification of X-ray pictures has also received much attention; there are two successful approaches to the problem: one makes use of electroluminescent phosphors to amplify the X-rays directly, the other is an image intensifier operating on a principle similar to a television system, which permits the observation of the X-ray picture at a remote place.

This may also be the place to call attention to a device which can be classified as an electron tube with as much justification as a cathode ray tube; it is the electron microscope. The development of this device into a practical tube for the physicist, metallurgist and others is due to Zworykin and Hillyer of RCA. In 1941 the first commercial model was offered; in 1943 a table top model, only 16 inches long, capable of providing magnification of 100,000 times was made available; and in 1951 a model in which the magnetic coil system was replaced by permanent magnets was developed.

It is claimed that at one third of the expense and complexity of larger electron microscopes, the instrument solves 90 per cent of the problems pertaining to electron microscopy.

So far we have been discussing what new types of tubes, or modifications of old ones, the last two decades have brought forth in the field of industrial electronics. But this is, of course, not the whole story. A brand new family of devices has been added to the tool chest of the industrial electronic engineer, and the magic word is "solid-state" devices. Crystal diodes, a refinement of the venerable cat whisker and galena crystal of the twenties, appeared in 1945. Then history appeared to be repeating itself. Fleming's valve was a diode, which became a control device when Lee De Forest added the grid to it. In 1948 Shockley, Bardeen and Brattain of the Bell Laboratories announced the point-contact transistor; they too had converted the diode into a control element by adding a third electrode. Some two years later the junction transistor was announced, which took its place very rapidly in the communication branch as well as the industrial branch of electronics.

In order to familiarize electrical engineers as quickly as possible with this new tool, it was perhaps natural to compare the transistor with a tube and to stress the similarities between the two devices. Recent books on electronic circuits quite often show such standard building blocks as multi-vibrators, Schmitt trigger circuits, etc., both in the tube and in the transistor version next to each other, thus apparently justifying the thought that a transistor is nothing but a solid-state tube. While this is certainly not the place to engage in a discussion of transistor characteristics, it may serve a purpose to call attention to some rather significant differences between the two devices. In the vacuum tube, control of the anode, or load current, is obtained by a volage applied to the grid, and the chief merit is that no current—and therefore no power—is demanded from the controlling voltage. If the grid does draw current, it is a deviation from the ideal condition. In a transistor operating in the common emitter connection (which is closest to the standard tube connection), on the other hand, control of the collector, or load current, is obtained by a current into (or out of) the base. The first feature to keep in mind is, therefore, that the transistor is a current-controlled, and not a voltage-controlled device.

The second significant point is the voltage drop across the tube or transistor. Both are control elements that are placed in series with a load across a source of voltage, similar to a rheostat, so to speak. A rheostat usually can be reduced to zero, in which case the full source voltage is applied to the load. To obtain such an action with a tube is nearly impossible, even by making the grid quite positive (although a look at the plate characteristics of a pentode show that, with this type of tube, one can come surprisingly close to this "bottoming" condition, as the British call it). A transistor, on the other hand, can be saturated quite easily; voltages in the order of only 10 to 100 mv are lost across the transistor. These are values that compare with the drop across an ordinary switch; it explains why in switching circuits transistors have become so popular. Owing to this low voltage drop under saturation conditions the heat developed in the transistor is, of course, also correspondingly small (a short-circuited rheostat does not become hot, neither does an open circuited one)!

The next important difference is far more radical than the two discussed so far and usually comes as a surprise to many electrical engineers. A vacuum tube can control the current in a load; but it is, at the same time, at all times a rectifier. Current flow cannot reverse; the supply voltage must always be positive. A tube cannot be used as a switch in an alternating current circuit, at least not if we wish to obtain positive as well as negative values. A transistor, on the other hand, with the proper direct current injected into the base will pass current either from collector to emitter, or in the opposite direction, so that it can be used as a switch in an ac circuit.

The fourth difference does not have to do with the characteristics of a given transistor itself, but is the fact that there are two kinds available, the pnp and the npn transistor. The two operate with reversed polarity. Only the man who has struggled with the design of dc amplifiers employing tubes can appreciate what it would have meant to him if he had a vacuum tube at his disposal that would operate with a negative voltage on the anode and in which the current would be decreased by making the grid more positive with respect to the cathode.

The characteristics just described evidently permit the transistor to do things which cannot be done by tubes; but this does not mean that it can in turn do all the things that a tube can do. For instance, where a very high input impedance is essential, tubes can outperform transistors; temperature drifts are also more serious for transistors, and so are the effects of nuclear radiation. It would appear that in the foreseeable future there is a field for both devices. As a matter of fact, it is gratifying to see in the recent literature descriptions of "hybrid" circuits with both tubes and transistors, utilizing the best features of both.

The high state of excitement produced by the advent of the transistor may have somewhat obscured the importance of a development that took place just in plain semi-conductor rectifiers. At first we had copper oxide rectifiers, then we had selenium rectifiers and therefore the appearance of the silicon rectifier in the middle of the last decade did not seem to be something to get very excited about. From the point of view of the circuit engineer that is perhaps justified. But when one compares the current densities and forward voltage drops of the silicon rectifier with those of the older devices, one realizes that nothing short of a revolution has taken place as far as space requirements go. With 18 ampere silicon rectifiers, about $\frac{1}{2}$ inch diameter, and not much more in length, available at quantity prices of about 60 cents, the days of the low-voltage dc generator in our cars seem to be numbered; alternators will take their place. The silicon rectifier is truly a most significant development in its own right.

In the case of the silicon rectifier, history also appears to have repeated itself. Vacuum diodes became control elements by the introduction of the grid; gaseous rectifiers with heated cathodes became controlled rectifiers which can turn on the current, but cannot turn it off. In 1958 General Electric announced the "solid-state thyratron" a name which aptly describes the action of the device, but which was quickly superseded by the three letters SCR, denoting silicon-controlled-rectifier. The SCR, just like its tube counterpart, the thyratron, can only initiate the current flow, but cannot stop it. But it has an advantage over the thyratron in two significant aspects. The voltage drop across it, while in the conducting state, is about one volt compared to the ten to fifteen volts arc drop of the gas tube. The circuit losses and the heat developed in the device are therefore also only a fraction of those encountered with gas tubes. Secondly, the turn-off time—the equivalent of the deionization time of the gas tube, is at least by an order of magnitude less than for gas-filled tubes. This increases the frequency range over which the SCR can be used, and it brings about a reduction of the size of certain circuit components, such as commutating capacitors, when the SCR is used in inverter circuits. At this time the current ratings of SCR's are still below 100 amperes, which is way under the several thousand amperes of the ignitron, but in applications within their ratings they certainly offer a number of advantages over tubes.

Even if this review of recent developments of interest, or possible interest, to the industrial electronic engineer had to be kept very sketchy, one new member should at least be mentioned, and that is the tunnel diode. It is clearly a low-power—indeed a very low-power device, but the frequency range over which it is capable of operating is truly fantastic. What jobs industry will assign to it, only the future will tell.

After having discussed the tools which were available, or were made newly available to the industrial electronic engineer in the past two decades, let us take a look at how he has applied them. Quite evidently, space does not permit a complete list or even a list of a very small fraction of all the applications that electron devices have been put to. Only very few examples can be selected for presentation here, and it can hardly be expected that the readers of this review will agree with the writer on the choice of the examples. If what is in your opinion the most outstanding application of electron tubes in the past 20 years is missing here, apologies are offered herewith. Again, we turn our attention first to the receiving-type tubes. They are relatively low-power devices and serve in industry essentially as measuring or controlling devices. In applications involving the control of a considerable amount of power, they are, of course, used only in the first stages, usually in the role of sensing elements. The story of the use of electron tubes or transistors in the field of industrial measurements and controls is really not the story of the tubes themselves, but the story of the transducers. Industrial processes call for the measurement or sensing of such things as distance force, stress, torque, speed, temperature and many others. But a tube or a transistor is a device which responds to voltage or current, and that is all. It can be of use only after somebody has invented a "transducer," that is, a device converting a physical quantity into another one. The transducers needed by industry in connection with electron devices are those that convert the quantities just mentioned into electrical voltages or currents. Now, if we have a transducer that converts the quantity we are interested in into a voltage or a current, why not measure it with a conventional volt meter or ammeter? Why throw in tubes or transistors? The answer is simple, and it is found in two characteristics possessed by both the tube and the transistor. The first is their ability to amplify, which permits them to accept signals of very low power, and the second one is their high speed of response. Most transducers by their nature can furnish only very minute amounts of electrical energy and could not possibly operate ordinary meters.

Many physical effects have been used in transducers; thus, a force applied to a piezoelectric crystal (quartz for instance) produces a voltage; a coil moving through a magnetic field has a voltage induced in it which is proportional to the speed with which the coil moves. these are examples of so-called "active" transducers. But there are also "passive" types. If a resistance changes its values, it can be made part of a Wheatstone bridge, where such a change will produce an unbalanced voltage, which is then a measure of the variation of the quantity originally changing the resistance value. The more commonly used transducers employ the following effects:

resistive, capacitive, inductive, piezoelectric, thermoelectric, photoelectric and magnetostrictive. They are used in the measurement of displacement, velocity, acceleration, force, stress, flow, humidity, temperature, and others. Many of the quantities can be sensed by more than one kind of transducer. Thus, displacement has been sensed by all of the transducers mentioned, except thermoelectric. However, most of these transducers could not possibly operate without the help of some amplifying means.

The most useful, and the most famous transducer is the well-known resistance strain gauge. Although the change of resistance of a wire when it is stressed, was discovered by that master experimenter, Lord Kelvin, the practical application of the principle had to wait until it could be teamed up with the vacuum tube or transistor. It is hard to assess how much the strain gauge contributed to our winning of the war. But strain gauges were plastered all over our experimental aircraft, and the results they furnished permitted the strengthening of the structures where needed, and the removal of material where the stresses were less than anticipated. In the testing of the Boeing B-52G, 2000 strain gauges were mounted on the wing and fusilage structure, giving the information needed by the designer. It is of interest to note that although strain gauges were no war secret and articles about them could be found in most magazines, the German literature shows that their importance was evidently completely overlooked. Strain gauges have also been combined with telemetering equipment, where their resistance change is used to modulate the frequency of an oscillator, thus broadcasting the desired information by frequency modulation. This permits measuring stresses in inaccessible or dangerous locations, and from moving or rotating parts of a structure.

As far as the measurement of small distances or displacements is concerned, the highest sensitivity is probably obtained today with transducers of the capacitive type. Circuits have been described capable of detecting a capacity change of 0.001 $\mu\mu$f. Two plates, each about $\frac{5}{16}\times\frac{5}{16}$, and spaced 0.005 inch apart change their capacity by such an amount if their distance is changed by approximately one microinch.

Transducers utilizing the inductive principle have been the subject of much study; there are several forms of these transducers which space does not permit to discuss in detail here. One of the most promising is based on observing the effect of the impedance of a coil when a conducting body is brought into its field. Sometimes the method is called the "eddy current method." The pioneering work in this field was done by the Foerster Research Institute in Germany. The method is also quite useful in the detection of flaws in a given test specimen.

Photoelectric transducers have almost limitless applications, which is no great surprise. Two applications in the steel industry may be worth mentioning. In 1960 a detector for pinholes in sheet steel was described capable of detecting pinholes 0.0005 inch in diameter in sheet steel traveling at a speed of 1700 feet per minute (about 20 mph). Another application is a photoelectric width gauge; mounted 15 feet agove the rolling table, it monitors the width of the steel strip which is several feet wide to between $\pm\frac{1}{8}$ inch.

In the early days of industrial electronics the steel industry was quite reluctant to make use of electron tubes, these fragile little bottles, but its attitude has changed considerably. The measurement of the width of a sheet has just been mentioned; measurement of the thickness of it while it is being rolled is, of course, of equal, if not greater, importance. In 1947 and 1948 there were described thickness gauges making use of beta rays and of X-rays.

One more example demonstrating the ability of electronic gear to respond to very small quantities will be mentioned. The magnetic field of the earth is in the order of $\frac{1}{2}$ to 1 Oersted. Electrical engineers are used to dealing with fields thousands of times more intense than this and, consequently, consider the magnetic field of the earth as quite a weak field. Yet, in geophysical prospecting for bodies of ore, the variation of this field from point to point on the surface is often an indication of the existence of iron containing bodies of ore. A magnetic survey of a large area used to be a very tedious and time-consuming project. In 1947 the Bell Laboratories described an air-borne magnetometer which was at the end of a cable trailing from an airplane. To express the variation of the intensity of the field from point to point, the Oersted (that weak field) is much too large a unit, and it is customary to express the variations in a smaller unit, the gamma, where one Oersted is 100,000 gammas. The Bell unit, when operating on its most sensitive range gives full scale deflection on a meter with a variation of 50 gammas, or one gamma per scale division; this is ten micro-oersteds per division! (Who ever heard of a micro-oersted!)

We shall now turn to the applications of high-power vacuum tubes in industry. At this time large amounts of power and high frequencies can be produced only with the aid of vacuum tubes operating as oscillators. Industry makes use of HF power mostly for two applications: induction and dielectric heating, both of which have seen spectacular growth and advances in the last two decades. For induction heating of thin metal or for surface hardening, the frequency is usually below 500 kc. One of the outstanding installations in the war years was furnished in 1943 by Westinghouse for the purpose of flowing tin on steel strip. The strip which had been electroplated with tin previously was traveling at a speed of 500 to 1000 feet/minute through the coils, which were supplied with 1200 kw at 200 kc. This method permitted a speed from 4 to 5 times as high as could have been accomplished with a gas-fired furnace or a hot oil bath. Within the past few years HF power has also been successfully applied to the welding of tubing, including the production of copper tubing from copper strip.

The second field of use of HF power is in dielectric heating. The first installation attracting wide attention was furnished by the Girdler Corporation in 1942 (the principle was demonstrated two years earlier). It was used for the bonding of plywood. Input was 400 kw at two Mc. In 1943 electronic sewing machines for plastics, operating at 60 Mc and RF guns for spot gluing, operating at 200 Mc were introduced. In 1946 Westinghouse furnished a 125 kw unit at 13.6 Mc to the Firestone Co. for curing and drying foam rubber. In 1952 industrial magnetrons for dielectric heating at frequencies from 915 to 2450 Mc were under consideration.

There are other uses of HF power in industry such as the production of ultrasonic power, but the two just mentioned represent by far the largest part.

Let us now examine the applications of gas tubes in industry. It has already been stated that these tubes are really the workhorses of the industrial power engineer, and it is again quite impossible to discuss more than a few applications. Spot, resistance and flash welding have assumed a dominant role in many manufacturing processes in this country and today almost all welding machines are controlled by ignitrons. As far as the number of controlled kilowatts is concerned, no other tube has contributed, or is contributing, as much to industry as the ignitron. But, while welding applications account for the largest number of ignitrons, they have, of course, found other uses, such as motor control in locomotives, in strip mills and in the control of pot lines in the aluminum industry. In 1943 a converter using ignitrons was furnished by General Electric to the Carnegie Illinois Steel Corporation; it served to convert 20,000 kw from 44 kv at 25 cps to 69 kv at 60 cps. The frequencies do not have to be exact.

The use of HF power for induction heating has already been discussed, but for the majority of heating applications such high frequencies are neither needed nor, as a matter of fact, desirable. Even today, there exists a crying need for economically priced conversion to power in the kilocycle range, from thousand to ten thousand cps. Gas tubes can be made to operate as inverters, and in 1945 Allis-Chalmers offered an inverter using excitron tubes to produce power in the 2000 cps range for induction melting furnaces. One very unusual application of ignitrons will serve to close this part. It is the power plant for the Bevatron, the high-energy particle accelerator of the University of California Radiation Laboratory. The magnetic field in the chamber must be built up to its maximum value and reduced to zero ten times per minute. During the buildup of the field, which takes about two seconds, a dc voltage varying between 18,000 volts at the start and dropping to 12,000 volts at the end of the two seconds is applied to the coil and the current rises from zero to 8333 amperes. The energy stored in the magnetic field is then 80 megajoules (80,000 kw seconds)!

The dc power is obtained through ignitrons from two ac generators, each rated at 46,000 kva, and each driven by an induction motor, rated at 3600 hp equipped with a solid steel plate flywheel weighing 67 tons. Most of the energy required during the current buildup comes from the flywheel. To bring the field down to zero, again in about two seconds, the firing control of the ignitrons is instantaneously changed (by back phasing) so that they act as inverters. The dc voltage at the coil changes instantaneously from +12 kv to −6 kv, increasing from this to about −16 kv during the time that the current decreases to zero. During this time the inverter action causes the energy to flow back into the ac generator and the flywheels increase in speed again. The driving motor has to furnish only enough energy to cover the losses during each cycle. The ignitrons are similar in design to those used in 3000 volt railroad service; the high direct voltage requires four of them in series, and the high peak current require four anodes in parallel. This is truly an engineering accomplishment of the first order.

X-rays have already been mentioned several times in this survey. Industry has made use of X-rays for many problems dealing with the inspection of products, as is well known. What is not so well known is that X-ray pictures can be produced with very short exposure times. In 1942 it was already possible to obtain the X-ray picture of a bullet while penetrating a steel plate, and in 1949 X-ray moving pictures were obtained on 9.4 inches wide film taken at a rate of 150 frames per second with an exposure time of 1/100,000 second.

We are now ready to turn to the latest member of the family, the solid-state devices. As far as transistors are concerned, their contribution is found mainly in a tremendous reduction in weight and size, and an increase in reliability in many devices formerly employing tubes. This might not appear to be a significant point, when we look at photoelectric relay, or some device operating with perhaps half a dozen tubes, but when thousands of tubes, as in a computer, are involved, space and weight savings produce really spectacular results. Add to this the fact that transistors can do many things that tubes cannot do (as explained earlier in this discussion) and it becomes understandable why a great number of electric devices are being "transistorized."

The silicon-controlled rectifier is only about four years old, and its cost is still quite a serious obstacle to widespread use. Nevertheless, there are already some applications indicating the trend that developments will take. In March, 1961 General Electric introduced a 50 kva converter, for converting 125 volts dc to 220/440 three-phase power at a frequency variable from 50 to 500 cps. This is the kind of development that industry has been waiting for and will watch with intense interest.

This short discussion of semiconductors should not be closed without at least mentioning a device which may well become one of the most important building blocks for the engineer interested in measurement, control and computing, and that is the Hall generator. The discovery by E. H. Hall in 1879 that a stream of electric charges in a metal (the word "electron" was not known at that time) could be deflected by a magnetic field perpendicular to the flow of charges was a landmark from a theoretical point of view, but the voltage produced by this squeezing of the charges to one side of the conductor was so minute as to be of little practical value. It was reserved for later generations of physicists to discover the relation between the Hall voltage and the carrier density and mobility in the conductor material. Suffice it to say here that the Hall voltage obtained from semiconductors is of practical value (in the order of hundreds of millivolts). Since the Hall voltage is proportional to the magnetic field density and to the current, we now have a device which is capable of generating a voltage that is proportional to the product of two quantities, provided we can convert the two quantities into a current and into a magnetic field density respectively. Simple wattmeters, operated over a wide frequency range, would appear to be possible by utilizing this effect.

Statistics showing how much industrial electronics has contributed to the economy are difficult to obtain, mainly because the dividing line between industrial and other electronics is hard to define.

One set of statistics divides the field in industrial and consumer electronics, the latter including entertainment, broadcast, television, radio, services and distribution. With this division the statistics[1] are as follows (the 1965 figures are projected):

	1940	*1950*	*1960*	*1965*
1) Industrial	4.5 million	680 million	2.8 billion	4.6 billion
2) Consumer		3.1 billion	5.35 billion	6.7 billion

It is seen that the rate of growth in the industrial field exceeds by far that in the consumer field and that the day when the two are equal is in the foreseeable future.

What will the future hold? In a field as fluid, not to say explosive, as electronics has proved to be, predicting what the future might bring is a risky business indeed. Who could have predicted in October 1906 that one month later Lee De Forest would give the world the vacuum triode, or who in 1947 could have predicted that the transistor would be born a year later? To be sure, if the doors of the research laboratories of the giants of the industry were all thrown open to a reporter, he could make quite some predictions (although they would, of course, not be predictions anymore). For many good and valid reasons, companies do not disclose the projects they are working on until the job is finished. To engage in flights of fancy has unfortunately never been a strong side of this reporter, and predictions will therefore be confined to things on which work is known to be in progress.

[1] The author is indebted to W. W. MacDonald, Editor of *Electronics*, who was kind enough to provide these figures.

Since tubes have been with us about 40 years longer than the recently developed semiconductor devices, it seems reasonable to expect more spectacular advances with the latter, (although the heaterless microminiature triode of General Electric described earlier makes one wonder what might happen in this field). Transistors of today are still low-power devices, just as the first vacuum tubes were. The material used in the present devices is either germanium or silicon. The reason for this is at least partly that these are simple four-valence elements, which made the development of the theory of the conduction of current through semiconductors less difficult. But attention is now being directed to more complicated materials, which may expand the range of the characteristics of these devices tremendously. In 1961 gallium arsenide has received the attention of semiconductor manufacturers. Theoretical considerations show that this material will be superior to silicon and germanium both for high frequencies and high-temperature performance, but at this time the preparation of the material in the required purity is more difficult. Experimental transistors have been built confirming the theoretical predictions. But the physicists are not stopping here; considerable work is being done on three element semiconductor materials, and their list is practically endless. One compound under investigation in the Bell Laboratories is silver antimony telluride ($AgSbTe_2$), which shows promise for use in thermoelectric refrigeration. Scientists have not stopped at these intermetallic compounds; work is even going on with organic semiconductors; at this time the subject of these studies is anthracene, one of the simplest organic compounds.

As far as industrial electronics is concerned, these future tools will provide the means to solve many more problems, and to conquer new fields. The semiconductor materials seem to hold the key to the direct conversion of heat into electricity, and the reverse, refrigeration by electricity. Ratings of SCR's will certainly go up, and turning the current off by gate action is a distinct possibility. As far as the consumer is concerned, the day when his car will be guided along the highway is perhaps quite near; RCA and General Motors are cooperating in the development of an electronic highway. Olson and Belar of RCA have presented a paper on a phonetic typewriter. From the General Electric laboratories comes a radically new system of recording called thermoplastic recording which possesses the advantage of almost instantaneous recording, and will produce pictures in either color or black and white which do not require chemical processing. For industry it may provide a new information storage system; it already can concentrate 100 times as much information in a given space as can magnetic recording. Truly, the future of industrial electronics looks more exciting than it ever did before.

Section 17

INFORMATION THEORY

Organized with the assistance of the IRE Professional Group on Information Theory

On Communication Before the Days of Radio*

COLIN CHERRY†

Summary—It is stressed that the really important factor in communication systems is not their speed of operation, but their reliability. This has been true throughout history. The earliest known postal system was that of the Persian empire which was later taken over by the Greeks and then the Romans, being used by them in their occupation of Europe 2000 years ago. The system which they adopted will be described briefly; it remained substantially unchanged in Europe until the later part of the Middle Ages. Every effort was made to make such systems reliable; it was of no value to Caesar to send messages if he could not be sure they would reach their destination.

These early systems were used by an aristocracy, and the most significant thing about modern telecommunication systems is their universal use by every man, woman and child. But their use is confined to areas of high literacy in the world, not so much because of wealth, but because of mental attitudes. The growth of modern postal services during the past 300 years is described and the effect of the coming of telephones and telegraphs commented upon.

WHEN modern communication systems and their influence upon us are discussed it is most usual that their speed is mentioned, whilst their effect upon "the tempo of life" (whatever that may mean) is stressed. In the author's opinion the really important social aspects of modern telecommunication derive, first, from their great reliability and, second, from their universality, by which is meant their use by every man, woman and child. These two factors have enabled the sheer size of societies to grow, from the village to the city-state, to the antique empires, until today our society, in the sense of areas of mutual dependence and cultural exchange, is being forced into global size. In early historic times there was indeed long-distance communication, covering empires and the known world, but it was confined to diplomatic, military and governmental use by emperors, generals, and other privileged aristocracy over the whole historic period from the Persian Empire to the coming of the railways. The structures of the dominant societies over the past two or three thousand years have taken a great variety of forms, but it is suggested that the types of civilized societies in which we live today are very much colored by the two factors mentioned—the utter reliability of our communication systems and their universal use by the "common man."

In today's world the use of our postal services, our telephones, telegraphs and all other forms of communication is confined to areas of high literacy. This is not only a matter of wealth, but one of mental attitude.[1] The same thing is true through history; literacy has always been an essential prerequisite for the adoption of all forms of communication service. An illiterate society is paralyzed; and we must not forget that even today nearly half the world's people are illiterate. Indeed we may argue that *societies can develop and "advance" only*

so fast as they can develop means of acquiring, recording and disseminating information.

Man's progress from the earliest communities, through the great empires of antiquity up to the gigantic and highly organized industrial societies of today, has been one long story of improved means of communication. As these have been developed, so the sizes of our communities have grown, giving all the advantages of the division of labor and production of wealth, of broadened cultural horizons, of control and protection of economies and other benefits of social *sharing*. The very word *communication* comes from the Latin *communico*, "I share."

But it is the *explosive* growth of all forms of communication which seems to be significant today. Print is only 400 years old, newspapers less than 200; telegraphs and telephones less than a century and radio half that time. Whereas the illiterate peasant of earlier centuries knew only of the doings of his own village (and indeed the same thing was true of a great bulk of our own people up to the days of our grandfathers), the thoughts of every literate man and woman nowadays are world-thoughts. Every time we open our morning newspapers we are confronted by the whole world's agonies. It is the suddenness with which this load has come upon our consciences which threatens to bring us to our knees.

Man is a communicating animal; he possesses the unique powers of speech and writing. Human experience is not a moment-by-moment affair, but has continuity; we have contact with our ancestors and our descendants, and we have a sense of history and tradition. All our communicable thoughts are bound by the structures of our languages and systems of symbolism, and these continually shift and change. The early Mediterranean scripts were in pictographs, ideographs and hieroglyphs, giving direct pictorial representation of objects and, by associations, of names, actions and ideas of all kinds. But it was the evolution of phonetic writing, during the Coptic period, which was the great step; speech and writing became closely linked. The civilizattions which did not adopt such techniques have been handicapped throughout their history, more so today than in earlier times.

We make relatively few *significantly* different sounds, when we speak, few phonetic symbols are needed. Phonetic writings settled down into sets of two or three dozen alphabetic letters, divided into consonants and vowels. This great simplification of script did not stop there. For example, ancient Hebrew script omitted the vowels. Deliberate condensation has been tried in numerous ancient writings; Church Slavonic abbreviated common words of religious texts, rather as today we write *cms* and U.S.A. for similar reasons of economy. Shorthand writing is another very early invention, said to be due to the Greek slave Tyro in recording the lengthy speeches of Cicero! This looks not unlike modern shorthand, but was based upon spelling; it continued to be used in Europe until the Middle Ages.

Together with these evolutionary steps and deliberate inventions for recording messages, other remarkably early developments took place for their transmission. Polybius, for example, is well known for his description of telecommunication techniques using torches and other visual means, and also for his coding of the alphabet.[2] The classical historians, Herodotus, Xenophon and Polybius, stress the need for communication services, based on central government, for control of scattered empires and for waging wars.

How were the great empires of antiquity held together? How did Caesar know what his generals were doing, or what revolts were taking place? By a system which was the forerunner of our present-day postal service. The earliest known postal service was that of the Persians, by which written letters were carried on horseback, in relays between established postal stations; this system was later introduced into Imperial Rome by Augustus. The Roman Empire was held together by an elaborate network of couriers, on horseback or in carriages, with relay posting stations at regular intervals along all main roads. Each postal station kept 40 horses and grooms,[3] and the speed was probably 50 miles a day[3-4] with accurate fixed times for collection and delivery. Similar systems were used by the Great Khan described by Marco Polo.

As I stressed at the opening of this article, it is *reliability* rather than speed which is the most important factor in communication. The various accounts of these ancient postal services all emphasize these points—precision of timing and certainty of arrival. Caesar had to know that his messages were received and when he could expect a reply. Truly we have increased the speed by one or two orders of magnitude in modern times, but of first importance is the fact that we have vastly increased the reliability and the scale. Caesar, in the form of authority, now appears in every home.

The Roman postal system was carried into Europe by the Roman occupation forces, and stayed there in various centers long after the collapse of their Empire. Indeed the system remained essentially the same until the late medieval period; at that early time several postal establishments in various states of Europe were run by the Universities! The University of Paris, for instance, ran a postal service[5] from the early 13th century until the 18th.

From the first days, postal services seem to have been organized under government control and used for carrying the kings' messages. It was not until the 17th century that the full social need for regular mail service to be used by government officials, merchants and all but

[5] The word *mail* comes from Old French *male* meaning a bag for travellers.

the "common people" was realized. In 1633 a weekly mail which took four to five days was set up between London, Antwerp and Brussels. By Cromwell's time (1599–1658) regular services were running on all main roads of England, under license from that remarkable new institution—the English Parliament.

Surprisingly enough there were several attempts by private persons to set up postal services. John Hill, for example, organized a *penny post* throughout England, but it was regularly attacked by Cromwell's soldiery. As early as 1680 a private London and suburban penny postal service was established[6]—with hourly collections, wall-boxes and sorting-offices which were later incorporated into the state system. Similar developments took place in America, at much the same date.

Throughout this early history of the postal services we read of constant efforts to improve the reliability of the mails, and of a steadily growing public confidence in this service. By Queen Anne's time, regular mails were reaching England's scattered colonial Empire and secrecy was (officially) ensured. Whereas under Cromwell's regime foreign mails were read by a board of examiners, now only Secretaries of State had authority to do this!

Attack and robbery on the highway was steadily defeated, by higher speeds and by arming the coach guards, so that public confidence increased. But it was the coming of the railways which finally established the postal services as part of the life of every man as something utterly reliable and always available—that which we accept today as our due, much as we take our air and water.

To quote figures from my own country, Britain, by the time of Sir Rowland Hill's Post Office Reform Bill (1837) letters in the mails totaled 88 million per annum (today there are 10,000 million packages a year of all kinds).

[6] By William Dockwra.

The railways were dominant too in the early history of telegraphy—theirs was the first "electronic" system of communication and the first alternative to the post. Although the suggestion that messages might be sent over a wire (by discharging a Leyden jar) was made[7] as early as 1753, the first really practical trials were made by the railway companies (starting in 1837) and for a long time telegraphs were confined to use by the railways. Even today we have the familiar sight of telegraph poles and wires through our railway carriage windows.

But soon companies were formed. In 1851 the stock exchanges in Paris and London were connected so that prices could be rapidly compared for the first time. Public confidence grew and people were prepared to pay high charges for telegrams; but for some years during the middle of the last century the service was confined to those towns and cities served by the railways.

Only brief reference is made here to the coming of telephones and radio, for their development falls within the lifetime of many of us or of our fathers. From the social point of view, their arrival had two major consequences. The telephone network required some form of *subscriber organization* for the first time (letters and telegrams are the affairs of individuals, but a telephone in your home requires a terminal connection, in your name, in the local exchange). The advent of radio brought mass-communication. Radio and television sets are now owned by people of all classes and conditions. The voice and vision of authority now appears in every home, to carry out education or propaganda, to inform or to deceive, to inflame or to hypnotise, to unify our language or to initiate clichés and slang, to model our heroes and set our norms. There is no doubt that radio and television will largely decide the road along which our society will pass into the future. They can be terrible instruments. We must watch ourselves.

Noise and Random Processes*

J. R. RAGAZZINI†, FELLOW, IRE AND S. S. L. CHANG, FELLOW‡, IRE

Summary—Early investigators in the field of communications first realized that the presence of unwanted random noise was an important factor following the discovery that the maximum gain of an amplifier was limited by the discrete nature of currents in electron tubes. Called *shot effect*, this was first explained by W. Schottky and later by many other investigators. Much research on this problem during the second and third decades of the twentieth century finally led to the rigorous formulation of the phenomenon by B. J. Thompson and others in 1940. Concurrently, the problem of spontaneous thermal noise effects in conductors was studied and formulated. By 1940, the situation was developed to an extent that the application of mathematical statistics to explain and solve broader noise problems in systems was inevitable. About this time, the basic contributions of N. Wiener led to an understanding of the optimum linear filtration of signals imbedded in random noise. His work influenced the entire course of development of theory on the optimization of filters designed to abstract a signal out of its noisy environment.

I. Introduction

THE THEORY of noise and random processes in electronic devices was developed in two stages. The first stage spanning the two decades following 1918 brought about the understanding of the nature and effects of noise in vacuum tubes and circuits. The second stage, initiated by Wiener in the early 1940's, established the theoretical basis for the analysis and synthesis of systems subjected to random signals and noise. His rationale for optimization and design of optimum linear filters subjected to Gaussian signals and noise set the direction for much of the subsequent research on this subject. While a detailed discussion of optimum filtration and detection of signals embedded in random noise is treated in a separate paper on information theory, the subject is discussed briefly to demonstrate its link to the early work on the subject. The literature on noise and random processes is so extensive as to make a complete coverage impractical. Only highlights and significant stepping stones in the development of the theory are described.

II. Early Work on Sources of Noise

The first realization that unwanted random noise was a factor to contend with in the field of communications came during World War I when attempts were being made to design high-gain vacuum-tube amplifiers. It was soon found that there was a limit to the number of stages which could be cascaded in the quest for high gain due to an unacceptably high background noise which masked the weak signals being amplified. In his classic paper[1] Schottky first explained one of these effects and formulated the random component in the plate current of a vacuum tube.

Schottky ascribed the random fluctuations in the plate current to the fact that this current is composed not of a continuum but rather of a sequence of discrete increments of charge carried by each electron arriving at the plate at random times. The average rate of charge arrival constitutes the dc component of the plate current on which is superimposed a fluctuation component as each discrete charge arrives. He referred to this phenomenon as *schroteffekt* or *shot-effect* as we call it.

In arriving at his result, Schottky made a number of important simplifying assumptions. First, he assumed that the transit time of an electron from cathode to plate was infinitesimal so that the current pulse produced by each electron could be represented by an impulse or delta function. This immediately postulated that the random component of the current had an infinite frequency spectrum or was "white." This approximation is not a serious limitation except at extremely high frequencies when the transit time is a sensible fraction of a period.

The second and more limiting assumption is that the only force acting on the electron in transit is the electrostatic field between cathode and plate. The forces produced by other electrons in the space charge are neglected. This assumption is valid only when the plate current is temperature limited. The expression for the power spectrum of the random component of the plate current obtained by Schottky was

$$W(f) = 2eI \ \text{a}^2/\text{cps}, \tag{1}$$

where e is the charge of the electron in coulombs and I is the dc plate current in amperes.

For the first time a quantitive expression for the random component of plate current became available and estimates of the ratio of signal-to-noise power could be made. But the formula suffers from a very serious defect, namely, that it is applicable only when the plate current is temperature limited. In practice, vacuum tubes were then and are now being operated with plate currents far below temperature saturation and the measured values of random noise in the plate current were much lower than those predicted by the Schottky formula. For many years attempts were made to explain

[1] W. Schottky, "Theory of shot effect," *Ann. phys.*, vol. 57, pp. 541–568; December, 1918.

this reduction of shot noise,[2-5] but most were empiric and did not get to the basic explanation of the mechanism by which space charge could affect the result.

A major contribution to the understanding of the source of shot noise in space-charge-limited vacuum tubes was made in a set of papers by Thompson, North, and Harris.[6] Briefly, these investigators showed that a negative compensatory current pulse is generated each time an electron crosses the potential minimum between cathode and plate. Referring to Fig. 1, the region between cathode and plate is divided into an α and β region to the left and right of the potential minimum, respectively. As an electron e passes from the α to the β region, it increases the population of the β region, thereby depressing the potential minimum slightly. This inhibits the transit of a certain amount of charge out of the α region and returns it to the cathode. In effect, this is equivalent to a reverse coherent current pulse, as shown in Fig. 2, where i_n is the forward pulse of current produced by an electron entering the β region and i_c is the negative current pulse. The relation between the two is given by

$$i_c = \lambda i_n, \tag{2}$$

where λ is a constant dependent on the degree of space-charge saturation of the plate current. This modification results in a power spectrum for the random component of the plate current given by

$$W(f) = 2\Gamma^2 eI \ \text{a}^2/\text{cps}, \tag{3}$$

where Γ^2 is $(1-\lambda^2)$. For zero space charge, Γ becomes unity and the power spectrum reduces to Schottky's result.

Thompson, North, and Harris computed Γ based on theoretical considerations and proved the result by experiment. A typical plot of Γ vs cathode temperature is shown in Fig. 3. It is seen that the power spectrum of the shot noise in a vacuum tube can be as little as 4 to 5 per cent of the values given by the Schottky formula. The authors extended the theory to cover multi-electrode vacuum tubes. This work essentially completed the basic theory of random noise in vacuum tubes insofar as random noise was concerned.

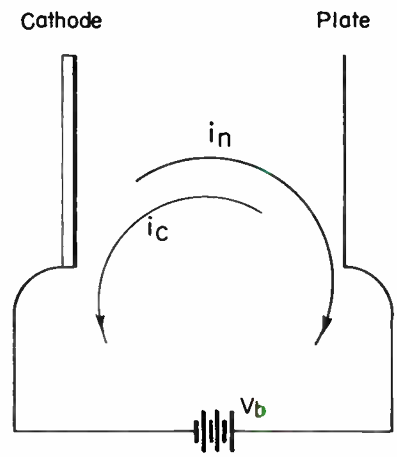

Fig. 2—Noise and compensating pulse produced in space-charge-limited diode.

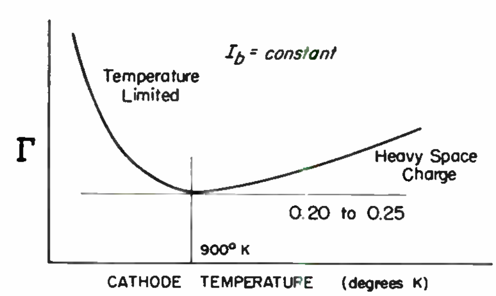

Fig. 3—Typical variation of Γ in a space-charge-limited diode with oxide-coated cathode.

In addition to fluctuation effects produced by vacuum tubes, it was found that random noise signals were generated in metallic resistors made of homogeneous materials. These effects were found to be temperature dependent and are known as thermal noise. A number of basic contributions to the understanding of thermal noise were made in the 1920's and 1930's[4,7,8] among which

was the outstanding paper by Johnson in 1925. The source of thermal conductor noise was traced to the random excitation of the electron gas in the conductor in consequence of its existence in an environment of thermally-agitated molecules. The effect is similar to the Brownian movement of particles suspended in a liquid in which the thermally-agitated molecules of the liquid collide with the suspended particle and impart to it a certain amount of energy. Since the particle is cohesive, collision with any one of its molecules sets the entire particle in motion thereby resulting in random movements observable under a microscope.

The basic principle used to explain Brownian movement is that of equipartition of energy. The cohesive molecular group constituting the particle has imparted to it by collision an equal share of energy per degree of freedom just as the individual free molecules in the liquid have themselves equal shares of thermal energy. In the case of Brownian movement, the particle has three degrees of freedom thereby giving three independent energy storage modes, each of which stores a mean energy given by $\frac{1}{2}KT$ where K is the Boltzman constant and T the absolute temperature.

Analagously, in the case of the electron gas in a conductor, the same cohesive property that exists in the particle can be postulated. If one electron is set in motion by a collision with a thermally-agitated molecule, the entire electron gas in the circuit is set in motion by the suddenly changing magnetic field generated by the accelerating electron. As a result, the principle of equipartition of energy can be applied to this phenomenon and the electron gas derives a share of energy equal to $\frac{1}{2}KT$ for each energy-storage mode such as a condenser or inductor in the circuit. Based on considerations like these, the power spectrum of equivalent generator associated with each resistor is given by

$$W(f) = 4KTR \text{ v}^2/\text{cps} \tag{4}$$

where K, the Boltzman constant, is 1.372×10^{-32} joules/°K, T is absolute temperature in °K, and R is the resistance in ohms. The correctness of the hypothesis and the resultant formula for the power spectrum has been proved experimentally. Thus, all resistances in a circuit can be represented by a resistance and a white noise generator in series as shown in Fig. 4. Resistance components which are not homogeneous, such as composition resistors, generally produce unpredictable noise effects several times greater than homogeneous resistors, due to "crazy contact" effects. As in the case of tube noise, it is fair to assume that thermal noise spectra are white since the electron pulses produced by molecular collision are extremely short in duration.

Thus, by the late 1930's there was good understanding of the mechanisms producing random noise in electronic circuits and it was possible to relate these sources to the performance of a system. The link which made this possible is the fact that the power spectrum is related to the Fourier spectrum of the random signal by the following:[9]

$$W(f) = \lim_{T\to\infty} \frac{2}{T} \left| G(j\omega) \right|^2, \tag{5}$$

where $G(j\omega)$ is the Fourier transform of the random signal $g(t)$, and $\omega = 2\pi f$. Thus, if such a random signal is applied to a linear filter as shown in Fig. 5, it follows readily from the fact that the Fourier transform of the output is the product of the Fourier transform of the input and the transfer function of the filter that the relation between the power spectrum at the input and the output is given by

$$W_y(f) = \left| H(j\omega) \right|^2 W_x(f), \tag{6}$$

where $H(j\omega)$ is the transfer function of the filter or the Fourier transform of its impulsive response. Coupled with the fact that the power spectrum $W_x(f)$ is related to the mean-square value of the signal by the integral

$$\overline{x^2} = \int_0^{+\infty} W_x(f)df, \tag{7}$$

the net effect of noise signals generated spontaneously in electronic circuits can be calculated.

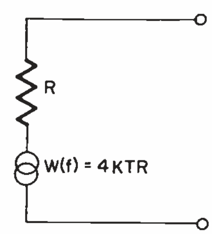

Fig. 4—Equivalent circuit of resistor including thermal-agitation noise-voltage generator.

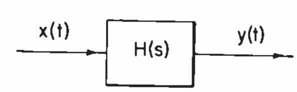

Fig. 5—Block diagram of linear filter with random input and output.

For convenience in analysis, the quantity spectral density $\Phi_{xx}(j\omega)$ is often used instead of power spectrum. Spectral density is an even function which extends from negative to positive infinite frequency and has values at each frequency half those of the power spectrum. Thus, the mean-square value of a signal is given by

$$\overline{x^2} = \frac{1}{2\pi} \int_{-\infty}^{\infty} \Phi_{xx}(j\omega)d\omega. \tag{8}$$

It should be noted here that noise sources so far considered are quite correctly assumed to generate white

[9] S. O. Rice, "Mathematical analysis of random noise," *Bell Sys. Tech. J.*, vol. 23, pp. 282–332, 1944; and vol. 24, pp. 46–156, 1945.

noise spectra based on an understanding of the originating mechanisms. Until the 1940's a certain amount of optimization by adjustment of circuit parameters to obtain optimum signal-to-noise ratios was possible by straightforward analysis. It was later that fundamental work was done in optimum filtering of signals in the presence of noise which is not necessarily white as described in subsequent sections.

III. More General Statistical Tools

The techniques which were used in expressing and analyzing the effects of random noise produced by vacuum tubes and resistors were, in fact, applicable to general problems. For instance, electronic equipments became part of more comprehensive systems such as radar-tracking systems, fire-control systems, navigation systems, etc., during the late 1930's and early 1940's. Analysis and optimization of such systems were urgently required, especially under the stresses of World War II when extension of system capabilities became a matter of national survival.

In most cases involving more comprehensive systems, the mechanisms generating random signals cannot be clearly specified or postulated as they can for shot effect and thermal noise. As a result, the statistical properties of random noise must be determined by experiment from time records of typical situations. A direct determination of power spectrum from these data is not as convenient as through the indirect approach using the autocorrelation function. As far back as 1930[10] Wiener showed a simple interrelationship between the autocorrelation function and the power spectrum, a relation which was to prove most useful in experimental as well as analytical operations. This expression is known as the Wiener-Khintchine relation in recognition of later independent work done by Khintchine.[11]

In order for the Wiener-Khintchine relation to apply, a number of assumptions must be made regarding the random signal. First, the random process of which a particular time record is a member must be stationary; that is, its statistical properties are independent of the origin of time. Secondly, the random process must satisfy the ergodic hypothesis. This implies that the stationary random time functions, an ensemble of which constitutes the random process, possess the same properties whether averaged over time on any one function or over an ensemble of functions at any given time. This means that such characteristics as the autocorrelation function can be obtained by integrating over time as well as over the ensemble. Within these limitations, the autocorrelation function of a random time function $x(t)$ is given[12] by

$$\phi_{xx}(\tau) = \lim_{T\to\infty} \frac{1}{T}\int_{-T/2}^{T/2} x(t)x(t-\tau)dt. \quad (9)$$

The function is a measure of the dependence of the values the time function at any one time to another time displaced τ seconds. For instance, white noise is completely uncorrelated, the correlation function being zero for all finite values of displacement τ. Its mathematical expression is the impulse-response function $\delta(\tau)$ multiplied by a constant.

The Wiener-Khintchine relation states that the spectral density $\Phi_{xx}(j\omega)$ is the Fourier transform of the autocorrelation function[13]

$$\Phi_{xx}(j\omega) = \int_{-\infty}^{\infty} \phi_{xx}(\tau)e^{-j\omega\tau}d\tau, \quad (10)$$

and conversely, the autocorrelation function is the inverse Fourier transform of the power spectrum

$$\phi_{xx}(\tau) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \Phi_{xx}(j\omega)e^{j\omega\tau}d\omega. \quad (11)$$

Similar expressions exist for the relation between two different random functions, $x(t)$ and $y(t)$:

$$\phi_{xy}(\tau) = \lim_{T\to\infty} \frac{1}{T}\int_{-T/2}^{T/2} x(t)y(t+\tau)dt \quad (12)$$

and

$$\Phi_{xy}(j\omega) = \int_{-\infty}^{+\infty} \phi_{xy}(\tau)e^{-j\omega\tau}d\tau \quad (13)$$

$$\phi_{xy}(\tau) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} \Phi_{xy}(j\omega)e^{j\omega\tau}d\omega, \quad (14)$$

where $\phi_{xy}(\tau)$ is known as the crosscorrelation function and $\Phi_{xy}(j\omega)$ the cross spectral density.

Eq. (6) can also be put in a more general form. Let y_1 and y_2 be the outputs from filters $H_1(j\omega)$ and $H_2(j\omega)$ with x_1 and x_2 as the respective inputs. Then

$$\Phi_{y_1y_2}(j\omega) = H_1(-j\omega)H_2(j\omega)\Phi_{x_1x_2}(j\omega). \quad (15)$$

In addition to its application in the analysis of systems in which random signals and noise exist, the Wiener-Khintchine relation is very useful for the experimental determination of pertinent properties of the signal. For instance, a computation and plot of the autocorrelation function can be made directly from the experimental records of a random signal. Usually, the procedure is to fit a convenient analytical expression to the experimental plot of the autocorrelation function and from this the power spectrum of the signal can be obtained. In cases where complex systems such as radar tracking systems must be optimized, information of this type is usually obtained in this manner.

[13] *Ibid.*, p. 283.

In most systems which are of interest to the engineer and the designer, random processes are assumed to be Gaussian or at least assumed to be satisfactorily approximated by such a distribution. As discussed previously, a random signal or noise is usually generated by a large number of independent events (the shot-effect noise is generated by thermoinic emission of individual electrons, etc.). It follows from the central limit theorem in probability theory that, not only is the amplitude of such a signal normally distributed, but the joint distribution function of various amplitudes at various times is also a multivariate normal distribution function. A random signal with this property is called Gaussian. A significant implication of the above is that all statistical properties can be determined from a knowledge of the autocorrelation function or, equivalently, the power spectrum. Furthermore, it can be shown that Gaussian signals remain Gaussian after passing through linear filters. In practical problems, therefore, the measurement of the autocorrelation and its conversion into the power spectrum by Fourier transformation gives all the necessary statistical parameters needed for optimization of systems using procedures which were developed in the World War II years and later.

An outstanding piece of work in this regard is due to Rice.[9] Rice gave an estimate of the closeness to Gaussian distribution of a signal of the shot-effect type; and assuming the distribution to be Gaussian, he derived equations for a number of significant relations, for instance: the distribution of the total power of a random signal, the number of zero crossings and maxima and minima per second, and the power spectrum of the output signal from a nonlinear device.

IV. The Concept of Optimization

There are two types of problems in communication and control in which random signals play an essential role, namely: a) processing and separation of signal from noise, and b) detection of weak signals embedded in noise. Fig. 6 illustrates a problem of type a). The desired output $v(t)$ is the result of a specified linear operation on a signal $r(t)$. The available input signal $r(t)$ is contaminated with random noise $n(t)$. The problem is to design a filter for $i(t)$ so that the output $c(t)$ is closest to $v(t)$ in some well-defined sense.

A major contribution to this problem was made by Wiener[14,15] who, in 1942, worked out an optimization theory of such significance that its influence was to dominate at least the next two decades. He introduced a criterion for closeness of the signal filtered signal $c(t)$ to the ideal signal $v(t)$ on the basis of a least squares difference between the two. Perhaps both mathematical expediency and universality of Gaussian random noise (and signal) conspired to influence him and other pioneer investigators to select the least square error criterion as they did.

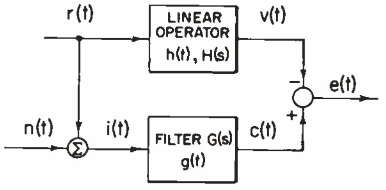

Fig. 6—Block diagram showing criterion for optimum filter.

The criterion for optimization in the case of random signal and noise is expressed as a cost $k(t)$ defined as

$$k(t) = \lim_{T\to\infty} \frac{1}{T} \int_{-T/2}^{+T/2} [e(t)]^2 dt. \tag{16}$$

The design of the so-called optimum filter $G(s)$ is dictated by a minimization of this cost function subject to the conditions that the filter be linear and physically realizable. The latter requires that impulsive response $g(t)$ be zero for negative time. By taking advantage of the fact that the noise and signal are Gaussian, and of the Wiener-Khintchine relation, Wiener solved the problem for the optimum linear filter.

Many modifications of his procedure[16,17] have appeared but, basically, the Wiener approach including the least-square-error criterion has not been altered fundamentally. Booton[18] has extended Wiener's theory to the case where both the signal $r(t)$ and the noise $n(t)$ are random but nonstationary. The difficulty with his result is that it resulted in no general analytic solution, although later investigators[19] obtained a solution which can be implemented only by the use of computers.

In the signal detection problem, many of the methods and criteria used by Wiener influenced the analysis of the problem of estimating the presence or nonpresence of a signal such as a pulse in the presence of random noise. A least-squares-error criterion was used by North[20] to maximize the predicted signal-to-noise ratio. Referring to Fig. 7, the impulse-response function of the predetection filter is denoted as $g(t)$. The problem is to decide whether a filtered output is due to noise alone $a_0(t)$, or due to signal plus noise $a_1(t)$. North solved this

problem for white noise and later investigators[21–26] further enlarged on variations of this problem. The concept of autocorrelation and crosscorrelation function, its relation to the spectral density and the selection of a least-mean-square-error criterion have resulted in significant advances in the optimization of linear filters to which are applied Gaussian noise and/or signal.

V. FUTURE TRENDS

As a result of intensive research in the past few decades, the field of noise and random processes is rapidly becoming mature. It is very unlikely that major contributions such as those made by Wiener are to be expected in the future. However, there are a few discernible trends which are noteworthy.

The understanding of the sources of noise in conductors, semiconductors and electron tubes is fairly well understood so that no important developments should be expected in these areas. On the other hand, in the field of optimization, developments on the concept, analysis and synthesis of adaptive systems which are responsive either to varying inputs or to environment are to be expected. The general subject of nonlinear optimum systems is still in a somewhat undeveloped state. The nonlinearity may already be present in an existing part of the system or may be deliberately introduced in the filter because the inputs are not Gaussian. Many special cases have been worked out, but results of a general nature are very few.

With the availability of fast computers of high capacity, it is expected that their employment as active in-line and off-line devices to implement optimum systems will increase. However, the underlying theory which postulates the employment of such computers in optimum systems is incomplete, and it is expected that research along these lines will be intensified.

Information Theory*

B. McMILLAN†, FELLOW, IRE AND D. SLEPIAN‡, FELLOW, IRE

***Summary*—During the last twenty years three theories dealing with the interaction of signals and noise in communication systems have come into being: detection theory; the statistical theory of filtering and prediction; and Shannon's information theory. They have developed rapidly and now play a key role in the communication engineer's understanding of his field. This paper presents a brief description of the central concepts of each of these theories, discusses their differences and common parts, and attempts to point out both their successes and shortcomings.**

I. INTRODUCTION

THE TERM "Information Theory" is used in the current technical literature with many different senses. Historically it seems first to have been generally applied to describe the specific mathematical model of communication systems developed in 1948 by Shannon [6].[1] In this pioneering paper, Shannon introduced a numerical measure, called by him and others entropy, of the randomness or uncertainty associated

[1] Indeed, Shannon himself in Ref. [6] uses the term (p. 20).

with a class of messages and showed that this quantity measures in a real sense the amount of communication facility needed to transmit with accuracy messages from the given class. He also showed (quite incidentally to his main argument) that this measure of uncertainty agreed *in certain aspects* with the common, vague intuitive notion of the "information content of a message." He accordingly used the words "information content" as a synonym for the precisely defined notion of entropy. As a result, his work and its immediate extensions became known as information theory. The other key concepts in Shannon's model, which will be discussed in detail later, are channel capacity and coding. Many workers today adhere to the following *Strict-Sense Definition: Information Theory is the study of the three concepts, entropy, channel capacity and coding, and of their interrelation either as abstract mathematics or in connection with their application to physical systems.*

As Shannon's work became widely known, a second more inclusive usage of the words came into being among electrical engineers. The exact boundaries of this wide-sense definition of Information Theory are as yet very fluid. For some engineers the words are used to describe all highly mathematical and theoretical investigations into the fundamental nature of the communication process. In this extended sense, information theory includes the study of filtering and prediction, signal detection, noise theory, signal representation, aspects of modulation theory and information processing systems, as well as the Shannon theory. The papers published in the IRE TRANSACTIONS ON INFORMATION THEORY serve as a guide to the subject matter covered by this definition. Other engineers, however, would restrict the usage of the words to those studies of the fundamentals of communications that involve probability theory and statistical notions so that, for example, signal representation and much of modulation theory would be stricken from the above list. These two versions of a wide-sense Information Theory sometimes pass under the names of Communication Theory and Statistical Communication Theory, respectively.

In recent years, particularly in Europe, a third even more extended meaning of the words Information Theory has become common. The term is used to describe any field or study in which "information" in any of its many shades of common meaning plays a role. In this widest sense, Information Theory covers a wide spectrum of disciplines. It includes parts of linguistics, cybernetics, physics, psychology, machine translation, statistics, pattern recognition, semantics, cryptography, data storage and retrieval, etc., as well as the subjects covered by the more restrictive definitions.

In this paper, we shall outline some of the more significant developments of the area referred to above as statistical communication theory. The subject can be divided into three parts: the theory of detection and signal extraction; the theory of filtering and prediction; and the Shannon model of communication systems. We hope to give the reader a general picture of each of these fields and to point out their differences and common parts. Limitations of space unfortunately restrict us to the most cursory of treatments: many important topics are slighted; credits for contributions are largely omitted. The few works cited in the Bibliography are only intended to give the reader some points of entry into the vast literature.

II. General Considerations in Statistical Communication Theory

There are two quite distinct fundamental reasons why probability theory plays such an important role in the description and understanding of communication systems. Both are associated with the engineer's lack of knowledge. The first arises from the fact that the designer of a communication system cannot know in full, microscopic detail the exact behavior, either of the parts of the system he is designing, or of the environment in which he will ultimately place it. At best, he can predict with reasonable accuracy only the average behavior of the system. Its departure from this average, he can only describe in probability terms. These fluctuations he calls "noise." Their importance as a limiting factor in the communication process was recognized at an early date.

The second reason for the appearance of probability theory stems from the fact that the designer cannot know in full detail the *exact* message for which he is designing the system. Indeed, if he knew the message beforehand, there would be little point in constructing the system. He can know, at most, only the class of messages from which the input to his system will be selected and the relative probabilities of selection of messages from that class. *It is this lack of detailed knowledge about the message that is the very reason for communication; it is lack of detailed knowledge of the communication system that limits the attainment of communication.*

As trivial as the point of the preceding paragraph may seem in hindsight, it was a long time in coming. Although hinted at many times earlier in the history of communications, it was not until the early forties, notably in the works of Wiener [11], that the importance and utility of regarding messages as stochastic in nature was clearly recognized. It was not until the work of Shannon that it was properly appreciated that *a priori uncertainty is the very commodity of communication.* The remarkable theoretical developments of the past twenty years are direct consequences of the emergence of this single idea.

Granted the foregoing description, modern communication theory can properly be considered to be an applied branch of probability theory. Its tools are those of the probabilist and statistician. Many of the tools were ready in the early forties, for probability theory, notably in the area of stochastic processes, was then undergoing a vigorous renaissance. (Perhaps this was the *reason* for the new look in communications.) Others developed later: the feedback of communication theory to probability theory is clearly discernible.

The probabilistic description and study of messages (=signals) alone or of noise alone falls in the province of noise theory which is treated in the article "Noise and Random Processes" by Ragazzini and Chang appearing in this issue on page 1146. The study of the *interaction* of signals and noise is the domain of statistical communication theory. Three quite distinct bodies of doctrine which answer this description are treated in the next sections of this paper. The first two, detection theory and filtering theory, treat specific tasks performed in certain parts of some communication systems. There is considerable overlap between these theories. Their classification as separate subjects, rather than as special cases of a larger theory, is now firmly entrenched, but appears to be for historical rather than logical reasons. The third subject, strict-sense information theory, treats the complete one-way communication system as a whole.

III. Detection Theory and Signal Extraction

An observer is presented with a number x known to be drawn from either of two populations—one P_0 is governed by a probability density $p_0(y)$; the other P_1 is governed by $p_1(y)$. Both functions, $p_0(y)$ and $p_1(y)$, are known to him. He must attempt to guess from which population his sample x was drawn. This situation, in its many generalizations and ramifications, forms the content of the subject that satisticians know as hypothesis testing. In communication work, it forms the core of detection theory. Here x (suitably generalized) repsents a received waveform, $p_0(y)$ describes a population of noise alone and $p_1(y)$ describes a population of signal and noise. The observer must hazard a guess to settle the quandary, "Is this wave-form noise alone, or is signal also present?"

Any rule that the observer arrives at for guessing can be described as a separation of all possible x values into two sets: the set for which he asserts P_0 and the set for which he asserts P_1. Following his rule, he can possibly make two kinds of errors: he may sometimes assert that the sample came from P_0 when it came from P_1; he may sometimes assert that the sample came from P_1 when indeed it came from P_0. How should he use his knowledge of $p_0(y)$ and $p_1(y)$ to make a good rule? The answer clearly depends on the relative cost to him of the two types of error just mentioned. It also depends on whether or not he has additional information, possibly in the form of *a priori* probabilities that the sample be drawn from P_0 or P_1. Finally, if the observer is allowed to take further samples from the unknown population, his rule for guessing may depend on the cost to him of making an additional observation.

The situation just described has been studied in considerable detail by statisticians under a wide variety of assumptions. However, the application of their results to the problems of the communication engineer is not in general a straightforward matter of substituting into existing formulae. The statistician has for the most part considered the sample x to be a single number, or at most a finite set of numbers. In many engineering problems, the observed sample, a waveform, is a continuum of numbers. Nontrivial limiting processes must frequently be investigated to extend the statistician's results to the engineer's needs. Then too the classical formulation appears deceptively easy: often relatively simple sounding engineering problems result in exceedingly complicated analysis, and one must be satisfied with approximate answers to the problems posed.

Technical details of the many engineering problems that have been treated by this extended theory of hypothesis testing are too involved for inclusion here. We mention only a few key concepts and results that have emerged. 1) Under a surprisingly large class of different assumptions regarding both *a priori* knowledge and the method of measuring cost of faulty decision, the form of the observer's best rule is the same. For his given sample x, he evaluates the "likelihood function" $l(x) \equiv p_0(x)/p_1(x)$. If this exceeds a critical number, k, called the threshold, he decides that x came from P_0; otherwise that it came from P_1. Differences in *a priori* assumptions and cost criteria only serve to alter the proper choice of k. 2) Many problems for which general solutions are not feasible in tractable form admit simple useful instrumentable results in limiting cases of very small or very large signal-to-noise ratios. 3) In the case of additive signals and noise, the assumption of very wide-band white noise yields great simplifications. Detectors, derivable by other means, emerge as optimum. Correlation detectors and matched filters play a key role here.

Closely associated with hypothesis testing is the theory of parameter estimation, or in communication language, the theory of signal extraction. In the statistical setting, an observer is given a sample x drawn from a population governed by probability density $p(x, \alpha)$ depending on a parameter α. The density $p(x, \alpha)$ is known to the observer as a function of x and α. He does not, however, know the value of α that maintained when his observation was drawn. He is to estimate this value from his observation x. To do this he forms an estimator function $\hat{\alpha}(x)$: evaluated at his observed sample x, $\hat{\alpha}$ is the observer's estimate of α. In communication applications, x is replaced by a received waveform consisting of a signal contaminated by noise. The observer knows the statistical structure of the noise and the analytic form of the signal. He does not know the precise value of certain parameters which enter into the description of the signal (*e.g.*, a shift of time origin or change in magnitude for a returning radar pulse). From this knowledge he can deduce a probability measure, the analog of $p(x, \alpha)$ just discussed, which describes the statistical structure of the possible received waveforms. This probability measure will depend on the literal parameters entering into the description of the signal. From examination of a particular received waveform, the observer wishes to deduce the probability measure describing the population from which it was drawn: that is, he seeks to determine the values of the signal parameters. As in hypothesis testing, application of the statistician's model to the communication engineer's needs calls for generalizing x from a number, or finite collection of numbers, to a function, or continuum of numbers.

If α can assume only one of two values, the situation just described is identical with that of hypothesis testing already discussed. If, as is usually the case, α can take a continuum of values, the situation is sufficiently different to warrant separate names and treatment for hypothesis testing and parameter estimation. In particular, the two types of error which play a key role in certain parts of hypothesis testing have no simple counterparts in parameter estimation.

What constitutes a good estimator $\hat{\alpha}(x)$ depends on how one measures the cost of guessing a faulty value for the parameter. One approach is to require that on the average $\hat{\alpha}(x)$ should yield the true value α of the parameter. Among such estimators, one of minimum variance is sought; that is, one seeks to minimize the average squared error of estimate. Such estimators do not always exist, however. Frequently the sample x is a sequence of numbers representing repeated independent samples from the population. In this case another weaker condition may be appropriate: one can ask merely that as the number N of samples increases the estimator $\hat{\alpha}_N(x)$ asymptotically have the unbiased and minimum variance properties just described. These and many other measures of effectiveness of estimators have been studied and applied to communication problems.

Detection and extraction theory have had many successes to date. Their earliest applications were to radar and various military systems. They are currently playing an important part in radio and radar astronomy and beyond-the-horizon radio communication systems. They can be expected to contribute significantly to problems of satellite communication and tracking, seismic analysis, and other systems operating with small signal-to-noise ratios.

The theories also have their limitations. We have already mentioned the difficulty of carrying out to completion solutions indicated theoretically. More fundamental are troubles of a conceptual sort found in specifying basic data required by the theory. The theories make use of *a priori* knowledge of signal and noise statistics to provide decisions which minimize some measure of the cost of faulty decisions. All too often in practical problems the *a priori* probabilities are poorly defined and the intelligent assignment of comparative costs for errors is difficult to make. Perhaps these difficulties should not be charged to the theory itself. Nevertheless, they limit its range of useful applicability.

IV. Filtering and Prediction Theory

The situation studied in what is commonly known as filtering and prediction theory is as follows. A received waveform $r(t)$ is available to an observer. It is known to be the *sum* of two parts, signal and noise: $r(t)=s(t)+n(t)$. The observer wishes to measure some attribute of $s(t)$ by performing a linear operation on $r(t)$. How should he choose the linear operation to best achieve this aim?

The problem can be regarded as a special case of estimation theory. The specialization lies in the assumed additivity of signal and noise and the restriction of the observer to linear operations. Historically this problem was treated in great detail [11] before the statistical theory of parameter estimation was carried over as a whole to communication problems. As a consequence it is generally regarded as a separate subject today.

The nature of the solution depends, of course, in the first place on what *a priori* knowledge the observer has about $s(t)$ and $n(t)$. If he has none, the problem is not very meaningful; if he knows either $s(t)$ or $n(t)$ exactly, the problem is trivial. A wide variety of interesting intermediate cases suggest themselves, and most have been studied. Typical are: 1) s and n are both continuous stochastic processes with known statistics; 2) n is stochastic and s is a polynomial of known degree but with unknown coefficients. The interval during which $r(t)$ may be observed can be finite or semi-infinite.

The nature of the solution also depends on what attribute of s is to be estimated as well as on the criterion by which errors of measurement are judged. As for the former, typical quantities to be estimated are: 1) s at some time instant past, present, or future, 2) the time derivative of s, or 3), in the case of a nonstochastic signal, some parameter entering the description of the signal. The error criterion most commonly considered is the mean squared deviation of the estimate from the true value of the quantity sought. This criterion is by far the simplest to deal with mathematically and in many situations is not unreasonable physically. For its computation, only second-order statistics of s and n are required and hence the linear operation (or filter) that yields the minimum mean squared error can be determined from the spectra and cross spectra of the signal and noise; these latter quantities are often available from engineering considerations. Some partial results are known for other error criteria.

Finally, the nature of the solution depends on restrictions that may be imposed on the class of linear operations within which a solution is to be found. In the case commonly treated, in which signal and noise are stationary, the filter is required to be physically realizable in the sense of circuit theory. It is the nature of the restrictions put upon the class of allowed solutions that to a large degree determines the mathematical difficulty encountered in finding a solution. In almost all problems of the class under discussion, the assumption of power spectra, for noise or signal plus noise, which are rational functions of frequency leads to significant simplification in the analytic difficulties encountered.

Experience has shown that in the neighborhood of the optimum filter, the mean square error is quite insensitive to (intelligent) changes in the filter design. It is true, then, that in practice very few filters are built following precisely the prescription of the theory: small changes can frequently effect considerable economy in equipment. Nevertheless, the theory has been an effective and valuable guide in the design of many practical systems and will undoubtedly continue to be of great value in the future.

V. Information Theory—Strict Sense

The mathematical models of the communication process sketched in the preceding paragraphs have tacitly fixed attention on what might be called the *problem of reception:* given a statistical, or parametric description of the class of signals, and of the noise, how to infer something desired about the original signal from a sample of noisy signal. The solution to a given problem of this kind describes, at least in mathematical terms, an optimum receiver for the particular classes of signals and noise involved. No attention is given in this model to the fact that often the engineer also has control, *e.g.*, by a choice of modulation scheme, over the class of signals for which his receiver is to be optimized. True, the model permits repeated optimization of the receiver for various classes of transmitted signals, so that one could in principle search for an optimum-optimum combination, but the theory offers no general guidance for this search nor does it give any description of the result of a successful search.

Shannon's theory, information theory in the strict sense, attacks the general problem of simultaneous design of transmitter and receiver for optimum communication of a given class of messages over a given medium. Furthermore the theory solves this problem and gives a quantitative description of the performance of the optimum combination. These are sweeping claims for a theory; our essay must now show both the scope and limitations of the model within which the theory operates.

Intrinsic to the strict-sense theory is a restriction to discrete or telegraph-like signals. Generalizations to signals taking a continuum of values have never successfully concealed this restriction; they have all made use of "quantizing," or reduction to a discrete situation. Shannon's model of an *information source* then begins with a discrete alphabet M of symbols, say $M_1, M_2, \cdots, M_K$. A simple case is that of telegraphy in which $K=2$, $M_1=0=$ space, $M_2=1=$ mark; this is usually called a binary source. At another extreme, $\log_2 K \doteq 40{,}000$ and M consists of all of the conceivable English paragraphs of fewer than 10,000 words.

An information source is just a stationary stochastic process whose sample sequences are strings of symbols out of the alphabet M. More mechanistically, an information source produces strings of text $\cdots m_{-1}, m_0, m_1, \cdots$ whose statistical properties are known. Here each m_i is drawn from the alphabet M, and one supposes that he can calculate all such probabilities as

$$\text{Prob}\left\{m_{-9} = M_{31} \text{ and } m_{-8} = M_9 \text{ and } \cdots m_{1057} = M_{93}\right\}.$$

Furthermore (stationarity), one requires that, *e.g.*, the probability above be equal to any one of the following:

$$\text{Prob}\left\{m_{-9+k} = M_{31} \text{ and } m_{-8+k} = M_9 \text{ and } \cdots \text{ and } m_{1057+k} = M_{93}\right\},$$

for $k=0, \pm 1, \pm 2, \cdots$. A time-shift does not change the statistics of the process.

The simplest kind of information source is one in which each M_i is drawn with probability p_i, $1 \leq i \leq K$, and successive choices are independent. The probabilities above would in this case all be the product $p_{31} \cdot p_9 \cdots p_{93}$. Such a source is called an independent source. The option to let M itself consist of very long sequences of text makes it possible to base the theory almost wholly on independent sources. In fact the known theory scarcely goes beyond this point, its greater generality being more in appearance than in fact.

Shannon shows that, when N is a large integer, long strings $m_1 m_2 \cdots m_N$ of text from the source have great statistical regularity. *E.g.*, for a binary source in which $p_1=0.99$ and $p_2=0.01$, it is highly probable that the proportion of spaces in a long string is very nearly 0.99. This numerically minute fraction of the possible long strings therefore exhausts most of the likely possibilities. In general, there is a number H, determined by the source, with the property that, given a large N, one can find approximately 2^{NH} strings $m_1 \cdots m_N$ which collectively exhaust almost all of the probability. More exactly, given two arbitrary small numbers $\epsilon > 0$, $\delta > 0$, there is a typically large $N_0(\epsilon, \delta)$ such that if $N \geq N_0$ then there is a set S of strings $m_1 \cdots m_N$ containing between 2^{NH} and $2^{N(H+\delta)}$ strings, such that the total probability of S exceeds $1-\epsilon$. We shall call S a set of "likely" strings of length N.

H is the *entropy* of the source. For an independent source, it can be shown that

$$H = \sum_{i=1}^{K} p_i \log_2 \frac{1}{p_i} \cdot$$

Always $H \leq \log_2 K$, and equality holds only when the source is independent and each $p_i = K^{-1}$.

There are exactly $2^{N(H+\delta)}$ distinct strings of binary symbols of length $N(H+\delta)$. One sees from the definition above therefore that there are enough such strings that one can establish a one-one correspondence, or code, between the likely source strings of length N and strings of binary symbols of length $N(H+\delta)$. Furthermore, one cannot succeed in this with fewer than 2^{NH} binary strings. Hence between H and $H+\delta$ binary symbols per symbol of text must be used for a one-one encoding of the likely source strings into strings of binary symbols. An alternative definition of H can be obtained from this fact. In any case, we see H as the minimum number of symbols of "standard" binary text needed, on the average, to represent one symbol of actual text. The relevance of such a measure of information rate to the design of commercial communication circuits should be clear.

Implicit in the concept of entropy or information rate is the notion of modulation—encoding the original text into symbols more suitable for transmission. H appears as the minimum amount of binary telegraphic capacity needed per unit of original text. Departures from this minimum may be needed to combat noise, as the theory will show.

The notion of a *noisy channel* requires two more discrete alphabets, say $A=(A_1, A_2, \cdots, A_F)$, an alphabet exhausting the possible or at least allowable input waveforms of unit duration, and $X=(X_1, \cdots, X_G)$, an alphabet of output waveforms. For realism, $G \geq F$, and typically $G \gg F$.

We think of each A_i and X_j as occupying a unit of time so that the channel takes as inputs the strings $\cdots \alpha_{-1}, \alpha_0, \alpha_1, \cdots$, and produces as outputs the strings $\cdots x_{-1}, x_0, x_1, \cdots$, where each α_i is from A and each x_i is from X. Noise on the channel is represented by the fact that, even when the whole input sequence $\cdots \alpha_{-1}, \alpha_0, \alpha_1, \cdots$ is given, the output sequence $\cdots x_{-1}, x_0, x_1, \cdots$ is not unique, and can only be described as a stochastic process—*i.e.*, in terms of probabilities like Prob $\{x_{-100}=X_{29}$ and $\cdots$ etc.$\}$. These probabilities depend, of course, on the particular input sequence assumed.

For realism, one must require of a channel that the statistics, say, of sequences $x_1, \cdots, x_L$ do not depend on the $\alpha_{L+1}, \alpha_{L+2}, \cdots$; *i.e.*, prediction is disallowed. For the theorems of the theory to be valid one must also require that the statistics of $x_1, \cdots, x_L$ do not depend in any material way upon the remote past—*e.g.*, upon $\alpha_{-R}, \alpha_{-R-1}, \cdots$ for large R; similarly, significant dependence on the remote future must be ruled out, for validity even if not for realism. Practically, these restrictions reduce the theory almost to considering only the *channel without memory:* this channel is described by a family $p(x, \alpha)$ of distributions already familiar to us: $p(x, \alpha)$ is the probability that x will be received when α is transmitted, x being drawn from the alphabet X, α from A. For this channel, the probability $p(x_1 \cdots x_N, \alpha_1 \cdots \alpha_N)$ that $x_1 \cdots x_N$ will be received when $\alpha_1 \cdots \alpha_N$ are transmitted is *by definition*

$$p(x_1 \cdots x_N, \alpha_1 \cdots \alpha_N) = p(x_1, \alpha_1)p(x_2, \alpha_2) \cdots p(x_N, \alpha_N),$$

independently of α_k for $k \leq 0$ and $k \geq N+1$.

The key to the strict-sense theory is the fact that the problem of estimation or reception becomes almost trivial when the integer parameter N which appeared above is large enough, *provided the engineer makes effective use of his option to select suitable transmitted sequences and in particular selects few enough of them.*

For channels without memory, and for certain simple generalizations of them, there exists a number C, called the *capacity* of the channel, whose properties are crucial. To describe these properties easily, we will introduce an auxiliary term: two input sequences $\alpha_1' \cdots \alpha_N'$ and $\alpha_1'' \cdots \alpha_N''$ will be called distinguishable at the level ϵ, where $\epsilon > 0$, if there is a set S_1 of sequences $x_1 \cdots x_N$ whose total probability under the distribution $p(x_1 \cdots x_N, \alpha_1' \cdots \alpha_N')$ exceeds $1-\epsilon$, and a set S_2 whose total probability under $p(x_1 \cdots x_N, \alpha_1'' \cdots \alpha_N'')$ exceeds $1-\epsilon$, such that S_1 and S_2 contain no sequences in common. This makes precise the idea that $\alpha_1' \cdots \alpha_N'$ and $\alpha_1'' \cdots \alpha_N''$ could with high probability be distinguished from each other at the output *provided no other inputs were allowed.*

A set of more than two input sequences will be called distinguishable at the level ϵ if each pair of them is so distinguishable. By restricting the channel inputs to sequences $\alpha_1 \cdots \alpha_N$ drawn from a set distinguishable at the level ϵ, the engineer simplifies almost to triviality the problem of "estimating" $\alpha_1 \cdots \alpha_N$ from $x_1 \cdots x_N$, and achieves an estimation, *i.e.*, communication, which is *exact* (without *any* error) with probability at least $1-\epsilon$.

The capacity C of a channel tells the engineer how many distinguishable sequences he can expect to find. Loosely, there are approximately 2^{NC} such sequences of length N. More exactly, given $\epsilon > 0$ and $\delta > 0$, there is an $N_0(\epsilon, \delta)$ such that, if $N \geq N_0$, there are at least $2^{N(C-\delta)}$ and no more than 2^{NC} sequences $\alpha_1 \cdots \alpha_N$ distinguishable at the level ϵ. The capacity C can be computed from the probabilities $p(x, \alpha)$.

Feinstein [2] gives a constructive process for finding approximately 2^{NC} distinguishable sequences. His method is of considerable theoretical importance, but unfortunately is too lengthy to be of use in the design of practical communication systems. The search for simple systematic methods to generate maximal sets of distinguishable sequences is called the coding problem. This problem has been studied at length for certain simple channels, and for moderate values of N some solutions [4], even practicable ones, have been found. It is the authors' impression that, even though the known solutions apply to highly idealized channels, their form has begun to guide the design of telegraph-like communication systems.

Given a source of entropy H per symbol, and a channel of capacity C per unit time, one can, with appropriate approximations as suggested by the discussion above, find a large L and a large N such that there are 2^{LH} likely sequences of text of length L from the source and 2^{NC} distinguishable sequences of length N available on the channel, and such that $2^{LH} \leq 2^{NC}$. Then one can imagine a code which establishes a uniquely determined and characteristic distinguishable channel input sequence $\alpha_1 \cdots \alpha_N$ for each likely sequence $m_1 \cdots m_L$ of text. This code describes the "modulator;" with the inverse "demodulator" or decoder at the receiver, it completes the "construction" of a communication system which averages H/C units of channel time to transmit one symbol of text from the source. Furthermore, it is only a rare sequence of text, or a rare event on the channel, which prevents *exact* recovery at the receiver of the text offered for transmission. The search for systematic rather than merely *ad hoc* "modulators" is sometimes included as part of the coding problem.

This completes our rather detailed and, hopefully, explanatory account of the elements of information theory in the strict sense. Our intent has been to show both its scope and its restrictions. In sum, it is larger in scope than the other theories here discussed because it includes explicitly the design of the "modulator" as well as of the "receiver." Nevertheless, it is restricted in its point of view to an idealization of the problem seen by the designer of a commercial communication service: performance is evaluated in terms of *channel time per unit of offered text*, and essentially exact transmission is the goal—there are no degrees or shades of "wrongness," all errors are equally serious, and it is the probability of error that one seeks to control.

We did not mention as restrictive the fact that the strict-sense theory as here described requires quantized signals and a quantized time parameter. Both of these elements of quantization are apparent in any extant version of the theory, and, practically, their presence is not really restrictive.

The authors tend to the belief that discreteness is intrinsic to the theory and cannot be eliminated. Attempts to conceal it are more for mathematical elegance than for increased scope.

One application of the theory to an apparently nondiscrete situation has become famous. Shannon calculates the capacity C of the band-limited channel with additive white Gaussian noise to be

$$C = W \log_2 \left(1 + \frac{S}{N}\right),$$

where W is the bandwidth in cycles per second, S is the average power of the transmitter in watts and N the average noise power in the band in watts. Specialized and idealized as this formula may be, it alone gives great insight into the quantitative factors that govern communication in the presence of additive noise.

The generality of the strict-sense theory is regarded by some as a weakness—it does not give specific hardware answers. This is, of course, because the model is not restricted to specific situations. In fact, specific situations can be treated within the framework of the model. The application then usually calls for computations of enormous complexity; in this the strict-sense theory is not unique.

The theory will probably always remain, like thermodynamics, conceptual and guiding rather than definitive. This is not because its calculations are difficult, but for a more basic reason: the theory presupposes something unattainable, namely, an exact knowledge in detail of the statistics of the source and of the channel. In this fact, again, the strict-sense theory is like most of the others here discussed.

Just because the theory has been largely guiding, it is difficult to point to specific accomplishments. The theory makes precise the idea that to combat noise one must use for transmission only a small fraction of the possible signals that the medium will support; nevertheless wide-band FM was invented, and even understood, long before the theory appeared. Similarly, the theory points strongly to quantization; nevertheless regenerative telegraph repeaters, and at least one independent invention of PCM, predate Shannon's papers. The theory also easily shows that (quantized) pulse-position modulation is as good as one can use for communicating at low ratios of signal to additive noise. Nevertheless, radar was invented almost two decades before this result. The least that one can say for the theory is that it has unified these, and many other, diverse appearing facts into a common conceptual framework. Perhaps the most that one can hope is that this framework will someday be enlarged to include without strain those problems, like that of radar, in which channel time per unit of text is not the quantity of primary or natural interest.

Frequency and Time Standards*

L. ESSEN†

Summary—**The gradual development of quartz and atomic clocks has resulted in an improvement in the accuracy of frequency measurement by a factor of at least 10^4 in the past 30 years. The best quartz clocks drift upwards in frequency at an average rate of about 1 part in 10^9 per month and operate with a day to day stability of a few parts in 10^{11}.**

A caesium standard based on the magnetic deflexion of an atomic beam has been in operation since 1955 and recent models of this type of standard enable frequency and time to be defined in terms of atomic constants with an accuracy of a few parts in 10^{11}. It has revealed irregular and seasonal variations in the length of the day of about 1 msec.

The techniques of optical pumping and detection, of the use of buffer gases, and of wall coatings which enable atoms to be reflected without undergoing transitions have made it possible to make working atomic standards which are already of great stability and may well be capable of still further improvement.

I. Introduction

No branch of physical measurement has made more rapid progress in recent years than that of the measurement of time and frequency, and this advance has depended very largely on developments in the field of radio engineering. This review overlaps in time that written in 1955 by Lewis [1] but deals more particularly with the subsequent developments.

Thirty years ago at the National Physical Laboratory the standard of frequency was a 1000 cps tuning fork, which was maintained in vibration in a valve circuit. The fork circuit drove a phonic motor at 10 revolutions per second, and a reduction gear wheel produced electrical impulses at intervals of 1 second. These seconds intervals were compared on a chronograph with seconds marks obtained from a standard pendulum clock and in this way the frequency of the fork was measured with an accuracy of about 1 part in 10^5. The rate of the pendulum clock was measured in terms of the mean solar second by daily comparisons with observatory time signals. Today the standard is a quartz clock which operates with a day to day stability within 1 part in 10^{10} and which is calibrated whenever necessary by means of a caesium atomic beam standard with a precision of a few parts in 10^{11}. The quartz clocks are used to integrate atomic time and one of the applications of this atomic time scale has been to measure variations in the rate of rotation of the earth.

This development illustrates the fact that there is no essential difference between a standard of time and a standard of frequency. The passage of time is measured by counting the repetitions of some regular event, and whether the rotations of the earth, the vibrations of a piece of quartz or the waves emitted by an atom are used is simply a matter of convenience and of the precision required. When the regular events occur many times in a second it is more convenient to speak of the number per second or their frequency rather than the time between each event. The suggestion which is sometimes made that a unit of frequency should be defined independently of the unit of time is thus based on a misunderstanding. A unit of frequency is also a unit of time and if the sug-

† National Physical Laboratory, Teddington, England.

gestion were adopted there would be two units of the same quantity.

There is, however, one distinction which should be made. The axial rotation of the earth not only provides a standard of time interval but it also determines the time of day and the word "time" is in consequence used in both senses. Now that there is an alternative standard it is becoming important to distinguish between time interval and time because whereas the atomic clock can provide the former, the time of day can only be determined by astronomical measurements of the position of a point on the earth's surface relative to the sun.

II. The Unit of Time Interval and Frequency

It may be useful here to give the present definition of the unit of time interval and to explain how it is linked with the atomic unit, which is essential for the most precise measurements. The definition was adopted in 1956 because the variations in the length of the day, *i.e.*, in mean solar time, were causing increasing difficulties in a number of fields of work including the tabulation of the positions of the bodies of the solar system. The new unit, the second of Ephemeris Time (ET), is based on the revolution of the earth around the sun and is defined as the fraction 1/31 556, 925.9747 of the tropical year for 1900 January 0 at 12h Ephemeris Time [2], [3]. The value is chosen so as to equal the average value of the mean solar second over the period of about 200 years covered by Newcomb's Tables, and it is referred to a particular epoch because it is subject to a slow secular change.

The laws of motion of the planets are determined from observations extending over the same period of 200 years, and their positions are tabulated with this unit of time as the independent variable.

If the positions are measured in terms of mean solar time [also called Universal Time (UT)], a comparison of the measured and tabulated values gives the difference UT−ET. The correction UT−ET can be determined only in retrospect as it must be averaged over a considerable number of years to obtain the required accuracy.

The value of the caesium frequency in terms of ET determined [4] from measurements extending over three years is 9, 192, 631, 770 $\pm$ 20 cps and the atomic clock can therefore be used to make the second of ephemeris time immediately available, with an accuracy of $\pm$20 cycles or $\pm$22 parts in 10^{10}.

The atomic clock can be used with a precision of 1 part in 10^{10} and the value 9, 192, 631, 770 cycles has been used provisionally as a unit of atomic time, although this may not be the value finally chosen. From the point of view of the physicist the actual value chosen is immaterial (so long as it is stated) as the unit is a fundamental atomic constant. The value must be chosen so as to link atomic and astronomical time in a manner most convenient to the many users, whose requirements are not necessarily the same.

III. Quartz Clocks

The tuning fork was developed to a point at which it gave a stability of 1 part in 10^7 per week [5] and could have been improved still further. By this time however, the first quartz clock had been made by Horton and Marrison [6], and it seemed clear that quartz possessed many advantages. One fundamental advantage was the higher frequency of quartz vibrations. Frequencies of many millions of cycles per second were already being used for radio transmissions, and it was not very convenient to measure them in terms of a standard having such a low value as 1 kc. The problems of manufacturing quartz oscillators on a commercial scale for the control of transmitting stations and other radio applications have been solved step by step and high quality oscillators are now readily available for any frequency below 10 Mc. At present, effort is being devoted to making them sufficiently rugged to withstand rocket flight while still preserving a stability to 1 part in 10^9 per day [7]. The work on commercial oscillators though remarkably successful did not have as much effect on quartz standards of the highest precision as might have been expected. The 100-kc GT plate was, however, fairly widely used for this purpose and selected samples of the 1-Mc and 2.5-Mc plates [8] (Fig. 1) are probably as stable as any in use today. The drift rate of the 2.5-Mc oscillators ranges from 1 to 10 parts in 10^{10} per month. The oscillators in use at the Bell Telephone Laboratories have shown drift rates of about 6 parts in 10^9 in 2 years. Short time variations are of the order of 1 part in 10^{10} to 1 part in 10^{11} depending upon the method used for measurement. However, two standards designed quite early in the history of the development of quartz clocks and made in small numbers "by hand," have continued to give comparable performance. These are the 60- and 66.$\dot{6}$-kc bars developed at the Physikalisch Technische Bundesanstalt in Germany [9] and the 100-kc rings developed at the National Physical Laboratory in England [10]. One of the main practical problems of the lower frequency crystals is to hold the quartz firmly without damping its oscillations, and an overtone vibration having nodal points is therefore chosen. It is doubtful, however, whether there are any true nodes in a quartz vibration and it is always necessary to allow a certain amount of resilience in the support. The rings as first made rested on three points located in radial grooves cut in the lower face of the ring as shown in Fig. 2, but later versions now made at the British Post Office are supported, as explained by Lewis [1], by nylon threads. Threads are also used to support the bars and the latest form adopted is shown in Fig. 3. Fig. 4 shows the bar as mounted.

Both of these standards are operated at the temperature at which the temperature coefficient is zero and the other conditions of operation are all carefully controlled. The standards increase in frequency at rates which vary between a few parts in 10^{10} to a few parts in 10^9 per month. The results for a number of the rings operated at

the NPL, the British Post Office and the U. S. Naval Observatory are shown in Fig. 5 after linear drifts have been removed [11]. The somewhat erratic behaviour of the NPL standards at the ends of 1955 and 1957 may be due to failures in the mains electrical supply occurring at these times. Very similar results have been published for the PTB bars [12], which do not appear to have been used elsewhere. Several of the bars have drift rates of less than 1×10^{-9} per month, and further improvements to the circuits and mounting have been made [13]. The new bars operate with a day to day stability of ± 1 part in 10^{11}. The performance of quartz standards may be improved when they are maintained at a low temperature. A quartz ring designed by the British Post Office to have a zero coefficient at the appropriate temperature of about 10°C was housed at the bottom of a 50 ft bore hole and tested as a resonator. In a period of 3 years it drifted 18 parts in 10^9. Similar studies have been made at the NBS, Boulder, with GT plates and 5-Mc plates [14]. Tests have been made at Boulder and at the Bell Laboratories at liquid nitrogen and at liquid helium temperatures where a Q of 5×10^7 was achieved [15] with a short time stability of 1 part in 10^{11}.

The main requirement of a quartz clock when used in conjunction with astronomical measurements to provide a scale of time is uniformity of operation over periods of a year or more. The astronomical measurements have to be averaged over long periods and it is clear that if the rate of the quartz clock is not constant or varying in a uniform manner it is impossible to determine its value and then to use it for extrapolating time beyond the astronomical observations. The clocks themselves can be compared with a precision of 1 part in 10^{10} but although such comparisons help the user to decide which are keeping more constant they did not provide a more accurate time scale. This was limited to an accuracy of about 5 parts in 10^9 by the errors in the astronomical measurements. The position is completely changed now that atomic standards are available. These enable the quartz clocks to be calibrated in a few minutes with an accuracy of a few parts in 10^{11}, and what is required is a very high stability for the few days or weeks during which they may be used between calibrations.

IV. Atomic Clocks

It is obvious from the Bohr relationship $f=(E_2-E_1)/h$ between two energy states of an atom E_1, E_2 and the frequency f of the wave emitted or absorbed in a transition between them that any spectral line is a potential standard of frequency and hence of time interval. The author recalls that one of the pioneer investigators of quartz oscillators, D. W. Dye, considered the possibility of making a quartz plate so thin, and therefore of such a high resonant frequency, that it could be maintained in oscillation by a suitable light source. The gap from, say, 10^8 cps to 10^{15} cps was however far too great for the practical realization of this idea, but the recollection illustrates that radio engineers were alive to such a possibility. It was not many years before the gap was bridged and in 1934 Cleeton and Williams [16] at Michigan University excited a spectral line of ammonia at a frequency of 23,870 Mcs by a source of radio waves generated in the laboratory. The source used by them for exciting the transitions was a magnetron which generated a fairly wide band of frequencies and the ammonia was at atmospheric pressure, at which only a very broad resonance effect is observed. The width was mainly due to the effect of collisions and this can be reduced by reducing the pressure. Other broadening effects such as the Doppler effect then become important and under optimum conditions the line width remains at about 500 kc.

As the standard of astronomical time is known to about 5 parts in 10^9 it is clear that an atomic standard does not become useful until it at least equals this accuracy. Radical improvements were needed to the source of oscillations which must be stable and "monochromatic" to a few parts in 10^{10} and also to the atomic resonance the fractional width of which must be reduced to about 10^{-8} corresponding to 240 cps for ammonia.

A. Sources of Oscillation

The klystron valve can be made to oscillate in the region of frequencies of the order of 10^{10} cps in which some of the RF spectral lines are found and it has a much narrower frequency band than the magnetron. It can be further improved by a stabilizing circuit designed by Pound [17] which maintains it at the frequency of an external cavity resonator. Using a large high Q cavity, Essen [18] obtained a bandwidth of 1 cps with such an oscillator, and, with J. V. L. Parry, used it for the first precise measurement of the caesium hyperfine line now used in atomic clocks [19]. The frequency of the source could be varied over a wide range enabling the hyperfine line to be found and also enabling the neighboring Zeeman pattern lines to be investigated, but careful adjustment of the circuit was needed to obtain the narrow bandwidth required. Quartz oscillators can be varied by a few parts in 10^5 and are more convenient to use when the frequency is known within these limits. They have been used to control klystron oscillators and also by frequency multiplication to provide the exciting source directly. In the latter method the power that can readily be obtained is a few milliwatts at 10^{10} cps. If a wide frequency range is required, frequency synthesisers are now available which will produce from a quartz crystal any frequency up to say 10 Mc. This variable frequency can be included somewhere in the multiplying chain from a quartz oscillator of, for example, 5 Mc to give the required output frequency. One disadvantage of this method is the difficulty of keeping the output frequency free from sidebands which can produce errors of setting to the spectral line. The most reliable method is probably to multiply the frequency of a suitable quartz oscillator and to adjust it to give the spectral line frequency exactly. The oscillator is then measured by any convenient means in terms of the quartz standard which is thereby calibrated in terms of the atomic resonance. In this part of the measurement a frequency synthesiser can be used because sidebands do not effect the accuracy. At the National Physical Laboratory a number of schemes have been used [20] and the one which has proved the most convenient [21] is shown in schematic form in Fig. 6. A high-quality quartz oscillator is varied smoothly through a small frequency range centered on 5.0069 Mc and this frequency is multiplied by 2 and then by 306 by valve circuits with a final triode giving a power of 0.5 watt at 3064.2 Mc. The third harmonic generated by a germanium diode excites the atomic resonance and when the frequency of the quartz oscillator is adjusted to the peak of the resonance it equals 1/1836 of the atomic frequency. Instead of using a synthesiser to generate the frequency by which the second stage in the multiplying chain differs from 10 Mc this difference frequency is obtained from an auxiliary quartz oscillator after division by 17. The frequency of nominal value 10 Mc left after subtraction is compared in a phase comparator with the 100-kc standard. Any departure in phase generates an error voltage which is used to adjust the auxiliary quartz oscillator in order to restore the phase equality. The 10-Mc signal is thus maintained at a value equal to exactly 100 times that of the standard. The measurement consists in setting the variable oscillator

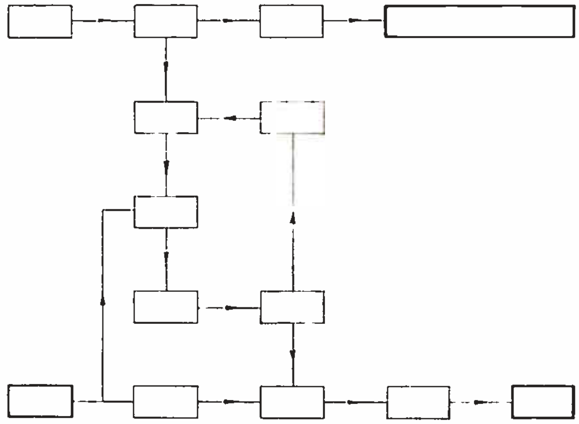

Fig. 6—National Physical Lab. scheme for exciting a caesium atomic beam.

to give the peak of the atomic resonance and then in measuring the frequency of the auxiliary quartz oscillator. This is done by comparison with the 100-kc standard, a small residual frequency being read off on a counter. If the frequency of the caesium resonance is taken as 9, 192, 631, 770 cps and the 100-kc standard has its nominal value, the counter reading will be 18, 826.7 cps. The difference from this, multiplied by 1.8357, gives the error of the 100-kc standard in terms of caesium in parts in 10^{10}.

This type of equipment is suitable when there are existing quartz clocks of high precision. The calibration in terms of the caesium only takes a few minutes and can be repeated as often as necessary—possibly two or three times a week. Atomic standards can, however, be made self contained by the incorporation of a quartz oscillator at a frequency of say 5 Mc and adjusting it by means of an electronic servo loop to keep a fixed relationship with the caesium resonance frequency. Such a scheme is used in the "Atomichron," a caesium atomic beam equipment [22] manufactured by the National Company, Inc. In this case (Fig. 7) the 5-Mc quartz oscillator is multiplied to 9180 Mc and also used in a synthesiser to generate a frequency of 12.63184 Mc which is added to 9180 Mc to give the caesium frequency. The division ratio, at the 1-Mc output is 9,192.631840 and as the frequency now being used for the caesium resonance is 9, 192, 631, 770 a small correction must be applied to the output frequencies of the Atomichron to make them correspond to this value of the unit of time.

B. Improvements to Intensity and Bandwidth

During the past decade there have been intensive and brilliantly successful programmes of work designed to increase the intensity and reduce the bandwidth of spectral lines. In the natural condition of a gas the two states that give a RF spectral line are almost equally populated. This can be changed and the intensity enormously increased by the process known as optical pumping [23]. A further improvement of intensity is

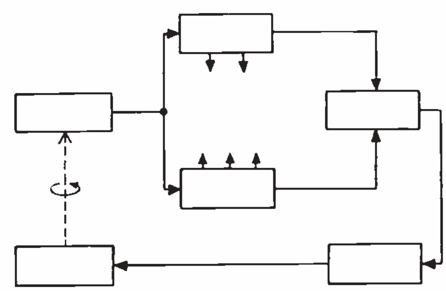

Fig. 7—Self-contained caesium beam standard using a servo controlled quartz oscillator, as in the "Atomichron."

afforded by using a measure of the light transmitted through the gas to detect the resonance. The Doppler width can be reduced and indeed almost eliminated by introducing a buffer gas [24], [25] or by coating the walls of the containing vessel. By using such methods atomic oscillators using the sodium resonance [26] at 1772 Mc, the rubidium resonance [27] at 6835 Mc, and the caesium resonance [28] at 9192 Mc have been constructed and a rubidium oscillator is in commercial production. Another approach led to the development of the ammonia maser [29] and quite recently to the hydrogen maser [30]. These developments are of great fundamental physical interest but have one drawback for frequency standardization in that the frequency is slightly affected by the devices used to secure the improvement in intensity and line width.

Up to the present, therefore, they have been used as constant oscillators but not for defining the natural Bohr frequency so closely that it can be used as a standard of frequency or time. This has however been accomplished in equipments based on the atomic beam method described in the next section.

C. Caesium Beam Standards

The difficulties of bandwidth and low intensity are most easily overcome by using the atomic beam magnetic resonance method developed at Columbia University by Rabi [31] and his co-workers. In this method, which can be used with atoms possessing a magnetic dipole moment, a beam of atoms (Fig. 8) passes to a detector through a system of magnets and a region of field alternating at the Bohr frequency. The magnets have a nonuniform field and deflect the atoms in one direction or the other according to which of the two energy levels they are in. When the frequency of the RF field is exactly equal to the Bohr frequency and is of the right amplitude transitions are induced and the deflections in the second magnet B are the opposite from those in the first magnet A and the atoms are thus focused on the detector. The width is governed only by the length of time the atoms spend in the exciting region in accordance with the Uncertainty Principle $\Delta f \Delta t = 1$, and the accuracy can be increased by increasing the length of path. This would have presented technical difficulties at the frequency of the caesium resonance (9192 Mc)

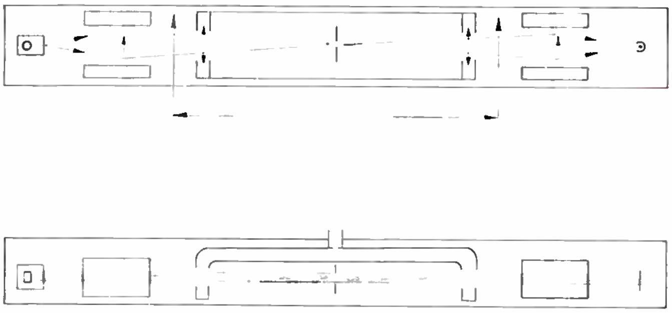

Fig. 8—National Physical Lab. caesium atomic beam chamber.

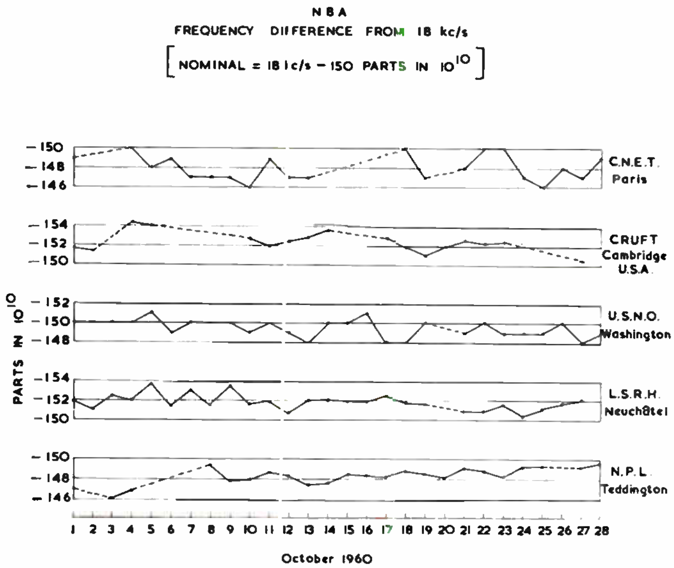

Fig. 9—The values of the frequency of the carrier wave of the station NBA as measured at a number of laboratories.

which is from many points of view the most convenient to use, but Ramsey made the very important suggestion that two short regions separated by a greater distance would be still more effective [32]. This configuration is ideal from the practical point of view as the short sections can consist of the standard waveguide used for such frequencies. Magnets of about 8000 Gauss with a similar gradient give deflections of the order of 1 mm so that wide slits and intense beams can be used. A strong signal is thus obtained at the detector and the radio frequency source can be set to the Bohr frequency with great precision and with very little experimental elaboration.

The development of an atomic beam standard was started by Lyons [33] at the National Bureau of Standards in Washington.

A thorough investigation of a beam standard constructed at the National Physical Laboratory by Essen and Parry [19] established that it could be used to define the Bohr frequency with a precision of 1 part in 10^{10}. A model built at M.I.T. by Zacharias [34] led to the construction of a commercial form known as the Atomichron, which was found to be in agreement [35] with the NPL standard to 2 parts in 10^{10}. The work on caesium standards was continued at the new laboratories of the National Bureau of Standards in Boulder by Mockler [36] and two equipments agreed in frequency to 2 parts in 10^{11}. Independently constructed standards have been completed at the National Research Council [37], the Laboratoire Suisse de Recherche Horlogeres [38], and the National Physical Laboratory [39]. The caesium beam standards of recent construction have a bandwidth of 50 cps or less and can be used with a precision of about 2 parts in 10^{11}. They are used to calibrate the working standards and measure the frequencies of a number of radio transmissions, which are controlled by high-quality quartz oscillators and are used for the widespread distribution of standard frequencies. The comparison of measurements made at a number of laboratories illustrates the state now reached in time and frequency measurements. Fig. 9 shows the different values obtained for station NBA operating at Summit, Canal Zone, during October 1960. They show that frequencies can be compared daily on a world-wide basis with an accuracy of ± 2 parts in 10^{10}.

The Measuring Devices of Electronics*

D. B. SINCLAIR†, FELLOW, IRE

***Summary*—As every branch of science develops, instrumentation especially adapted thereto develops with it. Electronics has been unusually fertile in spawning new ideas of all kinds, especially in measuring devices. This article discusses, in general, representative examples, as they relate to the needs that they satisfy or the novel concepts that they incorporate.**

Introduction

Significant measurements, in the early days of wireless, seemed not only hard to make but even hard to conceive. Maxwell's brilliant mathematical analysis had been completely verified by Hertz's experiments, and the fundamental interrelationships between electricity and magnetism thereby firmly established on a quantitative basis; but there yet remained an element of magic in electricity, safely contained within a circuit close at hand, suddenly appearing in another circuit remote from the original point of observation.

* Received by the IRE, July 25, 1961.
† General Radio Company, West Concord, Mass.

The concepts of inductance, resistance, and capacitance had been deduced from the behavior of circuits and components exposed to the influences of static charges and constant currents, and these concepts were extendable, without too much difficulty, to systems in which charges and currents varied relatively slowly with time. In wireless experiments, however, these quasi-steady-state conditions could not be assumed. Coils, which might be expected to behave like inductances, turned out to behave, instead, like capacitances; antenna wires acted sometimes like capacitances, sometimes like inductances, and sometimes like resistances; capacitances exposed to potential differences apparently well within their ratings inexplicably flashed over. These baffling phenomena were, of course, tangible manifestations of the three R's of this new art—resonance, radiation and reflections.

As these modes of behavior became understood, earlier concepts were interpreted in a wider framework to explain them. Thus, in particular, the concept of distributed parameters extended the ideas of inductance, resistance and capacitance to the analysis of antennas and transmission lines. Other concepts peculiar to the new devices, were found helpful—radiation resistance, propagation constant, characteristic impedance. These concepts and their definitions and measurement, illustrate the similarities and differences between what has, over the years, come to be known as electronics, and electricity or power. The basic quantities of electricity, their units of measurement, and their interrelationships with mass, length, time and the electromagnetic properties of free space, are well known. This article deals rather with those methods of measurement and those measuring devices that have arisen particularly from the problems and characteristics of electronic systems.

The Nature of Electronic Systems

The first question which one must ask is what these peculiar problems and characteristics are.

First and foremost, the power levels to be measured are frequently low. Although signals can be detected at great distances, these signals are weak, and the further one is away from the source the weaker they become. This led the Germans, who did much of the early work in radio-frequency systems, to characterize the entire field as *schwachstromtechnik*—weak current technology.

Second, the circuits used are frequently resonant or otherwise adjusted to a refined condition that is critically dependent upon the values of circuit parameters and sensitive to small disturbances of these values.

Third, the systems must respond over a band of frequencies so that information, as contrasted to power, can be transmitted from one point to another.

The implications of these characteristics are far reaching. The first demands high sensitivity in measurements of voltage, current and power; the second demands measuring devices that have negligible or highly predictable effects on the circuits in which measurements are to be made; and the third demands devices and techniques of measurement that can define behavior over substantial parts of the frequency or time domain.

Voltage and Power Measurements

Voltmeters

The device that first made electronics widely useful was, of course, the vacuum tube. Not only did it make possible the generation and reception of meaningful signals, but the very properties that made it useful for these functions made it equally so as a measuring tool.

Thus, its amplifying properties make it sensitive; its rectifying properties make it a splendid converter from hard-to-measure radio-frequency voltage to easy-to-measure direct current; its high input impedance makes its effect on circuits to which it is connected minimal; and it can easily be made to cover extensive frequency ranges without error.

It is interesting, in this connection, to note that the crystal rectifier, which had an honored position prior to the advent of the vacuum tube, has made a strong comeback in microwave applications. Neither the crystal diode nor the transistor, however, has yet become the basis of a classic instrument. The vacuum-tube voltmeter, on the other hand, has become one of the basic measuring instruments of electronics. It generally takes one of two forms, the peak-reading type[1] and the amplifier type.[2]

In the first type, a capacitor is charged up through a rectifier until the dc voltage across it equals the peak value of the applied ac voltage. This dc voltage is then amplified and used to actuate a dc meter. The rectifier circuit, which is widely used in "clamp" circuits, yields highly accurate, reproducible results at high voltages since departures from ideal performance cause variations only in the small *difference* between the applied peak voltage and the developed dc voltage. As the voltage to be measured decreases, however, this difference becomes larger and larger relative to the developed dc voltage, and at low voltages the response changes from "peak" to rms, or square-law and becomes critically dependent upon tube characteristics. This type of voltmeter is therefore best suited for voltage measurements above about one volt. It can be made to give accurate results at frequencies up to the hundreds of megacycles.

The second type of voltmeter uses a wide-band amplifier to make measurements at low voltages possible and, as a rule, uses negative feedback both to stabilize the amplifier and to "straighten out" the rectification characteristic. This provides a reliable "average" response that, in contrast to "peak," is often found useful when the waveform of the signal to be measured is not purely sinusoidal. Measurements can be made reliably, with voltmeters of this kind, at voltages of the order of 1 mv and above. However, the high sensitivity obtained with this instrument, when contrasted to that of the peak-reading type, is paid for by a decrease in the maximum frequency at which it is useful from the order of several hundred megacycles to the order of a few megacycles.

Standard-Signal Generators

For measurements at lower voltages and higher frequencies direct-reading voltmeters are no longer useful, and a completely different approach is to use a standard-signal generator[3] in a substitution procedure. This instrument, whose concept stems uniquely from the requirements of electronics, supplies a signal of known characteristics to compare with the unknown signal. From this comparison, a quantitative evaluation of the unknown can then be made.

A standard-signal generator comprises, basically an oscillator or oscillator-amplifier combination that can

[1] C. H. Sharp and E. D. Doyle, "Crest voltmeters," *Trans. AIEE*, vol. 35, pt. 1, pp. 99–107; February, 1916.

be tuned to cover the desired frequency range, a voltmeter that measures the oscillator output voltage, and an attenuator that reduces this output voltage by a known amount. It is particularly useful with a sensitive receiver as a comparison device. By setting the output of the standard-signal generator so that both the standard-signal generator and the unknown signal produce the same receiver output, one can make the standard-signal generator read directly. An extension of this technique enables one to determine the limitations of the receiver itself that are imposed by noise and, thereby, to determine the corrections necessary to measure signals so small that they are comparable to system noise levels.

Thermal Devices

The measurement of a standard-signal-generator reference voltage, from which the output voltage is derived, can be made by methods that are free from some of the limitations imposed upon voltmeters for general use. Thus, in particular, the voltage-measuring system need not have a negligible effect upon the circuit to which it is connected. This freedom makes possible the use of power-measuring devices, which have been found satisfactory for measuring rms voltages at frequencies up to thousands of megacycles.

These devices actually measure the power dissipated within themselves, the corresponding voltages being deduced therefrom through knowledge of their impedances. Since these impedances are generally low and resistive, the devices can be made to cover wide frequency bands in lumped-parameter circuits and, in distributed-parameter configurations, can be adjusted to match transmission lines and waveguides and minimize reflections. They use different means to indicate the power dissipated, but all rely upon temperature rise as the measuring quantity. In bolometers and barretters the change in resistance with temperature is measured at dc or audio frequencies; in thermocouple systems and calorimeters the temperature rise is measured thermometrically; in hot-wire meters the temperature coefficient of expansion actuates a mechanical system; in incandescent lamps the change in brilliance of the filament is a very sensitive measure of small changes in power.

Power-Output Meters

The importance of impedance matching in electronic systems emphasizes a significant difference between them and power systems. In power systems efficiency is extremely important. An ideal system would be one in which there were no losses in the generating and transmission system and all the power was dissipated in the load. Even in a practical system the losses are small compared with the useful power. Any attempt to draw maximum power from the system by matching impedance would be catastrophic. Component parts are not designed to cope with such operation, and power into a matching load is not a proper system specification. In contrast, in communications systems generally, there is a need at every point to extract the absolute maximum power from any signal to avoid degradation of signal-to-noise ratio. Although the efficiency is only 50 per cent, maximum power transfer in linear systems occurs when the source and load impedances are conjugate in angle and equal in magnitude, and optimum results are obtained when the impedances are purely resistive.

Not all generating systems in electronics are linear, independent of load, and maximum undistorted output is not always obtained under matched conditions. Nevertheless the maximum power output is an important specification, generally, whether limited by clipping, in overloaded nonlinear systems, or by impedance matching in linear systems. Another specialized measuring device, the power-output meter,[4] has therefore been developed to measure this characteristic, consisting simply of a variable-impedance load and associated meter that reads the power dissipated therein.

Directional Couplers

Primarily useful at audio frequencies, the power-output meter is supplemented, at high frequencies, by the directional coupler.[5]

Still another instrument that has been developed to meet the special requirements of communications, the directional coupler measures power flow in a coaxial line or waveguide. In a simple form it consists of an auxiliary transmission line, terminated in a matching impedance at each end, which is coupled to the transmission line in which the power flow is to be measured. By proper choice of coupling to the electric and magnetic fields in the main line one can cause waves to be induced in the measuring line which travel to one end or the other, according to whether they are initiated by the incident or reflected wave in the main line. The power dissipated in each measuring-line termination is then proportional to the corresponding power flow in the main line and can be used as a measure of it.

Field-Strength Meters

Measurements of voltages in closed spaces, where they can conveniently be confined and defined do not, however, meet all the needs of electronics. At the highest frequencies, when the physical dimensions of the system under study become comparable to the wavelength of the signal, and at any frequency, when the signal is transmitted through space, it is necessary to analyze performance in terms of electric and magnetic fields. Measuring devices directly responsive to these quantities, however, have not been developed. Instead, per-

[5] A. A. Pistolkors and M. S. Neuman, "Device for direct measurement of the coefficient of a travelling wave in feeders," *Elektrosvyaz'*, vol. 9, pp. 9–15; April, 1941.

formance of probes, loops and antennas has been calculated and used to relate the power picked up by them to the inducing fields. This power, when measured by the various methods previously noted, can then be used to indicate field strength. In illustration, the combination of a sensitive, stable receiver, a reference generator, and a loop antenna makes an excellent field-strength meter for radio-frequency measurements.[6]

Modulation and Waveform Measurements

Cathode-Ray Oscilloscopes

The essence of communication is change. If a given type of signal has existed from the remote past, is currently present, and continues on into the indefinite future, no information of any kind is conveyed thereby. Only if some property of the signal is modified as a function of time can intelligence be transmitted. In contrast to power-system requirements for measurements of sustained single-frequency voltages and currents, therefore, communication-system needs for methods of measuring changes with time have always been pressing. The cathode-ray oscilloscope has provided an excellent solution.

Coupled with the development of circuits to provide deflecting voltages that are accurately known as functions of time the low-inertia properties of the electron beam have made possible visual display of recurring waveforms at frequencies ranging upwards to the thousands of megacycles and photographic recording of single transients of very brief duration.

The requirement that a signal change as a function of time implies that the system in which it occurs must possess a finite bandwidth in the frequency domain, or be able to respond at a finite speed in the time domain. The cathode-ray oscilloscope can be used for analysis of either kind. In the frequency domain it can display sine-wave-modulation waveforms point-by-point, or swept; and in the time domain it can display pulse- or square-wave-modulation waveforms as recurrent phenomena, or the single-transient response to a step function.

Standard-Signal Generators

In addition to being a standard of voltage level, the standard-signal generator is a standard of modulation characteristics. Whatever the nature of the modulating voltage, the carrier signal must be varied in frequency or amplitude in accordance with it. The modulating system of the standard-signal generator supplies the known relationship between the modulating and modulated voltages; the response to the modulated signal of the system under test can be displayed as a function of time on a cathode-ray oscilloscope or measured in terms of its frequency components.

[6] C. R. Englund, "Note on the measurement of radio signals," Proc. IRE, vol. 11, pp. 26–33; February, 1923.

Wave Analyzer

For measurements of the Fourier-series components in a repetitive nonsinusoidal signal the wave analyzer offers high accuracy and convenience. It is, in common form, a highly selective heterodyne-type voltmeter which covers the audio-frequency range.[7] A variable-frequency local oscillator beats with the signal to yield a difference frequency that can be adjusted to pass through a narrow-band fixed-frequency filter. The filter bandwidth is chosen to be small compared with the spacing between frequency components that are to be separated, and individual measurements of their amplitudes can therefore be made. It is used principally to study distortion in sine-wave testing and frequency spectra in random-noise testing.

Spectrum Analyzer

Conventional wave analyzers have untuned input circuits and, because of this, their use is restricted to low frequencies. When they are used for measuring modulation characteristics, therefore, the signal must generally be rectified so that the modulation envelope can be examined rather than the modulated wave itself. When the actual modulated wave is to be analyzed it is necessary to use a highly selective voltmeter that can be tuned over a frequency range in the vicinity of the signal frequency.

For this kind of analysis the signal is considered as the combination of a carrier frequency and sideband frequencies that are created by the modulation process. A manually tuned, high-selectivity receiver can be used to separate these components, but it is frequently found more convenient to use a spectrum analyzer,[8] which, in effect, is a receiver of this kind that is swept electronically back and forth across the frequency band of interest. The output of a spectrum analyzer is presented, as a time-varying function, on a cathode-ray-oscilloscope screen.

Impedance Measurements

Direct-Deflection Methods

Early experimenters found the vacuum tube a good device to measure its own performance; they likewise found circuit behavior a good indicator of the circuit condition that determines it. Thus, not only is resonance a typical characteristic of high-frequency lumped-parameter circuits, but an understanding of resonance makes possible deduction of "unknown" parameters from the observed changes in behavior of resonant circuits when a "known" standard parameter is varied or connected in circuit.

For instance, it is easy to set maximum current in series-resonant circuits, or maximum voltage across

[7] L. B. Arguimbau, "Wave analysis," *General Radio Experimenter*, vol. 8, pp. 12–14; June–July, 1933.

[8] "Panoramic reception shows promise in radio navigation," *Electronics*, vol. 11, pp. 36–38; July, 1938.

parallel-resonant circuits, either by tuning a variable capacitor or by varying the frequency. It has been found that the value of the maximum current is inversely proportional to the effective resistance of the series-tuned circuit, and that the value of the maximum voltage is inversely proportional to the effective conductance of the parallel-tuned circuit. By comparing the change in maximum current or maximum voltage when an unknown impedance or admittance is connected to the circuit with the change that occurred when a known resistance or conductance is connected one can then deduce the resistance or conductance of the unknown. From the frequency and the capacitance change necessary to restore resonance when the unknown is connected one can deduce its reactance or susceptance. These methods have become known, respectively, as the resistance-variation[9] and conductance-variation[10] methods.

From the frequency and the shape of the resonance curve, when the tuning capacitance is varied, it has also been found possible to deduce the circuit losses. Both the resistance and reactance of an unknown impedance, connected in a series-resonant circuit, or the conductance and susceptance of an unknown admittance connected across a parallel-resonant circuit, can therefore be deduced from a single variable-capacitance standard. These methods have become known as the reactance-variation[11] and susceptance-variation[12] circuits.

It has also been found that the breadth of the resonance curve, when the frequency is varied, is inversely proportional to the storage factor, $Q=X/R=B/G$, of the tuned circuit, and that the ratio of the voltage occurring across one of the tuning elements in a series-tuned circuit to a voltage injected in series is also equal to Q. This principle of "resonant rise" is used in direct-reading q-meters for measuring coils.

Turning to distributed-parameter systems, one finds that not only is reflection of waves a typical characteristic but measurement, on a "smooth" line of known and constant characteristic impedance, of the distribution of the standing-wave pattern produced by a reflection yields all the information necessary to deduce the impedance mismatch that created it. A measuring tool of great use at the higher frequencies is therefore the slotted line, or slotted section, with which one can explore the distribution of standing waves in a coaxial-line or waveguide system.

Null Methods

In all the methods of measurement that fall in the general direct-reading category, the unknown parameters are related to standard parameters through observations of voltage or current ratios. Similar relationships can be established, with considerably higher precision, by balancing voltages to a null in the general manner of the Wheatstone bridge.

Bridges have traditionally been used for measurements of the highest accuracy, and attempts to extend low-frequency techniques to radio frequencies were made as early as 1897, when Nernst described bridge measurements at high frequencies using a spark-gap as an indicator of balance.[13] It was found very early in the game that excellent precision and resolution could be easily obtained, but that meaningful readings were frequently another story. The reason for the difficulties lies primarily in the relatively greater importance, as the frequency is raised, of the so-called residual parameters to be found, in combination with the desired parameters, in impedance standards and circuit components generally and in circuit connections and wiring which would ideally have no associated impedances or admittances at all. As our understanding of the nature, significance and causes of these has increased, better standards and improved configurations have made possible high-accuracy measurements with lumped-parameter bridges at frequencies up to the order of a few hundred megacycles. The use of distributed-parameter devices and connections has further extended null-method techniques to still higher frequencies.

Impedance Standards

A common denominator in all impedance measurements is the problem of securing accurate standards. The residual parameters, which may justifiably be listed as the fourth R of the electronic art, become progressively more and more serious as the frequency increases, usually as the square. There is therefore a great premium in selecting a standard that is as free from residuals as possible and in which the location and behavior of the residuals is best known. The problem is frequently compounded by the need for an adjustable parameter. A great deal of analysis and measurement has shown that the best lumped-parameter element for use at radio frequencies is the variable capacitor,[14] and it is used almost exclusively as the reference standard in impedance-measuring circuits of all kinds.

At microwave frequencies, interestingly enough, the problem becomes somewhat easier to solve. Inductance and capacitance are, dimensionally, specified by a length. At frequencies where physical dimensions are

comparable to the wavelength, therefore, simple geometric configurations lead to simple boundary conditions and simple solutions of the field equations. As under steady-current and static-charge conditions, therefore, one can compute with accuracy the electrical behavior of a device. In particular, the characteristic impedance of transmission lines can be calculated, and the input impedance can then be set to yield accurately known resistance or reactance values by proper adjustment of the termination and line length. In further illustration one can compute, with very high accuracy, the resonant frequencies of cavities.

Frequency and Time Measurements

Wavemeters

The phenomenon of resonance, which is so characteristic of electronic systems, not only serves as a convenient indicator of circuit conditions for impedance measurement but also of the frequency of the signal. Again, the functional device itself provides the measurement solution. Different signals are transmitted at different frequencies; resonant circuits are tuned to these different frequencies to separate the signals; therefore, calibrated tuned circuits measure the frequencies in accord with the manner in which they are used.

At low frequencies, wavemeters, comprised of lumped elements, have gradually fallen into disuse as requirements for accuracy of measurement have demanded stability of calibration and precision of adjustment further and further beyond their capabilities. At microwave frequencies, on the other hand, cavities of simple geometry and construction provide one or two orders better performance and still serve a useful function.

Frequency Standards

The requirements for more and more accurate frequency measurements, which have stemmed from the highly sophisticated electronic systems of today, have brought the problems of the physicist and the electronic engineer closer and closer together. Thus, high-frequency stability is needed for color television and nuclear resonance measurements; very precise timing is needed for astro-navigation systems and computers.

The quartz crystal, like the internal-combustion engine, has been developed to a pitch of performance that would, no doubt, have been unbelievable to the original experimenters. Short-term stabilities of the order of 10^{-11} have been achieved, representing a degree of perfection of a high order. Long-term drift, however, remains a problem. The fundamental properties of matter, as exemplified by the emission or absorption spectra, have therefore been harnessed to provide long-term stability of frequency that is, by definition, perfect.

Here, again, is an interesting interdisciplinary extension into astronomy. Because frequency is really a measure of time interval, the fundamental standard has, in the past, been time, as determined from astronomical observations. The need for accuracy in space, however, has now outstripped the accuracy of our optical observations in space; and time, it is now proposed, should henceforth be determined from the frequency of the absorption line of cesium. As a practical matter, all international standards of frequency are now determined in terms of the cesium beam, and transmissions at very low frequencies of the order of 10 to 100 kc make them available for intercomparison throughout the world with a minimum amount of error from propagation anomalies.

Counters

As the stability and accuracy of frequency standards has improved over the years there has arisen a corresponding need for more and more precise comparison of an unknown frequency with the standard. Digital counters, which stem from the scalers of atomic energy research, have furnished an increasingly popular solution.[15] They incorporate a frequency standard, which establishes an accurate time interval, and count the frequency as a number of quantized events occurring during that time interval. Like all digital devices, they have a precision of ± 1 count in the least significant figure, but this inherent imprecision can be made arbitrarily small in determining over-all accuracy by adding as many decades as are required.

Pulse Generators

Early developments in electronics were nearly all explained and measured in terms of frequency. In more recent years, however, time has become an important basic quantity in radar, computer, and navigation systems. Not only have instruments like the counter therefore appeared on the scene, but also analytical techniques and devices to study circuit behavior in the time domain.

The prime illustration of this class of instruments is the pulse generator, which provides "rectangular" waves, as opposed to sine waves, that range from brief pulses to square waves. The transition times can be as short as a few nanoseconds. When used with cathode-ray oscilloscopes, pulse generators provide information on behavior entirely in the time domain; when used with wave analyzers they form a system that links behavior in the time and frequency domains.

Noise Generators

A common characteristic of electronic-system analysis and design is determination of, and design for, ultimate performance. Fundamental limitations, whether in parametric amplifiers, communication channels, radar systems, or computers, arise from random noise. Another basic instrument is therefore the noise generator,

[15] I. E. Grosdoff, "Electronic Counters," *RCA Rev.*, vol. 7, pp. 438–447; September, 1946.

designed to give the best approximation to white, Gaussian noise. Taken with the cathode-ray oscilloscope, this instrument, like the pulse generator, gives information in the time domain; with the wave analyzer it gives similar information in the frequency domain.

Conclusion

The measuring tools of electronics have developed at the forefront of a wide range of new technologies. Some of the specific devices have been touched on briefly here, but there have been many that have not even been mentioned. Electronic methods, for instance, have been widely used in measuring light, sound, temperature, pressure, velocity, acceleration—in fact, well nigh any physical quantity that can be segregated and assigned a number. Microphones are electronic devices; so are photocells, vibration pickups, accelerometers, Kerr cells, masers and Hall-effect transducers. What started out as a dimly understood, difficult art has become, over the years, one of the most rigorously developed, fundamental and well instrumented. Some years ago I propounded the idea that electronics, far from being a narrow specialty within the profession of electrical engineering, in fact covered a broad spectrum within which "electrical engineering" represented but a narrow band. Promptly dubbed "Sinclair's heresy" by my colleagues, this doctrine appears closer and closer to being definitive.

Digital Display of Measurements in Instrumentation*

B. M. OLIVER†, FELLOW, IRE

Summary—**Being a short chronicle of the advent of digital display in divers new electronic instruments, sundry remarks telling of the wonders they can do, together with a few words to the wise concerning pitfalls which may accompany their indiscriminate use.**

During the last twenty years a whole new branch of electronics has grown up, a branch concerned with the electrical generation, processing, recording, reproduction and display of data in digital form. As is usually the case, this art did not spring into existence suddenly out of one particular invention, but instead developed gradually as the cumulative result of many contributions. It was nourished by, and in turn helped support, adjacent fields such as digital computers and pulse code systems. But while there is no one birthday to celebrate, certain key developments deserve recognition.

In digital circuitry probably the most important single device is the bistable circuit or "flip-flop." Used today in innumerable modifications, the original form of this circuit was developed in 1919 by Eccles and Jordan. During the late 1930's flip-flops in tandem connection began to be used by nuclear physicists to scale down the counting rate from Geiger-Muller counters by factors of 2^n. These devices were all essentially binary counters in which the last "carry" pulse was used as the output to a mechanical register. In 1944, Potter[1] described a scale-of-ten counter in which feedback caused a binary counter to skip six of its possible 16 states. A neon lamp indicating the state of each flip-flop provided a binary-coded readout for each decade. In 1946, Grosdoff[2] described another binary counter with feedback to provide a scale-of-ten circuit. Grosdoff's circuit featured a direct readout obtained by a matrix of resistors arranged to light one of ten neon lamps for each stable state of the counter. By connecting such decades in tandem direct reading decimal counting registers of arbitrarily large capacity were achieved and the way was cleared for the widespread application of high speed electronic counting.

During this same period and in later years many devices were developed which inherently have ten stable states. Examples are the ten anode glow transfer tube,[3,4] the latching beam cathode ray tube,[5] and the

magnetron type beam switching tube.[6] Because of performance or price limitations these devices have been less widely used than the decade constructed of binary flip-flops, though in certain applications they are probably superior.

In 1950 the first commercial instruments appeared[7,8] combining an electronic counter with a precision time base and gating circuits. With these instruments, precise unambiguous measurements of frequency, pulse rates, period or time interval could be quickly and conveniently made. They revolutionized the whole art of frequency and time measurement and found very widespread use. Later, devices were developed to print out the digital readings and thus provide a permanent record of a series of measurements.

In 1953 Hagelbarger at Bell Laboratories built a readout device consisting of a neon tube with a single anode and ten stacked wire cathodes in the shape of numerals.[9] When current is taken from one of these cathodes, a glowing numeral an inch or more in height appears. Smaller versions of this tube were later developed commercially,[10] and provide a large in-line readout which is gradually replacing the ten neon glow lamp type. Other devices employing electroluminescent segmented numerals, stacked edge lighted plastic sheets with engraved numerals, and optically projected numerals have also appeared. In the most recently developed electronic counters, neon glow lamps driven directly by each flip-flop are used to illuminate a photoconductor matrix, which in turn not only drives a numerical indicator tube but also stores the previous reading while the decade is counting new information. For very fast digital data presentation special cathode ray tubes having beams shaped by apertures into symbols have been produced, but their expense has limited their use to large complex systems.

By 1954 the first commercial digital voltmeter had appeared.[11] This unit was electromechanical but was soon followed by all electronic designs based upon circuit techniques originally employed in pulse code modulation encoders. With the advent of these voltmeters it became possible to present in digital form any quantity which, by means of an appropriate transducer, could first be converted to a proportional voltage. Since this list includes most physical variables, it was suddenly possible to record and process all telemetered or locally sensed data from a large scale test directly in digital form. As a result, digital voltmeters found a large market in large instrumentation systems.

Digital techniques have also been extended to signal sources of various sorts. Here the digital information constitutes the input rather than the output. Examples are digital pulse delay generators, ac and dc voltage sources and frequency synthesizers. These devices will be recognized as the counterparts of the digital time interval counter, the digital voltmeter, and the digital frequency counter.

Virtues of Digital Display

Probably the greatest single virtue of digital representation is its ability to present data with practically unlimited precision; for example, eight digit data in which the smallest digit is significant is easily presented on a commercial counter. This is a precision of 1 part in 10^8. Assuming one can read a pointer position to within 0.01 in., comparable precision in a full range analog device would require a scale length of 10^6 in. or 16 miles. Thus digital readout is unusually necessary for very high precision. An exception is the reading or monitoring of a quantity which varies by only a small fraction of its total value. Here suppressed zero analog readout may suffice.

Another advantage of digital representation is the ease with which data in this form may be stored or processed without loss of accuracy. Data in digital form may be printed numerically, punched on tape or cards, or recorded magnetically; it may be fed through computers and normalized, linearized, or operated upon in any desired fashion. It may be stored and re-used or transmitted over long distances. In fact much of the popularity of digital instrumentation stems from the existence of digital computers to handle the data and of digital means for storing it.

Digital readout devices are less apt to be misread, particularly by unskilled personnel than are meter faces, for example. The digital device has no parallax error and for a given panel space is legible at a much greater distance. As a result digital devices have found application in production testing and other areas where neither high precision nor data processing is involved.

Vices of Digital Display

It is so easy to wax enthusiastic about the virtues of digital display that one is apt to overlook certain very real disadvantages. The first is the fact that digital devices are in general more complex and costly than their analog counterparts. Unless needed for any of the reasons stated above, digital devices may often be rejected on this basis alone.

For certain types of measurement it is hard to imagine a worse form of presentation than a digital one. As

[6] J. Bjorkman and L. Lindberg, "Development of trochtrons," *Trans. Roy. Inst. Tech.*, Stockholm, Sweden, no. 80; 1900.

[7] Saul Kuchinsky, "Multi-output beam switching tubes for computer and general purpose use," 1953 IRE National Convention Record pt. 6; pp. 43–54.

[8] A device known as the EPUT (Events Per Unit Time) meter was introduced in 1950 by Berkeley Instruments. The maximum counting rate was 100 kc. In early 1951 the Hewlett-Packard Co. introduced a combined frequency and period measuring instrument with a counting rate of 10 Mc (*Hewlett-Packard J.*, vol. 2, No. 5; January, 1951).

[9] Prior art anticipating Hagelbarger's work was found in H. P. Boswau, "A Signalling System and Glow Lamp Therefor," U. S. Patent 2142106; filed May 9, 1934; issued January 3, 1939.

[10] The "Nixie" tube developed by Haydu (now Burroughs) and the "Inditron" developed by National Union are examples.

[11] Introduced by Non-Linear Systems, this meter grew out of a model developed for the Naval Electronics Laboratories.

an example, consider the use of a digital voltmeter to read the detector output when lining up an IF amplifier. The commotion that appears on the voltmeter with each adjustment bears no direct relation to the sense of the tuning. True, one can stop and interpret the result, but this is an extra mental operation. The situation is even worse when seeking a null, for the digital voltmeter is apt to change ranges several times and the resulting bedlam is very confusing. By contrast a simple d'Arsonval movement clearly indicates a maximum, or a null.

A digital record is a rather poor way of presenting certain data, such as temperature or frequency drift, as compared, say, with a strip chart recording. For this reason some digital printout devices[12] are provided with analog output by means of which an analog recording of the data may be made simultaneously with the printed record. By synthesizing a voltage from only that group of digits having significant variation, a recording with appropriate zero suppression and hence easy readability is obtained.

When a production adjustment must be made to an accuracy no greater than about ± 2 per cent, much time will be wasted if a normal digital readout is used. Consider a power supply which must be set at 300 v$\pm$2 per cent. It is almost psychologically impossible for the production tester to leave the reading at 304 v, or worse, 296 v. There is a strong temptation to try for the round number, for the bull's eye. By contrast, few people are bothered at leaving a meter reading anywhere between two indicated limits on a scale.

As a final caution, it is probably not amiss to remind the reader that behind the digital display there is usually an analog device and that *precision of readability does not ensure accuracy of measurement.* The accuracy of a frequency counter is no better than the standard oscillator used, the digital voltmeter is no more accurate than its internal reference, its range dividers, its comparison amplifiers, and its thermal EMF's allow, regardless of how many digits of display are provided.

Conclusion

Instruments with digital display as developed over the last two decades provide a high precision readout. Often this precision is justified by the accuracy of measurement of which the instrument is capable, and which the application demands. Or the digital form of data out put may be desirable because of legibility, or required by automatic devices into which the data is fed for storage or processing. When these requirements do not exist and when simpler analog instruments are available they should be used. This is particularly true where the reading is to be watched by eye for extreme values, or set within easily discernible limits.

Lest the impression be left that digital display in electrical measurements is something entirely new to the last two decades, let us recall two venerable devices: the decade bridge and the integrating watt-hour meter. Like many of the newer digital readout devices the latter is driven by an analog measuring device, and it too can beguile the user into never questioning its apparent accuracy.

MEDICAL ELECTRONICS

Organized with the assistance of the IRE Professional Group on Bio-Medical Electronics

History of Bio-Medical Electronics Art*

J. F. HERRICK†, MEMBER, IRE

Summary—**The almost phenomenal growth of the IRE Professional Group on Bio-Medical Electronics demonstrates the mutual interest that has been aroused both in engineering and in biology through new knowledge of living systems gained by instrumentation and technics recently available in this interzonal field.**

The engineer should develop a high-level respect for living systems at all stages of development, from that of unit cells to that of the amazing coordination of the living systems in the highly developed human being. An understanding of these systems will be advantageous to the physical sciences.

Engineers, physicists and biologists have learned that by serving each other they can serve their respective goals best.

The author believes that the science of electronics is the "liaison officer" responsible for converging the life sciences and the physical sciences into a single society. The organization of a society that would converge the man-made disciplines that cover the widely divergent fields reflected in the terms "bio-medical electronics," "biophysics" and "bio-medical engineering" was not achieved until the science of electronics was put to work in the life sciences.

ALMOST EVERY research scientist in the broad field of the life sciences today is turning his attention to the new methods and technics of investigations that employ the electronics art. The science of electronics is penetrating into every aspect of experimental biology and medicine, causing revolutionary changes owing to the stimulating and challenging technics for procuring new information under conditions that may not interfere with the living mechanisms.

The electronics scientist, on the other hand, is learning that living organisms have many engineering systems which, if understood, could be used to advantage in the further development of man-made systems of electronics. Thus, there are mutual rewards for both the research biologist and the research engineer in properly directed group studies in this very interesting interzonal field.

It must be made explicitly clear, first, that the field of bio-medical electronics is not limited to instrumentation; it is a separate discipline in science. Instrumentation is a fundamentally important requirement for obtaining desired information, preferably quantitative. However, the engineer's work should not be limited to that of a technician who may design, construct and maintain the instrument. Present types of instrumentation designed and developed by electronics engineers surpass the most fantastically imagined types of only a few years ago, but instrumentation is only a means to an end. The solution of a problem by electronic technics usually requires the engineer to understand the problem to be investigated and to take an active role in the design, application and performance of the electronic equipment as well as the

* Received by the IRE, August 7, 1961; revised manuscript received, October 30, 1961.

† Vista Laboratory, California Institute of Technology, Pasadena, Calif.

retrieval of data. The man who is responsible for the instrumentation should be the man who uses it in the research problem, at least in the early applications. Such participation will ensure a better solution of the research problem. The engineer will function also as a valuable assistant in data analysis.

Second, it should be made clear to the doctor of medicine that the nonmedical members of the research team respect highly the art of medicine—that aspect of medicine which is so necessary (and often confidential) for treating the patient as well as the disease. The engineer or physicist will not presume to enter this important realm of medicine. Obviously, bio-medical electronics is concerned with the purely objective scientific aspects of the research problem.

New knowledge or devices in the nonmedical sciences often raise the general question: Can these new agents be added to the armamentarium of the practicing physician? Unfortunately, historically the experimental use of some of these by those who had very limited fundamental understanding of them and who were bold enough to exploit them before fundamental studies were made placed many such procedures in the category of quacks and quackery. Needless to say, these circumstances did not command the respect of those whose interest and active participation were needed in order to place this wedding of medicine and physics at the proper level to attract the attention of our best scientists.

Some pioneer biophysicists defined this interzonal field as the application of the theory, laws and technics of physics to the broad field of biology. Knowing little about the hidden and intricate mechanisms of living things they expected to find obedience to the laws of nonliving things. They knew well the laws of nonliving things and found great satisfaction whenever they discovered conformity to these laws. Perhaps, in some instances, such obedience occurred when the conditions of experimental investigation altered the natural function. Unfortunately, the natural function was not always known and hence the interference with it by their experimental procedures was not recognized fully. Some investigators assumed that they had not altered the naturally performing functions significantly.

To search for the application of laws originating from inanimate things when beginning a study of living organisms seems to be investigating with preconceived ideas, which may impede the discovery of new laws—nature's laws for living things. The true biophysicist wants to obtain new information about the physics of living things, rather than to relate the conformity of living organisms to the already well-known laws of the nonliving. The pure scientist is more interested in new knowledge than in instances of conformities to old knowledge. Biophysics (bio-engineering or medical electronics) will emerge from adolescence when physical societies voluntarily invite sessions on the physics of living matter into their programming, thus recognizing the contributions to the field of physics.

Unfortunately, biologists have not demonstrated enthusiasm in trying to find new laws that might resolve some of their most basic problems; instead, they have been willing to accept the present-day laws of physics and chemistry. With introduction of the new electronic technics and with more rigorous thinking, perhaps they will seek more energetically for formulation of new laws.

Investigation of the biologic effects of various physical agents, an ever-present division of research in biophysics, has been very important therapeutically as well as academically. It has led to outstanding contributions to the life sciences, some of which have earned the Nobel prize for the investigator. The results of research on the biologic effects of the various types of electromagnetic radiations, namely microwaves; infrared, light and ultraviolet rays; X-rays; gamma rays; and secondary cosmic rays, have all been more interesting to the biologist than to the physicist or engineer. This type of research has added little new knowledge to the fields of physics and engineering. However, it has demonstrated clearly to the biologist the way of attacking a biologic problem by physicists or engineers who have been well trained in the fundamental methods for obtaining a quantitative understanding of complex problems in the physical sciences.

Pitfalls in the Development of a New Interzonal Field

All the man-separated disciplines in the broad field of the sciences are gradually coalescing. The life sciences seem to be entering the center of the stage, and because of the more penetrating studies in the dynamic aspects of the life sciences, the physical sciences are called in to play basic roles. In the achievement of such a coalescence, certain pitfalls must be avoided. One pitfall is that of the investigator who is competent in one discipline of science and assumes that he can just "read up" in another discipline and proceed to enter upon a research problem; this has occurred in biophysics particularly. Before schools for studying biophysics had been established, the physicist who had decided to become a biophysicist assumed that he could begin a research project by bringing his tools (instruments, measurement technics, and theoretical as well as experimental methods of attack) to the biology laboratory. Since some biologists were not competent in the fields of mathematics, physics and engineering, it seemed that fairly rapid progress could be made in this interzonal field when the self-styled biophysicist entered. However, the true researcher soon realized that the problem was more difficult than he had anticipated, that the many variables in the biologic fields could not be controlled so readily, and that he could not learn biology by just "reading up" on it. He gradually realized that the biologist was doing exceedingly well with what appeared to be less modern technics.

This early method of attack found more than one opportunist working in a "no-man's-land," where the biologist could not understand the biophysicist because of his limited training in physics and where the physicist could not understand the biophysicist because of his limited training in biology. Such an opportunist would conduct an investigation either theoretically or experimentally and submit for publication a manuscript that was difficult to review critically because reviewers equally competent in both biology and physics were not readily available. Such a state of affairs placed the science of biophysics on an insecure basis which it has taken years to correct.

Very few scientists today are competent to do research single-handedly in interzonal fields without reaching their limit in any of the various disciplines required for the complete and correct solution of the given problem. The solution of an interzonal problem, therefore, demands group research. Group research when well organized and properly directed can achieve remarkable results. Although original ideas do come from individuals, the dissemination of these ideas through the generous sharing of them enriches the world of science. Selfish individuals do not belong in the great field of group research—selflessness is needed for objective team work. Nor can the situation be dominated by a "master mind"—an individual who presumes to have superhuman insight and who regards other members of the team as his assistants, his technicians. Such conditions attenuate or suppress completely the potentialities of the talents and responsibilities of the "assistants," who will not cooperate under these circumstances in the search for pay dirt in the digging processes. A most necessary requirement for group research, however, is a competent coordinator with true wisdom and with ability to finger-point highly significant contributory facets to the new knowledge, thereby gaining a quantitative understanding of biologic systems. The correct coordination of these facets may lead to the recognition of the particular biologic system.

Instrumentation

The list of present-day instruments for research in bio-medical electronics is truly fantastic. The complete history of almost any component part of these instruments would prove to be intensely interesting to any reader when written by a person gifted for describing details in an entertaining manner. The history of such component parts as the vacuum tube, the transistor, waveguides, magnetic tape, transducers, thermistors, capacitors, transformers, relays, delay lines—to mention only a few—would proclaim the ingenuity, know-how skill, and the many years of drudgery in research, academic and applied, of many who played a role in the evolution of today's product. Electronic instrumentation demands high-level competency in circuitry, in lay-out design and in meticulous insight and care in construction. The final instrument is truly a work of art.

Computers that simulate memory and intelligence, electroencephalographs that measure the electrical characteristics of the central nervous system, electrocardiographs together with the most recently developed ballistocardiographs that measure the performance of nature's amazing circulatory pump, electromyographs that portray fundamental information relative to living servomechanisms—these are only a few of the instruments that are being applied in the search for a quantitative understanding of living systems.

Some research biologists may not be favorably disposed toward these apparently complex instruments. They prefer to use simpler and more direct methods. Obviously, a simple and direct method is the ultimate goal in experimental procedures, and major contributions to science have been made by such methods. However, the phrase "simple and direct" is relative and depends upon the attitude of the researcher and the problem to be investigated. The living organism itself is the most complex system in any biologic research problem. This living organism must dominate the experiment at all times and not play a secondary role when intricate manipulations are required for operating the electronic instruments.

Instruments, even the most complex, are only a means to an end, and represent a wasted effort if not used. The instrumentologist's responsibility is not terminated when he delivers his instrument to the biology laboratory. He should be eager to know that it is performing its duty efficiently in the retrieval of knowledge. The proper use of any instrument should be the major concern of the manufacturer. An electronic instrument is the culmination of the efforts of many great scientific minds coordinated and determined hopefully to add new knowledge for a higher level of civilization. It is not static but is ever improving according to new component parts and materials. Electronic instruments become obsolete with the advancement of new materials, new discoveries that may replace the older component parts, new ideas for circuitry, and the like.

Medical Electronics Advantageous to the Electronic Engineer and (as Well as) the Biologist

The advances in the physical sciences through research into nonliving phenomena have been so outstanding that whatever contributions have come from the biologic sciences to the physical sciences seem to have received little emphasis.[1] After all, it was the lowly

[1] K. S. Cole, "Four Lectures on Biophysics," Instituto de Biofisica, Universidade do Brasil, Rio de Janeiro, pp. 7–17; 1947.

frog that demonstrated a physiologic characteristic that triggered the idea for the galvanic or voltaic cell (the early source of continuous electromotive force). Two other examples of contributions to the engineering sciences (not directly to bio-medical electronics) are countercurrent exchange and the law of flow in tubes. The former phenomenon is nature's feat for cooling arterial blood. This mechanism permits the penguin to stand foot deep in ice water for prolonged periods without losing body heat. Before the arterial blood reaches the feet it loses heat to the proximal veins which are returning blood to the trunk. Engineers use an analogous system for cooling liquids flowing in pipes. The law of Poiseuille was born from a study of the circulation of blood in the capillaries of the mesentery of small animals. Poiseuille was a doctor of medicine who was a physicist at heart. His investigations prompted him to go to small glass capillary tubes for further studies. The absolute unit of viscosity, the poise, honors his name. He gave a fundamental law to physical sciences.

The animal world contains amazing systems which are attracting the attention of our competent engineers and physicists. If these systems could be incorporated into man-made systems, certain innovations would be achieved. A few very interesting living systems that I would mention are:

1) The sonar systems of bats and moths. These systems surpass the best sonar system that technologists have produced so far. Bats can detect their specific signals in the midst of intense noise.
2) The radar system of the electric fish, which deserves study for innovations in man-made radar systems.
3) The computer systems of several animals, particularly the amazing computer system of man, which are receiving intense study at the present time.
4) The communication system of many living infrahumans, which is attracting the attention of numerous investigators trained in the engineering and physical sciences.
5) Nature's semiconductors, which are demonstrating new aspects advantageous to the physical sciences.
6) Nature's amazing transducers such as the eye, the ear and the skin, which challenge the physical scientist who is attempting to make better transducers.

One of our leading American biophysicists has described one over-all contribution of the life sciences to the science of electronics very adequately in the following sentence: "The requirements of meaningful biological measurements have continually stimulated the development of electronic components and systems to new levels of sensitivity, stability, accuracy and general sophistication."[2]

Superficial review of the contributions of electronics to the life sciences indicates that the major contribution has been in the form of instruments. As stated previously, instrumentation is only a means to an end. Placing an instrument in a biology laboratory should not terminate the responsibility of the true instrumentologist who is seriously interested in the application of his instruments for obtaining reliable data—data that cannot be retrieved by other devices. He entertains hopefully a desire to make a contribution for beneficent purposes.

Living organisms possess complex living systems. Engineers are trained in systems engineering, so biologists have turned to the engineer to search for a quantitative understanding of these complex living systems. The engineer as a co-scientist with the biologist will bring a new way of thinking to biology. He must become a full-time member of the group engaged in the solution of problems that require his skill and know-how for the correct and complete resolution of the given problem in the life sciences.

Organizational Difficulties

The science of biophysics is as old as, or older than, the man-named discipline, physics. Many pioneer physicists made notable contributions to the life sciences. However, throughout these many years a society of biophysicists was never achieved until the recent organization of the Biophysical Society. Perhaps this prolonged delay in organization was caused by the lack of a unifying factor, that is, lack of a common denominator for the widely divergent activities of scientists who called themselves biophysicists. Another fundamental factor which may have contributed to the delay in organizing a society was the aloofness of the medical profession toward technical assistants (their "nonprofessional" associates).

An organization that preceded development of the Biophysical Society by about 5 years is the IRE Professional Group on Medical Electronics (presently named the Professional Group on Bio-Medical Electronics). The rapid growth of the IRE Professional Group on Medical Electronics, which was conceived in 1951 and born in 1952, indicates the intense interest and general activity in this interzonal field of science. The membership in this professional group today exceeds that of the American Physiological Society, which held its semicentennial celebration in 1938. The innovation of forming professional groups within the Institute of Radio Engineers was a profound and brilliant idea for maintaining the togetherness of a society which today

[2] Personal communication from K. S. Cole, Natl. Institutes of Health (NINDB), Bethesda, Md.

is rapidly approaching a membership of more than 85,000. The historical background of this idea is described well by Van Atta.[3] The origin of the Professional Group on Medical Electronics has been described completely by Montgomery,[4] who is to be commended highly for organizing this group. Perhaps organization of the IRE Professional Group on Medical Electronics may have functioned as a catalyst in bringing about the subsequent organization of other societies (in this interzonal field) which were so difficult to organize previously. For our readers who may wish to have more detailed information concerning the convergence of the two widely divergent fields of knowledge, namely physics and biology, the author highly recommends some intensely interesting papers written by Schmitt.[5–7]

A broad view of the history of bio-medical electronics points to electronics as a common denominator that has been a dynamic agent for converging the divergent sciences of physics, chemistry, engineering, biology and medicine. The science of bio-medical electronics has a brilliant future.

Electronics in Clinical Research*

R. STUART MACKAY†, SENIOR MEMBER, IRE

Summary—**Engineering training can profitably be applied to medical problems, both for better understanding of biological mechanisms and for development of more effective clinical methods. Also from clinical investigations, one can derive concepts applicable to nonbiological systems. Examples of developments from clinically-oriented research are cited to show some of the possibilities and problems in this field.**

Introduction

ELECTRONICS as a tool (the instrumentation aspect) enters most modern technology. In recent years, it has come to be considered as proper for electrical engineers to apply their talents and training to the problems of biology and medicine as to, say, those of computation or communication. In addition to serving as a useful tool, understanding of basic biological processes can be furthered by those with training in medical electronics or biophysics. Thus, generation of nerve impulses or the processing of sensory information seem best understood by those with some such training. A more specific example is how feedback theory gives us an understanding of the clinical observation that strychnine produces convulsions by depressing post-synaptic inhibition, and thus removes stabilizing negative feedback. Conversely, useful concepts in the technology of computation and complex system engineering have originated after study of biological systems. We will have some distance to go before we can approach the perfection of the frequency-modulated sonar of some bats, or the subtlety of performance of the human nervous and other regulatory systems. It seems likely that it is in some of these hybrid fields that the largest steps and most rapid progress are to be expected.

By electronics, we may mean circuits containing components in which the mean path of the current carriers is comparable with the physical dimensions of the elements. These can amplify (*e.g.*, thyratrons, transistors, tubes) and give rapid responses. Thus, they are useful components of systems for monitoring electrical signals accompanying various bodily processes. Also, many physiological variables are best measured using electronic techniques in conjunction with transducers of pressure, blood velocity, temperature, gas concentration, etc. Clinical procedures can often be considered either diagnostic or therapeutic, and there are also therapeutic methods which depend upon the effect of electricity, radiation, or ultrasonics on the human body.

In this short space, it is possible only to cite a few examples and problems from this diverse field, and to present some of the exciting future possibilities. Results of investigations most directly applicable to the treatment of patients will be stressed. Of course, more basic

investigations often require the most sophisticated instrumentation and observation interpretation, with results becoming incorporated into routine procedures. For example, a method for measuring the electrical negative resistance of nerve fibers gives one a tool for investigating the effects of poisons or anesthetics, and possibly eventually a clinical measure of nerve function in special cases.

Tonometry and Pressure Measurement

Of all people over 40, several per cent are presently going blind from glaucoma, a major cause of irreversible adult blindness. Here, an increase in pressure within the eye, if not detected and treated, will be followed by permanent blindness. Devices for detecting this increase in pressure are called tonometers, and the introduction of electronic methods seems likely to revolutionize their use and spread their application to a larger section of the population. The difficulties have been that the procedure is cumbersome and somewhat inaccurate, and furthermore, anesthetics had to be applied to the eye in order that the patient tolerate the hardware placed upon his eyeball.

There are two new principles. The first might be called acoustic tonometry. This is suggested by the observation that increasing tension in a drumhead causes a rise in frequency. Similarly, increasing pressure in the human eye might give it a higher characteristic frequency if set vibrating. One might measure the acoustic impedance of the eye by placing into contact with it a core driven by a coil fed from an ac source. From acoustic impedance, one obtains two numbers corresponding to real and imaginary parts. One is related to the springiness of the eye and the other to viscous and other losses within the eye and associated vessels. The latter might be correlated with clinical abnormalities, but the former is of interest here.

The magnitude of this "springiness factor" can be estimated as follows.[1] If a flat plate is pressed against the surface of a sphere (the eye), then an increase in area of contact proportional to deflection results; for a small deflection, there will be little increase in pressure within the sphere. Simple geometry indicates a force increasing directly proportional to deflection, and thus release of the plate should yield simple harmonic motion, with the eye acting as a perfect spring. The frequency of oscillation should be approximately independent of vibration amplitude or initial pressure:

$$F = \sqrt{\frac{RP}{2\pi M}}$$

where M is the mass of the flat-ended plunger momentarily pressed against the eye, R is the radius of the eyeball, and P is the pressure within the eye.

In Fig. 1, this is seen to give the correct order of magnitude in the normal range of pressures, with some spread in the readings. Each point shows the frequency of maximum vibration amplitude, for a given pressure, as the exciting frequency to a solenoid driven plunger was varied. Response amplitude as a function of frequency at any one pressure indicates a Q factor of approximately four. There are deviations from ideal performance due to damping and nonlinear bending forces, and so this method seems most applicable to basic studies of the visco-elastic properties of the cornea.

Classic tonometers, and their electronic relatives using a transducer rather than a lever to measure motion, have either measured the force required to flatten a predetermined area of the eye against a transparent plate, or else have measured the indentation of the cornea by a plunger of known weight. The latter procedure doubles the pressure within the eye. Sources of error in tonometers are variable corneal stiffness opposing probe approach, tissue tension tending to expel a plunger, surface tension of tears, variable eye size, the variable curvature of astigmatism, corneal scarring, etc. None of these affect the reading of the instrument

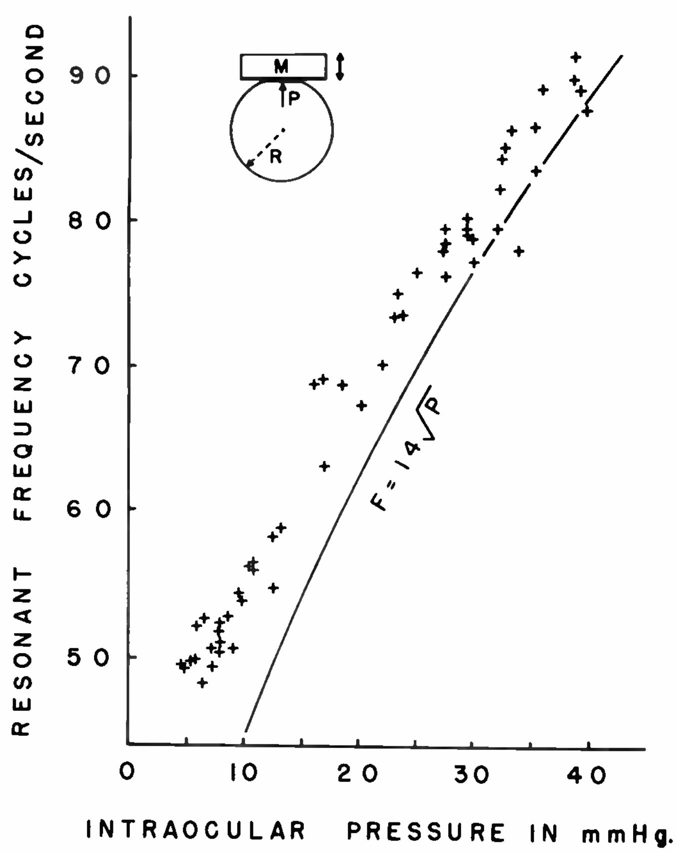

Fig. 1—Experiment of plate vibrating against eye. Plot of characteristic frequency vs intraocular pressure observed with five rabbit eyes of approximately uniform size. An idealized theoretical curve neglecting the damping term and elastic forces is included. Adjustment of initial force and correction for finite Q improves fit.

[1] W. K. McEwen, D. M. Maurice, R. S. Mackay, M. Margolis, R. Vreeland, R. St. Helen and M. J. Hogan, "Investigations of the Mechanical Properties of the Eye, Part I. Acoustical Tonometry of Enucleated Rabbit Eyes," unpublished study, 1954–1958.

of Fig. 2, according to first-order theory.[2] Here, the eye is momentarily flattened to beyond the pressure-sensitive center of the probe (1.5-mm diameter), and the only force exerted on the plunger is the intraocular pressure, if the plunger end does not deviate from the plane of the surrounding ring. Any minute motion of the plunger is sensed by the variable inductance displacement detector, and this signal is amplified and fed back to an electromagnet to supply an increasing force to return the plunger. Magnet current is a direct measure of applied force and, if the gain of the feedback system approaches infinity, then the resulting displacement will approach zero. The measurement is absolute and, since there is no plunger motion, field nonuniformities do not introduce nonlinearities in the scale, and friction problems are minimized. Recent models have used a sensitive differential transformer as the displacement detector (deflection of a half micro-inch per millimeter mercury pressure) and a relatively stiff spring rather than feedback to oppose motion. Silicone rubber here pots the transformer core within the transformer to supply support, bearing, and spring. Acceleration insensitive units also have been constructed from a small quartz crystal mounted flush in a plate. The entire observation can be made in any orientation in a second without anesthetic (a thin layer of liquid remaining between probe and eye probably reduces sensation). The last advantages are important for drug-testing animals and for use with children.

Too much probe force raises the eye pressure, but there must be enough force to flatten the cornea. As the probe advances against the eye, the output signal is observed to rise and then drop somewhat before rising again. If the cornea suddenly buckled (like a bistable oil-can bottom), then the intraocular pressure would be measured by the first crest height. Experiment proved

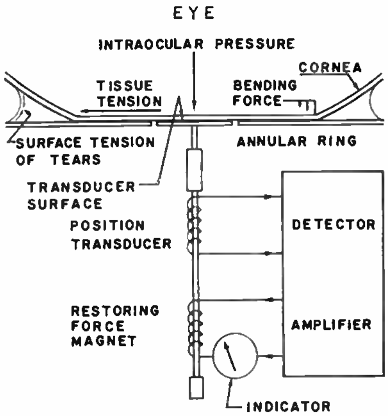

Fig. 2—Flattening the eye to beyond the pressure sensitive plunger assures intraocular pressure alone being measured. Tendency toward motion is opposed by the feedback current, which thus measures the pressure.

[2] R. S. Mackay, E. Marg and R. Oechsli, "Automatic tonometer with exact theory: Various biological applications," *Science*, vol. 131, pp. 1668–1669; June 3, 1960.

the alternative explanation, involving the interaction of the bending forces before the flattened area extends beyond the pressure sensitive area. Pressure then is measured by trough height, and the excess height of the first crest measures corneal stiffness. Information about plastic effects and fluid outflow rate from the eye's anterior chamber is provided by comparing corresponding points on the curve produced while the probe is advancing and then receding.

Ease of fluid outflow from the eye can be inferred by comparing the indication above with a measure of area of flattening (the force on the handle or on the "guard ring" alone). With the newest methods, the noise level before contact is limited by brownian motion in the transducers.

Application off of center allows measurement while looking into the eye. Pressing variably until one sees the pulse start and stop (ophthalmodynamometry) allows estimation of the arterial blood pressure in the retina, which is close to the pressure in the internal carotid artery, of interest for cardiovascular diagnosis. A difference between eyes indicates occlusion in the vessels.

This principle is applicable to the measurement of other pressures such as within the head of a reclining infant, inside a bladder, uterus,[3] or within an intact blood vessel. The thickness of the wall to be flattened determines the probe diameter. In cases of enlarged spleen, this technique may approximate the pressure in the portal system, which observation presently necessitates a serious surgical procedure. It may prove useful to evaluate muscle tone by pressing the tonometer against the bundle. While with A. A. Ismail in Egypt, some observations with a larger unit were made on the abdomen and its ascetic fluid. People there suffer from bilharzia and may display a distended abdomen due to the presence of a dozen liters of fluid, releasable by puncture. Such a unit applied to the top and bottom of the abdomen of a seated subject indicates an appreciable difference in reading due to the column of fluid. On the other hand, a subject suffering from heart failure may show a distended abdomen due to lack of rapid elimination of swallowed air (nitrogen). Then the two tonometer readings are about the same, and the subject should not be punctured, but rather placed in an oxygen tent. In this application, nonuniformities in the abdomen wall (fat lumps) may give an elevated reading. A plunger with a swivel action with respect to the plane of the surrounding ring may overcome this difficulty. All these applications use the consequences of the simple fact that the pressures on two sides of a flat surface are the same.

The feedback tonometer, like any regulator, can be adjusted to oscillate. It then acts as a negative resistance coupled to the eye through a bilateral force transducer. Oscillation frequency is observed to increase with intraocular pressure, as expected.

Oculography and Hangovers

The human eye acts like a battery in that there is a relatively steady dc voltage existing between the cornea and the retina, making the front positive with respect to the back. Thus, if a person rolls his eyes to the left, the left side of his head will become a few hundred microvolts positive relative to the right side. One has the action of a potentiometer, the magnitude of these voltages being proportional to the angle of the eyes from straight forward. By recording these voltages from surface electrodes placed around the eye sockets, one can determine where a person is looking. The method has been used to study the fashion in which people observe a scene, and the regions of special importance, in subjects ranging from advertising posters, circuit diagrams, and airplane cockpits, to pictures of pretty girls.

Some of the more remarkable applications of the technique have been in clinical and basic studies of the central nervous system and the effects of drugs thereon.[4] Nystagmus is a vibratory motion of the eyes, which may rotate to one side and then snap back cyclically (*e.g.*, when an inexperienced person spins on the dance floor). It is observed as a result of vestibular lesions. Another form follows consumption of alcohol. This last usually occurs with closed eyelids, but by this electrical method one can tell where a person "is looking" though the eyes are shut. A typical experiment involves drinking a measured quantity of whiskey and then laying down on one's back with head turned to one side. Soon it is recorded that the eyes beat to the right when the head is to the right, and vice versa. This continues for about three hours, followed by one to two hours of no abnormal tracings. Then, for 10 to 20 hours (long after all alcohol has left the body), a second phase of vibration is found. Jerking of the eyes now is in the opposite direction relative to head position. It is at this time that the person reports the subjective feeling of a hangover. Drugs that interfered with this second stage of eye activity were tested[4] and found to interfere with the sensation of hangover; *i.e.*, unpleasant symptoms became less marked. The effect of a new alcohol dose ("pick-me-up") was studied similarly.

Circuits are being designed to analyze automatically a tape-recorded nystagmus pattern for degree of activity. They will be used to study the site and mechanism of action of certain drugs on the central nervous system. One of the major problems for workers in medical electronics is the reduction and understanding of large masses of data.

The effects of drugs on motor activity and the impairment of coordination due to hypoxia, etc., can be studied using classic tests such as standing steadiness, finger-finger touching,[5] etc. These can all be made more sensitive by incorporating electronic measurements and, if the signals are recorded in electrical form (magnetic tape), then results are subject to automatic analysis.

In connection with the human eye, other work might be mentioned. Various television systems have been designed to measure pupil diameter. It is a significant clinical entity, since the pupil pathway goes through many important areas of the brain. It has been known that a spot of light imaged on the edge of the iris of the eye produces oscillation of pupil size. Recently,[6] this has been analyzed in servomechanism terms. Oscillation frequency depends on certain physiological variables, and such an effect might be used in testing drugs, quite aside from its basic interest. Similarly, one might investigate oscillations produced by feeding back eye position to an oscilloscope spot being observed, after administration of drugs. Biological observations and theories often yield practical medical applications.

Radiology

Of the clinical specialties, possibly radiology is most susceptible to physical analysis and reduction of empiricism by the application of information theory and biophysical investigation. This applies to the production of a radiogram to give maximum information with minimum dose for diagnostic purposes. The analysis of a radiogram is an extremely complicated procedure, and even the radiologists themselves cannot say exactly what they do when they, for example, read a chest film. It is much more than, say, comparison of the two lungs. Even following the pattern of eye motion during reading does not give too much help, and conception of an automatic chest film reader is an extremely difficult problem in pattern recognition. (Some success with the cancer cell screening problem has been achieved.[7]) However, the production of the radiograph itself could probably be made automatic with the present state of our knowledge.

Conditions for minimum dose are 1) a constant intensity image,[8] and 2) either a monochromatic X-ray source or a color display or equivalent[9] (all require electronic methods). Intensifiers have absolute limits that prevent indefinite improvement.[10] Electronic, and especially television techniques, have given the radiologist a step forward in recent years. Television techniques allow the production of bright multiple images

remote from scattered radiation. By viewing the fluorescent screen on which a fluoroscopic image appears with a television system, it is possible to observe finer detail with more sensitivity without dark adaptation, and thus with less dose to patient and physician. This is not only an aid in routine clinical procedures, but is of help to clinical instruction where a whole class can follow the course of an examination on remote multiple viewing screens.

Furthermore, the image can permanently be recorded in the form of an X-ray motion picture. Since television output brightness can be increased as desired, the radiation exposure of the patient can be determined by the fineness of detail to be observed, rather than by the sensitivity of available photographic emulsions.[11] A movie is extremely useful for instruction, research, and in normal practice. It is impossible to look everywhere at once, and the rerunning of the moving picture of an examination tends to bring out some new aspects on each successive viewing. The recording of the video image on a magnetic tape can also result in less patient dose than if an ordinary movie camera were used to photograph a television monitor.[11] The possibility here of immediate viewing and reviewing of the sequence is important. Storage of the image in electrical form is also useful in that appearance can be modified during playback to the optimum by altering contrast, etc. The single-frame viewing possibility of the newer helical-scan recorders is very useful in radiology. An application example is the use of mouth and throat pictures to aid a subject in speech therapy, to determine advisability of surgery for malformation, and to make a normal bodily function graphic in anatomy classes.

A film or recording can contain subtle pieces of information unnoticeable to the human eye, which requires brightness differences of roughly one per cent for detection. Simple contrast enhancing circuits can unveil these. Mixing with a signal some of its own derivatives emphasizes edges or contours. Restricting the low-frequency response of the television system increases the contrast in fine structure without slow variations in intensity driving part of the over-all system out of the useful range (equivalent to "logetronics"). These methods[10] have proven clinically useful. Actually, a kind of edge enhancement due to interaction between adjacent receptors may normally sharpen all senses to their stimuli. One attempts the opposite of edge enhancement in "removing" spots from clothing. A slight motion of an object can make structure more noticeable because of the effect on the retinal receptors.

The graph of the variable density pattern in a single subject plane (single television line display)[11] may help clinical accuracy and be useful in making radiology more quantitative. Also, one can see smaller density variations as a deviation in the density plot than one can observe directly on a television monitor or radiograph. To do this, one must restrict the high-frequency response with a condenser to reduce noise; this also cuts out the finest detail, which provides another example of the general rule[10] that one can trade resolution in brightness for geometrical resolving power (by integration over a different area size). Contrast enhancement is effective only if there is no detail of interest finer than a specified amount, for similar reasons.

Some blurring is inevitable in forming any image. If one knows the way in which any point on the object becomes blurred in the image, and if one has the final image, then by a suitable mathematical transformation, one can say what the object actually looked like. This deblurring process does not disobey any entropy or information theory considerations, and it can be approximated in some cases by mixing with a signal a suitable selection of its derivatives. Thus, one might build a high intensity X-ray tube using a broad focal spot that would yield somewhat blurred images. These images would be blurred in a known way and thus, in principle, could be rendered sharp by after-treatment. However, one would pay a high penalty in signal-to-noise ratio because of the emphasis by this process of high-frequency noise.

Besides edge emphasis and deblurring, such procedures might also be used to emphasize structure in the image in a particular range of sizes. One can do this using television techniques, but it is interesting that these procedures can also be carried out by optical methods that draw on electrical engineering filtering concepts. An image (subject) placed in the optical system of Fig. 3 is considered as made up of various Fourier components in the vertical direction. One is shown acting as a diffraction grating. The high-frequency components corresponding to fine detail deviate the output monochromatic light beam more than the low-frequency components. A diaphragm or stop placed before the final camera can be used to reject all structure of a particular spacing or size, *i.e.*, to act as a filter for a particular object periodicity or frequency. A suitable image there could constitute a matched filter for a given subject. By using long focal length lenses, these diffraction effects can be observed with normal-sized photographic images. One can approximate deblurring action by the edge emphasis mentioned above, and this has been tested in preliminary experiments by placing before the camera a graded stop that is relatively dark at the center, and which gradually drops off in density toward the edge. The radial rate of dropoff of opacity is the same in some cases as the frequency response of the corresponding differentiating circuit in a television system. Optical filters can be more arbitrarily determined than electrical ones, though negative signals can cause problems.

Viewing a television image of a rotating object with an extra time delay to one eye gives a true three-

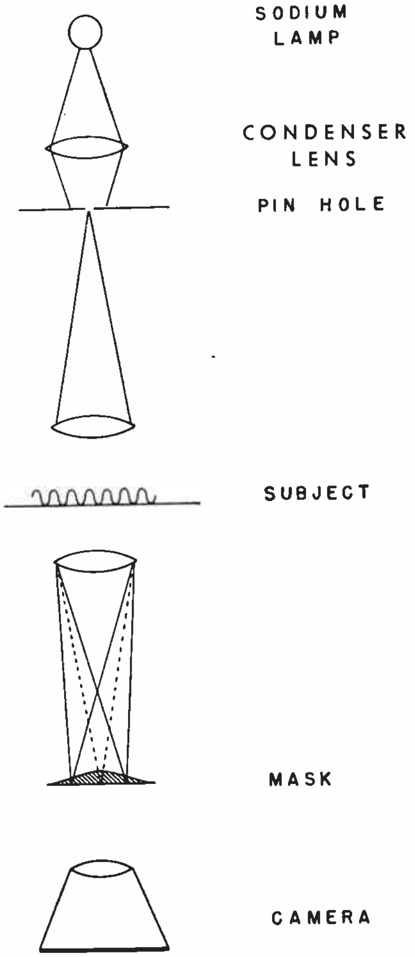

Fig. 3—Optical system capable of filtering out selected frequency components in a subject to emphasize edges or elements in a particular range of sizes. The camera photographs the object, one frequency component of which is shown producing diffraction.

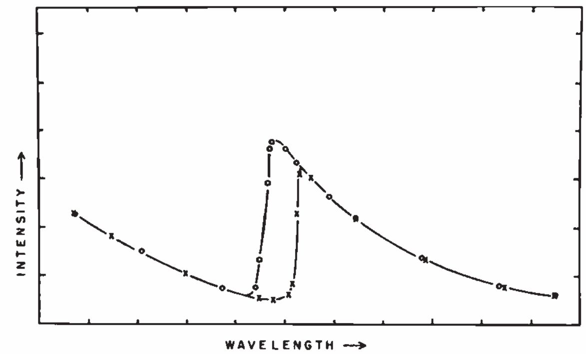

Fig. 4—Intensity of X rays transmitted by one or the other of two elements. For iodine and barium, the K edges fall at 0.373 and 0.331Å (33.2 and 37.4 kv), respectively. Falloff outside this region is largely determined by the spectrum emitted by the tube.

dimensional image, and this can be done by simply placing a neutral filter before one eye.[12] The accompanying random noise pattern then takes on a depthy swirling-cloud appearance. This may provide a way to study either the statistics of noise, or binocular depth perception using patterns without cues other than binocular parallax.

The presence and distribution of one element may be important, *e.g.*, of iodine introduced into a body cavity to outline it, or pulsed into the heart for visualization of blood flow pattern. Special X-ray equipment using the spectral information in an image, in addition to the usual lumped absorption pattern, permits working with smaller quantities. The graph of absorption of an element as the incident X-ray frequency (kilovoltage) is increased displays a sudden drop in transmission as the quantum energy becomes sufficient to dislodge K electrons (Fig. 4). Two elements can be adjusted so that their absorptions coincide everywhere except between their K edges.[13] An image of an object formed from an X-ray beam filtered by one element will differ from the image formed by filtration with the next higher element, mostly in those regions where there was present some of the first element, since all other elements in the subject will have similar absorptions in the two transmitted spectra.[14] For example, the distribution of iodine within a subject might be obtained by subtracting images produced with iodine and with barium filtration. Spectral information is not wasted as in ordinary radiography.

Two photographic images are not sufficiently comparable, and a detector-memory combination of high precision seems needed for subtraction. A television tube can be used as the detector (Fig. 5) with a spinning filter pair, and then any given detection point need only maintain constant sensitivity for the time of a half-revolution (say 1/30th second). A property of the visual system allows dispensing with an electronic storage system and differencing mechanism for the two images. Flicker is seen in two light distributions alternating at low speed in those regions where the intensity is different. Alternatively, the two images can be compared by conversion to color, where local differences in intensity appear as a shift in hue. In preliminary experiments, differentiation by color was demonstrated, though no evaluation of ultimate sensitivity has yet been made. The filter pair consisted of solutions of barium chloride and sodium iodide to avoid possible diffraction effects, the second ion having remote characteristic absorptions and apparently tolerable unbalancing action. Three filters might similarly effectively isolate two wavelengths for a three-color display.[14] For better resolution and lower dose, the X-ray tube can be placed to one side to produce characteristic secondary radiation that then traverses the subject from a fluorescent source incorpo-

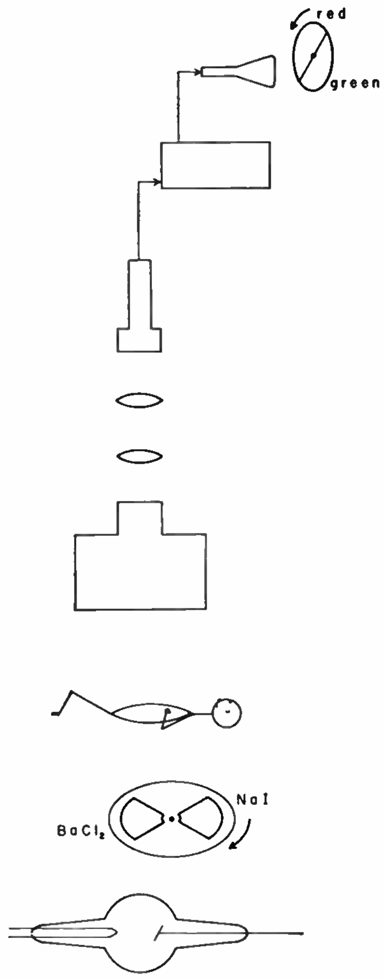

Fig. 5—Television system for visualizing the distribution of iodine (not necessarily radioactive) in the body. The source preferably has characteristic lines on both sides of the iodine absorption edge.

rating cesium, barium, or lanthanum; a special tube with a barium sulphide target would have a similar effect.

The efficient television detectors that are now almost exclusively used show storage, since at each point the effect of each interacting quantum is added to that of all the rest that arrive there in the interval since the previous frame scan passed that point. Then, the total signal is suddenly released as scanned. In Fig. 5, the change of filters, flyback, and then pulsing the X-ray source must be almost simultaneous to avoid mixing "illuminants"; source pulsing might be replaced by having the line of scanning out information from the orthicon just follow the image of the line of demarcation between X-ray wavelengths as it advances over the subject. Intensifier persistence and noise both limit performance.

The advantage of this method is that special equipment over that already found in hospitals is minimal. A lower radiation dose method using a special X-ray tube with rotating secondary emitters to produce two alternating monochromatic beams, has been demonstrated and it gave 100 times the usual radiographic sensitivity to the presence of iodine,[10] while also providing ***in vivo*** quantitative chemical analysis.

In the future, remote vision and hearing might actually be augmented by remote feeling, in the fashion of remote manipulators, to allow remote diagnosis and therapy. Certainly, a central pool of specialists for referral is possible, the most immediately practical one being of radiologists to read films presented over a television link.

The Heart and Learning Filters

Electrical signals which can be picked up from the surface of the body accompany the action of muscles. For example, the electrocardiogram is a display of the voltage picked up by electrodes as the heart muscles work.[15] Ramifications employ various electrodes, three-dimensional displays of the potential pattern or vector displays of the equivalent dipole, displays of derivatives or integrals of the potential, autocorrelation functions, etc. Abnormalities warn of arythmias or malfunction. The foetal heart deserves special attention, not only as an index of well-being, but because the signal may warn of a multiple pregnancy.

It is now possible to study the onset of conditions such as heart failure, or in general, to make a continuous recording of the start of an event that may only happen once at an unknown time. A patient with expected difficulties can be fitted with electrodes and a frequency-modulated transmitter to telemeter his electrocardiographic potentials to a laboratory for recording as he moves about freely. The first of two tape recorders runs continuously and has a loop of tape corresponding to a time of a few minutes per turn; this passes through an erase head and then a nearby record head. At all times on this loop of tape are recorded the previous few minutes of heart action. At any time, if irregularity (for example, a significant variation in frequency) is noted, this first recorder is stopped and the unmodified second recorder is simultaneously started to carry out a prolonged recording of the subsequent action in the usual way. From these two recordings, one can study the onset and subsequent history of any irregularity.

Heart action often is studied by listening to chest sounds with a stethoscope. Fidelity is improved by employing an electrical transducer and amplifier. Thus far, acceptance of this has been poor, apparently not because of greater complexity or cost, but because too much unfamiliar signal is produced. Another method of circulatory system study relates to the fact that everyone at some time has lain in bed and heard the springs squeak in time to his heart beat. (Some then decide they are having heart trouble, and the squeak becomes faster and louder.) Quantitating this effect with motion

[15] O. H. Schmitt, "The biophysical basis of electrocardiography," *Proc. 1st Natl. Bio-Phys. Conf.*, Columbus, Ohio, March, 1957, H. Quastler and H. J. Morowitz, Eds., Yale University Press, New Haven, Conn., pp. 510–562; 1959.

transducers has opened the field of ballistocardiography.

In both the electrical and the acoustical situation, the filtering out of extraneous noise is helpful. One might consider the optimum linear filter for these purposes, or better, the optimum nonlinear filter. Gabor has discussed filters that match themselves to a type of waveform through a learning process.[16] In essence, the matching process samples the sample functions at the Nyquist interval, *e.g.*, with a tapped delay line or a multiple-head tape recorder. A function involving internal machine coefficients and the various samples is formed. Internal coefficients are varied in a systematic way until the mean-square-error difference between the function and the desired output (the task) is a minimum, this being taken over the entire ensemble of inputs. The process produces a match.

The nonlinear filter might adjust itself to some abnormality. In principle, one might take a long record of heart signals (sound or electrical, on tape) and produce the final message (task desired) by filtering out everything but the arythmias. The filter will learn, to the best of its ability, to give a response when the arythmia comes along. In the above double tape recorder method, the observation of the waveform and the decision that an irregularity is present can be made by a human operator. This is a normal function of the cardiologist who studies his patient's electrocardiographic records and then proposes suitable therapy. However, it seems possible that these filters could be designed to recognize the various waveforms and distinguish abnormal from normal ones. These would be useful both in clinical diagnosis, and to initiate the above-mentioned switching operation. In building any filters, one is not only limited by the technical possibilities of design, but one will inevitably build in his own bias as to what constitutes a normal and an abnormal pattern. In some cases, experienced clinicians cannot agree, and so the problem is not always a simple one.

If a variety of abnormal waveforms were repeatedly played into a learning filter, it would gradually (subject to certain orthogonality conditions), so to speak, pick out what was statistically similar in all of them and arrange itself to respond to this similarity. Besides adjusting itself to a match, it might actually extract some common factor or statistical regularity between the various records (input teaching samples) that would be overlooked by a human making judgments.

Recently, two groups described experimental work on adaptive waveform recognition and self-optimizing nonlinear filters.[17,18] Such a filter might also in part substitute for the eternal search for the transfer function of a person, or his parts, by acting as a human simulator. To cause such a filter to simulate a person, one would repeatedly play in suitable functions and simultaneously the person's actual response as the target function (task). After the filter had adjusted itself to simulate the response of the person, then other inputs could be tested. It might be noted that the transfer function of a person is not constant. The adjustment of a human transfer function to a task is demonstrated by engraving or dissecting under a microscope, wherein stability results though the gain may be 100 times higher than in normal freehand dissection or engraving.

These considerations apply to the recording of any of the other electrical potentials generated in the course of body functioning, whether they result from uterine contractions, brain activity, the response of the retina to a flash of light, or etc. Some such potentials have magnitudes less than the noise level (biological or amplifier) of the experiment, but if they are evoked by a controlled stimulus, then addition of a number of responses (*e.g.*, on a storage tube) gives a clear signal with the noise averaged out.[19]

The human heart is a large muscular structure of four chambers; it displays certain difficulties that can be treated electrically. An experiment to visualize one problem employs a jellyfish with its central part cut out to leave a ring of muscle and nerve. Stimulation of one point produces a muscular impulse traveling out in both directions around the circle to meet and cancel as each runs into the refractory state left behind the other. Squeezing the ring prevents passage of one of the two impulses, and this temporary block can be removed before the other impulse arrives there. Such a ring left sitting in a pan of seawater can conduct an impulse around and around for a week. A temperature rise increases velocity and diminishes the number of similar impulses that can simultaneously travel around the ring in one direction. Such a system is one of the newest suggestions for a computer storage and logic element,[20] using a thread of nerve analog.[21] In the heart, nonuniformities can result in small waves propagating themselves around the various chambers in a so-called circus movement that prevents a coordinated contraction from pumping blood. Either the auricles or ventricles can show this fibrillation, the chambers of the human heart being large enough to sustain such continuously varying circular paths. Ventricular fibrillation is fatal and can be induced by some anesthetics or by chest

surgery irritation, and it often is the cause of death following electric shock. Though not spontaneously reversible, it can be interrupted with a massive electrical shock to the heart, following which, normal beating is usually resumed. Proper values of current and voltage are known and, with an exposed heart, "plugging into" the 110-volt, 60-cycle line for a fraction of a second is appropriate. Successful impromptu emergency defibrillation in a hospital has been produced by wrapping the exposed ends of a light fixture cord around surgical instruments applied to opposite sides of the patient's heart, and inserting the plug into the wall for an instant.[22] Closed chest defibrillation requires correspondingly more power.[22]

With heart block, the contraction of the auricles does not spread down to the ventricles, and the latter, perhaps contracting at their own intrinsic slow rate, may inadequately pump blood. The heart can be stimulated into periodic contractions by cyclically applying small shocks from a so-called pacemaker. This can be implanted, but if powered by a mercury cell, would require changing every five years.[23] Success in recharging endoradiosondes without interrupting transmission suggests powering a pacemaker by a rechargeable nickel-cadmium cell. Then it would only be necessary for the subject to sleep in the vicinity of a suitable radio-frequency oscillator once a week for battery recharge. A signal from the auricles might trip a relaxation oscillator that would pulse the ventricles, thus bringing them into synchronization, to match body needs. Investigation of a self-powered unit, in which a small transducer attached to the auricles would directly generate the voltage for the ventricles, has thus far yielded no results, nor have more complicated arrangements in which the relatively powerful contraction of the ventricles would store energy to be used in generating the pulse to initiate the next contraction of the ventricles.

Instantaneous Frequency Determination

In observing heart rate, muscle or nerve impulses, bat sonar, etc., one may need instantaneous frequency indications rather than averages over several cycles. The start of a period can commence a condenser discharging and the end terminate it. Discharge through an element having current proportional to voltage squared yields a final condenser voltage linearly proportional to frequency (inversely proportional to time). Resistively shunted thyrite or a biased diode network can display suitable nonlinearity. This has proven to be one of the more useful methods.[24] The principle, which has general frequency modulation detector applications, has been used to produce an oscilloscope display of reciprocal time.[25]

Seemingly, the initial condenser voltage must be infinite, which is inconvenient. Instead (Fig. 6), the initial condenser voltage V_1 corresponds to the minimum expected period T_1 or the maximum frequency. Discharge is delayed by a monostable circuit for this time, during which the previous reading is recorded and the condenser recharged to V_1. This circuit is sensitive while its memory is undergoing readout and resetting. With aperiodic cycles (*e.g.*, velocity inferred from time for labeled flow to traverse a fixed distance), the rate is stored for interrogation until the last possible moment during the start of the succeeding operation.

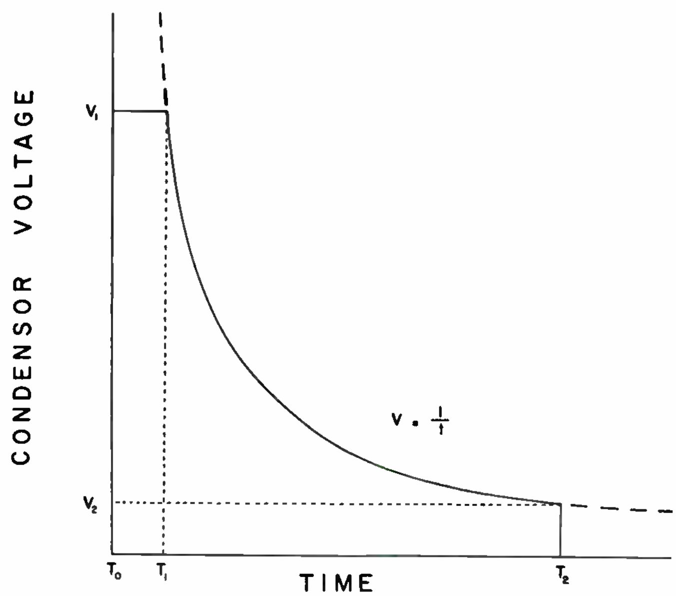

Fig. 6—If the time for one cycle of an event is T_2 and condenser discharge starts at T_1 from V_1, through a square-law device, then frequency indication is linearly proportional to the final condenser voltage V_2. The period T_0 to T_1 can be used for readout and resetting from the previous cycle.

Radio Telemetering to and From Within the Body

One can transmit signals into the body. Passive receivers (a tuned circuit plus diode) have been implanted to stimulate the brains of experimental animals in several laboratories. A heart pacemaker can similarly be powered. Such a receiver in a tooth could pick up the signal from a pocket-carried hearing aid and invisibly deliver the signal, via a tooth, by bone conduction. Also, the release of drugs from a capsule could be controlled externally.

Recording of various internal physiological variables with minimum surgical or other interference with the normal state is desirable. An approach places within

the body a small transducer-transmitter combination. Swallowable radio transmitters called endoradiosondes thus far have performed satisfactorily while traveling the entire length of the gastrointestinal tract, and also after insertion into the bladder. A smaller transmitter has been designed for insertion into the anterior chamber of the eye to study pressure fluctuations and glaucoma. Related pressure transmitters have application to studies of teeth clenching and standing steadiness. The devices presently further animal studies, drug research and testing, routine human observation, etc. Some variables transmitted are pressure, temperature, oxygen concentration, acidity, and radiation intensity.

The frequency characteristic of a tuned circuit can be measured by bringing near it a grid-dip meter. Thus, the first experiments of this general nature attempted to measure the motion of an iron core near a tuned circuit in response to pressure changes. Signals thus generated seemed weak and unreliable, and so when junction transistors were perfected, passive transmitters were temporarily abandoned, and active ones containing a battery were tested.[26] Independent work from various parts of the world was described.[27,28] Passive transmission has been reported[29] and suggested for a two-valued variable.[30] There are differences in requirements for active and passive transmitters, and these are mentioned in a general summary of this field.[31]

One transmitter is shown in Fig. 7, and its signal pattern in Fig. 8. The transistorized Hartley oscillator is frequency-modulated by core motion, most of the radiation coming from the coil. Restoring force to the core is supplied by air pocket compressibility, and it is possible to balance the effect of temperature on this against that on the ferrite, tuning capacitor, and transistor. Temperature sensitivity can be enhanced by adjustment in the other sense. Variable resistance sensors of temperature and of pressure (liquids with a void between electrodes, or conducting epoxy) also worked. Pressure-responsive modulation by a light aluminum armature in place of the ferrite core of Fig. 7 seems advisable in variable g situations (rocket or satellite experiments), and in restraint-of-pill experiments by external magnets; transmitters of other variables are relatively insensitive to gravitational and magnetic fields. In a variable acceleration situation, a projecting ring prevents direct pressure by the body on the diaphragm. Transmission frequency is usually in the range of $\frac{1}{2}$ to 10 Mc.

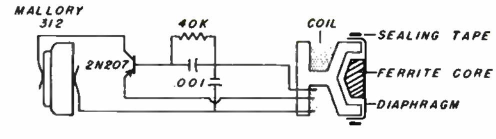

Fig. 7—Frequency-modulated radio transmitter to be swallowed for telemetering pressure or temperature. This unit is 9 mm in diameter, being determined by battery size.

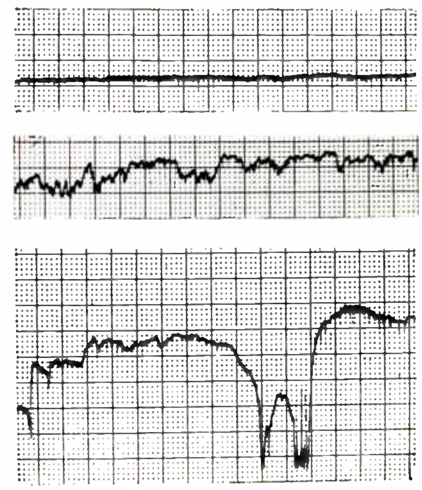

Fig. 8—Spontaneous restoration of peristalsis in the large intestine (cecum) after cessation following the trauma of abdominal surgery (removal of gall bladder). The small regular fluctuations are pressure changes due to breathing. Major vertical divisions are 20-second intervals. Top: after one hour, no activity. Center: 10 minutes later, activity starts. Bottom: three hours after center. At top and center, the deflection times 1.6 gives pressure in millimeters mercury; at bottom, multiply by 3.2. From a study by Dr. John Carbone and the author on the effect of the drug Cozyme or Ilopan in hastening intestinal activity in the post-operative period. (The above records are without drug.)

Methods of reception and demodulation have been given.[31] Two methods for overcoming loss of signal with pill reorientation are essentially either to switch cyclically between three perpendicularly (or otherwise) oriented receiving loops, or else to take the signal from the three receiving loops and feed each to a frequency doubler before addition and presentation to a receiver. The resulting signal is frequency-modulated and does not vanish for any capsule orientation.[32] Booster transmitters, using a frequency shift between input and output to prevent oscillation, can be used to relay signals. Multiple transmitters record gradients. Subject freedom is important in animal experiments where there is no discussion or cooperation.

Reversible mechanical expansion has been used to sense acidity[33] and oxygen concentration[32] changes, but electrochemical methods now seem better. With nonlinear condensers as modulators, one obtains the 100-megohm input resistance required by a glass electrode

to make pH measurements.[31,34] A representative problem for such a unit would be to see if vitamin D administration to a child with rickets changes the pH in the intestine due to the effect on calcium. A problem for further investigation is the detection of the site of blood leakage into the gastrointestinal tract (or even to distinguish stomach from duodenum). Blood can show a dielectric constant of several thousand, but a capacitor probe does not make a satisfactory *in vivo* detector.[31] An earlier method[35] was to label red corpuscles with radioactive iron and to form the radio capsule into a low-voltage radiation detector by placing a fluorescent screen around the exposed transistor. Greater sensitivity is sought.

Sound and Ultrasound

The detection of auditory malingering and psychogenic deafness is a subtle problem. In the former, a person may feign deafness and learn to overcome normal responses to startling sounds. Electronics can help. A time delay for acoustic signals is a tape recorder playing a loop in quick succession through an erase, a record, and a readout head. It is a remarkably startling effect to read aloud from a book and have a throat microphone signal played back into the ears after a quarter-second time delay. The speed of reading *will* diminish or halt[36] if the person can hear.

Possibly related to this is the observation that playing a loud, steady noise into a stammerer's ear may relieve his affliction.[37] Recent reports of painless dentistry employing loud noises may have a limited nonphysiological basis.[38] Adequate validation is a major problem here, as with any innovation.

Extremely intense sounds affect the ear, as judged by the reports of deafness and loss of equilibrium of early jet fliers. But then Ménière's disease, which has been treated by surgical destruction of the labyrinth, might be alleviated by intense sound application; this apparently is being tested in several laboratories.

Audio methods can indicate when a pair of grasping forceps comes into contact with a hard foreign object.[39] A sound transducer mounted beyond the handle of forceps will generate an audible signal whenever the tips of the forceps contact and grasp a hard object. This has been used to grasp gall stones in a common duct operation without tearing loose normal tissue, and in detecting and grasping kidney stones, some of which cannot be seen in an X-ray image and hence are called "pale stones." Radio transmission of these signals is quite convenient.

K. Mooslin has noted that a suitably placed stethoscope reveals a harsh sound during micturization if a urethral stricture is present. An electronic extension of the method to blood flow may warn of impending vascular difficulty (bruits of aneurisms are already observable).

Bringing an extremely simple innovation into a foreign study can often provide a major contribution. Thus, neurology may be helped by a vibrator constructed from a modified earphone. Peripheral neuritis can result from vitamin deficiency, chronic alcoholism, pernicious anemia, etc., and its first symptom is early loss of vibration sense. This is possibly dependent on bone motion and transmitted as a deep sensation over separate channels (posterior column of spinal cord) in the nervous system. The condition is accompanied by loss of equilibrium and a lack of knowledge as to where the feet are, thus making it difficult to walk at night. The vibration sense is tested by applying the handle of a tuning fork over various bony regions (standard sites); 64 cycles is a standard frequency, but 50 to 60 are as good. The test is sometimes considered unreliable and unreproducible because of the lack of constancy of the vibration of the tuning forks, both in application at a single site and when making comparisons at corresponding sites on opposite halves of the body. A vibrator driven from the ac line can maintain steady amplitude and give the subject time to decide on responses. If vibration is perpendicular to the subject probe, then application variations will not affect vibration amplitude.

To digress momentarily, sonic techniques are not always best for locating foreign bodies. Metal fragments can be localized by passing near them a probe containing suitably energized coils. Thus, a balanced differential transformer will give an unbalance audio signal if any metal is brought near its end; a complete localizer, including power source, can be formed into a probe the size of a large pen. This is useful for eye splinters, bullet fragments, broken hypodermic needles, etc. It will detect either iron or nonferrous fragments, and one can construct electromagnets that will attract and possibly withdraw copper, lead, etc., as well as iron.[40]

An interesting problem recently referred to the author by a foreign police is of a clinical type, though having to do with foreign bodies, camels, and the law. The problem was how to detect from a herd one camel into whose stomach had been loaded 30 pounds of polyethylene-encased marijuana for smuggling purposes. An economical solution seems to be the use of a conductiv-

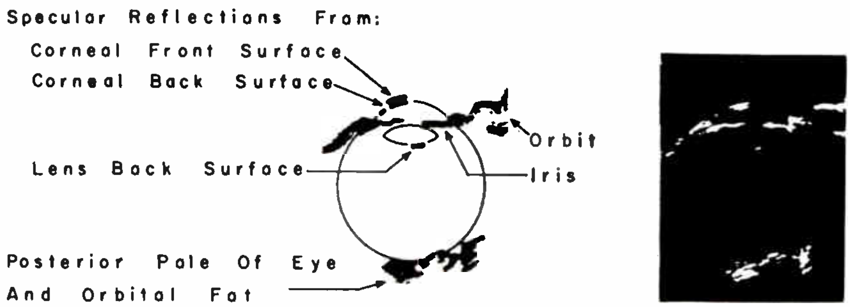

Fig. 9—Sound image of cross section of living human eye using 15-Mc sound pulses. The simple scan mode here does not visualize the lens.

ity test of the abdominal region. It may prove feasible to do this without contacting the animal by using a nonmetallic mine detecting circuit. Sonic exploration would also work.

In recent years, sonar techniques have been used to explore the body by scanning with a piezoelectric crystal which is periodically pulsed and receives returning echoes from interfaces separating various organs and structures. In this way, a detailed map in the form of a cross section can be built up. Ultrasonic echoes have recently been used to detect shifts in the midline of the brain due to tumors or injuries.[41] Abnormalities from cancers to foreign bodies have been visualized by Wild, Howry and other workers.[42] Fig. 9, made with E. Marg and R. Oechsli, shows the resolution in the eye obtainable with 15-Mc sound pulses. Nonmechanical scanning is being investigated. Acoustic attenuation increases with frequency; lower frequencies are needed to penetrate large structures, while higher frequencies increase angular resolving power. Sound at low intensities does not seem to have undesirable cumulative effects that may be characteristic of X-rays.

Another sonic technique involves irradiating the subject by a continuous sound source and placing beyond the subject a biconcave polystyrene lens to focus an image, in sound waves, of the subject onto a television-type tube.[43,44] This tube is fronted by a quartz sheet, and the piezo voltages are scanned off to convert the sound image into a video signal for television viewing. Diffuse sound illumination and frequency modulation (or source pulsing) should be used here to remove specular and diffraction effects respectively. Momentarily pulsing on the source and then the detector (point-by-point, or all-over as an electron mirror) should allow imaging a single layer (depth), and without glare or dazzle from strong surface reflections. Some of these tubes, if slowly discharged, have the potentially useful property of displaying only moving objects.[43] Recently Jacobs, Cugell and Phan have built an ultrasonic vidicon, showing storage, using phonon-induced conductivity in cadmium sulphide. (Note: more recently see Hutson, *et al.*, *Phys. Rev. Lett.*, vol. 7, pp. 237–239; September 15, 1961.)

More intense ultrasonic beams have been used to perform brain surgery that has helped cases of Parkinsonism and of phantom limb pain.[45] Zinser has used a long, thin, flexible magnetostrictive "drill" that is passed up the urethra past the bladder to fragment kidney stones stuck in a ureter; yet ultrasound can clean teeth safely.

Gas Analysis and Control

Respiratory function has many aspects. Gas flow velocity is one, and it can be measured in the lung.[46] Gas composition is important. Deep sea divers must control oxygen concentration to avoid both anoxia and oxygen poisoning; computers are being designed to study these problems and then to control gas mixtures. Even at atmospheric pressure, premature infants placed in an incubator with improper oxygen control can be blinded by retrolentalfibroplasia. Oxygen gas is usually analyzed by its magnetic properties, or by polarography after diffusion through a teflon membrane into a test region.

Another important normal component of the breath is carbon dioxide. One method of analysis employs a nondispersive infrared gas analyzer, which performs the interesting function of quantitatively detecting the presence of an organic gas after a sample of it is placed in the instrument. One form functions as follows. A nichrome wire heated by a current emits infrared energy through a thin mica window into a chamber with a flexible back that acts as a condenser microphone. To

[46] J. B. West, "Bronchial flow meter for measuring air flow inside the lung," *Proc. 3rd Conf. on Med. Electronics*, London, England, July, 1960, IEE; 1961.

detect carbon dioxide, place carbon dioxide gas in this chamber to expand under the heating action of the infrared source. Only those wavelengths characteristic of carbon dioxide will be absorbed from the continuum emitted. Gases breathed through the space between source and chamber will generally absorb at other wavelengths and not diminish the heating action; any carbon dioxide present will reduce the signal from the microphone. The heat source is periodically interrupted at, say, 10 cps, and the ac signal used as the output to avoid drifts due to ambient temperature changes.

A clinical test using a gas analyzer involves holding a breath containing $\frac{1}{2}$ per cent carbon *monoxide*. One measures how much CO is removed in the exhalate, relative to the original. This allows a measurement of diffusion rate into the lung capillaries, which can change with respiratory ailments. Dilution effects in this method can be calculated by noting the simultaneous effect on some other gas, such as helium, which can better be analyzed by thermal conductivity or acoustic velocity methods. In connection with such investigations, it might be noted that digital computers are useful for discrete variables and data storage (*e.g.*, diagnosis and symptoms), but analog computers are often more convenient for visualizing function. One of the first analog computers was probably a collection of tubes used to study breathing function.

The administration of anesthetic gases brings in another variable. Depth of anesthesia has been controlled automatically by a regulator circuit that senses certain components in the electroencephalographic pattern and increases or decreases anesthetic gas administration accordingly.[47]

[47] J. W. Bellville and G. M. Attura, "How electronics controls depths of anesthesia," *Electronics*, vol. 32, pp. 43–44; January 30, 1959.

Conclusion

Changes are to be expected in all these fields, especially when there is "cross fertilization" between the physical and biological sciences. As an example of the great changes within the realm of possibility, the often discussed proposal for electrical anesthesia was recently tested in the successful performance of major surgery with its use.[48] Similarly, blood clotting can either be hastened or retarded by a direct electric current of suitable polarity.[49] Furthermore, it apparently has become possible to produce selected sensations such as pleasure by direct electrical stimulation of selected parts of the brain.

It is hoped that the entrance of more physical scientists into biological fields will result in the selection of more suitable variables to measure and the design of more decisive experiments, and that attempts at computer diagnosis will force a greater uniformity and precision upon medical nomenclature.

In closing, it should be said that in the allotted space, it is impossible to mention most of the possibilities included in the title. The selection was obtained in the simplest possible way, being merely items with which the author has special interest or familiarity. For a more complete listing of workers and works, the reader is referred to the "Bibliography on Bio-Medical Electronics," presently occupying three volumes, prepared by The Medical Electronics Center of the Rockefeller Institute, and published by the Professional Group on Bio-Medical Electronics of the Institute of Radio Engineers.

Data Handling, Computers and Diagnosis*

LEE B. LUSTED†, FELLOW, IRE

Summary—**As quantitative bio-medical science develops, the amount of data to be handled will increase. Already the investigator frequently finds that the analysis of the data he has collected is beyond his computational ability and he is forced to turn to automatic data processing. The bio-medical investigator must have access to a variety of both analog and digital computing equipment if progress is to be made in biomedical research.**

Automatic data-processing techniques and equipment need to be introduced to the areas of public health and patient care. Projects dealing with medical records, medical literature retrieval, automatic chemical analysis, the recording of signs, symptoms, nurses' notes, etc., must all be tied together in regional medical computing systems as soon as possible. Particular attention must be given to this systematic collection and analysis of medical data before regional computing systems can help physicians with diagnosis and treatment.

I. Introduction

ONE of the most important changes ever to take place in bio-medical science is now in progress. Previously, work was primarily of a qualitative and descriptive character, whereas present and future efforts will be to develop a quantitative bio-medical science. Part of this change is represented by the expanding fields of biophysics and bio-medical engineering and by the current interest in bio-medical computing.

The development of instrumentation and the application of mathematics and statistics to bio-medical problems have greatly increased the amount of data to be handled. The invesigator frequently finds that the analysis of the data he has collected is beyond his computational ability as well as his patience, and he is forced to turn to automatic computation methods. It is the author's belief that, if we are to make progress in bio-medical research, the investigator must have ready access to a variety of both analog and digital computing equipment.

There are, for the investigator, at least two major categories of activity which may prove to be even more important than the increased speed and accuracy associated with automatic computing. These are 1) the revelation of hidden correlations which cannot be extracted by other than computer techniques, *e.g.*, on-line recording and analysis of psychophysiologic data, and 2) the design of models for testing their potentiality for prediction. These contributions should help increase the amount of investigation and should open new areas of research.

In the recent past only a few bio-medical research projects have used automatic data processing. The National Institutes of Health Advisory Committee on Computers in Research has been making a study of this field and has estimated that, at present, no more than 1 project in 20 is seriously utilizing computers. The funds allocated to such work are probably less than 0.3 per cent of the bio-medical research funds. It seems likely that in five to ten years, the use of automatic computing and mathematical analysis will have influenced bio-medical research, so that 75 per cent of the projects will be using mathematics and data processing, and at least 50 per cent of all research projects will require automatic computation.

The study of the biomedical computing field made by the NIH Advisory Committee on Computers has revealed that an effort must be made to develop each of the categories listed in Table I if bio-medical computing is to progress.

TABLE I

A. General Facility Developments
- 1) Large computing-center development.
  - a) Single-purpose geographically oriented bio-medical computing center.
  - b) Partial use of institution-wide large computing center.
- 2) Small bio-medical computing centers (serves medical school or department complex).

B. Laboratory Facility Developments
- 1) Small general-purpose computer facilities for individual laboratories.
- 2) Special-purpose computer facilities for specific laboratory functions.
  - a) On-line use of general-purpose computer.
  - b) Adapted, altered or specifically constructed computers.
- 3) Peripheral computer facilities.
  - a) Analog-digital conversion facilities.
  - b) Data-handling facilities.

C. Computer Use Projects
- 1) Investigations of possible computer uses.
  - a) Utilizing bio-medical computing facilities.
  - b) Purchasing time on already available institution or industry computers.
- 2) Investigations of mathematical and other techniques which may lead to computer use.

D. Computer Technology Projects
- 1) Development of computers (digital and analog) to meet the needs of the bio-medical field.
- 2) Development of accessory equipment such as special input-output devices for the bio-medical investigator.
- 3) Investigations of programs and programming.

E. Training in Bio-medical Computing

If bio-medical computing is a very important part of the current bio-medical revolution, then it is obviously in the best interests of the country to develop bio-medical computing and facilities as rapidly as possible. Fortunately, the National Institutes of Health, the National Science Foundation, the National Academy of Sciences—National Research Council and a panel of the

* Received by the IRE, June 29, 1961.
† Dept. of Radiology, University of Rochester School of Medicine and Dentistry, Rochester, N. Y.

President's Science Advisory Committee have taken an active interest in the problems of the bio-medical computing field. The interests and activities of these groups must be coordinated if bio-medical computing is to be developed to an optimum degree in the United States.

From the general categories of Table I three subjects have been selected for further discussion, namely, 1) training, 2) computer technology projects, and 3) the geographically oriented bio-medical computer center.

II. Training in Bio-medical Computing

In the past biologists and medical investigators have not had extensive training in mathematics and quantitative methods [20]. Therefore, the success of the change to a quantitative bio-medical science depends upon retraining existing scientists and the training of future scientists. The number of people who have had experience with automatic computing is small, and there is great need for training programs which will acquaint the bio-medical investigator with automatic data processing.

One of the questions now under discussion is whether the biologist and the medical scientist need more extensive mathematic training in order to make the best use of automatic data processing. The importance of this question is emphasized by a study made recently by Hopkins and Berry [1] on the mathematics background of medical students. They state:

> From these results, even allowing for imperfections in test procedures, we conclude that on the average these students generally, though sufficiently apt and scholarly in quantitative relations, are not sufficiently equipped with basic mathematics to master an introductory course in statistical methods. With this deficiency standing in the way of mastery of the fundamental philosophy and techniques of science, we should think again when we talk about producing physicians who are scientists as well as physicians.

If we believe that computers will extend the ability of the investigator to solve problems and also to seek new ways to extend his problem solving ability [2], then it may be very important to ask that the biologist and medical investigator be well acquainted with mathematics.

At the present time it seems highly inefficient and practically impossible for a single individual to execute all the different aspects of bio-medical computing, such as planning, logical analysis, coding and debugging. Therefore, it probably will be necessary to have teams of workers among whom communication will be fairly easy. This implies that the bio-medical computing worker must be facile not only with computer programming and operation but also with bio-medical concepts. He will require a special kind of training, and a high priority must be placed on the development of bio-medical computing training programs. Scientists who attended the course have been enthusiastic about the M.I.T. Research Training Conference on Computer Techniques for Biological Scientists directed by Dr. T. T. Sand and held at M.I.T. during the summer of 1961. More courses of a similar nature are needed.

III. Computer Technology Projects

A great deal of thought needs to be given to the specifications for bio-medical computing equipment. Some of the early computers which were developed for business applications or the physical sciences are not well suited for solving problems in biology and medicine. The fact seems to have escaped the attention of many computer designers that the computer should be considered in the context of the environment in which it operates. This applies also to input-output equipment design. The concept of man-computer symbiosis [3] is one of particular importance to the future of bio-medical computing. The best attitude at present is one of flexibility, which means that computers of different designs and different sizes will be tried by investigators in an attempt to determine what type of machine gives the most help in solving certain classes of problems. This does not mean, however, that we should allow the effort to proceed in an unorganized manner. Each investigator should be free to choose the type of automatic data-processing equipment he prefers, but he should be asked to report back to a central clearing house at the end of each year on how well the equipment worked in solving his specific problems. Thus we could readily accumulate a great deal of information which would be helpful in designing future machinery for bio-medical computing.

This effort should be organized on a national basis because of the great importance of automatic data processing to the bio-medical sciences and because of the amount of money involved in the development of computing equipment, displays and controls.

Let me cite a problem which has convinced me that an organized development of the bio-medical computing field is necessary. This problem concerns the standardization of recording techniques and equipment for analysis of neurophysiologic and electroencephalographic data.

The amount of automatic data processing using special-purpose analog devices and large general-purpose computers has been steadily increasing in such fields as brain research, psychophysiologic research and cardiovascular research. An investigator in one of these fields may wish to compare his data with that of a colleague who is doing a similar set of experiments, but suddenly he finds to his dismay that the colleague is using a different type of data-accumulation system and it is difficult, if not impossible, for them to compare data. Of course the investigator is disturbed, and he may request help from the electronic manufacturer who supplied his data-accumulation system. The manufacturer may wish to help the investigator, and may even try to make a survey, hoping he can determine the specifications for an "optimal" computer which will meet the needs of a large number of investigators. But the manufacturer usually becomes quite bewildered by the conflicting requests for different sampling rates, for the number of channels for magnetic-tape recording, and for the bandwidth requirements for the data to be handled, etc.

Thus far several preliminary attempts to get investigators to resolve these differences of opinion have failed.

To help solve this kind of problem and that related to input and output equipment development, etc., the NAS-NRC Committee on the Use of Computers in the Life Sciences, and the NIH Advisory Committee on Computers in Research can do much by inviting groups of investigators and engineers to meet regularly and to work out specifications.

IV. The Geographically Oriented Bio-medical Computing Center

When Zworykin [4] suggested in 1956 that automatic data processing could prove extremely useful in reducing the case load of the physician, he stirred up a storm of protest from the medical profession.[1] However, as Zworykin [5] observed three years later in opening the First Conference on Diagnostic Data Processing at the Rockefeller Institute, "We understand now that this criticism was due mostly to the misconception that we were trying to replace the doctor by a cold, hard calculating machine. Instead, of course, we are trying to introduce a new scientific tool to aid the diagnostician." In 1959 Ledley and Lusted [6] proposed the idea of a health computing system as an aid to physicians, and the Jones Committee of Consultants on Medical Research [7] has recommended that regional computing centers be established for bio-medical data processing. As a result of the interest in the "center idea," the 87th Congress appropriated a sum of 5 million dollars to be used for bio-medical instrumentation and bio-medical computing centers.

Although preliminary plans have been completed for several regional centers, none are in operation. There are a number of reasons for starting the regional centers as soon as possible.

During the last four years, a time when the number of college graduates has been increasing, the number of college students applying to medical schools has dropped. This trend has occurred at the same time that the population in this country has been increasing and constitutes a serious threat to an increase in the number of physicians. To keep the present physician/population ratio of 141/100,000, the United States must increase the annual number of graduates from the 1959 level of 7400 physicians to a level of 11,000 by 1975 [8]. Further estimates indicate that to reach this level we would need 16 new 2-year medical colleges and 18 new 4-year medical schools. Some grave doubts have been expressed that this goal can be reached, or indeed that it need be attained, since it may be unnecessary to maintain the present physician/population ratio. If we can supply the physician with instrumentation and computer aids for diagnosis, he should be able to practice more efficiently and see more patients than he did formerly. A regional bio-medical computing center for processing the medical data on all patients in the area would be an important diagnostic aid for physicians. Because the regional center will serve many physicians and hospitals it is obvious that the cooperation of medical schools, the medical profession, computer engineers, hospital administrators and health organizations will be required to establish and maintain it.

The regional bio-medical computing center of the future probably will carry on research activity as well as service activity, and both of these, at least in the early stages of development, will be concerned with problems of medical diagnosis. Before we can decide what kind of computing equipment and input-output devices are needed, we need to know more about the kind of data we are working with.

Let us consider the physician taking care of the patient in the hospital since this represents a more complex situation than the physician's office.

The data on the patient comes from the history, physical examination, laboratory tests, special examinations and the nurses' notes. There are problems in collecting data from each of these sources, and we have just begun to try to solve them. For instance, an easy method has not been devised for recording history and physical examination data. Some experiments have been tried using "mark-sense" cards and "mark-sense" sheets are being developed. Progress has been made in the development of automatic laboratory test equipment [9], and it should not be difficult to transmit the output to the bio-medical computing center. Blumberg [10] has recently pointed out that 13 per cent of nursing time is spent on charting nurses' notes, and about 1/6 of the nursing budget is spent for nurses' time on clerical tasks concerned with recording and performing medication orders. This is certainly an attractive area in which to introduce automatic data processing. Blumberg has made some tests with a system he calls the Hospital Indicator for Physician Orders (HIPO), which could transmit data directly to the central data processor.

I have purposely avoided a discussion of the computer equipment in the bio-medical computing center. At present we can only guess at what types of machines will be needed. Probably we shall need some machines capable of doing scientific computing and others capable of storing a sizeable amount of data from medical records. They should be expansible and able to handle multiple inputs of analog and digital data simultaneously. The output data should be presented in a form most suitable to the person needing the data. Obviously, we must wait on the advancement of computer technology and the

[1] A recent statement by Dr. Peter Forsham, Prof. of Medicine, University of California, San Francisco shows the extent to which some physicians have become convinced about the future role of computer aids to medical diagnosis. Dr. Forsham says, "By the year 2000, both diagnosis and treatment will be largely turned over to technicians equipped with electronic devices. The physician's job will then be essentially what it was in the nineteenth century—to serve as friend and confessor to the patient, counsel him on emotional problems, and help him adjust to diseases the machines are still unable to lick." (*Med. Economics*, vol. 38, p. 71; May 8, 1961.)

development of better displays and controls before we can meet all of these requirements.

The physician would like to ask questions of the regional computing center such as: From the patient data which I just sent you what is the differential diagnosis (please list the most probable diseases)? What further information do I need in order to make a definite diagnosis? What is the latest information on the treatment of this disease? On the basis of the patient's response to this particular treatment during the past week, what is the prognosis (what can be expected in the future)?

The medical information needed to answer these questions has not been collected in computer usable form. We need to undertake the collection of the necessary data by teams of physicians as soon as possible. Otherwise, we will have developed excellent data-processing equipment, but we will not have reliable data to process, and we will be operating, as one observer recently noted, in the "disposall mode," *i.e.*, garbage-in processed garbage-out, with output dependent on a "packing factor."

When groups of physicians do start to collect and to process quantitative medical data, they are going to be confronted with a number of problems. First, in many areas of medicine the signs and symptoms have never been rigorously defined [11]. Second, physicians have not studied carefully for some fields of medicine the accuracy of medical diagnostic procedures and the effect of observer error on the final diagnosis [12]. And third, the internal inconsistencies in the body of medical knowledge have not been searched for carefully. It would seem that the real revolution in clinical medicine will begin when physicians start to work on these problems. The study will be an enormous task. There is already an indication of the magnitude of the task from preliminary work done in hematology [13]. For this single medical specialty it took over 5 man-years to examine carefully the literature, the signs and symptoms, and the diagnoses. Many internal inconsistencies in the body of hematology literature were found, and the investigators have concluded that it will be necessary to collect a new body of hematology data using carefully defined signs, symptoms and laboratory tests.

On the basis of the hematology study, a rough estimate of the amount of work required to examine the entire body of medical literature and to collect new data on the basis of carefully defined standards would be 500–600 man-years. This does not seem unreasonable since it is in the same order of magnitude as the amount of work required to develop the SAGE radar system. Until this work is done, it seems quite certain that the physician will not be helped by "computer-aided" diagnosis.

For the past five years, Dr. Ledley and the author have studied the role of computers in medical diagnosis. Our attention has been concentrated on mathematical models of various aspects of the medical diagnostic processes, which can form the basis of computer programs. In addition, we have considered problems that arise in the compiling of statistics that relate symptom-disease combinations and in the accumulating and recalling of the desired aspects of a patient's total medical record, including individual bio-chemical and physiologic norms [6], [14]. We believe that these mathematical techniques will be helpful to the physicians who undertake the systematic collection and analysis of medical data in the future.

The mathematical models which we have presented represent a more precise formulation of the reasoning foundations of medical diagnosis where sequential decision techniques use 1) logical analysis to determine possible alternative diagnoses, 2) probabilistic analysis to determine the probabilities of these alternatives, and 3) value theory to assist in the choice of treatment plan. In practice, the physician first utilizes an iterative procedure of logical analysis and diagnostic testing, employing in each cycle tests of an increasingly specific nature for narrowing the alternative possible diagnoses. When alternatives still remain, Bayes' formula presents important quantitative insight into the relative roles played in the diagnostic decision by both the disease-symptom relationships of medical knowledge and the circumstantial factors involved in the location, season, epidemics, etc. At present the primary purpose for making a diagnosis is to guide the processes of treatment-plan formulation, but perhaps in the future, with computer help, the diagnosis step can be omitted and the treatment considered directly. Frequently, there is a choice among alternative treatments, which choice can involve decisions under certainty, under risk, and under uncertainty. In those cases for which the treatment plan must be formulated in the absence of a precisely defined diagnosis, a diagnosis-analysis treatment-formulation iterative cycle, in the dynamic programming sense, can be utilized [15].

If such procedures are to be applied in practical situations, the use of high-speed electronic computers is certainly indicated. Recent work by Warner [16] on congenital heart disease cases and by van Woerksom and Brodman [17] on the use of the Cornell Medical Index has demonstrated the help that conditional probability and Bayes' formula calculations can give the physician. Some questions have been raised concerning the size of the computer memory which may be needed. The first projects will probably be concerned with the amount of data in a medical specialty or subspeciality. This might range from 200 symptoms and 300 diseases to 800 symptoms and 100 diseases [15], [18]. Suppose we have a textbook of 400 pages for a medical specialty; the book would then contain approximately 1.2×10^6 characters. By allowing symbolic logic a 10-to-1 reduction in characters with six bits per character, we should be able to record the book in 720,000 bits, which is easily attainable on a modern drum memory. Ledley has made the following estimate [18]. Suppose there are

20,000 possible symptom-disease complexes associated with 300 diseases and 200 symptoms. Then, allowing 500 bits for each symptom-disease complex, $500 \times 20,000 = 10 \times 10^6$ bits would be required. There are many manufacturers today who make 10,000,000-bit drums. However, if we assume that these 300 diseases enter into only 1000 different disease complexes, and that 20 bits are sufficient for each disease complex, then, on a 10,000,000-bit drum, there will be 9,980,000 bits remaining for symptom complexes. Thus a 10,000,000-bit drum would easily record about 50 symptom complexes for each disease complex, or 50,000 symptom-disease complexes at 200 symptoms per complex.

A few of the problems which must be solved for the regional bio-medical computing centers have been outlined in general terms. No plea for the development of these centers could be more eloquent than a quotation from a recent editorial in the *Journal of the American Medical Association.* [19]:

> Scientific data are accumulating at an ever increasing pace, which threatens to outdistance the ability of the physician to keep abreast of new knowledge. Medicine faces a difficult problem, since there is an urgent need for some device to make pertinent information available promptly to the physician. Without some device for making the information available to the physician of today and tomorrow he will be less competent in the care of the patient than formerly.

Education for Engineers in Bio-Medical Research*

SAMUEL A. TALBOT†

Summary—**Current bio-medical research is not only more demanding instrumentally, but inquires into biological phenomena which are far more complex physically and chemically than twenty years ago. It results that the instrumental requirements for significant observations are often misinterpreted by biologists because of inadequate concepts of the systems involved. Consequently, the engineer himself must understand the bio-systems and the design of the experiment to assess the adequacy of instrumentation and interpretation of readings. So complex are most bio-systems that this, in general, requires the most advanced engineering concepts.**

Education in engineering with some physiology to the master's level may yield adequate technical results, but does not produce or earn a satisfactory scientific relationship. For this a much higher scientific competence is needed in engineering, in biological understanding and in the interdisciplinary area. The latter is the special application of engineering science to bio-systems: a body of knowledge still barely begun, but rapidly growing. Discussed herein is the nature of such engineering, biological and interdisciplinary training, which should lead to a satisfying career as an engineering scientist in bio-medical research. For good reasons, this is seen as a collaborative relation.

TWENTY YEARS AGO, the engineer associated with medical research was mainly occupied with designing equipment. Bio-amplifiers became specialized; versatile stimulators, optical and mechanical components—all presented problems suited to the engineering training of the day. The bio-medical problems were simpler too: description, mapping, recording simple functions in one or two channels, taking perhaps a derivative or integral, and passive electric analogs of bio-systems satisfied the bio-scientist.

Today the demands of measuring devices are increasingly difficult. Inertialess implants, versatile catheter tips, broadcasting, sensors and drivers in new ranges of sensitivity and precision, in multiple channels and scanned arrays, must still be developed. Besides an observable, its variances and several derivatives as to time and space are needed. Stimuli are subtle, involving time and space patterns. With miniaturization and multiplexing of sensors and equipment, one must detect ever finer detail: millimicrons, milli g's, millidynes, millidegrees, microwatts, microlumens, at ever faster speeds—micro- and nanoseconds. Correlations, transforms and digitization are common.

Such discriminative, multiplex and sensitive instrumentation indicates that the biologist's problems are much more complex today. His hypotheses and models have become sophisticated. The cell membrane is a complex mechanism for which simple concepts from chemistry and physics do not suffice. Neural summation is not just addition. Arterial pulsation fits neither an RC or resonator model. Scores of bio-control systems emerge, involving multiple sensors and actuators, parametric modulation, nonlinear ranges and adaptive transforms. In short, modern instrumentation reveals performance for which the physiologist has inadequate physical concepts, but which the engineer without detailed physiology cannot even recognize, much less analyze. Today the biomedical engineer is needed as much for experimental design, reduction and interpretation of observations, as for instrumentation.

It is fortunate that with this revolution in biological research has come a revolution in engineering science. The modern engineer, with advanced training, encounters coupled electrical, mechanical, hydromechanical and chemical systems, almost complex enough to use as building blocks for bio-systems. The organism has routinely used pattern-transforms in time and space domains, only now being discovered in signal theory. Switching networks, statistical storage, combined digital and analog processes are ancient in the brain. In mechanics, shear and viscoelastic propagation are just what is needed for heart-sounds. In chemical engineering, the nonequilibrium chain reaction is reached just before the student's Ph.D., but goes on in each of his cells. In a word, engineering science is just beginning to produce concepts adequate for biological models and experiments, as similarly, twenty years before, the engineering art was barely able to handle bio-measurements.

Apparently several *kinds* of bio-medical engineers are needed. To assemble existing components into special systems, to modify measurements, to help with complex data processing in real time, needs practical instrument engineers. With fair success, men with experience in industrial research can grow to fill this requirement.

But to design the specifications of today's bio-instruments may mean knowing the physical aspects of a bio-problem better than the biologist. For example, the biologist calls a "sonic catheter" a device whose threshold is far above vascular sound. To evolve a nerve-impulse analyzer requires not only a critical knowledge of analytic methods but clear understanding of activity patterns in a nucleus or bundle. Today's designer of bio-instruments must know a great deal about a special biological field. For this requirement, a master's training in engineering, a study of biological instrumentation

* Received by the IRE, July 10, 1961.
† School of Medicine, The Johns Hopkins University, Baltimore, Md.

in a special field (such as neuro or cardiovascular physiology), and some understanding of current research in this area can produce an instrument designer of great value in biomedical research.

Our present problem, however, is education for engineers in bio-medical *research*. By this we mean one who seeks to understand and formulate biological behavior and processes in terms of the engineering theory of systems organization. He differs from the biomedical scientist in that he brings to his problems analytical methods and concepts derived from the advanced engineering sciences. He differs from the bio-physicist in that he is familiar with the analysis and synthesis of complex dynamic systems, whether physical, chemical or psychological.

For instance, he asks whether a membrane, a hormone system or a flow-pattern operates as it does, through a balance of forces, a stationary entropy state (open or cyclic), or by dynamic error-minimizing. If the latter, what are the dynamic characteristics of the sensing mechanism, in what order and range do the parametric actuators operate, what is the range of stability and what pathologies disturb it and how? In dealing with the electrocardiogram, the bio-engineer seeks not only its minimal eigen vectors, but totally new representations that carry more clinical information. In respiratory or muscle physiology he seeks models of increasing competence, but with observables chosen so as to keep them tractable. In this way, working closely with the bio-specialist, he contributes significantly to the pattern of scientific understanding. But also, he builds a scientific foundation for the applications engineer to design his bionics and medical research instrumentation.

The need for such engineering scientists arises 1) in aerospace research, where biological problems cannot be isolated, but appear always in systems context, and often combine observations at high (cognitive, affective) and low (physiological) levels of organization; 2) in commercial bio-instrumentation to plan the validation and evaluation of research and clinical devices; 3) in bio-medical research to study alternative ways of data processing, and in designing experiments to test models of bio-systems. Bio-medical engineers are especially needed to formulate the dynamics and stability of biological control and goal-seeking systems. This is an area of research inaccessible to biologists alone, but of great bio-medical importance. 4) In universities, both to teach and to systematize knowledge in this growing field.

We must face frankly the problem of status. In the academic world, as in scientific societies, the doctorate becomes essential to acceptance or advancement. The experienced instrument designer's status in a group of bio-scientists is not high. The remedy is straightforward: today, the bio-medical engineer can make unique contributions to the *science* of bio-systems, if he will acquire the knowledge and experience to do it.

Training for engineers in bio-medical research raises questions of depth and breadth in engineering, in biology and in the interdisciplinary area. Engineering faculties have found that most of their sciences at the graduate level have biological application. Especially on the conceptual side, advanced thermodynamics, fluid and solid dynamics, electrical systems and signal theory, transforms, nonlinear and complex functions, matrix and numerical analysis have proved a foundation for the science of biological systems. Particular engineering applications such as solid-state devices, plastics, transport processes, may be sacrificed, if anything. Two solid years of such advanced engineering studies are not excessive. It is debatable whether "modern physics," except for its mathematical training, relates closely to the levels of organization composing bio-systems. But the theory of mechanics, electricity and physical chemistry are all heavily involved; a doctorate in any of these fields would lead to broad areas of biological research. A composite emphasis on "systems engineering" where possible, would sensitize the student to the cybernetic problems in the strange mixture of chemical, mechanical, electrical and informational processes found in biology.

The present impetus in training for biomedical engineering in electrical engineering departments rises partly from the wide use of electrical methods in transducing and recording, in data transforms, handling, storage and computation. Partly, it comes from interest of E.E.'s in control systems and nets, in communications, and the advanced analysis of performance and stability. Partly too, the electrical manifestations and mechanisms of living organisms have attracted study from the days of Galvani, not to mention electrodiagnosis and therapy. Electrical observations are easier than mechanical or chemical, more accessible and versatile. However, to current bio-medical science, electrical observations are less interesting than many chemical processes. The bio-medical engineer cannot afford to be ignorant of the hormone systems, immunologic reactions, junctional transmission, anabolism and metabolism, as well as acoustics, hydrodynamics, and transmembrane thermodynamics. If we identify bio-medical engineering with electrical techniques and problems, we lose a great deal of interest by and contact with the biological sciences.

Generality of engineering principles and training is increasing in modern engineering schools. Increasingly it is recognized that many special sciences are but particular aspects, and engineering departments now offer more joint and generalized courses. *Thermodynamics* now covers heat engines, open nonequilibrium chemical systems, mechanical, chemical and electrical crosscoefficients in a unitary way. Its new notation applies as well to every level or organization, not only the physicochemical. The bio-medical engineer needs these powerful general concepts, transcending the equations of motion, conservation of matter and energetics. *Signal* *theory* is no longer restricted to electrical filters and time series. Its generalized form encompasses any observable in *n* space, with limited aspects in the space defined by each observing or analyzing system. This is excellent for the bio-medical engineer, who cannot neglect the manifold manifestations needed to measure a complex observable such as anxiety in an astronaut. As the engineer distinguishes his physicochemical phenomena from his generalized mathematical vehicles, the unity of nature and the imperfection of his tools become clear. So, in his preparation, the bio-medical engineer with an eye to the future should seek those graduate schools where engineering is taught in its greatest generality, though without neglect of special applications. Fortunately some of these schools offer bio-medical engineering too.

What *biological* education should be undertaken? To understand the problem and communicate with biologists there can never be too much—some advocate equality. To answer this question, we may consider the need to know current research. His colleagues in biology can do better with the bio-medical literature, but the literature of engineering theory and practice pertinent to biosystems is growing by leaps. This suggests a collaborative responsibility: the engineering scientist must know biological science in general, his field of biological problems well, but the engineering sciences as an expert. Even Helmholtz today could not be equally a biological and physical scientist. Admitting some limitation, we ask, "How much bio-science is really necessary?"

Should we say: enough to have perspective, to see the operative factors, to be communicative and responsive with bio-scientists, and to be able to shift one's activity as opportunity offers and knowledge opens? A mere survey can give a false sense of understanding. Further, if one is not to be at a disadvantage among bio-medical scientists, and if one is to know what they take for granted, the course in medical physiology would seem to be the minimum for biomedical engineering research. First, one obtains for the first time an appreciation of the complexity of the working bio-system, the tentativeness of inferences, conclusions from conflicting evidence, the design of biological experiments, multiple variation, the expertise needed to avoid artefact, faulty preparation, and the time factor. The delightful childlike simplicity of physical experiments becomes appreciated. Second, the nature of biological materials is sensed, through sight, touch, sound and smell. Their fragility, intricacy, inaccessibility become clear through experience. The immanency of injury and death bear home. Responsibility is a part of every experiment—hours of preparation and after-care are involved. This is a new world, to some. All these attitudes and sensitivities are important for research among bio-scientists.

The full course in medical physiology will prove difficult for those without an excellent memory for unrelated facts. Nevertheless, it gives a foundation on which specialization in any kind of bio-medical problem is quickly built, with the guarantee that thereafter no system will be regarded as alone. The research engineer needs this breadth and adaptability if he works as one of his kind in a medical research center. Naturally for his research field he eventually must go much deeper in biology, whether in formal courses or by reading.

Physiology was mentioned as minimal. Some biophysicists will urge the indispensability of cytology, since the cell is the basic bio-system; and, for the specialist in bio-chemical systems, this is essential. Psychologists similarly will urge an introduction to psychophysics and operant behaviorism—important to understanding the sensory systems. Furthermore, essential prerequisites to physiology are anatomy and physiological chemistry, both loaded with memory work. Some compromise can be made here by dropping their laboratories and concentrating on theoretical aspects. Experience shows that a single anatomical technic can later be learned if needed. While there is no substitute for anatomy in the round, in bio-medical research one seldom works alone.

Medical biochemistry is essential, because of the enormous importance of its control systems, which tie in closely with the neural mechanisms, not to mention the circulatory, muscular and sensory. Physical in viewpoint, systematic and thermodynamic, it is less of a departure. But, like all bio-sciences it abounds with minute facts one cannot neglect. (One need not be bothered because general biology and organic chemistry are pre-entry requirements. They are offered in every summer school.) Discussions with numerous bio-scientists about bio-medical engineering have shown that the foundation here described should be adequate. It adds to about a solid half-year of biological science at the graduate level, which should be creditable as one minor toward the engineering doctorate.

Thus far we have spoken of *bio-sciences* and *engineering sciences*. There remains the interdisciplinary science of "bio-medical engineering" itself. Nuclear engineering is more than a set of standard engineering courses with nuclear physics added. Similarly, bio-medical engineering has its own body of combinational knowledge, now being assembled. The propagation of elastic waves through tissue cannot be described by the equations of any problem in inanimate mechanics: the terms and parameters needed in this case only occur here. Although multipole radiation theory does apply in the body, the field is neither "near" nor "far," but intermediate, a case rarely needed inanimately. In the nervous system the "noise" of an incoming time-series is converted from the frequency domain to a spatial domain. Bio-systems encompass enormous dynamic ranges by shifting mechanisms. The "velocity-constants" in biochemistry turn out to be hormone-operated valves in systems with neural components. Bio-transducers have modulatable gage-factors. And the adaptive, navigational, goal-seeking, anticipatory aspects of even simple processes are striking. In both analytic and synthetic aspects, a bio-system raises new physical problems not familiar in inanimate engineering. Their solutions constitute the interdisciplinary science.

Educationally speaking, then, there already exists *interdisciplinary* knowledge which might be surveyed in half a year. We have a fairly extensive quantitative and theoretical formulation of the basic physical properties and effects of bio-materials and structures, as to electromagnetic, sonic, mechanical (including fluid) coefficients: absorptive, transmissive, and conductive. The photic, radiation and nuclear aspects are well explored. Secondly, a number of bio-processes have been described in mechanistic terms between input and output; many simple modular fragments and chains of action are now in significant analytic form, transcending mere families of curves. These raise at once challenging problems of formulation. Thirdly, there is the integrative aspect: what we know at present of bio-systems (control, adaptive, goal-seeking, self-organizing) at various levels from intracellular to organismic behavior. Not a single problem is completely solved, in the sense of explaining each function in the flow-diagram, but the loops and nodes are known in a few cases. Many are partly explored and dynamically modeled in segments. Fourthly, the bio-medical engineering scientist must readily present his observations into computable form. Training in the variations of parameters by analogs, and with transforms and combinations by digitals, is now part of the art of experimentation, as well as interpretation, which he can contribute to a bio-research team. Biological data (especially clinical) is so massive and digital computers still so awkward in handling it, that one must keep up in this field. The representation of multidimensional biological data, and its optimization is also our task. Lastly the biological system itself as a computer also warrants intensive study. Its powers exceed and its methods excel our present computing approaches.

In sum, we have just sketched a solid year of bioscience and of its interaction with advanced engineering science. To do this and qualify for the engineering doctorate in some schools may require an extra year. A compromise may be possible in the *dissertation*. A biological problem from an engineering point of view need not involve the anatomy of living tissue; or, if so, this part may be collaborative. The conceptual, analytic and experimental design, the observations and analyses may suffice for the engineering degree. Can such a graduate turn at once to productive work? All our experience with doctoral education says that he must first gain experience and knowledge of practical ways. In industry this is systematic, and should also be so in bio-medical engineering. A wide range of biomedical methodology is not hard to acquire by "rotating internship" in a well-organized training program. During this time, one can also dig deep in a special field—nervous, cardiovascular, behavioral, endocrine—and gain that expertise by which one becomes self-supporting and self-generating of research results.

A man so educated is a generalist. He can move where opportunity offers. Not only can he supervise the design of *instrumentation* from the applications point of view, but also he can contribute valuably to design of the biological experiment in terms of observations which employ mathematically feasible models and hypotheses which connect the biological and physical science. Therefore he has a future not only as a consultant, but also an educator, which qualifies him for academic appointments in the bio-medical milieu to the highest level of his ability.

Many engineers in biomedical research are not yet convinced that there exists such a field of science. Or if there does, that the time has not yet come for an organized academic pattern. This is a matter of temperament and judgment. The fact remains that such programs are now widely being established, and, by cooperation, are organizing the interdisciplinary knowledge. By the *standards of competence and excellence* they set, the graduates in biomedical engineering can gain respect and recognition worthy of the reputation of their schools.

Section 20

MICROWAVES

Organized with the assistance of the IRE Professional Group on Microwave Theory and Techniques

Survey and History of the Progress of the Microwave Arts*

GEORGE C. SOUTHWORTH†, FELLOW, IRE

Summary—**This is a review of the history and technical progress of the microwave techniques beginning with fundamental research and continuing to present-day practical applications. Particular emphasis is placed on the evolution of techniques that are now of great practical importance. Included are the ordinary 2-wire transmission line and the useful tuning devices that it has provided and also the more recent waveguide techniques which have added not only a new medium of transmission but new antennas for radiating and receiving electromagnetic waves, and a new type of circuitry for dealing with microwaves. Reflecting discontinuities, sometimes conductive and sometimes reactive, when judiciously located inside a waveguide, may perform numerous useful functions such as matching transformers, frequency filters and special networks that very knowingly allow wave power to pass in one direction and not in the reverse. The present paper is a greatly condensed portion of certain chapters of a new book entitled "Forty Years of Radio Research."[1] The latter tells of the author's personal experiences, not only in connection with microwaves, but in connection with the development of much of the rest of the radio spectrum as well.**

Introduction

MICROWAVES represent the newest and possibly the most useful band of the entire radio spectrum. Beginning at roughly one thousand million cycles, known as one kilomegacycle (sometimes called one gigacycle) and abbreviated 1 kMc, it extends upward to a frontier now temporarily poised at about 30 kMc. These limits correspond to wavelengths of 30 cm and 1 cm, respectively. Current research extends far beyond, possibly to 100 kMc or even higher. Included in this new band are all of the known forms of electrical communications—telegraphy, telephony, television and radar.

Microwaves are characterized by various new techniques. In place of the coils and condensers of conventional radio, which upon approaching this frequency range were becoming vanishingly small, equivalent results in this new band are accomplished by properly spaced discontinuities. Also in this band, radio directivity, one of the time-honored objectives of radio engineering, is at its best. In this band too, another of the objectives of electrical communications is also at its best; that is, the transmission from one point to another, almost as a single package, of a maximum of information. For example there may be transmitted over the same facility, alternatively, either several television channels, or many hundreds of telephone channels, or a very great number of telegraph channels. Although this is the proud accomplishment of a radio system in the microwave range, there is in prospect in this same range of frequencies, a waveguide transmission line that has far wider bandwidth potentialities. Thus, in this upper register of frequencies both radio and guided

waves may become worthy competitors for similar jobs. These and other features of this new band of frequencies will be discussed below.

It is not known for certain when the term *microwaves* originated. It is known, however, that a somewhat related term *microrayons* was used about 1933 by Andre Clavier and his associates of *Les Laboratories Le Materiel Telephonique* in describing a newly developed directive radio system for communicating across the English Channel. The frequency was about 1.75 kMc ($\lambda = 17$ cm). The available power was roughly 1 watt. Directive antennas used at each end, having power gains of 2000 (33 db), gave the 1 watt of power the effect, by ordinary radio standards of the time, of 4 kw. These directive gains are comparable with present-day microwave practice. This was a truly pioneering venture as it pointed the way to the rich rewards that come from the use of the higher radio frequencies.

Beginnings of Microwaves

Like radio itself, and like many other branches of electrical technology, microwaves had their origin in the fundamental electromagnetic theory. One group of mathematical physicists, bent on explaining the behavior of conventional two-wire lines, adapted the electromagnetic equations to the cases of two parallel conductors and also to two coaxial conductors. From these deductions developed much of the basic theory underlying ordinary transmission lines and also the various standing-wave phenomena now so widely used in microwave circuitry. Somewhat later, another group of mathematicians fitted the same electromagnetic equations to hollow metal pipes and to dielectric wires and, by invoking similarities with ordinary two-wire lines, they extended the theory to waveguides generally. These two techniques, coaxial and waveguide, remain as important methods for dealing with microwaves. Often the roles are complementary. Sometimes they appear in the same piece of apparatus, often in a way that makes it difficult to distinguish between the two. In recent years, a very useful microwave technique has grown from a special adaptation of two-conductor theory. In this case two flat conductors are mounted on opposite sides of a thin insulator. This is referred to as strip-line technique.

Early History of Waveguides

Waveguides, as contrasted with coaxial lines, have an extremely interesting past. That it might be possible to transmit electromagnetic waves through hollow metal pipes must have occurred to physicists almost as soon as the nature of electromagnetic waves became fully appreciated. That this might actually be accomplished in practice was probably in considerable doubt, for certain conclusions of the mathematical theory of electricity seemed to indicate that, without a return conductor, it would not be possible to support inside a hollow conductor the lines of electric force of which waves were assumed to consist. Heaviside was one of the early doubters.[2]

Perhaps the first analysis suggesting the possibility of waves in hollow pipes appeared in 1893 in the book "Recent Researches in Electricity and Magnetism" by J. J. Thomson.[3] This book, which was written as a sequel to Maxwell's "Treatise on Electricity and Magnetism," examined mathematically the hypothetical question of what might result if an electric charge should be released on the interior wall of a closed metal cylinder. Even now, this problem is of considerable interest in connection with resonance in hollow metal chambers. A much more significant analysis, relating particularly to propagation through dielectrically filled pipes, both of circular and rectangular cross section, was published in 1897 by Lord Rayleigh.[4]

As regards experimental verification, it is of interest that Sir Oliver Lodge[5] as early as 1894 approached, but probably did not quite realize, actual waveguide transmission. Of much greater significance were some experiments reported a year later by Viktor von Lang[6] who repeated for electric waves the interference experiment that had been performed for acoustic waves by Quincke some years earlier. Other similar experiments were performed later by Drude[7] and Weber.[8] All these experiments were done with the damped waves from spark discharges.

In about 1913 Professor Zahn[9] of the University of Kiel became interested in this problem and assigned certain of its aspects to Schriever and Reuter, two young candidates for the doctorate. They had barely started when World War I broke out, and both left for the front. Reuter was killed at Champagne in the autumn of 1915, but Schriever survived and returned to complete his thesis in 1920,[10] using for his source the newly available Barkhausen oscillator. Schriever's work was aimed specifically at dielectric wires, and was the first to use continuous waves.

The contributions of Thomson, Rayleigh, and their followers were, of course, purely mathematical. Those of von Lang, Drude, Weber, and Schriever were experimental, but they were of rather limited scope. The con-

cept of the hollow pipe as a useful transmission element, for example as a radiator or as a resonant circuit, apparently did not exist at these early dates. Nothing was yet known quantitatively about attenuation, and little or nothing of the present-day experimental technique had yet appeared. At this time, the position of this new art was perhaps comparable with that of radio prior to the time of Marconi. The reader who wishes to learn more about the early history of microwaves should consult standard textbooks on the subject.[11]

Later History of Waveguides

The history of waveguides changed abruptly in about 1931 when it was shown for the first time that they could be put to practical use. Several patent applications were filed, and numerous scientific papers[12–15] were published. More recently, a great many papers have appeared; too many, in fact, for detailed consideration at this time.

The author's interest in guided waves stems from some experiments done while working with Lecher wires in a trough of water about 1920. In one case there were found, superimposed on the guided waves that might normally travel along two parallel conductors, other waves having a velocity that somehow depended on the dimensions of the trough. These may now be identified as the so-called dominant or TE_{11} type. Eleven years later, this work was resumed, and since that time a continued effort has been made to develop a useful technique for dealing with microwaves from fundamental principles of waveguide transmission.

The earliest experiments consisted of transmitting electromagnetic waves through tall cylinders of water. Thus, it became possible to set up, in the relatively small space of one of these cylinders, many of the wave configurations predicted by theory. In addition it was possible, by producing standing waves, to measure their apparent wavelength and thereby calculate their phase velocity. Also, by investigating the surface of the water by means of a probe, the directions and also the relative intensities of lines of electric force in the wave front could be mapped. It is probable that certain of these modes were observed and identified for the first time. Figs. 1 and 2 show the nature of this early apparatus and the types of wave configuration that were mapped. A more complete account of this early work may be found in an early article by the author.[14]

[15] G. C. Southworth and A. P. King, "Metal horns as directive receivers of ultra-short waves," Proc. IRE, vol. 27, pp. 95–102; February, 1939.

Shortly afterwards (1933), sources giving wavelengths in air of 15 cm became available, and the experimental work was transferred to air-filled copper pipes only 5 in in diameter. At this time, a 5-in hollow-pipe transmission line 875 ft in length was built, through which both telegraph and telephone signals were transmitted (Fig. 3). Measurements showed that the attenuation was relatively small.

It was recognized at an early date that a short waveguide line, with suitable modification, might function as a radiator and also as a reactive element. Most obvious were the electromagnetic horn and the resonant cavity. These properties were likewise investigated experimentally, and numerous useful applications were proposed. Descriptions of these early methods may be found in another early article by the author[13] as well as in several of the early patents. As will be noted, modern waveguide circuitry had its beginnings in the efforts to obtain a more efficient transfer of microwave power from a source to a waveguide transmission line, thereby providing the elements of a transmitter, and again the efficient recovery of the microwave power at the receiving end, thereby providing the elements of a receiver.

As might be expected, a great many people contributed in one way or another to the early success of this venture. Particular mention should be made of the very important parts played by the author's colleagues, A. E. Bowen and A. P. King, who, during its early and less promising years, contributed much toward transforming rather abstract ideas into practical working equipment, such as frequency meters, standing-wave detectors, and terminations. Much of this equipment was found to be of important military use immediately upon the advent of war. Also of great importance were the parts played by the author's colleagues, Dr. S. A. Schelkunoff, J. R. Carson, and Mrs. S. P. Meade, who, in the early days of this work, provided a substantial segment of mathematical theory that previously was missing. During the succeeding years, Dr. Schelkunoff, in particular, made invaluable contributions in the form of analyses which, in some cases, indicated the direction toward which experiment should proceed and, in others, merely confirmed experiment, while in still others, gave answers not readily obtainable by experiment alone. A particularly important result of this analysis was the discovery that, for one of the types of waves that may be propagated through a circular metal pipe of given diameter, the attenuation decreases with increasing frequency. It is expected that this principle will play a very important role in the future of microwaves.

Beginning sometime prior to 1936, Dr. W. L. Barrow, then of the Massachusetts Institute of Technology, also became interested in this subject and, together with numerous associates, made very substantial contributions particularly in the direction of determining the best proportions for electromagnetic horns. No less than eight scientific papers were published covering

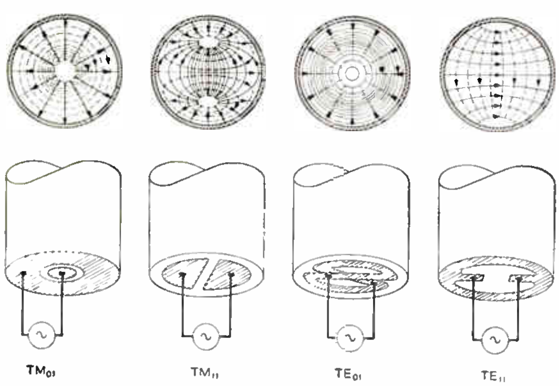

Fig. 2—Schematic of various launching devices used to set up various modes.

special features of hollow-pipe transmission lines and electromagnetic horns.[16–18] For several years the work at the Massachusetts Institute of Technology and at the Bell Telephone Laboratories probably represented the major portion of, if not indeed the only, work of this kind in progress, but with the advent of World War II, hundreds or perhaps thousands of others entered the field. For the most part, the latter were workers on various military projects. Beginning with the considerable accumulation of unpublished technique which was made freely available to them at the outset of the war, these workers, along with others in similar positions

elsewhere in this country and in Europe, have helped to bring this technique to its present very satisfactory state of development.

More About the Prewar Development

The progress made before World War II is conveyed in part by Figs. 4–9. Fig. 4 shows numerous pieces of measuring equipment fundamental to the development of microwaves. It is representative of techniques as of about 1934. Figs. 5 and 6 show a platform as it appeared for the presentation of two demonstration lectures before the IRE on February 2, 1938, and again on February 1, 1939. In the first, four of the more important modes were produced in the apparatus shown, and their orientations were plotted for the audience on a blackboard placed over the several sources. As an added feature, 3-kMc ($\lambda = 10$ cm) waves were produced and were propagated through a 3-in metal pipe and received in a loosely-coupled resonant chamber.

The second demonstration, in 1939 (Fig. 6) had two objectives. In the first objective, a match termination was developed by a step-by-step process as the audience observed the gradual disappearance of the standing wave. By this time the standing-wave detector had become a standard piece of measuring apparatus much as we know it today. The second objective of this demonstration was to plot for the audience the directive patterns of several electromagnetic horns. Both lectures were repeated before various sections of the IRE.

A third demonstration lecture was planned which was aimed particularly at reactive elements in a waveguide,

including such composites as filters, transformers, and waveguide matching devices, but the gathering war clouds over Europe made its presentation appear unwise.

The principle of multiple reflection from discontinuities and the associated principle of cavity resonance played an important part in microwave development. In some cases they were used to match a source of power to a waveguide. In others they served to match the waveguide to a receiver, perhaps a crystal detector. In still others they served to pass freely a band of frequencies, perhaps a television channel, while discriminating sharply against adjacent frequencies. Together these principles formed the foundations of microwave circuitry.

The evolution of microwave circuitry was greatly aided by mathematical theory. The latter showed that the various reflecting discontinuities, such as irises and semiconducting bodies could produce certain impedance effects not unlike those of familiar radio practice. The relationships, however, were rather complicated and in extreme cases involved hyperbolic functions, a subject which many engineers find difficult. Engineering analysis was greatly facilitated by certain graphical analyses devised by Phillip H. Smith.[19] Not only were laborious calculations avoided, but, while the work was in progress, the engineer could visualize the step-by-step processes under way. Indeed, in some cases he could look

[19] P. H. Smith, "Transmission line calculator," *Electronics*, vol. 12, pp. 29–31; January, 1939. "An improved transmission line calculator," *Electronics*, vol. 17, pp. 130–133, 318, 320, 322, 324–325; January, 1944.

forward to the answer. Few gadgets of microwave circuitry have been more useful than the Smith diagram.

Special Materials

There developed at an early date a need for special materials. Not only was there a need for metals of good conductivity, for example, silver, but there was a need for special dielectrics and also a need for magnetically permeable materials. The latter were not readily achieved, but ultimately they too appeared. Not always was there a need for low-loss materials, but indeed sometimes the need was for materials with substantial loss. Early forms were resistance films and also absorbing plugs placed in the path of guided waves. As they were made more stable, some became standards of attenuation and others became terminators for microwave transmission systems. Such materials have played a very important part in the development of methods of microwave measurements.[20]

Sometimes the need was for rather unusual materials. One such need was for a material whose resistance varied nonlinearly with amplitude. Such a material already existed in the form of the crystal detector of early radio practice. Starting from these humble beginnings, the crystal detector was greatly improved by Russell Ohl of the Bell Telephone Laboratories and many others, and became a thoroughly stable rectifier. With the advent of double detection in microwaves followed by certain related modulation processes, the crystal detector became an extremely important device, in both the modulation and the demodulation of signals. An even more important use of this principle made it possible to generate harmonics and thereby extend materially the frequency frontier of microwave research. A great deal of research has gone into the improvement of good nonlinear materials. It is especially interesting, too, that this research triggered off the chain reaction that led ultimately to both the transistor and the solar battery, as well as to the important branch of physics known as physics of the solid state.

Another important microwave device of the prewar era was the thermistor. It depends for its success on the properties of certain materials, notably the oxides of manganese, cobalt, nickel, and copper, to change resistance with temperature. A tiny bead made from a mixture of these materials, when matched to a waveguide and heated by received wave power, provides a measure of microwave power. It first came into use in 1936. The wavemeter and the standing-wave detector shown in Fig. 4, together with the stabilized detector, the thermistor, and the standard decibel attenuator provided many of the measurements necessary for the early development of microwaves. Today all remain important elements in microwave measurements.

In the late summer of 1940 a visiting mission from England brought to America their best radar techniques, including the pulsed magnetron, a device giving not only greatly increased power, but an output signal that was well adapted to radar. At the Bell Telephone Laboratories, in particular, the visitors saw the latest in microwave techniques. These later proved of great value in pushing radar to the higher frequencies needed for accurate bombing and for the precise directing of naval gunfire.

[20] G. K. Teal, M. D. Rigterink and C. J. Frosch, "Attenuator materials, attenuators and terminations for microwaves," *Trans. AIEE*, vol. 67, pp. 754–757; August, 1948.

Wartime Development

The development of microwaves was greatly accelerated in the late summer of 1940 when the National Defense Research Committee was formed, with radar as one of its principal objectives. This organization promptly set up, both at the Massachusetts Institute of Technology and at Columbia University, special laboratories to develop and apply microwave techniques to radar problems. This grew rather rapidly to a huge organization of several thousand top-flight scientists marshalled mainly from universities of the United States and Canada. In addition, very important but less publicized parts were played by other organizations.

Microwave research continued at the Bell Telephone Laboratories, and shortly there followed radar designs for field use, for use in fire control on ships and for use on both submarines and airplanes. Comparable research and design came from the Radiation Laboratory of the Massachusetts Institute of Technology. Composites of the best designs were subsequently manufactured in quantity. Fig. 10, selected largely for its ready availability, is representative of the end results of this work, and is important because it represents early fruition of microwave techniques.

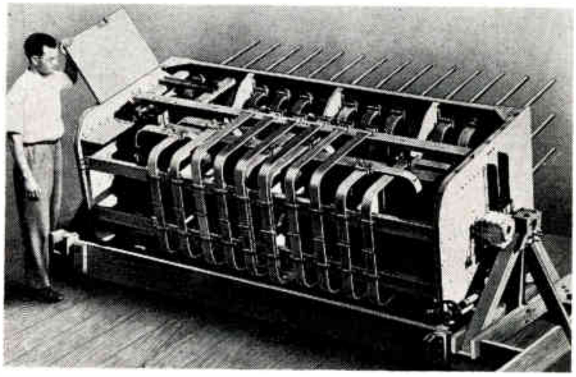

Fig. 10—An early form of microwave radar utilizing waveguide techniques. Not only were microwaves guided to the various antennas, but the phase was varied progressively, thereby causing the beam to scan a distant landscape.

The fundamental building blocks comprising microwave techniques were by no means complete before the War. A great many came during the War and a few followed the War. Because of wartime restrictions and the necessity of close team work, individual credits were often sacrificed. Mention should be made, in particular, of devices by which phase could be added progressively to a waveguide line. This was a product of A. G. Fox of the Bell Telephone Laboratories in 1941.[21]

Also, there were junctions of four waveguides so arranged that when power was introduced in one branch it divided equally between two alternate branches while being balanced at the fourth branch. This had a counterpart in the hybrid balance of ordinary telephone practice. It was proposed by W. A. Tyrrell of the Bell Telephone Laboratories in 1941.[22] Almost as important was a particular form of the balance in which there was an uneven balance between adjacent arms while a balance was maintained at the fourth arm. The latter became known as the directional coupler. Its origin is somewhat obscure because of the many people in war work at the time. However, one early description was given by Mumford in 1947.[23] All of these devices promptly found practical use.

During the War, it was discovered by Robertson and King[24] that falling rain could absorb and scatter large amounts of passing wave power at all frequencies above about 10 kMc. Also it was predicted by Van Vleck and verified by Becker and Autler that there was an absorption band for water vapor (not water droplets) at 22.3 kMc. Other absorption bands were predicted by Van Vleck and verified by Beringer for oxygen at 60 kMc and 120 kMc as well as many others at still higher frequencies. Rain absorption in particular seemed very important for it posed a considerable threat for the future use of the higher frequencies for purely radio uses.

The absorption bands due to water vapor and oxygen came as no surprise, for Professor Williams and Dr. Cleeton[25] of the University of Michigan, several years before, had found that ammonia gas absorbed a narrow band of frequencies centering around 45,000 Mc. This was the forerunner of some very fruitful molecular and atomic research in which the microwave techniques were to play a very important role.

It was in this period of microwave research, too, that it was discovered that measurable amounts of microwave radiation could be received from the sun.[26] This discovery, together with Jansky's discovery of noise from interstellar space, ushered in modern radio astronomy. Although initiated in America, this work was quickly endorsed in both Australia and England, and impressive research programs were set up promptly. Radio astronomy now represents one of the more important areas of fundamental investigation, with budgets amounting to millions. It is the proud accomplishment of microwaves development that it should be able to aid in the exploration of both the infinities of outer space and the infinitesimal interior of the atom.

In this wartime period microwaves virtually leapfrogged their way across the frequency spectrum from 3 kMc to possibly 30 kMc, all in a period of two or three years. In each case new sources of power were needed to make a new beachhead while the needed measuring apparatus was being developed, preliminary to the evolution of new electronic devices. To break an apparent stalemate and supply, when needed, adequate research tools, the expedient was used of generating, by means of crystals, the harmonics of such frequencies as were readily available. Steps from 3 kMc to 9 kMc to 27 kMc were typical. Good measuring equipment including wavemeters, standing-wave detectors, power-measuring devices, and standard attenuators were built for all of these ranges prior to 1943. Today harmonic production remains one of the favored methods of exploring the frequency frontier. Microwave measurements were naturally an essential part of microwave research.

Microwaves in the Post-War Period

Although the number of fundamentally new principles of the microwave techniques diminished after the War, the number of applications increased markedly. Released from urgent wartime responsibilities, engineers turned naturally to peacetime uses. Communication, as contrasted with radar, was perhaps the most obvious alternative. Research had already evolved various microwave sources and also before the War had come an amplifier for such signals. The postwar period was to see a marked extension of its frequency range. The klystron, the first practicable electronic device to break from conventional principles, was a most welcomed prewar entrant to the microwave field. Soon came the closely-spaced triode, an ingenious adaptation of the space-charge principle to the new microwave task. Shortly, there came the traveling-wave amplifier, a device that could amplify extremely wide bands of frequencies. All three devices could assume the form of oscillators as well as amplifiers, thereby providing sources of microwave power at ever increasing frequencies. Details of the development of electronic devices are covered in other articles of this issue. These have been important in the history of microwaves, for they have paved the way to wider use.

Microwaves were aided tremendously in the postwar period by the development of new materials. Of particular importance, were the ferrites, insulating materials that exhibited pronounced magnetic properties. Particular ferrites were able to produce, in the microwave range, the effect of Faraday rotation so familiar in optics. One result of this development was a new family of microwave circuit components, each capable of a

variety of useful functions. In one particular case, a ferrite device passed microwave power freely in one direction, while discriminating sharply against power in the reverse direction. All of this may be accomplished without the loss of one half of the transmitted power that is inherent in most wave-balancing systems. (This material is described more completely in other articles of this issue.)

Other devices playing an increasingly important part in microwaves resulted from the further study of the general subject of solid-state physics, which has already led to such important devices as tunnel diodes, parametric amplifiers, masers, and to low-noise receivers, generally. The latter are particularly useful in radio astronomy and also offer promise of being useful in the intercontinental communications by way of reflecting satellites. It is too early to properly evaluate the importance of such devices, but it is quite obvious that they will be very important.

Some Postwar Research and Application

While the development of microwave radar has continued unabated for both military and peacetime uses, many other applications have appeared. In particular, microwaves have become very useful in the radio relaying cross-country of broadbands of visual, audio, and telegraph signals. Continuing a program started in 1941 but interrupted by the War, the Bell System resumed the task in 1943 and in 1947 set up a thoroughly practicable radio relay system between Boston and New York on a frequency centering of about 4 kMc. Repeater stations located at intervals of perhaps thirty miles picked up attenuated signals, demodulated them to a relatively low frequency, and after remodulation and amplification transmitted them onward at a slightly different frequency. The system often referred to as TD-2 was soon extended from New York to Chicago and ultimately to the Coast. It is now a vast network estimated in 1960 at 40,000 route miles comprising nearly 40 per cent of the total Bell System intercity circuit mileage. In the meantime similar systems have been developed by others in America and elsewhere. In particular, considerable use of microwave radio relay is also being made by the U. S. Government, the Western Union Telegraph Company and the various pipe-line companies and Turnpike Commissions. The combined use of such systems is estimated (1960) at 32,000 route miles.

Improvements in microwave relay systems have made it possible, by using frequencies as high as 6 kMc, to transmit over the same system alternatively either 10,800 telephone channels or perhaps a half dozen television channels. This newer application is sometimes referred to in Bell System circles as the TH system.

In 1960 experiments were started looking toward microwave communications over transoceanic distances, through the intermediary of a reflecting balloon orbiting at perhaps 1000 miles above the surface of the earth. Satellite periods of two hours were typical. Though the useful period of a single orbiting reflector is, according to this plan, definitely limited to a few minutes for each transit, it is expected that several such reflectors will provide practically continuous service. Frequencies of the order of 7 kMc are contemplated. Although the research leading to this rather unusual relay system, has, for the most part, made use of conventional methods, there are notable exceptions. Like the receivers of radio astronomy which look toward the low temperatures of interstellar space, these receivers may also profitably use low-noise detectors. This has entailed an interesting bit of solid-state research on the fringe of microwave research.

Much of the early research with microwaves centered around the so-called dominant or TE_{11} mode, from which have flowed most of our present-day microwave applications, both in radio and radar. The dominant mode is but one of the double infinity of modes or configurations that are possible in a waveguide. There is another mode of great practical interest, particularly in cases where it is desirable to guide microwaves to great distances. In this mode, which is known as TE^0_{01}, the lines of electric force are everywhere coaxial circles, parallel to the walls of the circular conducting pipe and for this case the attenuation, since it involves only tangential currents, progressively decreases as the frequency is indefinitely increased. During the thirty years since this principle was first understood, there has been the constant hope that a microwave transmission line might sometime be evolved that would incorporate bandwidth with relatively low attenuation.

After years of painstaking research, the practical realization of this objective now seems assured. Attenuation of the order of 2.5 db per mile is typical with bands corresponding to perhaps 200,000 speech channels. This assumes pipes to be perhaps 2 in. in diameter. Thus future communications seem to be leading not only toward radio but toward a form of the time-honored wire line. Only time can tell how the work-load will be divided between the two media. It is likely that both will be used. Radio will probably be preferred both for the mobile services and for radar. But guided transmission will probably be preferred in cases where either privacy or freedom from interference is paramount.

Microwave Measurements*

HAROLD A. WHEELER†, FELLOW, IRE

Summary—**There are presented briefly the measurement techniques that are most closely associated with microwaves (the frequency range of 0.3 to 300 Gc or the wavelength range of 1 meter to 1 mm). After a logical classification of such measurements in confined space (such as waveguides) the subject is introduced by a review of the principles peculiar to microwaves. Typical of this frequency range is the standing-wave technique and the reflection chart, utilized for evaluating and presenting the "normalized" value of any impedance relative to the wave impedance in a waveguide. More conventional methods are employed for evaluating transmission properties (attenuation and phase shift) by comparison with primary or secondary standards. Various special methods are discussed, including some of those most in need of further development in the future.**

I. Introduction

The subject of microwave measurements will be presented briefly with reference to its general scope and some of its more interesting features. This article is one of the several sponsored by the Professional Group on Microwave Theory and Techniques (PGMTT) for the Fiftieth Anniversary Issue of the Proceedings of the IRE.

In the preparation of this brief article, it has been necessary to rely on a thin sampling of the great variety of techniques that are now associated with the subject. The emphasis will be placed on those techniques of measurement which are peculiar to the field of microwaves, or at least are most closely associated with this field. Also the attention will be directed mainly to laboratory tests essential for design and for proof of performance, rather than operational tests suitable for monitoring the behavior of equipment in the field.

Table I is a brief outline of some aspects of microwaves and their measurement. It indicates in some degree the limits that have been adopted for this article. The frequency range of 0.3 to 300 gigacycles per second corresponds to a wavelength range from 1 meter down to 1 millimeter, being roughly the limits over which a hollow waveguide is useful in single-mode propagation. Over this same range, space-charge electronics is utilized mainly in microscopic dimensions in the solid state (crystal rectifiers, etc.) while free electrons in a vacuum are utilized in terms of their transit time (magnetrons, klystrons, etc.). Measurements and standards are patterned after ac measurements at lower frequencies, but are typically based on electric and magnetic fields rather than voltage and current.

Frequency standards and measurements are omitted here because they are to be covered in a separate article sponsored by the Professional Group on Instrumentation (PGI). Free-space measurements are omitted because they fall in the scope of the Professional Group on Antennas and Propagation (PGAP) rather than the PGMTT.

TABLE I
Microwaves—Scope of this Article

- Frequency Range.
  - Frequency 0.3–300 Gc.
  - Wavelength 1 meter—1 mm.
- Location of Typical Phenomena.
  - Confined space.
    - Waveguides, hollow.
    - Rectifiers, crystal.
    - Electronics, transit-time.
  - Free space (outside of scope of article).
- Measurements and Standards.
  - Frequency, wavelength (EM field).
  - Modulation, spectrum.
  - Power (EM field products).
  - Impedance (EM field quotients).

This presentation will rely on outlines in tables for broad coverage, and these are intended to be self-explanatory. The text and illustrations will be directed to a few topics selected for their importance or particular interest in the field of microwaves. A carefully selected list of references is appended for further information.

II. Classification of Microwave Measurements

The next few tables give some outlines indicating the scope of certain major parts of the entire field.

Table II is an outline of measurements in confined space, analogous to wired circuits at lower frequencies. Here they are typically based on electric and magnetic (EM fields) rather than voltage and current. These fields are usually confined by conducting walls that serve as a shield. Otherwise, this outline is mainly taken over from lower frequencies and included here as a reminder.

Table III is an outline of some concepts that are common in the measurement of linear impedance with respect to waves in a guide (or in free space). It is customary to define the wave impedance of a square area of wavefront, or of the bounded wavefront in a waveguide, and then to use this value as the reference for "normalizing" any other impedance, such as an obstacle in a waveguide. The latter is then expressed simply by a ratio.

Implicit in these outlines are the phenomena and practices that are peculiar to microwaves and their measurement, as will here be discussed further.

MICROWAVE MEASUREMENTS—LINEAR IMPEDANCE

Dimensions.
- EM quotient.
  - Impedance (Z).
  - Admittance (Y).

Ratios (in waveguide).
- Normalized Z or Y (relative to wave Z_0 or Y_0).
- Reflection coefficient (related to SWR).
  - Return loss.
  - Return angle, phase shift.
- Transmission coefficient.
  - Gain or loss, attenuation.
  - Angle, phase shift.

Parts, Real and Imaginary.
- Rectangular, in-phase and quadrature.
- Logarithmic, magnitude and angle.

III. PRINCIPLES PECULIAR TO MICROWAVES

In microwaves, the wavelengths (1 meter to 1 mm) are such that components of wavelength dimensions can be made and used in the laboratory and in operational equipment. In this respect, microwaves in the electromagnetic medium, free space, are comparable with sonic and ultrasonic waves in acoustic mediums (gases, liquids, solids); however, free space is unique in its monolithic set of electromagnetic properties, as distinguished from the idiosyncrasies of material mediums.

Microwave components, being of wavelength dimensions, have peculiarities in which they differ from components for the lower or higher frequencies.

At lower frequencies, a reactive component is specialized as to its properties of electric or magnetic energy storage, whereas a microwave component typically has a mixed field. At lower frequencies, connections are made by wires, and a pair of terminals is required at a "port," whereas microwave connections are typically made by pipes and flanges ("plumbing") and only an opening is required at a port [29], [30].

At higher frequencies (exemplified by light waves) the reverse is true. Components are many wavelengths in size, and intercoupling is accomplished through the mechanism of waves. The smallest waveguides (glass fibers) still support propagation in many modes. The highest degree of reflection is far inferior to that obtainable for microwaves.

The most distinctive technique of microwaves is the measurement of reflection coefficient by the use of a slotted section, and its presentation by plotting on the reflection chart. This is enabled by the convenience of wavelength dimensions in the laboratory. The following section is devoted to this subject.

Microwave signal sources rely on free electrons, as a rule, in applications utilizing their transit time. At lower frequencies, electron tubes utilize space charge, and there are various other kinds of sources. At higher frequencies, there are no sources of similar character, and coherent sources are just being discovered for certain discrete frequencies.

The use of transit time in microwave sources enables "voltage tuning" by control of electron velocity. Even in the complicated integral structure that is typical of microwave oscillators, there are designs in which voltage variation can sweep the frequency over a ratio of 1:2.

A microwave signal detector of simplest form is the crystal rectifier. It operates by virtue of electron space charge in a microscopic space in the solid state.

While any particular indicator for lower frequencies is usually responsive to voltage or current, the typical microwave indicator is responsive to power. It is customary to "tune" the load to a "matched" condition in which it takes all the "available power."

Where microwaves are propagated through a waveguide having lateral dimensions exceeding the wavelength, there are possible several modes of propagation. In such "multimode" behavior, each mode is analogous to a separate circuit. This is comparable with the series and parallel modes of a pair of wires over a ground plane.

Departure from reciprocity in two-port microwave devices is analogous to that at lower frequencies, but usually is manifested in a different kind of environment. The electronic amplifier relying on grid-voltage control of space current at lower frequencies is supplanted by one utilizing electric-field control of beam velocity. The familiar electromechanical gyrator (exemplified by the loudspeaker voice coil) has an analog in the magnetoelectronic electron-spin gyrator in ferrites at microwave frequencies. Such principles have been utilized in a variety of nonreciprocal devices that are convenient only in the field of microwaves.

The analysis of multiport networks in the terms of determinants, tensors and matrices has been extended to the form known as the "scattering matrix" [18], for which the writer prefers the more descriptive designation, "wave-transmission matrix." This form, which may have originated in the M.I.T. Radiation Laboratory, is a matrix of transmission coefficients among a set of ports. From one port to the same port, in the main diagonal of the matrix, this becomes the reflection coefficient. In the ideal form, the coefficients are all voltage ratios, or all current ratios, referred to a constant wave resistance which is the same at all ports. This emphasizes the applicability of such a matrix to power transmission among several ports in waveguide. It is this utility that is responsible for its common use in microwave devices, both reciprocal and nonreciprocal.

Two of the most common waveguide junctions offer the best examples of the wave-transmission matrix. One is the hybrid junction (exemplified by the "magic T") which has one pair of waveguides in series and parallel connections with another pair. The other is the directional coupler between a parallel pair of waveguides, each having ports at both ends. Their respective matrices have the following forms:

$$\begin{bmatrix} 0 & 0 & a & b \\ 0 & 0 & -b & a \\ a & -b & 0 & 0 \\ b & a & 0 & 0 \end{bmatrix} \qquad \begin{bmatrix} 0 & 0 & a & jb \\ 0 & 0 & jb & a \\ a & jb & 0 & 0 \\ jb & a & 0 & 0 \end{bmatrix}.$$

In either case, $a^2+b^2=1$, for conservation of power. In the simplest form, $a=b=1/\sqrt{2}$. The zeros in the main diagonal indicate nonreflecting or matched terminations. The zeros in the minor diagonals indicate decoupled or conjugate pairs. The latter are analogous to an ordinary bridge circuit in a balanced condition.

IV. Standing-Wave Technique and Reflection Chart

The technique of measuring reflection in a waveguide by observing a standing-wave pattern is well adapted to the wavelengths of microwaves. If the sole cause of the reflection is the load impedance at the output end of the waveguide, this impedance can be computed from the measured complex reflection coefficient in the manner proposed by the late P. S. Carter about 1937 and published in 1939 [23]. This is a practical method in which the waveguide is a primary standard of impedance, based on mechanical dimensions, and the standing wave provides a comparison ratio relative to the standard.

Fig. 1 shows the well-known slotted section of rectangular waveguide for observing the standing-wave pattern. The two usual observations are the distance (d) from the load back to the point of minimum voltage, and the standing-wave ratio (SWR) of maximum over minimum voltage (VSWR). The latter is conveniently expressed in decibels (db) as indicated. The distance is expressed as a number of wavelengths (λ_g) in the guide.

In practice, there may be several wavelengths of waveguide between the slot and the load. This separation becomes immaterial if, at the same frequency of measurement, a reference observation of this distance (d_0) is made with a short-circuit (SC) reflecting plane substituted for the load. Then the load impedance is determined by the shift of the minimum ($d-d_0$).

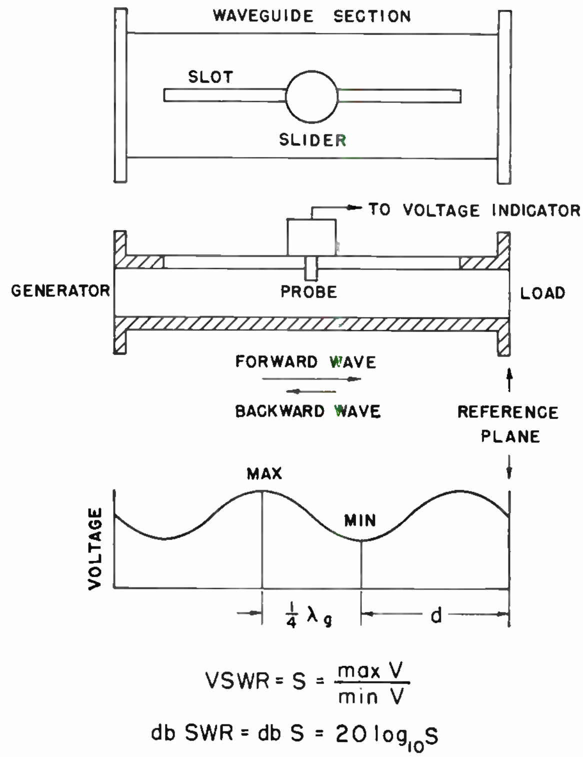

Fig. 1—The slotted section used for standing-wave measurements in a waveguide.

The complex voltage reflection coefficient ($VRC=\rho$) is determined from the observations as follows, in terms of its magnitude and angle:

$$|\rho| = \frac{S-1}{S+1}; \qquad \angle\rho = \theta = \frac{d-d_0}{\lambda_g}360° \pm 180°.$$

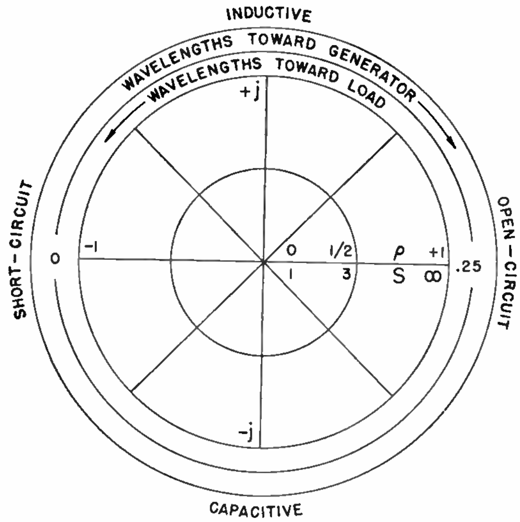
The load impedance (Z) is then computed relative to the guide wave impedance (Z_0) as follows:

$$\frac{Z}{Z_0} = \frac{1+\rho}{1-\rho}.$$

This ratio is the "normalized" load impedance. The computations by the above three formulas are usually avoided by the use of the reflection chart to be described.

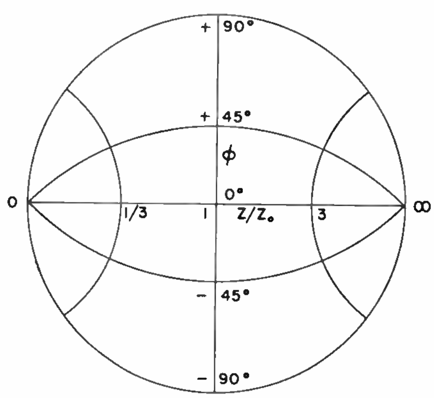
Fig. 2(a) shows the essentials of the reflection chart, in an arrangement which has been tentatively selected by a committee of Electronic Industries Association (EIA). The voltage reflection coefficient is plotted on the complex plane in the conventional manner, so all values fall within the unit circle [18], [23]–[25], [34]. The contours of magnitude and angle are respectively concentric circles and radials. The outermost notations refer to the character of the load impedance corresponding to various parts of the chart. The wavelength scales, having ½ wavelength around the circle, indicate the relation between angle and length of waveguide.

The contours of SWR also are concentric circles. Therefore it is customary to plot a point on the chart

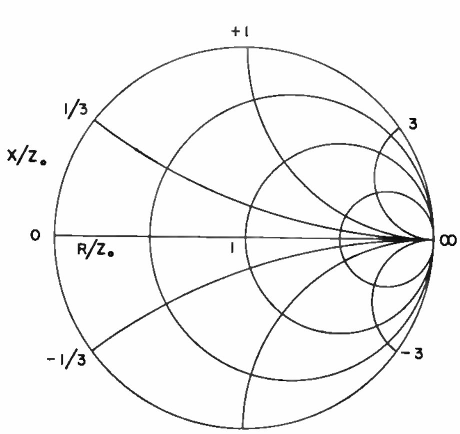


(a) Voltage reflection coefficient, $\rho = |\rho| \exp j\theta$; $|\rho|$ circles, θ radials.

$$\text{VSWR} = S = \frac{1 + |\theta|}{1 - |\theta|} \text{ circles.}$$



(b) Impedance, $Z = |Z| \exp j\phi$; $|Z|$ latitude, ϕ longitude. (Carter chart)



(c) Impedance, $Z = R + jX$; R circles, X arcs. (Smith chart)

Fig. 2—The reflection chart.

with the aid of a radius arm having a scale of SWR (most conveniently, db SWR).

Other sets of contours on the reflection chart may be used as graph paper or as transparent overlays, if the load impedance is to be reduced to numerical components. Fig. 2(b) and (c) show the forms commonly used for this purpose. Fig. 2(b) shows the Carter chart [23], having contours of impedance magnitude ($|Z/Z_0|$) and phase angle (ϕ). Fig. 2(c) shows the Smith chart [24], having contours of the real and imaginary parts of impedance; these are essential for adding impedances in series. A rotation of this form by 180° gives the parts needed for adding admittances in parallel.

There are variations of the reflection chart, both circular and otherwise, that are adapted for special purposes. A notable one of these is the "projective" chart of Deschamps [18], which retains the same circular rim but has a different radial scale.

The standing-wave technique may be simplified if it is required only to measure the magnitude of reflection coefficient or SWR. This can be measured by a two-way directional coupler and a ratio meter (forming a reflectometer). The ratio can be plotted instantaneously against a sweeping frequency on a scope. This method is most useful if the objective is merely to show that the reflection is within a tolerance.

V. Test Equipment

Table IV is intended to show some of the principal types of test equipment that are essential in microwave measurements. These are largely parallel to those for lower frequencies, but with emphasis on some that are adapted to waveguide techniques as distinguished from wired circuits.

VI. Signal Sources and Indicators

For any part of the frequency spectrum, signal sources and indicators are related in several respects. The source power must exceed the indicator power level of detection, preferably by several orders of magnitude. Furthermore, this relationship must be obtained for some practical kind of modulation, if any is required to increase the sensitivity of detection.

Table V lists some typical sources useful for microwave measurements [17]. The frequency ranges and power levels are estimates and intended merely to indicate the order of magnitude. The listed devices are those likely to be used for laboratory tests, as distinguished from high-power transmitters, but naturally the latter are required for some tests.

Table VI lists some typical indicators useful for microwave measurements. Here also the frequency ranges and power levels are estimates intended merely to indicate the order of magnitude. The listed devices are those likely to be used for laboratory tests, as distin-

    - Thermistor (semiconductor, small bead).
  - Gas expansion (Golay cell).
    - 100–300 Gc.
    - Resistance sheet (thin film).

guished from sensitive receivers, but naturally the latter are required for some tests.

VII. SPECTRUM ANALYZER

The principle and utility of the spectrum analyzer are general in their application over the entire radio-frequency spectrum. However, it happens that the development and application of this device have been most closely associated with microwaves, because it was made available to meet some specific needs which arose in this field [10].

The spectrum analyzer is essentially a narrow-band receiver provided with frequency sweep and instantaneous display of amplitude frequency spectrum on a scope. Fig. 3 shows the resulting patterns for some typical cases. In the display for a pulsed signal, there is a comb of vertical lines, as shown in Fig. 3(a), (b) and (d); the spectrum is the envelope of these lines. In the display for a steady signal, or for random noise smoothed by a filter, the spectrum is simply plotted as shown in Fig. 3(c) and (e).

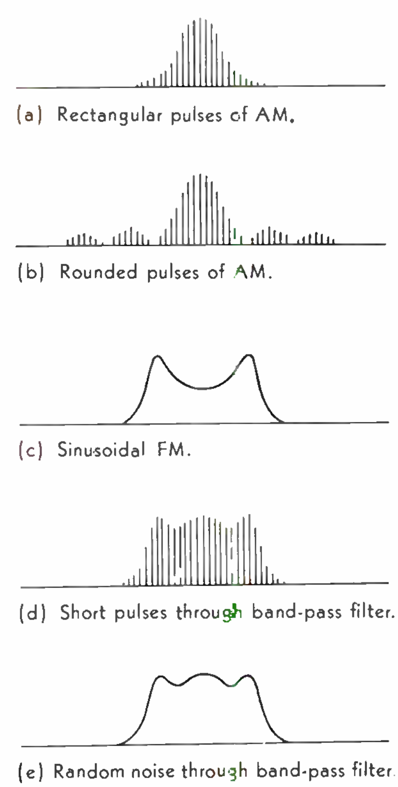

Fig. 3—The frequency-spectrum display for typical cases.

VIII. Frequency Standards and Wavemeters

As mentioned above, standard-frequency generators are outside the scope of this article. However, the use of a hollow-cavity resonator as a wavemeter is peculiar to microwaves and is here included in the form of one example.

Fig. 4 shows a resonator bounded by a right-circular cylinder of conducting walls (preferably silver-plated). One end of the active space is a piston supported without conductive contact to the cylinder, and provided with a micrometer drive and scale. The diameter is somewhat greater than the cut-off wavelength (λ_c) and the length is $\frac{1}{2}$ the guide wavelength (λ_g). The pattern of the magnetic field (H) is indicated. This cavity is coupled with one or two connecting waveguides through small holes, not shown, and resonance is indicated by a transmission or absorption method.

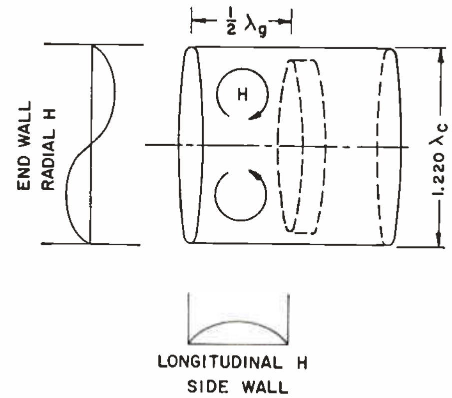

Fig. 4—A wavemeter utilizing the TE-01 mode in in circular waveguide.

IX. Power Measurement and Calibration

Microwave power measurement usually relies on the heating of a load impedance by all the power or by a small fraction of the power. This is distinguished from the low-frequency indication of the product of voltage and current in a wattmeter. Reference is made to some of the indicators listed in Table VI.

The thermal measurement of average power in some devices offers the advantage of direct comparison between RF power to be measured and dc power which can be directly metered. The comparison is nearly independent of the properties of the load resistor. This principle is developed to greatest refinement in the self-balancing "bolometer bridge," where the RF power is read directly on a dc meter. The required temperature-sensitive resistor is made of a fine wire of metal ("barretter") or a small piece of semiconductor material ("thermistor").

X. Impedance Standards and Comparators

The customary standard of impedance is the wave resistance presented in a rectangular waveguide supporting a single-mode propagation. The walls (of high conductivity) are nearly perfect reflectors, so the dimensions determine the impedance as closely as they can be measured. Therefore the waveguide provides a primary standard for common use, which is remarkable in the practice of measurements. (The air has a slight effect which can be taken into account if significant.) Usually this impedance is not expressed numerically, but any measured impedance is expressed relative to this standard (Z/Z_0).

In this situation, self-impedance is identified with reflection coefficient in the manner explained above with reference to the reflection chart. Also the standing-wave technique is a direct method for comparing an unknown impedance with the waveguide as a standard.

Fig. 5 shows some standards of reflection (or impedance) that are adapted for inclusion in a waveguide. The fixed standard Fig. 5(a) is stable and closely computable, so it approaches the status of a primary standard.

An adjustable standard of reflection (or impedance) is more difficult because it involves motion in two dimensions and a corresponding calibration in two parameters (such as R/Z_0 and X/Z_0) for each frequency of operation. Fig. 5(b) shows one form that is suitable for rectangular waveguide, and is useful over a wide range of values. The reference plane is stationary (as at the mid-position of the center of the sliding insert) so the motion enables all phase angles of reflection coefficient. The sliding insert may be made of metal like the waveguide walls, or may be made of dielectric material to avoid the problems of contact at the edges of the slot.

Primary and secondary standards of transmission properties are more highly developed and more diversified. A number of types are listed in Table VII. Attenuation or irreducible loss has an absolute significance, relative to zero in a lossless waveguide. Angle or phase shift has only a relative or differential significance, since it is present in all waveguide connections. In each case, there are some primary standards dependent on dimensions rather than materials, and some secondary standards dependent on material properties such as dissipation or dielectric constant.

Transmission measurements are made by comparing the unknown with a standard by one of the usual methods. If the differential or substitution method is used, the RF circuit to be tested may be followed by a superheterodyne receiver, and its transmission properties measured by an equal change in the IF circuit of the receiver. This procedure is well adapted for a piston attenuator and a phase rotator in the IF circuit.

In the use of either reflection or transmission standards, a balancing method with a null indicator is capable of the highest degree of refinement. In waveguides, the ideal comparator is the symmetrical hybrid-T ("magic-T") junction, shown in Fig. 6 [35]. The indicated external connections to the four arms are those used for comparison of reflections (or impedance), in which case the junction performs the function of the

pair of equal arms in a Wheatstone bridge. The equality of these arms is assured by mechanical symmetry of structure.

XI. MICROWAVE SPECTROSCOPY

Microwave spectroscopy [14], [17], [19], like its counterparts at wavelengths from infrared through X rays, consists basically of some observation of the frequencies of emission or absorption of energy by the molecules of a particular substance, usually in gaseous form. Each "line" which lies in the microwave portion of the spectrum represents an energy transition between two of the various rotational or vibrational states of a molecule; therefore the materials studied are usually those having a polyatomic molecular structure that is mechanically well defined.

A typical microwave absorption spectrometer comprises a signal source with the required frequency variation, a long waveguide filled with a gas under test, and a signal indicator that is sensitive to small changes in output power. Unusual refinements are required in frequency stability and measurement.

Important applications of microwave spectroscopy are found in the "ammonia clock," and the "maser," the optical maser or "laser," and the use of the hydrogen line in radio astronomy.

XII. DEVELOPMENTS NEEDED FOR FUTURE

In general, there are great opportunities for refinement of the techniques described and of some others closely related. A few of the needs for improvement may be mentioned here.

Comparison standards of reflection and impedance are needed in adjustable form, with convenient calibration for use in a balance method.

Microwave beam deflection in an oscilloscope has been demonstrated, but needs development into a convenient laboratory form.

Multimode techniques in waveguide are steadily progressing to a higher degree of understanding and utility.

For the shortest (millimeter) waves, there will always be an increasing need for signal sources and indicators; also further opportunity for refinement of single-mode waveguide techniques and for alternative methods related to optical practices.

The rating of a multiport device in terms of the wave-transmission matrix is due for increasing use, especially with further experience in the required methods of measurement.

XIII. CONCLUSION

An attempt has been made to present in a compact form some of the more interesting and significant developments in the field of microwave measurements. These reflect remarkable progress over 25 years of activity, stimulated especially by the needs of radar, guided missiles and communication relay networks.

ACKNOWLEDGMENT

It is a pleasure to acknowledge the writer's reliance on 20 years' experience with engineering groups active in microwave measurements, first in Hazeltine Corporation during World War II, and subsequently in Wheeler Laboratories. In particular, he is grateful to his associates, P. A. Loth and I. Koffman, for their helpful cooperation in the preparation of this paper.

The Future of Microwave Communications*

S. E. MILLER†, FELLOW, IRE

Summary—The future of microwave communications is foreseen by noting the status of advanced research and then deducing its logical impact on future systems. The trend toward higher frequencies is expected to result in millimeter waveguide systems, and perhaps in communication using visible radiation, with an order of magnitude more channel capacity than the largest existing commercial systems. Satellite radio communications are expected to provide versatile broad-band international communications in an era when tying together the world's major population centers is of first importance. Point-to-point radio-relay systems are expected to provide the largest volume of domestic long-distance circuits, with explosive growth in the near future. New solid-state devices have appeared and should lead to systems with lower power consumption, longer component life, and eventually lower operating cost.

WHAT IS THE *future* for *microwave* communications?[1] We shall try to foresee the future of microwave communication technique in the sense that communication research unfolds the future. By contrast we shall not attempt a prediction of the business trends which influence the magnitude of commercial communications systems, important as these trends certainly are. We must also avoid the folly of trying to predict the unknown. The present task only becomes feasible to the extent that we can proceed from existing new components and ideas to the probable influence on future communication systems. We might hope to find a situation analogous to that wherein this year's birth rate largely determines the size of the kindergarten classes five years from now, and the size of the college entrance group 18 years from now.

I am a firm believer that many, if not most, *major* communication system advances come as a consequence of new communications components, which in turn come directly or indirectly from improved knowledge in physics. During the last ten years new results from physics have created revolutionary opportunities for communication engineers. First consider, for example, the *nonreciprocal* components based on the ferrites or garnets, and second, the semiconductor devices giving gain with very little power consumption. Remarkable changes in communication systems resulted. Are such changes at an end? I believe not, and will try to lead the reader to that conclusion.

What is included in *microwave?* There appears to be no concise definition in IRE literature, but an accepted lower limit is around 1000 Mc. For the upper limit we are more completely on our own. Regarding microwave as synonymous with micro-meter, or micron, we arrive at the region near 3×10^{14} cps, or 300 teracycles. This is just below the visible spectrum where, indeed, communication techniques are appearing, and it seems logical to include this region in the present discussion.

Potential Communication Needs

One of the motivations for advancements in the communications art is an unsatisfied need for service. We can point to a number of such needs as a prelude to anticipating the future trend of the microwave communications art.

There is as yet no satisfactory method of sending live television across the ocean. Few doubt that an economically attractive method would experience widespread commercial usage. Systematic expansion of the present types of services—telephone, data transmission, etc.—will also increase the need for overseas facilities as business and social ties become more international.

Similar expansion of the existing communication needs occurs in the domestic area where the population growth and associated expansion of business indicates an expanding demand for service. The existing types of microwave systems, point-to-point radio relay and tropospheric scatter, will continue to provide valuable communication service but there is simply not enough available radio spectrum (unimpaired by atmospheric transmission difficulties) to take care of the foreseeable needs for communication service of the present commercial types. In addition, we may expect the creation of new types of services, which would necessitate additional expansion of communication facilities. For example, almost any form of person-to-person television would make existing commercial communication systems totally inadequate.

Going to Higher Frequencies

Viewing the past 40 years most generally, communication advances have formed a pattern of going to higher frequencies. Why? Principally to fulfill communication needs, for at the higher frequencies more bandwidth is available. A complementary point of view is that by going to higher frequencies more bandwidth is technically feasible, and this feasibility itself serves as a stimulus for additional communications usage. That trend is expected to continue.

In the microwave region, the earliest services were provided at the lower frequencies followed by exploitation of common carrier bands in the 4000, 6000 and 11,000 Mc regions. Above about 11,000 Mc, rain attenuation and other atmospheric propagation effects

* Received by the IRE, July 5, 1961; revised manuscript received, November 24, 1961.
† Guided Wave Research, Bell Telephone Laboratories, Red Bank, N. J.
[1] The emphasis is on *future* and *microwave*, as suggested by the Anniversary Issue Editors.

begin to become serious. However, in shielded media, research indicates the likelihood of commercial utilization of the 35,000 to 100,000 Mc band, with higher bands as a research possibility. Recently, an initial milepost has been reached in the 300 teracycle region—the creation of coherent sources of power. Thus both in the 100,000 Mc region and in the teracycle region, the frequency frontiers of communication technology are being pushed back.

In going to higher frequencies, we must mate a suitable transmission medium with suitable techniques of signal generation, amplification, modulation and the usual signal handling components such as hybrids, filters, multiplex equipment, etc. Invention, innovation and pioneering development will be required. Next we consider how a few of the new results seem likely to project importantly on communication in the microwave region.

Optical or Teracycle Region Systems

Two coherent sources of power in a teracycle region have been created; using pulsed operation due to power limitations, a ruby maser-type oscillator has been operated in the region near 433 teracycles. Also, a CW helium-neon gaseous maser with power output of a few milliwatts has been operated near 260 teracycles. In the initial experiments, the stability of output frequency vs time or stability of amplitude vs time leave much to be desired from a communications standpoint. Nonetheless, the accomplishments are exciting in their implications. A 10 per cent band, which is normally achievable with relative ease in microwave communication components, would make available a bandwidth of 30,000,000 Mc for communication!

What would the medium be for such frequencies? One is tempted to think in terms of conventional radio-type transmission because some of the numbers appear so attractive. For example, a five-inch antenna (telescope) operating at 300 teracycles would have a half-power beamwidth of 1.6 seconds of arc, and at a distance of 25 miles (present-day radio-relay-station spacing) the diameter of the beam would only be of the order of one foot. Two such five-inch antennas having a spacing of 25 miles are not in the far field zone and would have an insertion loss in the order of 10 to 15 db in vacuum. However, when both ends of the circuit are on the ground, atmospheric propagation effects (notably refraction and rain attenuation) are almost certain to be very serious. One is inclined, therefore, to think in terms of some kind of a pipe as a shelter for the medium with suitable mirrors or lenses to guide the beam between repeater points. For space communication, more conventional radio methods may be attractive.

What modulation and multiplexing systems will be feasible? What kinds of detectors and modulating devices will such a system use? How is signal-to-noise to be defined and calculated in this region where the quanta is large and $h\nu > kT$? It is apparent that we have here a fertile field for research, the outcome of which may be revolutionary.

TE_{01} Waveguide Systems

Conventional types of microwave services will continue to expand and this will inevitably lead to serious problems of mutual interference and frequency occupancy. The severity of these problems is greater in more densely populated areas, and already congestion of the common carrier bands is threatening cities like New York and Los Angeles. On going to higher frequencies to seek relief, one encounters serious atmospheric absorption and diffraction effects. One is forced to seek transmission media other than the atmosphere at frequencies above 15,000–30,000 Mc. Spurred on by this need, research is well advanced on the communication use of the TE_{01} wave in round guides, and future commercial application appears virtually certain.

A two-inch ID perfect copper tube has a theoretical loss of 3 db per mile at 35,000 Mc and $\frac{3}{4}$ db per mile at 90,000 Mc. Recent experimental results at the Bell Telephone Laboratories on 400-foot to 2000-foot lengths have shown practical loss values around 3.5 db per mile at 35,000 Mc and 1.7 db per mile at 90,000 Mc. Because hundreds of modes can propagate and multipath transmission is experienced, PCM is likely to be used as the signaling method. A single pipe, operating in the 35,000–90,000 Mc region, is expected to be able to handle 100,000 two-way voice channels, 100 standard black-and-white or color television channels in two directions, or the equivalent bandwidth of other grades of service.

One key to the achievement of attractive transmission losses has been the development of multimode waveguides with controlled characteristics for the undesired as well as desired modes. In the 2-inch ID guide referred to above, hundreds of modes can propagate. Fortunately, only a few are important when the structure is carefully controlled, and these few modes can be given approximately-predetermined loss and phase constants. Even in components such as hybrids and channel filters, it has been advantageous to use multimode structures to achieve broader bands or lower losses. These techniques have become familiar in research, and may be expected to find engineering application in fields outside millimeter wave communication as well as for that purpose.

The most fundamental limitation in the transmission medium appears to be straightness deviations having a wavelength equal to electrical beat wavelength, $2\pi/\beta_1-\beta_2$ where β_1 is the phase constant for the circular electric wave and β_2 is the phase constant for any of several low-order parasitic modes coupled to the circular electric wave by the straightness deviation. For the 2-inch ID guide at 35–90 kMc, this critical straightness wavelength is on the order of one to five feet, and it is necessary to maintain manufacturing deviations and installation deviations of that particular period at a small value. However, it is noteworthy that smooth changes of direction on the order of 1° per foot can easily be accommodated if not performed too frequently, and one-fifth that value on a continuous basis with tolerable penalty. Abrupt changes of direction can be made by tapering to a smaller diameter, or by using mirrors. Thus, the installation problem for long-distance TE_{01} waveguides at the present state of the art is uncritical with regard to following hills and dales and changes in direction horizontally. Two miles of helix waveguide, a preferred form of mode discriminating waveguide, have been fabricated in the research laboratory, and in the immediate future a study will be made of the correspondence between a theoretical model of the multimode medium and the experimentally observed transmission properties. Looking farther ahead, the future prospect for the present medium lies in moving the operating frequency upwards in the spectrum where even more bandwidth and less delay distortion are theoretically available; the prospect of devising simplified forms of mode discriminating waveguides is also promising.

Really long haul (4000-mile) application of the waveguide medium calls for acceptance of a relatively imperfect loss frequency characteristic due to higher-order mode interactions. The use of PCM with regenerative repeaters effectively accommodates these medium imperfections, simultaneously relieves repeater-circuit tolerances (another necessity at the carrier frequencies employed), and is economical in the use of signaling power. Extensive electronics research and development work over a 15-year period has succeeded in producing the necessary signal sources, amplifiers, regenerators, and communication circuitry for this frequency region. Experimental models have been demonstrated on a component basis in the center of the 35–90 kMc region, and a research model of a complete PCM repeater is in the final stages of preparation for over-all performance evaluation.

An important communication problem, not characteristic of waveguide and microwave alone but perhaps appearing here for the first time, is the technique of operating a nationwide network of digital signals, maintaining the various channels which are to be interleaved with sufficient accuracy of pulse-to-pulse timing so that the interleaving may be done on a time division basis. This represents a challenge whose solution lies somewhere in the future. With the marked increase in digital communication it is believed to be important.

Viewed broadly, waveguide systems can now be engineered with specific commercial objectives, and the initial steps for such development are being undertaken in several countries. The engineering challenge is to create complete designs and establish economically optimum manufacturing techniques. The tempo of such work will be tied in closely with over-all service demands. The cost per channel in a fully loaded waveguide is expected to be appreciably lower than that of existing communication systems, but the magnitude of initial investment is such that a minimum service requirement of the order of 10,000–20,000 equivalent voice circuits is estimated to be necessary to make the system prove in. Thus the waveguide system will be a superhighway of communications, which incidently will increase the demand for lower-capacity feeder routes via microwave radio relay and other techniques.

From the research point of view waveguide communication is a dynamic field with more sophisticated media, more sophisticated solid-state components and more sophisticated modulation systems lying ahead of us.

One immediate challenge in the research area is signal generation and amplification in the region above 100,000 Mc. Solid-state techniques are beginning to appear and seem almost certain to attract additional pioneering work. Tunnel-diode oscillators have been made at the microwatt level at 100,000 Mc and tunnel-diode amplifiers with 15–18 db noise figure have been made experimentally in the region near 55,000 Mc. A variable capacitance parametric amplifier with double sideband noise figure around 6 db was made at 17,000 Mc, and a similar unit operated without precision measurements at 30,000 Mc. The future should bring advances in these arts. Greater power capacity is needed in these solid-state devices which, if achieved, would make feasible all-solid-state repeaters.

Just as research work to date has established a good way to make a waveguide system, future research is expected to lead to more advantageous solutions to critical problems.

Satellite Radio Communications

A new "transmission medium" recently became available—earth satellites. Radio communication from one ground point to another has been carried out by passive reflection from a 100-foot diameter balloon and preliminary experiments are being conducted to employ a belt of metallic dipoles as a semi-continuous reflecting layer for communication signals. Alternatively, work is progressing on an active system using a solar power operated repeater on the satellite itself. By operating in the 1- to 10-kMc regions, background noise from the sky is very low and the very attractive noise figures of masers can be used to advantage. System input-noise temperatures below 30°K have been achieved.

These early experiments certainly predict a substantial expansion of overseas communication via satellites. New demands appear on many of the old components as a result of this system development. Antennas with the highest practical gain and lowest possible sidelobes are needed, with consequent challenges in mechanical design of the very large but necessarily precise structures which result. The very highest power CW microwave sources are needed in passive systems in order to provide adequate SNR's. There is a great premium on very low-power consumption in the repeaters to be used in the satellites and on obtaining long life due to the very high cost of replacing repeaters. These are old requirements in the submarine cable business but represent new standards in the evolution of microwave techniques. The first proposed satellite repeater systems call for vacuum tubes (broad-band low-noise traveling-wave tubes) in the repeater, but in the future there certainly will be a strong attempt to do the job with low-power solid-state devices.

The microwave and other portions of the satellite repeater will experience new environmental requirements due to radiation in the Van Allen belts. Once again this has brought physics more closely into the engineering activities.

The proposed satellite systems have created a use for an old invention—frequency modulation with feedback, proposed prior to 1940. FM with feedback did not find commercial use in point-to-point radio-relay systems but its ability to improve the noise breaking point for an FM circuit is at the present state of the art a very valuable contribution to system feasibility. Future work is needed to improve our understanding of FM with feedback, and to try to achieve even better power efficiency.

We anticipate a need somewhat later for satellite-to-ground communications of a broad-band nature in which orientation of the satellite antennas will be used. The small amount of atmosphere between the satellite and ground station may permit the use of the millimeter wave or teracycle regions with the associated reduction in power loss for limited satellite antenna size, provided it is acceptable to be out of service during occasional bad weather. Satellite-to-satellite communication on paths wherein there is no atmosphere at all may be needed, and there the principal problems will be to provide equipment with very low-power drain and a high order of reliability using antennas of limited size.

These notes on space communication barely hint at the fascination which the subject holds for those working on it. The new technical challenges are combined with the more subtle glamour of space activities generally which captures the imagination of technical and nontechnical men alike. Even the most pedestrian of communication techniques applied between two manned space vehicles will be exciting. But, in addition, satellite communication systems should provide versatility in international broad-band communications in an era when tying together the world's major population centers is of first importance. We can anticipate unparalleled consumer interest in this field as well as genuine technical challenges and resulting contributions.

Conventional Microwave Communication Systems

Despite the glamour of satellite communication realities and of optical communication potentialities, the work horse of domestic long-distance communications for the next ten years is going to be conventional point-to-point microwave radio relay. Some people have referred to this situation as the forthcoming "microwave explosion." But the systems used will not necessarily be present-day systems. Viewing the spectrum broadly, increased congestion will necessitate improved frequency stability, improved antenna directivity, and efficient multiplexing methods. The solid-state art is only now beginning to be felt in this region. Parametric amplifiers and tunnel-diode devices are in various stages of research or exploratory development but have not yet had a real impact on complete systems. There are great prospective advantages for these newer techniques. Perhaps most outstanding is the hope that lower power consumption and longer life for the solid-state elements will lead to eventual lower operating costs. In addition, very low-noise figures have been achieved, less than 1 db (double sideband[2]) in the 6000 Mc region with refrigeration of the diode and 3.5 db with 1000 Mc bandwidth at 11,000 Mc without refrigeration. Techniques for thermoelectric refrigeration of the input circuits are in exploratory phases and might be expected to appear in finished systems in the years ahead.

A Note on a Possible Future Design Philosophy

In order to meet current communication needs, a system designer must employ components which exist—components whose characteristic behavior is sufficiently well understood to permit system interactions between components to be engineered with assurance. This is important. The man who insists on using existing components is not against progress—he merely recognizes that he cannot provide communication service with *ideas* alone. But with the component art moving ahead at such a rapid rate, new and improved systems are becoming feasible at shorter time intervals. To me as an individual the answer would appear to be the design of systems with evolution in mind—evolution to meet communication needs with the latest advances in component art. This is not as simple to do as one might presume at first thought. The more completely one optimizes all the system design interactions, the less the flexibility which remains in the final layout. A system aimed at planned evolution will show long range performance advantages to offset shorter range off-optimum design choices. But it must be done in a hard-headed way to avoid paying seriously for "future gains" which never materialize.

Mobile Communications

It seems highly probable that the future will see an explosive growth of mobile communications. Personal paging, land vehicular, air-to-ground, satellite telemetering and control, air-traffic control—these and other mobile services are in growing demand. It is possible but not certain that microwaves will be used to satisfy them. One requirement is for low-power-consumption miniaturized receivers which can now be realized more easily at frequencies below 1000 Mc, but the pressures of increased demands for frequency space may force some of these services above 1000 Mc.

[2] With signal received on both sidebands, as in radioastronomy.

Microwave Local Transmission

In the millimeter-wave region, antenna beams of 1° or less can be obtained with an aperture of one foot. If solid-state microwave sources should become feasible *and inexpensive* at power levels of a few milliwatts, radio transmission in this frequency region might become useful as a short-distance local plant facility. Atmospheric losses, which are too great to permit long distance transmission, can be tolerated for distances of a mile or so. Broad radio bands not otherwise employed might find use, and the local communication plant might get a wide-band service capability not easily obtained by other methods. The essential low-cost property may follow feasibility without great delay due to the large volume requirements associated with local plant equipment. This is speculative, but possible.

Other Services

Special services such as military communications and tropospheric scatter microwave radio will profit from the same microwave advances noted above and might be expected to evolve along similar lines.

Conclusion

The future for microwave communications is indeed bright. We can see in today's new developments the seeds of much future progress in the technique of communication, and there is apparent a growing service demand which will require these advances.

Spanning the Microwave Infrared Gap*

PAUL D. COLEMAN†, MEMBER, IRE

Summary—**The basic problems encountered in both classical and quantum electronics when attempting to produce coherent radiation in the microwave-infrared gap region extending from roughly 100- to 1000-microns wavelength are reviewed. Brief historical accounts are given of past work leading up to the submillimeter wave frontier. Some selected examples of current work are described to indicate the direction research in this area is taking. While it is the conclusion that a real breakthrough in the microwave infrared problem is not imminent, it is felt that the new background knowledge and the increased applied physics experience now acquired by the ultramicrowave engineer will hasten the day when a solution to the problem will be obtained.**

Introduction

Basically the radio, electronics, and communication engineer is interested in problems of generation, transmission, detection, and modulation of coherent electromagnetic radiation. Also the physicist has long employed electromagnetic radiation as a diagnostic tool for studying matter.

Useful amounts of RF coherent power became available with the invention of the triode by de Forest[1] in 1907, although the first feed-back oscillator of Meissner's[2] did not appear until 1913. By 1936, a microwave electronic tube, the magnetron,[3] had been extended to a wavelength of 6 mm. However, in the last 25 years microwave electronics devices have been pushed only about a factor of three further, so that today one frontier of the microwave-infrared gap stands at the order of 2 mm wavelength.[4]

Recently, the achievement of an optical maser,[5,6] the laser, has produced coherent power in the visible range of the spectrum. Thus the microwave-infrared gap now stands bracketed from below by both classical and quantum electronics devices and from above by quantum electronics devices.

Care must be exercised, however, in jumping to the conclusion that since the gap region has been bracketed, it is about to be spanned.[7–10] While all ultramicrowave engineers firmly believe the problem will be solved, there still remains much hard work and origination of ideas before the bridge is completed.

Classical electronics devices have utilized lumped circuits, transmission lines, and waveguides as the fre-

quency limit has moved upward to its present frontier of around 150 kMc. The difficulty of extending microwave electronics devices further strongly suggests that the new marriage of electronics should be with physical optics structures. This does not mean that microwave electronic tubes cannot be pushed still further, anymore than that triode tubes cannot be pushed to *S*-band, but it does mean that the difficulties may increase to the point that it is desirable to look for other techniques.

Quantum electronics devices initially were built at *K*-band.[11] Here microwave structures were employed to contain the maser material. However, the laser, in leaping over the microwave-infrared gap up to the visible part of the spectrum, utilized a physical optics structure, the Fabry-Perot resonator.[12] Given the appropriate maser material, there is no reason to believe that a maser system using a Fabry-Perot resonator cannot span the entire microwave-infrared gap. This does not mean that all other schemes should be abandoned anymore than microwave tubes should have been discarded when the microwave maser was invented.

The question of whether a classical electronics device can successfully invade the submillimeter range has yet to be answered. If the answer is negative, then the submillimeter area represents a demarcation line between classical and quantum physics.

In the last 50 years, the radio engineer has successfully met the challenge of producing higher and higher frequencies. The transition from lumped circuits to waveguides required learning field theory. Combining semiconductor, ferrite, and plasma devices with microwave circuits required learning solid-state and plasma physics. Microwave masers required a knowledge of quantum mechanics. Hence, today the ultramicrowave radio engineer is essentially an applied physicist. It is this training, this new experience, this broader outlook, that will enable him to successfully conquer this microwave-infrared-gap ogre and exploit it for the benefit of man.

Basic Interactions

Electromagnetic energy can only be produced in essentially two ways:

1) The classical method of retarding electrons by electromagnetic fields, and thereby converting their kinetic energy into electromagnetic energy.
2) The quantum method of permitting a system to interact with an electromagnetic field to undergo a transition from a higher energy state to a lower energy state, thereby converting its internal energy into electromagnetic energy.

The classical electronics problem involves the solution of Maxwell's and Newton's equations simultaneously in the case of a self-excited system or separately in the case of a driven system. A breakthrough in the submillimeter wave problem from a classical electronics point of view would mean finding the appropriate medium and boundary conditions that would yield practical design values and useful power outputs.

In the quantum electronics problem, a knowledge of the induced and spontaneous emission probabilities of the energy level scheme is required. In theory, these quantities could be calculated from Schrodinger's equation, but in practice they are usually experimentally measured. Thus, success in this area is closely associated with problems and knowledge of materials.

In attempting to invade the submillimeter region, both classical and quantum electronics devices encounter the same fundamental problems:

1) a coherence problem,
2) a field containment problem,
3) an energy conversion problem,
4) a characteristic frequency problem.

Coherence in classical schemes requires electron bunching or collective interaction as opposed to individual behavior. Coherence in quantum schemes requires locating the molecules in a coherent electromagnetic field to induce transitions that are phase-related to the inducing field.

In both the classical and quantum systems a coherent electromagnetic field is needed to exist somewhere in space. Classically, the electrons must work against an external field or in the case of accelerated motion against its own field. Both microwave masers and tubes, of course, use microwave waveguides or cavities for field containment. The frequency limit of such devices is, therefore, directly dependent on the frequency limits of microwave structures.

All oscillators, by definition, are energy converters, their aim being to transform readily available energy into the desired coherent energy of a given frequency. Availability, efficiency, coupling the energy in and out of the system, saturation, etc., are practical problems that must be considered.

Finally, an oscillator must have some type of characteristic frequency associated with it to determine its operating point. This frequency can be a resonant frequency, a frequency for synchronization, a cyclotron frequency, a frequency determined by an energy level, a harmonic frequency, a plasma frequency, a Doppler shifted frequency, etc.

At the moment, classical electronics devices are mainly limited by the field containment problem. However, several selected examples will be discussed later to suggest how this problem may be solved. Quantum electronics devices for the microwave-infrared gap are presently limited by the characteristic frequency problem in the form of a search for suitable maser materials.

Classical Electronics

The last twenty years have seen the rapid development of microwave electronics sources such as the magnetron, klystron, and traveling-wave tube. In all these devices, the microwave circuit, the field containment structure, is an integral part of the tube. Progress toward higher frequencies with these tubes has principally involved refinement and development of better microwave circuits and the forming and focusing of dense, sharply defined electron streams. While a better microwave circuit relieves some of the requirements on the electron beam and better electron beams[13] relieve some of the requirements on the circuit, it now appears that the practical limits of devices of this type are around 1 to 2 mm wavelength.

The state of the art of conventional backward-wave oscillators is perhaps best represented by the *O*-type Carcinotrons of Compagnie Generale de Telegraphie Sans Fil (CSF). Proposals[14] aimed at 600 kMc with power outputs approaching a milliwatt are being considered. Remarkable as this achievement would be, it represents extending microwave-type techniques beyond their normal practical limits because of a lack of appropriate new ideas for the gap region.

If microwave field containment structures represent a major obstacle in pushing on to higher frequencies, how then might electron beams be used in physical optics type of devices which are appropriate to the submillimeter part of the spectrum?

There are two basic ways of achieving a structure having a phase velocity v_p less than that of light c. The first is to use a periodic metallic guide; the second is to use a material medium having an index of refraction greater than one. This second approach naturally leads to the study of the Cerenkov[15] effect, *i.e.*, the radiation of electromagnetic energy by a charged particle q moving through a material medium with a uniform velocity v greater than the phase velocity v_p of light in the medium.

Since the ionization losses of a charge passing through a medium would be excessive, the practical realization of the Cerenkov effect requires that the charge pass near or through a hole in the medium. Also, to achieve coherent Cerenkov radiation having a line spectrum, a bunched electron beam must be used as in any microwave tube. Fig. 1 illustrates a typical Cerenkov configuration wherein a bunched, cylindrical beam having a velocity v, is passed through a cylindrical hole in an infinite dielectric medium having a dielectric constant ϵ.

Coherence requires that the bunched beam move the distance AC in the time the Cerenkov radiation moves the distance AB and that the time phase difference between points A and B is a multiple of 2π.

Thus

$$t = \frac{AC}{v} = \frac{AB}{v_p} \quad \text{or} \quad \cos\vartheta = \frac{AB}{AC} = \frac{v_p}{v}, \tag{1}$$

and

$$\omega t = \omega\left(\frac{2\pi}{\omega_0}\right) = 2\pi n \quad \text{or} \quad \omega = n\omega_0, \tag{2}$$

where ω is the frequency of the Cerenkov radiation, ω_0 is the electron beam fundamental bunching frequency and n a positive integer.

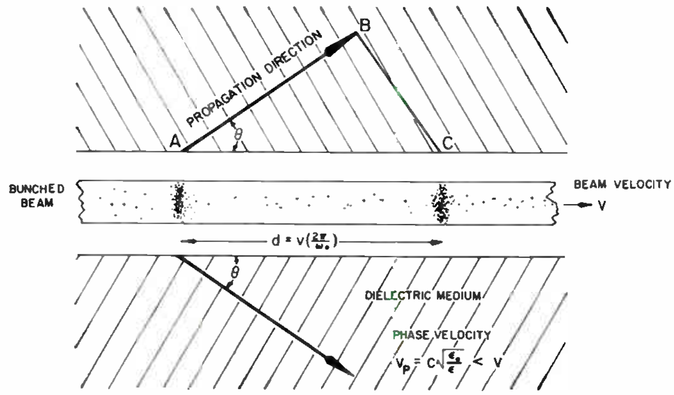

Fig. 1—Cerenkov radiation produced by a bunched electron beam in infinite, nondispersive, dielectric medium.

The Cerenkov radiation propagates away from the electron beam in a cone of semi apex angle θ and contains frequencies corresponding to each current harmonic frequency of the bunched beam.

Thus in this Cerenkov system, the coherence problem is solved by the beam bunching which at the same time determines characteristic frequencies $n\omega_0$. Since no resonance effects are required in the dielectric medium, the physical size of the dielectric can be arbitrarily large with no mode problems in the microwave sense. The field containment problem involved reduces to a proximity problem in that the beam must pass near the dielectric or through a hole in it.

The z component of the electric field for the case being considered varies as $I_0[\omega r/v(1-\beta^2)^{-\frac{1}{2}}]$ where I_0 is the modified Bessel function of the first kind. As the beam velocity $v = \beta c$ approaches c, the velocity of light, it is seen that the argument of I_0 becomes smaller because of the $(1-\beta^2)^{\frac{1}{2}}$ factor, resulting in the electric field decreasing less rapidly away from the dielectric surface. Thus the requirements on the proximity problem can be relaxed at relativistic velocities.

Finally, how is the energy coupled in and out of the structure? This can be easily done by shaping the dielectric from geometric optics ray tracing considera-

tions as shown in Fig. 2.[16] The angles α and ϕ of the dielectric cone are chosen so that the coherent Cerenkov radiation emerging at the characteristic angle ϑ is internally reflected by surface 1, strikes surface 2 at the Brewster angle and then escapes parallel to the cone axis. The dielectric cone acts both as a beam-coupling structure and an aperture antenna.

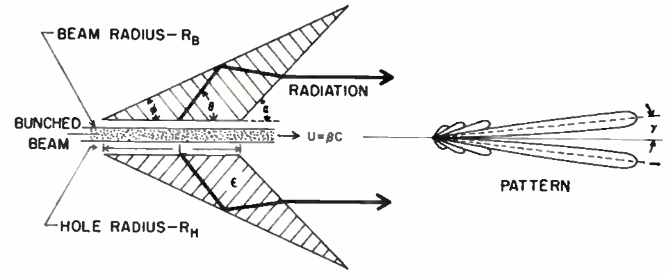
The Cerenkov cone represents a Maxwell problem in that the bunched beam (charge ρ and current $\bar{J}$) is given with the problem to compute the fields and the interaction. It is assumed that in the case of a megavolt bunched beam, the fields generated by the beam are not of sufficient intensity to affect its motion (the constant current generator approximation).

Producing a high-energy bunched beam[17] represents a Newton problem. Here the appropriate field of frequency f_0 must be determined to exert forces on the electrons to accelerate and bunch them in the desired fashion. If this bunching can be done with a field at a fundamental frequency of 35 kMc and if appreciable harmonic currents up through the 50th can be obtained, then coherent power up to and beyond 1750 kMc could be produced.

Work on this type of Cerenkov coupler has already produced 8-mm power at the watt level. Investigation of an optical type of feedback is underway to further increase the power output.[18] Also, anisotropic media, wherein there are strong, high Q absorptions, should be expected to couple strongly to a beam at frequencies in the vicinity of the resonance. In this area, maser materials and classical Cerenkov couplers may have overlapping interests.

Since the Fabry-Perot resonator has been used with great success in the laser, consider how this genuine physical optics structure can be used with an electron beam. A physical optics system, being in general very large compared to the operating wavelength, usually involves essentially plane waves wherein the electric and magnetic fields are transverse to the direction of propagation. For an electron beam to interact with this TEM wave, it must interact obliquely so as to obtain a component of the electric field in the direction of the beam as illustrated in Fig. 3.

The synchronism condition for the beam and the wave to maintain constant phase relationship is readily seen to be $v \cos = v_p$ which means $v_p < v < c$ for a practical case. Hence the plane wave has to exist in the appropriate dielectric medium. Assuming the electric field $\bar{E}$ and the current density $\bar{J}$ shown, the average power-per-unit length P/D delivered to the wave is $-\frac{1}{2}E_0I_0$ tan, where I_0 is the current amplitude.



CERENKOV CONE COUPLER

Fig. 2—A megavolt electronics—Cerenkov radiator employing geometric optics techniques.

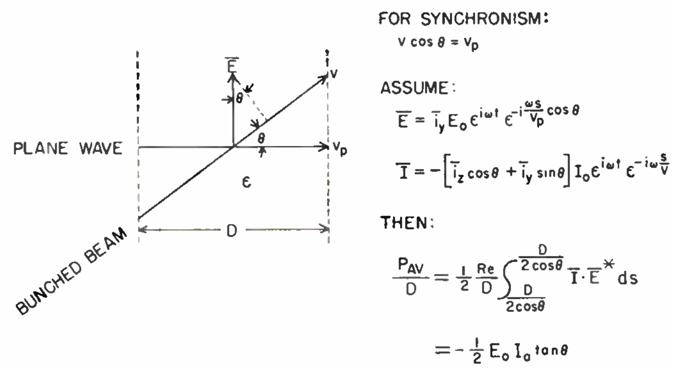


Fig. 3—Interaction of a bunched electron beam with a pulse wave at oblique incidence.

If these ideas[19] are applied to a Fabry-Perot resonator, an arrangement such as that indicated in Fig. 4 is obtained. Here the resonator consists of a large teflon cylinder of cross sectional area A and length D between two metal plates. One of the metal plates has a circular metal grating to permit the polarized radiation to be focused by a lens. Using a 14 ma, 0.88 Mev, S-band Rebatron beam, a power output of 150 mw[20] was obtained at 36.9 kMc for the condition $A=46$ cm^2 and $D=8.5$ cm in excellent agreement with theory.

A final example of the most elementary classical electronics scheme which neatly solves all the four basic problems but suffers somewhat from efficiency is the coherent radiation annihilation method[21] shown in Fig. 5. Here, a bunched electron beam of velocity $v=\beta c$ strikes a metal target where it is abruptly brought to rest and disappears. If ω_0 is the fundamental bunching frequency of the beam, I_n the current amplitude of the nth harmonic, the angle between the beam direction and a point of observation, and η the free-space impedance, then the power radiated into the hemisphere (2π steradians) is given by the expression[21]

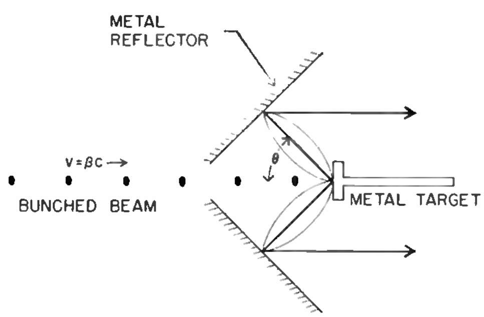

Fig. 5—Production of coherent annihilation radiation by a bunched megavolt beam.

$$P(n\omega_0) = \int P(n\omega_0, \bar{r}_0)d\Omega = \int \frac{\eta I_n{}^2\beta^2 \sin^2\vartheta}{8\pi^2(1-\beta^2\cos^2\vartheta)^2}\,d\Omega,$$

which gives

$$P(n\omega_0) = \tfrac{1}{2}I_n{}^2\left\{\frac{\eta}{4\pi}\left[\frac{1+\beta^2}{2\beta}\ln\left(\frac{1+\beta}{1-\beta}\right)-1\right]\right\},$$

where $d\Omega$ is the element of solid angle. It will be observed that the interaction resistance (term in curly brackets) is independent of the frequency. For a $\beta=0.97$ (2-Mev beam), this resistance has the value 96 ohms. If the metal target is small, power will also appear in the second hemisphere so that the resistance can be approximately doubled if so desired. In this case a current amplitude I_n of 0.1 amperes would yield 1 watt of power.

The point of the preceding selected examples is to give support to the idea that classical electronics has not reached a barrier around one mm wavelength if microwave field containment structures are abandoned.[22] What is needed is a change in viewpoint from extending techniques appropriate to one spectrum region into another spectrum region where they are not suited. It will, of course, be difficult for engineers, who live with deadlines and target dates, to venture into unknown areas filled with always expected hazards. However, it is hoped that a few hardy pioneers will make it.

Quantum Electronics

Quantum electronics might be said to have begun in 1917, not long after the founding of the IRE, with a paper by Einstein[23] on stimulated and spontaneous emission of radiation by molecules. However it was not until 1950 that knowledge and background experimental techniques, particularly in the field of microwave spectroscopy, had reached the stage where the time was ripe for various people to begin to formulate ideas[24] and proposals in the direction of molecular amplification. It required another four years before the first ammonia maser was operated by Townes[11] and associates. In 1956, the three-level, CW, solid-state maser was proposed by Bloembergen[25] and built by Scovil[26] and associates in 1957. Finally in 1960, Maiman[5] successfully demonstrated an optically-pumped, three-level, ruby maser (the laser) in the visible part of the spectrum. Thus, the last five years have seen the rapid application of basic physics principles in quantum mechanics to the problems of generation and amplification of coherent radiation. These principles, experimental techniques, and knowledge of materials had been developing over a period of thirty years.

Since the maser has been successfully operated on both sides of the microwave-infrared gap, what are some of the problems involved in covering the entire region?

First consider a three-level maser illustrated in Fig. 6(a). Energy is pumped in at frequency ν_{13} and coherent radiation produced at either frequency ν_{23} or ν_{12}. The drive power must be great enough to overcome thermal relaxation effects so that roughly[27]

$$P > Nh\nu_{13}p_{31} = Nh\nu_{13}/T_1,$$

where N is the number of molecules, p_{31} is the transition probability and T_1 the relaxation time.

Typical numbers for a microwave case are $N\simeq 4\times 10^{19}$, $T_1\simeq 0.2$ seconds, $h\nu_{13}\simeq 6\times 10^{-24}$ joules, yielding a pump power in excess of 1.2 mw. In the ruby laser $N\simeq 10^{18}$, $T_1\simeq 10^{-5}$ seconds, $h\nu\simeq 3\times 10^{-19}$ joules, yielding pump power of the order of 30 kw. Optical power outputs of this magnitude can be obtained by pulsing a flash tube at the megawatt level.

The problem of the pump frequency always being greater than the signal frequency in the three-level

[27] J. P. Wittke, "Molecular amplification and generation of microwaves," Proc. IRE, vol. 45, pp. 291–316; March, 1957.

scheme, causes some difficulty even when the system can be pumped with incoherent optical power. Suppose the wavelength of interest were 0.56 mm (*i.e.*, 10^3 larger than the 5600 A pump line in ruby). Assuming one could devise a scheme that yielded one photon out for each pump photon in, the efficiency could not exceed 10^{-3} because of the difference in energy of the photons. In practice, many other competing decay processes would occur to further reduce the efficiency.

To avoid the high-frequency pump problem, schemes such as the two-level pulsed field maser and harmonic pumping have been considered.

Fig. 6(b) schematically representes a paramagnetic material where the energy level spacing is a function of the applied magnetic field H. The idea[28] is to invert the spin population at a low-frequency ν_{12}, then increase H from H_i to H_f in a time short compared to the relaxation time and obtain oscillation at the higher-frequency ν_{34}. Unfortunately, the wavelength obtained is given approximately by the relation λ (mm) H (gauss)$\simeq 10^5$. Hence, to obtain wavelengths below one millimeter, magnetic fields in excess of 100,000 gauss are required.

To understand the idea of harmonic pumping, consider the Hamiltonian of a molecule in the presence of a radiation field. The energy will consist of three terms

$$H = H_M + H_R + H_I$$

where H_M is the energy of the molecule, H_R the energy of the radiation field alone, and H_I the interaction energy. In the typical maser case H_I is small compared to the other two terms. However, suppose in the case of the transition in ammonia at 24 kMc the energy density $E^2/2$ in the electric field is made the order of the dipole interaction energy density $N\mu E$. Let $N=3\times10^{19}$ molecules/cm³, then for $\mu=10^{-18}$ esu, the electric field intensity E equals 60 esu or 18000 v/cm. For field strength of this order, H_I will be comparable with H_R and thus lead to higher order (harmonic terms) in the perturbation theory. In effect, the belief[29] is that the maser level can be pumped at a subharmonic of the level spacing frequency ν as indicated in Fig. 7 where the third subharmonic is shown. While this scheme has not as yet been proven to work, it suffers from the problem of high input power requirements and most likely the difficulty of all practicable realizable nonlinear systems in that the efficiency of conversion to higher harmonics falls off rapidly with harmonic number.

The submillimeter maser problem is quite different from the classical electronics problem of building a tube for 5 cm wavelength after having built tubes for 10 cm and 1 cm. Much hard work remains before the maser will invade the microwave-infrared gap. Also problems of modulation and tunability of masers are very young and seeking ideas for solution.

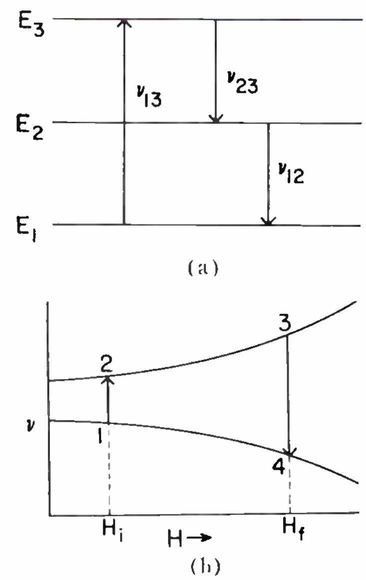

Fig. 6—(a) Three- and (b) two-level maser energy levels.

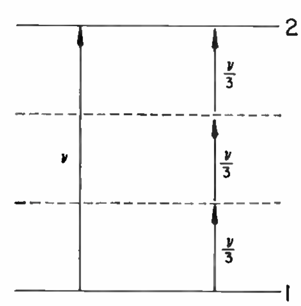

Fig. 7—Harmonic pumping of a two-level maser.

CONCLUSIONS

It was the intent of this paper to show that while rapid progress has and is being made, a real breakthrough on the microwave-infrared gap problem has not been achieved. Many difficulties still plague both the classical and quantum electronic engineer in trying to span this gap region with a coherent radiation source.

The detector problem, while not mentioned in this paper, appears to be of comparable difficulty to the source problem. In the near future, as work on sources progresses, more effort will undoubtedly have to be shifted into the detector area.

Real progress has been made on the transmission problem by Goubau[30] and associates with their beam waveguides.

Someday soon, it is hoped that a sufficient number of pieces will fall into place to permit a practical submillimeter wave system to be built. In the meantime, for those persons who enjoy a challenge, this gap region has much to offer.

Microwave Interaction with Matter*

M. L. STITCH†, SENIOR MEMBER, IRE

Summary—**The interaction between microwaves and matter is illustrated by two classes of phenomenon: those in which as a result of the interaction the microwave field loses energy, and those in which it gains energy. Among the first class, there are two ways of marking the interaction: one is by detecting the radiation, the other is by detecting the matter. The first way is explained by the technique of microwave spectroscopy, electron spin resonance spectroscopy, and optical pumping. The second way is explained by the technique of molecular beams. Then the second class is introduced by the ammonia maser. Next it is shown how the maser principle led to the solid-state maser amplifier, and how it was extended into the infrared and optical region to bring about the laser. The current state-of-the-art is illustrated by the CW gas laser and the atomic hydrogen maser. Throughout these explanations the methods by which the resolution is increased is examined.**

Introduction

THIS TOPIC of Microwave Interaction with Matter is so broad and well documented that it would be impossible to give anything but the barest statements within the allotted space if we did not restrict the range of our subject matter in some fashion. Likewise, even with a limited selection of topics if any attempt were made to delineate all the key advances together with the contributors to these advances, we should require many additional pages to list the bibliography.

Therefore, we shall limit the discussion to microwave radiation interactions that occur with neutral matter. The subject of interaction with plasmas and electron streams would be of greater interest to our colleagues of the professional groups on Nuclear Science and Electron Devices. We shall further exclude the interaction of matter with electromagnetic fields produced by high-velocity electrons such that the velocity exceeds the velocity of light in the material media; *i.e.*, Cerenkov radiation. This will be discussed by Prof. Coleman elsewhere. Within the scope of neutral matter lies ferromagnetic materials. But the subject of ferrites has been covered exhaustively in the pages of the IRE PROCEEDINGS. Indeed it has been the subject of a special PROCEEDINGS IRE issue. We shall therefore not cover this topic. We shall mention only the principal investigators who presided at the founding of a field or technique.

The States of Matter

Neutral matter, by which we mean bound electron states of matter, can exist in either the ground state or excited states. Though it is neutral, it can possess both electric and magnetic dipoles or higher-order multipoles. The mechanism of energy transfer between matter and radiation is most commonly by coupling between the electric component of the radiation field and the electric dipole, or between magnetic field component and magnetic dipole. The energy transfer may occur over a broad band of frequencies or it may be a sharp "line" resonance transfer.

If, as a result of the interaction, the microwave radiation field loses energy to the material medium, absorption has taken place and we shall classify the material as passive. If the converse is true, emission has occurred and we shall call the material active.

The transfer of energy between a radiation field and atoms or molecules which can undergo transitions between an excited state of energy E_e and a ground state of energy E_g must obey the Bohr condition on frequency:

$$E_e - E_g = h\nu,$$

where ν is the frequency. If E_e and E_g are sharp states, ν is sharply defined for each molecule, though owing to the Doppler effect the frequency "seen" by an individual molecule in motion is not necessarily that which appears on the fixed instruments in the laboratory. If E_e and/or E_g occupy a band of states, then a corresponding band of radiation field frequencies can interact with the molecule or atom.

At steady state, and at temperatures T, the ratio of atoms or molecules N_e occupying an excited state of energy E_e to those, N_g, occupying the ground state of lower energy E_g is given by the Boltzmann factor

$$R = N_e/N_g = \exp - (E_e - E_g)/kT. \quad (1)$$

Under normal finite positive temperature conditions, it is evident that R is less than one. It is then not surprising that the earliest work in the field involved an absorptive interaction.

Microwave Spectroscopy

Work on microwave spectroscopy was done by Cleeton and Williams [1] at the University of Michigan around 1934. They filled a rubberized cloth container with NH_3 gas at a slight excess over atmospheric pressure, and then directed the output of an early magnetron type oscillator on to an optical-style echelette grating of 18 elements. The reflection of appropriate order was then directed on the ammonia sample and the transmitted intensity measured by means of a thermoelectric element. The absorption vs frequency was plotted. This exhibited a characteristic peaked resonance response; the peak lay near 24 kMc, with a bandwidth at half power of approximately 12 kMc. With a Q of approxi-

† Hughes Aircraft Company, Culver City, Calif.

mately 2, this could hardly be called a sharp resonance but it was a beginning.

At the close of World War II the general availability of reasonably monochromatic, tunable, CW microwave-signal generators in the form of klystrons, invented by the late Varian brothers,[1] opened up the era of modern high-resolution microwave spectroscopy.

Three groups, working independently, set the stage for a period of intensive exploration in this field: Bleaney and Penrose [2] at Oxford University; Good [3] at the University of Pittsburgh, and later at Westinghouse Laboratories, and Townes [4] at Bell Laboratories and later at Columbia University. Like the earlier Cleeton and Williams experiment, the sample used was ammonia, and the methods used to study the interaction phenomenon was to examine the effect of the interaction on the microwave radiation.

The Good experiment will serve as an example of the technique. See Fig. 1. The microwave radiation emitted by the klystron is divided between the waveguide cell containing ammonia and the attenuator. The two outputs are rectified and presented at the input of a differential amplifier which feeds the vertical plates of a CR tube. Ideally the outputs are balanced so that at a frequency off resonance, there is no output at the differential amplifier. Then if the cell arm and the attenuator arm were reasonably nonresonant structures, and the klystron was frequency modulated by a sawtooth voltage applied simultaneously to the horizontal plates of the CR tube, any resonant absorptions in the ammonia gas would be displayed as an absorption vs frequency line on the face of the CR tube.

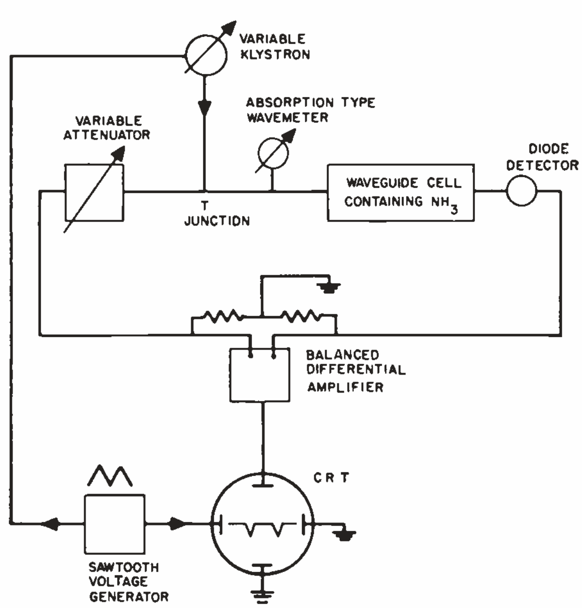

Fig. 1—Simplified block diagram of a microwave spectrometer of the type first used by W. Good.

[1] Sometime after this paper was submitted the author was saddened to hear of the accidental death of Sigurd Varian, who so follows his brother.

Attainment of Narrow Lines

This and the other two experiments were performed at pressures considerably lower than used by Cleeton and Williams. Both Good and Townes worked at under 0.1 mm Hg pressure, and Bleaney and Penrose at 0.2 mm Hg. For reasons that will be explained later, this gave very narrow lines. Indeed Townes, who was first among the three to discuss the role of saturation [4] as a line broadening mechanism, obtained in those early experiments a half-power line width of only 200 kc. This corresponded to a Q in excess of 10^5, a vast increase over the days of Cleeton and Williams.

The ammonia resonance, called an "inversion" resonance, is a complex quantum mechanical phenomena which involves the ammonia molecule turning itself inside out and will not be discussed here. However, it may be said that the resonances were sharp enough in these early experiments to detect the so-called hyperfine structure caused by magnetic-dipole interaction between the N^{14} atomic nucleus and internal molecular magnetic fields. To understand the reasons for the sizeable increase in resolution, which is to say the decrease in line width achieved by these and later experiments, we review briefly the mechanisms of absorption and line broadening.

The microwave radiation induces the ground-state molecules to undergo transition to the appropriate excited state, and vice-versa. Probabilities for such transitions are identical in either direction and are dependent on the microwave field strength. Let p be the probability per unit time of a transition in either direction; and N_g, N_e, respectively, are the molecular populations in the ground and excited states. Then by definition of probability, it is evident that

$$dN_e/dt = -dN_g/dt = (N_g - N_e)p. \qquad (2)$$

From (2) above we see that absorption of radiation and the consequent transition of molecules from ground to excited states is dependent on maintaining a net excess of molecules in the ground state. At first glance these seem to be a logically inconsistent set of conditions: a sizeable number of transitions from the ground state to the excited state should soon reduce the excess to zero, and thus eliminate absorption. The resolution of this apparent paradox is that there exist relaxation mechanisms by which the molecules return to the ground state without re-emitting energy back to the microwave field.

For gases this relaxation mechanism is provided by collisions. These serve to re-establish temperature equilibrium and reassert the population distribution between ground and excited states expressed by (1). A semiclassical way to look at this is to assume that the collisions interrupt the absorption process. Thus one has absorption given by a pulsed sinusoid with an envelope of width τ, where τ is the mean time between collisions. This leads in the well-known way to a Fourier transform with a spectral width which is reciprocal to τ. Since collision rate is proportional to pressure p, one has for line width, $\Delta\nu_p$, due to "pressure broadening,"

$$\Delta\nu_p \propto p$$

as mentioned above.

We might well inquire if one continuously reduces the pressure, where is the limit to line width? This limit is provided in two ways. First, as pressure decreases the time between relaxation collisions increases and one starts to get into the region of saturation. That is: at the center of the absorption line, where the absorption rate is the greatest, the process expressed by (2) is not sufficiently offset by relaxation with the result that the population departs markedly from the Boltzmann distribution (1), in that the excess in the ground state is greatly reduced (*i.e.*, the equivalent temperature T in (1) is increased). This reduces the absorption intensity. In the "wings" of the absorption line, where the absorption is less, this saturation effect is less and therefore the reduction in absorption intensity is less. As a result the absorption intensity is reduced mostly in the center of the line. Thus the half-power points occur at lower absorption corresponding to a greater frequency width. See Fig. 2.

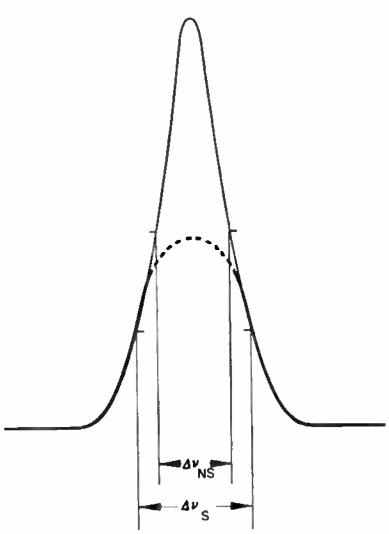

Fig. 2—Illustration of how any mechanism which decreases the intensity at the center of a resonance increases its apparent half-power width.

Saturation broadening can be alleviated by decreasing the microwave power as much as the sensitivity of the detector will allow. A second limit on line width vs pressure decrease is collisions with the walls. This can be decreased by increasing the dimensions of the sample cell or lowering the temperature. Another lower limit is set by so-called Doppler broadening. This is based on the above-mentioned fact that the rapidly moving molecules "see" different frequencies from that emitted by the microwave generator, and as the frequency of the incident wave is varied, different velocity classes of molecules "see" the appropriate frequency. From kinetic theory the velocity dependence and therefore the Doppler width is proportional to $(T/M)^{1/2}$, where M is the molecular weight. For NH_3 at room temperature $(\Delta\nu)_{Doppler}$ is approximately 70 kc. Methods which reduce Doppler width will be discussed at appropriate places.

The floodgate was opened by the early high-resolution microwave spectroscopy work. Many ingenious ways to decrease the line width and increase the resolution, to extend the list of materials which could be examined, to extend the frequencies up to millimeter waves, etc. could be chronicled. As a result of this work much was learned about molecular and nuclear parameters, collision processes, and valence theory, as well as other fields.

Electron Spin Resonance

A varient of the microwave spectrometer is the electron spin resonance spectrometer. In this device, the matter is frequently in liquid or solid form. Further this matter must be restricted to atoms or molecules in which an unpaired electron exists; *i.e.*, paramagnetic material or free radicals. The reason for this is evident from an explanation of its principle of operation. An electron in a magnetic field assumes one of two orientations. Either its magnetic moment axis is parallel or antiparallel to the applied field. The energy difference between these two states is proportional to the applied magnetic field. The resonance frequency for the transition is given by

$$\nu(\text{mc}) \approx 2.8 \times 10^6 H \text{ (gauss)}$$

for a free electron.

The presence of other contributions to the local magnetic field at a bound electron caused by chemical binding and nuclear perturbations in effect makes the paramagnetic electron a minute probe of the molecular and nuclear parameters as well as a tool for exploring relaxation processes. The technique is more sensitive at microwave frequencies corresponding to higher applied external magnetic fields than at radio frequencies. This is because $E_e - E_g$ is greater in (1) leading to greater ground population excess. Experimentally, electron spin resonance is much like microwave spectroscopy except that an external magnetic field is used. Since the microwave frequency can be fixed and the magnetic field varied, many of the problems caused by the necessity for broad-band operation of microwave spectrometers is avoided here. The higher concentrations of the condensed phase of matter increase sensitivity of this method. Early work was done by groups in the U.S.S.R. [5], the United States [6], and Great Britain [7].

Double Resonance and Optical Pumping

One problem that microwave spectroscopic techniques have is that the fractional excess of molecules is given by the Boltzman distribution of (1), corresponding to microwave frequencies and room temperatures. Thus, at K band the excess is ≈ 0.4 per cent. This excess we recall is what provides a net absorption when stimulated by the presence of resonant microwave radiation.

A technique for altering the distribution of population so as to increase the disparity between two states involved in a microwave transition and thus increase the magnitude of the microwave resonance is the method of double resonance. The philosophy here is to cause a simultaneous resonant interaction between one of the two states and a third state while observing the microwave resonance interaction between the original two. One such method involves a close lying state, a nuclear interaction state, and requires an RF signal. This method, invented by Feher [8] at Bell Laboratories in 1956, is called the ENDOR (Electron Nuclear DOuble Resonance) technique. It provides an enormous increase in resolution by permitting one to sweep the second resonance frequency. Another technique which we shall briefly describe is the method of "optical pumping" or optical orientation. This grew out of the work of Bitter [9] at M.I.T. and Kastler [10] and Brossel [11] in Paris.

For an illustration, we will make use of the simplified scheme in Fig. 3. Optical radiation at frequency ν_{23} is supplied to the system. This stimulates atoms in State 2 to absorb radiation and jump to State 3. Within $\approx 10^{-8}$ seconds the excited atoms spontaneously emit with equal probability at frequencies ν_{32} and ν_{31} which carries them in equal numbers back into states No. 1 and No. 2. The net effect of this process is to increase the population in State 1 at the expense of State 2, and so microwave absorption at frequency ν_{12} is enhanced.

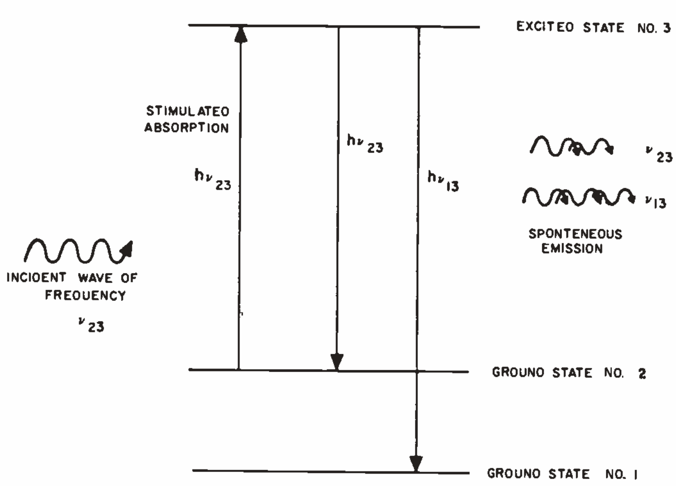

Fig. 3—Simplified optical pumping scheme (not drawn to scale, typically $\nu_{13}/\nu_{12} \approx 10^5$).

A second accomplishment of this technique is that no longer is collision required as a mechanism for relaxation since the pumping radiation maintains the population disparity and thus performs this function. If a way could be found to prevent the atoms from interacting with each other, a very sharp resonance could be achieved. Typically the atoms, alkali metal vapor, are placed in a transparent sealed container to be irradiated with light and microwaves. The pressure of the alkali metal vapor is determined by controlling the temperature of the container.

How can the atoms be isolated from each other? One must decrease the vapor density of alkali atoms until the average time between interatomic collisions is increased sufficiently. Unfortunately collisions with the container walls, which now predominate, still set an upper time limit to the length of the microwave train $\approx 10^{-4}$ to 10^{-3} sec. Not only does this give rise to undesired broadening of the microwave resonance line, but the relatively short time the atoms spend between collisions in the weak optical radiation available is insufficient to effect a sizeable population shift. In other words, the amount of population shift (sometimes called the "degree of optical alignment" or atomic "orientation" or "polarization" because the effect of optical absorption and re-emission is to transfer net angular momentum and hence magnetic moment to the atoms of alkali metal vapor) increases with the intensity of optical resonance radiation and the duration of uninterrupted (by collisions) optical absorption by the atoms.

Dicke [12] of Princeton University proposed an ingenious solution to these difficulties: In addition to the dilute alkali metal vapor at a pressure $\approx 10^{-7}$, a so-called buffer gas composed of magnetically inert atoms such as argon or helium at a relatively high pressure of ≈ 1 mm is put into the cell. The actively absorbing alkali metal atoms, too dilute to collide with each other, collide with the numerous neutral buffer gas atoms. These collisions can be shown to cause almost negligible perturbations of the state of the alkali metal atoms. As a result, the alkali metals perform a random walk and thus spend appreciable time (≈ 1 sec) in both optical and microwave radiation fields. Dicke showed further that there results a sort of "collision narrowing" in which the Doppler width is replaced by a line width due only to the finite time spent in the interaction field, *i.e.*, the Fourier transform of a pulse of duration τ.

A block diagram of an optical pumping apparatus is shown in Fig. 4. The resonance is monitored by the optical rather than the microwave radiation. An examination of Fig. 3 will make it apparent that at steady state a single photon absorption at microwave frequency at resonance is accompanied by a single photon absorption at optical frequency. Since typical optical detectors will detect of the order of an optical photon whereas typical microwave detectors require several hundred microwave photons to overcome noise, there is an enormous gain in sensitivity in optical detection. An obvious application of the foregoing technique is in the commercially available Rb gas cell frequency standard which combines better than 1 part in 10^9 stability with small size and high portability.

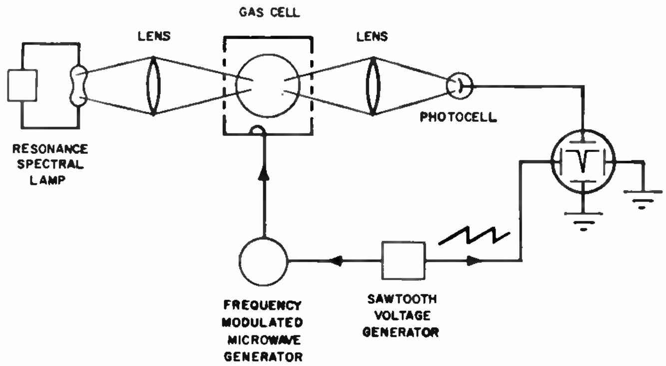

Fig. 4—Block diagram of an optical pumping double-resonance apparatus.

Molecular Beam Magnetic Resonance

Thus far we have discussed techniques in which the interaction between radiation and matter is observed by monitoring the radiation. We examine next the converse scheme in which the interaction between microwave field and matter is examined by observing some change in a property of the latter.

This work grows out of the elegant molecular beam magnetic resonance method of Rabi [13] and collaborators at Columbia University which led to his Nobel award. The molecular beams magnetic resonance method is the earliest of the precision radio frequency spectroscopy techniques and dates back to 1937. We use the generic term "molecular beam" to describe a beam of atoms or molecules.

The technique is as follows: atoms of the material, typically in the condensed phase, are sputtered out of an oven through a series of collimating slits all in a very high vacuum ($\approx 10^{-9}$ mm Hg or better). The resulting beam is composed of atoms so isolated from each other as to behave like independent particles (Rabi once said, "They are more isolated from each other than the stars."). This beam then travels along the axes of a long tube containing two inhomogeneous magnetic fields separated by an RF interaction region in which the electromagnetic fields are introduced. At the far end of the tube are some stops and a particle detector. The sketch in Fig. 5 illustrates a so-called "Flop-in" type of apparatus. Being a magnetic resonance, the property which changes at resonance is the magnetic moment. The first and second inhomogeneous fields deflect unchanged atomic states in the same direction into a stop. The atoms which have flopped are refocused into the detector.

The method of atomic beams requires no relaxation processes to maintain a steady state because the atoms involved in the interaction are constantly being replaced by fresh ones. This is why they may be isolated from each other. If the microwave field is so arranged that its propagation vector is normal to the beam path, Doppler broadening is minimized. Once again as in optical pumping one can conceive of the line width as being inversely proportional to interaction time. The

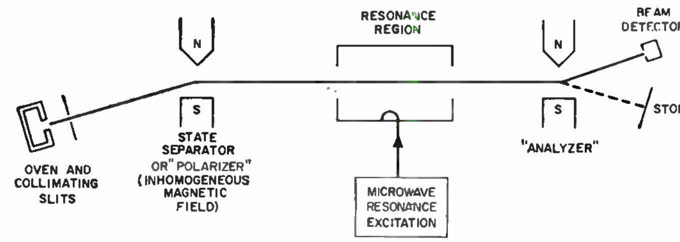

Fig. 5—Atomic beam apparatus.

first use of the conventional magnetic resonance methods at microwave frequencies (*i.e.*, greater than 1 kMc) was made by groups at Columbia [14] and M.I.T. [15] using the so-called weak field $\Delta F=1$ Hyperfine interaction of atomic hydrogen.

In addition to its use as a spectroscopic tool of enormous resolution and sensitivity, the molecular beam with Cs source leads to an X-band microwave resonance line. This has been embodied into a sophisticated frequency standard with a long term stability of the order of 1 part in 10^{11} and sold by one company as an off-the-shelf item!

A particular application of an atomic beam magnetic resonance at microwave frequencies up to 10 kMc was actually used earlier in a brilliant experiment by Lamb [16] and Retherford that led to a Nobel award for Lamb. Technically, one can call this a spectroscopy experiment in that transitions between the metastable $2S_{1/2}$ state and excited P states of atomic hydrogen are observed in a magnetic field. However this is somewhat analogous to calling the development of the nuclear fission bomb an experiment in collision cross sections. For one thing the experiment produces and detects metastable $2^2S_{1/2}$ hydrogen atoms which had not been isolated in a clear cut manner previously, let alone stimulated into magnetic resonances. Space does not permit a recounting of this specialized experiment beyond saying that it had a profound effect on the development of theoretical physics.

Active States and the Maser Principle

At this point we note that both microwave spectroscopy and the molecular beam resonance method deal with passive matter and microwave absorption. However for optical pumping this is not necessarily so. It is apparent from Fig. 3 that if the pumping transition were initiated from ground state No. 1 instead of No. 2 there would be an excess in State No. 2, and the microwave transition would envolve stimulated emission rather than absorption. But the optical transition is still an absorptive one.

If it were possible to obtain a sufficient population excess in an excited state, the fact that stimulated emission is always exactly in phase with the excitation should make it possible to obtain a molecular amplifier, and by feeding back the amplified radiation one should obtain a molecular oscillator.

This was first mentioned in a public meeting by A. H.

Nethercott on behalf of C. H. Townes of Columbia at a Symposium on submillimeter waves at the University of Illinois in May 1951. The first report in print was the proposed design of a beam type device in the Columbia Radiation Laboratory Quarterly Progress Reports of December 31, 1951, by Townes and associates. Successful operation of this device was reported by Gordon, Zeiger and Townes [17]. Independently Weber of the University of Maryland proposed a device at the IRE Electron Tube Confe.ence in Ottawa in June 1952 and published his discussion [18] in 1953, but never published any claims for successful operation of this device. Also independently, Basov and Prokhorov [19] of the Lebedev Institute, Moscow, gave some designs for a beam type device.

The Townes device was called a MASER (Microwave Amplification by Stimulated Emission of Radiation) and made use of an electrostatic state selector acting on a beam of ammonia molecules. To understand its operation, consider a uniform beam of excited ammonia molecules going through a microwave cavity. If the losses are low enough, the time in which the microwave fields and ammonia particles interact long enough, the excited population of the beam dense enough, and the coupling between the microwave field and particles strong enough, the amplification from noise at the resonant frequency will be sufficient to overcome losses, and regenerative oscillation will occur. This can be restated succinctly by the following relation.

Condition for oscillation:

$$(Q)(L/V)(\rho)(\mu^2) = \text{a certain constant},$$

where Q is the cavity Q, L is the cavity length, V is the mean beam velocity, ρ is the mean beam density, and μ is the molecular dipole moment. Since it has received widespread publicity and is probably familiar to most of the scientific community, we will save space by omitting an illustration of the NH_3 maser.

The main reasons that an optically pumped Rb, say, gas cell will not go into maser oscillation is that μ for the magnetic dipole transition of Rb is several orders of magnitude smaller than μ for the electric dipole transition for NH_3, and ρ for the gas cell must be kept low enough to prevent complete "screening" of the volume of gas due to the enormous cross section for optical resonance photons.

The gas maser oscillator possesses the highest short term stability ever obtained at any radio frequency. Because it is an amplifier that does not suffer from the noise due to charged particles, the maser is capable of very low noise when used as an amplifier. The use of gas beams with their sharp resonances and low densities rules out much amplifier bandwidth. The hope for reasonable bandwidths and power has required a solid-state maser.

The first sold-state system which could operate continuously was proposed by Bloembergen [20] of Harvard University. It has a three-level system similar in function to the optical pumping scheme of Fig. 3, and one of his proposed materials was soon made to operate. The use of an external magnetic field to obtain the ground state splitting of the maser materials allowed construction of tunable maser amplifiers. The noise figures were so close to 1 that it became fashionable to use equivalent noise temperatures to describe the noise. Noise temperatures so low that a few microwave photons can be detected have become commonplace, and maser amplifiers have become commercially important in radio astronomy, tracking systems, proposed space communication systems and wherever extremely low-noise amplification is needed.

The Laser

One of the most spectacular achievements of the kind of conceptualizing that produced the maser was ushered in by the appearance of a paper by Schawlow and Townes [21] late in 1958 proposing masers that would operate at optical and infrared frequencies. They included some detailed calculations on general design considerations and operating characteristics as well as on a particular system using potassium vapor.

They proposed the use of a multi-mode cavity with strong mode selection by means of a pair of Fabry-Perot plates. The normally reflecting mode has the highest Q, builds up the quickest, and selectively robs all competing modes of excited population in stimulating emission. Because of the highly directional plane wave emitted the fractional amount of spontaneous emission, which is omnidirectional, is quite small within the highly directional beam output.

A later paper by one of the authors [22] suggested the use of a red ruby rod with optically flat parallel faces, one partially silvered, the other entirely silvered. It would operate at low temperature in a 4-level scheme, in which the pumping is between the ground level and the top level, actually a band of levels that will accept a wide band of pumping illumination in the green region of the spectrum. The stimulated emission would be between the 2nd and 3rd states. In 1961 Schawlow actually got the red ruby scheme to work, although experimental difficulties have at the time of this writing prevented the potassium, or other optically excited alkali-metal-vapor systems, from working.

After the original Schawlow-Townes paper a widespread competition was set off to get the first operational laser as many called it (for Light Amplification by Stimulated Emission of Radiation). The honor for the first successful operation of a laser went to Maiman [23], then at Hughes Aircraft Company, who used a low Cr ion concentration pink ruby in the main fluorescent, R_1 line, for a brute-force 3-level scheme of operation that required the pump to transport more than half the population out of the ground state for laser action. This was because the ground state was the terminal state for the stimulated emission. Maiman was able to get 10 kw bursts of radiation at 6943 Å in the deep red!

He used for his pump an intense source of light, a Xenon flash tube excited by a capacity discharge of over a thousand joules at a rate of several megowatts. (See Fig. 6.)

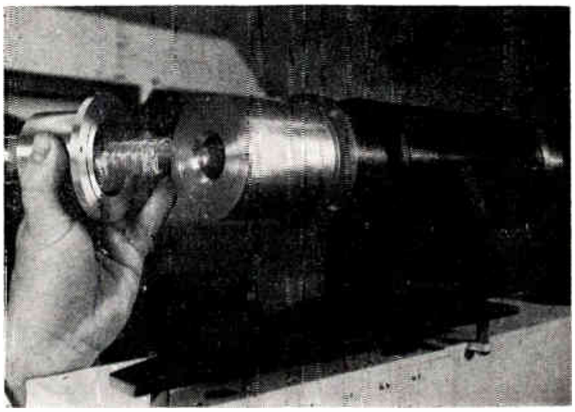

Fig. 6—Ruby laser showing flashtube and ruby.

The chief virtue of the ruby laser is that it is a brightness intensifier. At the typical current state-of-the-art it emits a highly collimated beam whose brightness is approximately 10^6 times that of the flash tube which excites it. If one takes account of the monochromaticity, the brightness per unit wavelength (or frequency) is approximately 10^{11} times that of the exciting flash tube.

The coherence property of lasers is more strikingly demonstrated in a CW gas laser first proposed [24] and later built by A. Javan and collaborators at Bell Laboratories. The technique was to use a mixture of two gases, helium and neon. The first gas is excited by electrical discharge and transfers its energy to the second gas. This device worked in the near IR region at approximately 1 μ and delivered approximately 15 mw power in a beam of a few seconds of arc angular width and with a line width under 1 kc! The equivalent Q here is greater than 3×10^{11}!

The applications which await the successful development of a high-power, monochromatic CW or controllable pulse laser are enormous. Likewise the development of a tunable IR frequency laser, will be of great value to the spectrographic study of chemical reaction parameters.

The Hydrogen Maser

The ammonia beam type maser, too, has evolved to the point where an atomic hydrogen beam maser, using the storage box techniques first proposed by Ramsey [25] of Harvard, has been made at that University. In this technique the resonant cavity contains a coated quartz bulb. The hydrocarbon coating does not quench the interaction between the active atoms and the microwave field in the cavity for a comparatively long period (though it may perturb the frequency slightly). Ultimate absolute precision could be as high as one part in 10^{14}—with even higher short-term stability. And this device could be of great value as an active frequency standard.

The Early History of Radar*

R. M. PAGE†, FELLOW, IRE

***Summary*—Five basic ideas are identified, the combination of which consitutes radar. A clear distinction is then made between this combination of ideas, the contemporary technology from which it grew, and the contemporary scientific knowledge on which it was based. The mainstream of the development of radar is traced in a sequence of related events from 1922 to 1941. The technical problems encountered and the solutions employed in the first radar development are outlined in some detail. Two sidestreams of radar development are identified. The relationships among the three streams are discussed.**

TECHNOLOGICAL innovation grows out of contemporary technology, which in turn rests on the research and scientific discoveries of an earlier day. Only when clear distinction is made between innovation, contemporary technology, and contemporary scientific knowledge can lines of interdependence be meaningfully drawn.

The combination of five basic ideas constitutes the innovation which is radar. They are 1) that electromagnetic radiation at high radio frequency be used to detect and locate remote reflecting objects, 2) that the radiation be sent out in pulses of a few microseconds duration, separated by "silent" intervals very many times the pulse duration, 3) that pulses returned from reflecting objects be detected and displayed by receiving equipment located at the point of transmission, 4) that distance be determined by measuring in terms of an independent time standard the time of flight of pulses to "target" and back, and 5) that direction be determined by use of highly directive radio antennas.

We first identify the scientific knowledge underlying these ideas. Faraday and Maxwell had established the theoretical possibility of the electromagnetic field. Hughs had demonstrated its existence at radio frequency. Hertz had demonstrated that radio waves behaved as light waves, obeying the known laws of propagation and reflection. Appleton and Barnet had demonstrated that radio waves could be used in interferometer fashion to determine apparent height of the ionosphere. Their method used phase velocity to measure the difference in length of two propagation paths. Swann and Frayne had suggested and Breit, Tuve, and Taylor had demonstrated that radio waves could be used to measure ionosphere height by observing the relative flight time of pulses of radio transmission. Their method used group velocity to measure the difference in length of two propagation paths. Various experimenters in radio, including Breit and Tuve of the Carnegie Institution, working with ionosphere measurements, engineers of the British Post Office working with short wave radio, and engineers of the Bell Telephone Laboratories working with television, had observed that aircraft flying near their receivers or transmitters created noticeable disturbances in the radio propagation field. This was regarded merely as interference with their experiments, and otherwise ignored. These constitute the elements of scientific knowledge basic to the idea of radar. Since radar was not in any way an objec-

* Received by the IRE, August 8, 1961.
† U. S. Naval Research Laboratory, Washington, D. C.

tive in the discovery of these facts, since no problem was recognized for which radar was the proposed solution, and since radar was only one of many technological innovations dependent on these same scientific discoveries, it is not proper to ascribe to any of the named discoverers any responsibility for the origin of radar by virtue of their discoveries.

Our next step is to identify the contemporary technology out of which radar grew. A catalogue of the state of the art in radio engineering in the 1930's would be both tedious and superfluous. Certain elements have a degree of specificity to radar, however, and require special mention. The cathode-ray tube, devised by the German scientist Braun in 1897 and used on an experimental basis in the early 1920's, became generally available as a laboratory tool in the early 1930's. In 1900 Nikola Tesla suggested the use of electromagnetic waves to determine relative position, speed, and course of a moving object. In 1903 Huelsmeyer applied for a patent in Germany on an anti-collision device for ships, based on directive transmission and reception of continuous waves at very short radio wavelength. Transmitter and receiver were shown on the same ship, but separated as widely as possible. In June 1922 Marconi again suggested the use of radio as an anti-collision device. In 1923 Loewy filed a patent application in the U. S. Patent Office for a radio object detector employing the Fizeau principle. The transmission consisted of chopped CW, with approximately equal intervals on and off. A target would be detected when its reflection coincided with the intervals between transmission. While Loewy's disclosure appears at first to anticipate radar, it fails to meet the requirements for radar, since range indication is ambiguous, and the presence of one target would jam the system for all other targets. Thus it gave no operational advantage over Huelsmeyer, except the possibility of locating transmitter and receiver close together. In 1925 Breit and Tuve proposed a radio pulse method, which they credited originally to Swann and Frayne of the University of Minnesota, for probing the ionosphere. In cooperation with Taylor, Young, and Gebhard of the Naval Research Laboratory the method was used for the first time in that same year. Although this has been said to demonstrate the basic principles of radar, it fails to meet the radar criteria on several counts. The pulses were much too long, being about half a millisecond. This would blank out the first 50 miles of range. The ratio of pulse spacing to pulse duration was too low, being only four or five, therefore subject to saturation by a very few targets. The receiving equipment was not at the point of transmission, so time of flight of radio pulses to target and back could not be measured in terms of an independent time standard. Only the difference in length of two propagation paths was measured, and direction was not indicated. These deficiencies from the radar viewpoint were imposed by the state of the art in 1925. They detracted nothing from the excellence of the method or the apparatus for probing the ionosphere. In 1930 patent applications were filed by Wolf and Hart for a radio pulse altimeter. The disclosures were based on the technology of the ionosphere probe, and were therefore subject to some of the same limitations. No development of radar apparatus resulted from these disclosures. In November, 1933, Hershberger (U. S. Signal Corps) proposed a method essentially similar to that of Loewy and then did some work on microwave generators in a vain attempt to obtain the power required for useful echoes. In 1936 the French liner Normandie was equipped with a microwave anti-collision device similar to that of Huelsmeyer.

It is now obvious that contemporary technology contained much that was suggestive of radar. However, none of the art described contained all five elements necessary to radar, and no radar development resulted from any of it. It is therefore inappropriate to trace the development of radar to any of these proposals or related developments.

The first incident that led ultimately to radar was the accidental observation by Taylor and Young in September 1922 that a ship interrupted some experimental high-frequency radio communication across the Potomac when it intercepted the propagation path between transmitter and receiver. Taylor and Young had for many years been employed by the Navy, and were keenly aware of the problem of screening Naval forces from penetration by other ships in darkness and fog. Though the observation was unrelated to their experiment, the application was obvious to them, and they immediately proposed that high-frequency radio transmitters and receivers be installed on destroyers to detect the passage of other ships between any two destroyers in radio contact. Obviously this was not radar. It did not even involve reflection of radio waves, and was in no way related to Marconi's suggestion, as has sometimes been inferred. It is identified with radar here only because Taylor and Young later originated the first radar development project, and this incident started them thinking in terms of detection of moving objects by radio.

The second incident was another accidental observation, this time by Hyland, a colleague of Taylor and Young. During experiments on high-frequency radio direction finding in June 1930, he detected a severe disturbance of the propagation field by an airplane flying overhead. Hyland was also an experienced Navy employee, and was sensitive to the potential threat of military aircraft and the need for warning devices against them. The observation again was unrelated to his experiment, but the application was obvious, and he immediately proposed that high-frequency radio be used for aircraft warning.

On Taylor's recommendation a project was established at the Naval Research Laboratory in January 1931 for "Detection of Enemy Vessels and Aircraft by Radio." Work on this project continued for several years. The "beat" method was employed, in which transmitter and receiver were widely separated and shielded from each other, transmission was CW and reception observed the fluctuating signals, called "beats," when an airplane flew through the radio propagation field. Detection ranges of 40 miles were obtained in these experiments.

The required wide separation of transmitter and receiver precluded the use of the beat method on ships and limited its usefulness to the protection of large land areas such as cities and military bases. Since this was exclusively the responsibility of the Army, it was proposed in January, 1932, that the Army take over the development for its use in that function. Subsequently, Navy interest in the problem lagged until Young suggested to Taylor that the pulse method be tried. Young's proposal combined for the first time all five elements essential to radar. Ultimately, Taylor accepted the proposal and assigned to the author, working under Young's supervision, the task of developing pulse radar. The author's work on this task was started on March 14, 1934.[1]

The first step was to develop an indicator to display the outputs of transmitter and receiver. A suitable sweep circuit was built for a commercially produced 5-in cathode-ray oscilloscope. The next step was development of a pulse transmitter. The transmitter frequncy of 60 Mc was chosen because that was the frequency then used in the beat method. Pulse length was slightly under 10 μsec, and pulse spacing, 100 μsec, these being chosen as appropriate experimental values. The keyer was an asymmetric multivibrator. The antenna was a single half-wave horizontal doublet with a single resonant reflector. The pulse power was estimated to be between 100 and 200 w. The first question to be resolved was whether echo pulse energy could be detected during the intervals between transmitted pulses, since synchronous detection, characteristic of the beat method, was known to be more sensitive than asynchronous detection, characteristic of the pulse method. Autocorrelation and crosscorrelation were unheard of in those days, and the trade-off between time and bandwidth disclosed by Hartley,[2] as well as the significance of average energy were not too well understood. The only sure recourse was to try it, and skepticism was great. A broad-band high-gain experimental communications receiver was borrowed and connected to a second antenna similar to the transmitting antenna. Coupling between the two antennas was appreciable, and the transmitted pulse caused the receiver to ring for 30 to 40 μsec. However, when a small airplane flew across the beam at a distance of about a mile, the received signal caused the receiver output following the transmitted pulse to fluctuate violently between zero and saturation. This test was completed in December,

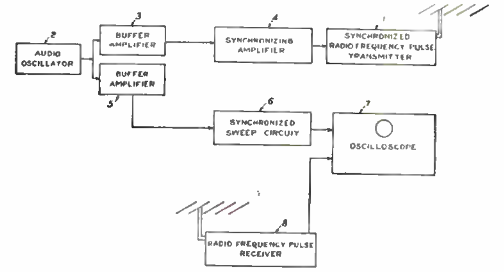

Fig. 1—Block diagram of radars operated in 1936. The block diagram for the radar tested in December, 1934, was similar to this one.

1934. Although synchronous detection prevailed due to the transient ringing of the receiver, the great amplitude of the response left no doubt that an asynchronous detector would also have responded to the reflected pulse. The result was accepted as evidence that echo signals could be detected during the intervals between transmitted pulses, and development of a superior radar receiver was immediately undertaken.

Radar imposed four severe requirements on the receiver which were not encountered in conventional receivers of the time. Close proximity of receiver and transmitter subjected the receiver to paralyzing overload, from which recovery to full sensitivity in the incredibly short time of a few microseconds was mandatory. The first design requirement was to eliminate grid blocking. This was achieved by using a tuned grid circuit with the grid returned to the cathode through the tuning coil. Grid coupling capacitance was then reduced to a minimum by using maximum inductance to capacitance ratio in the tuned circuit, and loading the tuned circuit to the proper Q value with the driving plate resistor.

The second design requirement was to minimize the ring time of tuned circuits from the transmitter-induced high signal level. This was achieved by returning grids to cathodes without bias, thus limiting the level to which the circuits could be driven by the transmitter.

The third requirement was fast response to amplify the short pulse echoes. This meant tailoring the Q values of all tuned circuits so that the composite Q of the receiver would match the pulse length. This was accomplished with the help of the appropriate equation published by Mesny.[3]

The fourth requirement was complete absence of regenerative feed-back in the presence of high gain. A communication receiver of that day was considered stable if it did not oscillate. Equivalent Q, however, is a sensitive function of feed-back, and response characteristics are readily altered by feed-back long before the point of oscillation is reached. This requirement was met by using a superheterodyne receiver, limiting volt-

age gain on any one frequency to one thousand, and changing intermediate frequency as required to accomplish an over-all voltage gain on the order of $10.^7$ In addition, extreme precautions were taken in shielding, filtering, and common point grounding.

The receiver was intended for a 5-μsec pulse. The over-all response was 90 per cent of steady state in 5 μsec. This characteristic was independent of gain up to the point where thermal noise at the input filled the cathode-ray screen.

A new transmitter of the self-quenching or "squegging" type was built to go with the new receiver. The transmitting antenna was a 4×4-wavelength curtain array with resonant reflector. The receiving antenna was a single half-wave doublet with single resonant reflector. The frequency was 28.6 Mc, with pulse length of 5 μsec and pulse recurrence rate of 3720/sec giving a range scale of 25 statute miles. The system went on the air in April, 1936. The receiver recovery to full sensitivity following the transmitted pulse appeared to be instantaneous. Beautifully sharp echoes from aircraft were observed almost at once, and within a few days they appeared all the way to the 25-mile limit of the indicator.

The spectacular success of the experiment was followed by a greatly intensified effort. A primary objective was to reduce the size of the equipment so it could be used on ships. The 28.6-Mc antenna was about 200 ft square. Reduction in directivity of antenna pattern was not desired. A smaller antenna therefore meant higher frequency. On July 22, 1936, a small radar was put in operation on 200 Mc. In that same month the first radar duplexer was successfully tested, also on 200 Mc, enabling both transmitter and receiver to use the same antenna. These two quick developments made it

possible to put radar on a ship for tests at sea. The first seagoing radar tests were made in April, 1937, on the USS *Leary*, an old destroyer of the Atlantic Fleet. The success of these tests led to the development of the model XAF, designed for Naval service at sea. Extensive tests on the USS *New York* in 1939 disclosed operational values beyond all dreams. The XAF was made prototype for the model CXAM, which was in service on 19 ships, the only U. S. Naval radar in service on December 7, 1941. It made an excellent wartime record.

This is a brief outline of the main stream in the early development of radar, resting on a sequence of related events from 1922 to 1941. Up to the summer of 1935 it was a single stream. At that time two other streams started, both remarkably parallel to the main stream. The one in England, sparked by the proposal of Watson-Watt in February, 1935, and conducted under the aegis of the Royal Air Force, was completely independent of the American developments until 1940, at which time the two countries pooled their resources. In the technological trade, America gained the uniquely-British cavity magnetron, and Britain gained the uniquely-American duplexer. The trade was not as one-sided as may have been inferred in some of the postwar literature. The pooled resources formed the technological capital for the newly-formed National Defense Research Committee in the superb development of microwave radar by the Radiation Laboratory of the Massachusetts Institute of Technology. The other stream, in the U. S. Army Signal Corps, sparked by the dynamic leadership of Colonel Roger B. Colton, was independent in part, but received much stimulation, both competitive and cooperative, from the more advanced work of the U. S. Naval Research Laboratory. It is one of the most remarkable coincidences in history that the three streams of radar development, operating more or less independently, issued in three vital but non-overlapping employments, each requiring basically different designs. At the war's beginning the finest mobile ground-based radar came from the U. S. Army Signal Corps, the finest airborne radar came from the Royal Air Force, and the finest Naval radar came from the U. S. Navy.

The Impact of Missiles and Space on Electronics*

SIMON RAMO†, FELLOW, IRE

Summary—**The ways in which government-sponsored research and development and procurement have influenced electronics in the U.S.A. are discussed. It is concluded that missiles and space have moved to first place in impact on technical advance, industrial organization, and industry-government relations. Major changes have taken place, as a result of these programs, on both technical and administrative fronts, with many unsolved problems remaining in adjusting to the coming expanding missile and space programs.**

In the last two decades, the single most important influence on the electronics profession and industry has been government-sponsored development and production. In more recent years, the fields of guided missiles and space technology have become the most significant areas of military or peacetime government sponsorship. Hardly any organization dealing with the electronics field remains untouched either directly or indirectly by the nation's guided missile and space programs.

This is especially true of everything that is new. The missile and space requirements have pushed the art so rapidly, and technological obsolescence has been so quick, as almost to preclude the attainment of a base of stabilized products. This newness factor has been so dominant, in fact, that a large fraction of the entire electronics industry seems to have been transformed from production activities, for which a good many of the groups were founded, into research and development operations.

This article will call out some of the ways in which the advent of guided missiles and space technology projects have already influenced the electronics field and will indicate something of the likely future trends.

Broad Technological Advances

The missile and space programs have had behind them a sense of urgency previously unknown in the United States in peacetime and an allocation of resources that have made possible parallel attacks on virtually every frontier of electronics research and electronics design engineering. The requirements of missiles and space have been such as to force effort on seemingly every technical front that previously limited what could be done. The research has yielded new answers, and ingenuity has reached new heights. Thus, the requirements, though severe, have been met by the expanding state of the art.

Missiles and space technology have required generation and reception of power over the entire conceivable frequency spectrum of use in communications and control. Power outputs have risen and signal-to-noise ratios have been improved. Decreases have taken place in sizes and weights. Broader bands have been handled. Directivities have been increased. Virtually every determining physical parameter setting specifications for designs has involved higher precisions and higher rates, while all the time the complexity has been growing by leaps and bounds.

With the increase in complexity, accompanied by the new habit of working with devices born yesterday but applied on a crash basis today, reliability problems have assumed a new position. While old lessons were relearned by a wave of new young inventors and designers, an increasing array of devices has nevertheless quickly attained reliabilities that would not have been considered likely a few years back.

The severe requirements of the missile and space program could not have been met by careful or even inspired design if based solely on the physical principles available in the 1940's. There had to be a tremendous effort to achieve a more fundamental knowledge of the physical science underlying electronics engineering requirements. The solid-state field, for example, has expanded largely because of the mass attack on this field made possible directly and indirectly by the accelerated military support for all of electronics. Microwave techniques, given their first great acceleration by the radar work of World War II, have received a vigorous second wave of expansion.

To be sure, an urgent specific requirement cannot and did not trigger fundamental discoveries. But it is usually a long, hard road between such early basic conceptions or experiments and the attainment of practical and useful end results in the numerous forms required to have a major impact on engineering. Parallel and broadly-based attacks on a large scale, once a new approach appears to have promise for solving an important problem, have in the case of the missile and space field provided the accelerated time scale needed.

Electronics research has been expanded from emphasis on the physics that deals with a stream of free electrons in vacuum to the whole range of possible electrical effects in any form of matter right down to the nucleus of atoms—this, as the quest for ability to generate, amplify, and otherwise control electrical effects over a broader range of levels of power and spectrum of wavelengths, and with increasing precision and control, has continued to develop.

* Received by the IRE, August 7, 1961.
† Thompson Ramo Wooldridge, Inc., Los Angeles, Calif.

Similarly, the comparatively narrow role of the electronics engineer in providing a means for communicating intelligence between points, either by wire or unguided electromagnetic waves, has broadened to embrace the full implications of the concepts of control of automated or semiautomated systems. While "communications" still is at the bottom of all that the electronics engineer does in one sense, the notion of what communications is understood to mean has been enlarged. In such examples as operational intercontinental ballistic missile systems, a myriad of men and machines over a wide geographical span are tied together in a complex web of interrelationships and made to work as a harmonious ensemble as a result of the efforts of the electronics engineer.

The match between the urgent needs and the potentialities of recent scientific discoveries has often caused it to be true in missiles and space that new discoveries in physical science are put into almost immediate use, often without time for the digesting of the phenomenon before its application becomes serious. The maser and the broader molecular and atomic resonance phenomena of which it is a part represent an example of this. Electronics engineering always has been closely related to physical research in electronics, and indeed such organizations as the Institute of Radio Engineers always have had a large representation from individuals who think of themselves as "physicists" rather than as "engineers." However, this interrelationship between the engineering and the physics of electronics has become closer.

In electronics engineering today, a larger fraction than ever of the individuals involved were trained as physicists. Most think of themselves as interested in basic underlying physical science rather than in design and application. Actually, of course, in the sense that most of it is so soon applied, most of the group can also be considered as engineers, with the variation only in the degree of formal training and interest in the physical science as against the design of systems using that science. So broadly confused has this interrelationship between science and engineering become that the newspapers tend to refer to all engineers as scientists, even though most of the time the projects to which the public gives its attention are clearly engineering projects, such as lunar vehicles or intercontinental ballistic missiles. Moreover, in almost every university today there is soul searching between the electrical engineering department (now mostly electronics) and the physics department (now at least half electronics, space, solid state, or nuclear resonance) in an effort to understand how they should differ from one another.

Miniaturization and Environmental Engineering

The days are gone when the average electronics engineer can play with circuits alone, disregarding many other aspects of over-all design. Electronics engineering, mechanical engineering, heat transfer engineering, and materials engineering have come together more strongly and have required a more unified design effort as a result of the impact of guided missiles and space. This has often been manifested in the need for major decreases in size and weight of electronic subsystems and components.

While in most guided missile and space vehicle systems the electronics—the "brain" and "nervous system" of the whole beast—constitutes a very small fraction of the total size and weight, the burden for miniaturization nevertheless falls heavily on the electronics engineer. There are several reasons for this.

One is that, in general, the electronics equipment of all airborne or spaceborne systems must go to the "end" while, in contrast, a good deal of the initial weight, notably fuel and oftentimes major portions of the propulsion system, will have been exhausted and purposely dropped along the way to lighten the load. The guidance and control must be present to the last moment where any unnecessary weight exacts a severe penalty.

Another reason for the emphasis on miniaturization of electronic equipment is that it *can* be miniaturized, and any weight that can be saved must be saved. If the art simply will not yield a smaller propulsion system but will yield a smaller guidance and control system, then at least the latter miniaturizing should be done.

In space missions as well as in intercontinental ballistic missiles, there is a fairly direct relationship between the size of the initial booster thrust, which is today a limiting factor, and the size of the final payload, much of which involves electronics gear.

The complex and numerous detailed and sophisticated tasks performed by electronics equipment in guided missiles and space vehicles could not have been seriously contemplated without the major subminiaturization programs and the beneficial results so attained; that is, by the means and components available ten years ago, the equipments that would have been required on board for a typical complex missile or space mission realizable today would have weighed so much more than could have been lifted by a realizable propulsion plant that the whole project could not have been seriously contemplated. The reductions in size and weight attained by the advances in electronics have made possible the project of today.

Computers and Simulators

A large fraction of today's electronics industry is interested in computers, including computers for commercial uses of all kinds as well as for military applications. If one looks carefully at the history of the development of a large-scale computer during the last ten or fifteen years, the impetus given to these developments by military sponsorship becomes evident.

Every missile and space system uses computers. Also, with a large fraction of the industry being in defense, and a large fraction of the defense industry using computers for engineering designs, every missile and space program supports large-scale computer installations. The making of engineering calculations on them and the programming of the computers, in addition to the use of computers directly in the weapons system as ground or vehicle equipment, constitute a large fraction of the total effort.

It would have been out of the question for us to have attained so quickly an intercontinental ballistic missile of proven design such as the Atlas had we not been able to extend the capabilities of the engineering design team by large-scale computers. Actually, only a few dozen full-scale flight tests were required to completely prove out the design in every way. This is, however, because the equivalent of tens of thousands of flights were made by computers in the laboratory. This simulated flight-testing selected, from the infinity of possibilities, a reasonably optimum ensemble of design parameters in a short time. The almost trial-and-error approach that would otherwise have been needed would have had us flying missiles in test after test for many, many years before a design could have been settled on and confirmed.

Of special importance is the relationship between the techniques involved in the handling of information in the computer elements and the process of communication. These two separate fields of electronics engineering have come together in theories that start from basic new concepts of information itself, its quantitative measure, storage, transfer, and processing. To a considerable extent, it is because of the missile effort that the electronics industry is heavily concerned not only with communications, but with every facet of information, including its derivation and its use, for control of a system of equipment and men.

Systems Engineering

Systems engineering—the design of the entire complex of men and machines as against the detailed design of its parts, and the specifying of the individual parts of the over-all so that in combination they will yield the performance desired—is an old facet of engineering. However, in recent years, the term "systems engineering" has taken on broader meaning and greater usage. This is in part because a larger fraction of the engineering body is concerned with the design of the whole as distinct from design of the components, this in turn, as the projects become larger and more complex, with greater interactions.

This expansion of systems engineering has been especially important in guided missile and space phenomena. Moreover, electronics engineers have had a larger hand in systems engineering than have engineers coming from other specialized branches of the whole. This, of course, is natural, because the electronics engineer deals with the intelligence flow throughout the system that ties it together and that has more of a unifying effect on the working of the whole than does, let us say, the propulsion or aerodynamic aspects of a guided missile, or the structural aspects of a space probe. In a sense, the electronic aspects of a project cannot be so easily compartmentalized; electronics is everywhere.

When a large number of people and machines are tied together, we find major problems of over-all stability, unwanted mode possibilities, feedback loops (unavoidable as well as intended), and the accumulation of errors that affect the operation of the entire system. These are, of course, very close to the traditional fields of the electronics engineer in communications, with error accumulation problems very similar to the customary signal-to-noise ratio problems, and with the stability and unwanted mode problems similar to the stability and oscillation problems of typical electronic feedback circuits. Thus, while the over-all problem of systems engineering of a guided missile or a space system involves all fields in addition to electronics, the electronics engineer has a larger fraction of the background and tools needed for the integration engineering.

The electronics engineering fraternity also has a larger fraction of the broader trained physicists who are accustomed to dealing with more difficult conceptual matters and the wider range of science fundamentals applicable in common to all branches of engineering. When one attempts to predict and understand the performance of a large complex system, that is, in effect to try to write its laws and then set up experiments to understand and confirm laws of behavior, the problem is not unlike that of tackling a new branch of nature to bring the level of understanding up to the quantitative point. This, in effect, is the work of the physical scientist.

The analysis of complex ensembles of equipment and people often requires a major emphasis on the use of computers and simulators. Here, again, the electronics engineer is more prepared. The electronics engineer, always closer to physics and mathematics than those in most other areas of engineering, but especially more familiar with the use of electronic tools as represented by the electronic computer, was able to take up the difficult systems engineering problem more rapidly than his fellows.

Large-scale systems analyses often have to be handled on a statistical basis. Random phenomena and statistical techniques are more familiar to the electronics engineer, from his basic noise and modulation experience, and to the physicist, the adopted member of the electronics engineering team, from his basic training in modern physical theory.

For these various reasons, then, the electronics engineer has become the most influential systems engineer, on the average, in the guided missile and space programs. This, in turn, has affected the nature of electronics engineering, the training for it and the way it is practiced, and has influenced the nature of the industry as well as the professional groups. Partially, that is, systems engineering and electronics engineering seem almost to have become synonymous, with the well-trained electronics engineer and the broadly-based electronics engineering organization being one that is capable of handling integration. By contrast, other specialized engineering groups are less inclined to branch out and provide the competence to handle well the systems engineering job.

Industry Organization and Industry-Government Relationships

The electronics industry has become greatly dependent now on government support, as have the universities. It is not only that government support furnishes financial backing for research and development and a large fraction of potential business. The reason is probably more because the fraction of business that is government supported involves the very newest techniques. A commercial venture has to concern itself with the fact that its competitors, if engaged in similar military projects, may develop positions, know-how, and specific products as participants. Competing with this large sponsorship by private funds begins to look less promising than trying to become a part of the family so as to have the same benefits as the competitor.

The large government sponsorship in missiles and space has added a new factor of more rapid technological obsolescence. That is, a private organization engaged in some aspect of electronics may find the field moving past its product line because the whole technology is changing so rapidly, spear-headed especially by the government programs.

The industry has been shifting from a production emphasis, with a relatively small investment in pure research and a good share of earnings plowed back only in new product developments, to dependence on a large research and development laboratory mainly government-supported. This has required major industrial adjustments not yet all complete. Amongst other loose, unfinished ends are needed new concepts in patent protection and, generally, the problem of incentives for private investment.

The total production requirements of missiles and space can be easily handled by the capacity of today's American electronics industry. Also, while there is a shortage of true geniuses, and technological breakthroughs are not everyday affairs, useful research and development (in the sense of making substantive, desirable, and nearly satisfactory advances for the resources allocated) can apparently be performed by a large fraction of organizations involved in electronics today. With supply greater than demand, the entire electronics industry finds itself with more intense competition and the distinct possibility of a poor return on investment. These effects, taken together, tend to reduce private capital available for risk and create in turn a greater interest in assuring government sponsorship to back up private capital risked for new ventures.

Meanwhile, as the technological front widens and deepens and as government control and direction of electronics engineering grow, the government has an increasing problem of planning, directing, and assessing the programs. It becomes increasingly difficult for government to decide how to relate itself to industry and how, as a matter of fact, to organize individual projects and to allocate portions of them to individual competitive industrial organizations.

Since the organization of electronics engineering efforts has a great effect on the quality and nature of that effort, this matter of government-industry relations, as especially manifested by the missile and space programs of the nation, is probably of importance second to none in studying the impact of missiles and space on electronics.

Electronics and the Space and Missile Race

The public in general, understands that the U.S.A., after some years of programs that were much too modest, embarked on a huge crash program to create the intercontinental ballistic missile in record time, and that it succeeded in doing so. Also, it understands that despite this effort we may, in some aspects of ballistic missiles, still be behind the U.S.S.R., whose large program started much earlier. Furthermore, we are behind in some aspects of space technology, notably in size of thrust available for take-off.

It is a special credit to the electronics engineers and to the electronics industry of the nation that in the electronics aspects—guidance, control, communications, accuracy, versatility, and over-all performance—there is no evidence that we are behind the Russians. Complex range instrumentation and precision guidance have been demonstrated on a wide range of guided missiles in the United States, and this not only in the intercontinental ballistic missile field. By having precision guidance, we have been able to count on smaller misses, hence could get by with smaller warheads, and thus could tolerate smaller thrusts.

Turning to space, we note that the American Pioneer V's record for communicating back valuable and high quantity data on many physical phenomena measured and recorded simultaneously at a distance of over twenty million miles still remains unsurpassed today. The best available evidence suggests that U.S.A.'s space flights have brought back much more data than have the Russians', and this can be traced directly to our relative excellence in all aspects of electronics in space.

The Future

It would appear that missiles and space will continue for many years to hold a commanding position in government programs and that government programs, in turn, will continue to hold a dominant position in their influence on the electronics profession and industry.

Early in the guided missile efforts, it was customary to give first priority to getting a substantial mass up to high speed on a trajectory that was more or less the intended one. Soon it was seen, however, that the electronics of the operation was the true, high-priority item because it was the most serious factor in over-all performance and in efficacy of the entire mission. Similarly, it may be assumed that, within a few years, the matter of thrust in space will have been taken care of by proper development programs and space missions will clearly be dependent more on continued development of the payload. The sophisticated electronic passenger will be more important than the vehicle that takes it there, and putting equipment into orbit or out into interplanetary space will be easier than insuring that through this equipment the vehicle will serve a useful purpose.

In particular, we may expect that space technology will have a greater impact on communications than any other new developments in the field of communications. International communications systems, depending upon equipment in space, will expand the flow of information for commercial as well as military purposes.

The desired future missions will, if anything, continue to demand a parade of increasingly advanced electronics developments. Need for smarter circuits with higher reliability, probably in part due to built-in redundancy, will most likely maintain the pressure for reduction in size and weight of electronics apparatus. While there are aspects other than that of missiles and space that influence the effort towards further miniaturization, the requirements from these fields will probably be sufficient to hold the attention of a large body of engineers and physical scientists for years to come.

Electronics engineering will continue to be in close partnership with new physical science, and the systems engineering aspects will continue to press electronics engineering towards over-all system considerations.

The more exotic, newer possibilities in space technology propulsion may well lie in electronic propulsion techniques and in the generation and control of power by direct conversion from heat and chemical energy to electrical energy. These areas may become of increasing interest to electronics engineers, who again will come closest to having the background to move rapidly into these new fields. Thus, we may in the future find that electronics engineering will expand through total information processing, control, and systems engineering to power generation and conversion, with missiles and space as the spearhead.

Very likely space electronics will take over from missile electronics, although these two will always remain related, as the number one sponsorship source for new electronics developments. Because space appears to be a government area as against a private area for all practical purposes, the present trend towards dependence of the electronics industry and the profession on government projects will probably increase rather than decrease.

A Summary of Military Communication in the United States—1860 to 1962*

J. D. O'Connell†, fellow, ire, A. L. Pachynski‡, senior member, ire, and L. S. Howeth||

Summary—**Military progress in communications in the United States really started back in 1860, and both before and since the birth of the IRE, it has been inextricably a part of the development of the communications industry, national communications policy, the IRE and scientific research and development in this art. The U. S. Navy played a particularly important part in the development of maritime and coastal radio systems and in the development of early radio wireless policy. In both major wars and increasing rapidly since World War II, the requirements of the military services for communications to keep pace with successive revolutions in speed, scope, range and nuclear power have increased exponentially, and beyond the capabilities of conventional or commercial systems. The vital significance of adequate communications and the part they play in the success of military operations and weapons systems has been consistently undervalued in the past. The cost of undervaluation and unreadiness in communications has been mounting rapidly in step with orders of magnitude increases in nuclear power and speed of delivery.**

‡ Major General, U. S. Air Force (Ret.); Lenkurt Electric Company, San Carlos, Calif.
|| Captain, U. S. Navy (Ret.), Box 381, Morris St., Oxford, Md.

THIS YEAR marks half a century of phenomenal progress and growth of the Institute of Radio Engineers. Inextricably involved in this half century of progress of the Institute, of industry and of science have been the Military Services of the United States.

Any attempt to outline the course of U. S. military communications should include another half century of progress because just before and during our Civil War an idea was born which would grow—the first integrated concept of an organized military communication organization.

The record of his achievements and thoughts for the future leaves no doubt that Assistant Surgeon, Dr. Albert J. Myer (later Major Myer, first Army Chief Signal Officer; later Brigadier General Myer, promoter of our National Weather Service and International Weather Reporting) would be at home in the military communication world of today. Aggressively seizing upon every available technical capability of his time, he stimulated the development of the Beardslee portable electromagnetic telegraph, mobile telegraph wagons, observation balloons for combat surveillance, and an over-all communication system with flags and torches. He organized, innovated, trained, administered, promoted and, most important of all, lit a flame of military interest in the art of communication and endowed an organization with the spirit to keep this flame burning through the years.

During this war period the U. S. Navy was also making strides in communication: the two services in an early effort of joint service coordination adopted for the first time the same system of flag and torch signaling and, for a time, instruction in this common system was included in the course at both Annapolis and West Point.

The end of the Civil War brought military reaction and decimation of budgets and personnel—elimination of the concepts of research and study of improved services—"an army should be prepared to fight and not play around in a laboratory." To do both was not considered necessary or practical. But despite apathy and resistance on the part of both military and civilian leadership—typical of the national attitude when not confronted by crises, there was, none the less, continued effort and accomplishment—the linkage of the western army posts with telegraph communication; the initiation of weather reporting from army stations; the formation of the weather service and international weather reporting; hazardous polar exploration as part of the International Polar Year, 1882–1883—significant contributions from military communication beginnings to the progress of a growing nation.

In world communications, the British with great vision and initiative pushed the extension of submarine cable service to most major world ports, thereby linking the British Empire and facilitating their world trade. The U. S. Navy was quick to use this service in keeping naval units informed and coordinated. But in the wars that followed, the U. S. Navy was the first to learn the problems and penalties of dependence on a communication system operated under foreign control.

On inauguration day, March 4, 1897, during the traditional drive from the Capitol to the White House, Mr. Cleveland was prophetic to McKinley: "I am deeply sorry, Mr. President, to pass on to you a war with Spain. It will come within two years. Nothing can stop it."[1]

Sparked by the President's interest, the two military services had an opportunity for advance planning and although still unready in communications when the war came, performed prodigies of recruitment, organization and operations. Receiving orders on April 9, 1898, Captain C. F. Goodrich, U. S. Navy, within 30 days not only organized but had in operation a Coast Signal System of 230 stations connected to telephone and telegraph systems and equipped with telescopes and binoculars.

Thus began a span of years of war emergency in U. S. military communications which educated the Services in broader requirments both for communication to theaters of war beyond the continental limits of the United States and for the establishment of communication within those theaters. Again the vital need was recognized for better communication for joint Navy-Army operations in Cuba, in the Philippines, and in China. Telegraph and telephone sysems were installed by the Army—3500 miles in Cuba, 6434 miles in the Philippines where the Signal Corps entered a new field of submarine cable laying and operation (1326 miles). Both systems were turned over later to commercial use. During this same period, on May 26, 1900, Congress acted to bring the isolated settlements in Alaska into electrical communication with the United States by charging the Army Signal Corps with construction and operation of such a system. Construction started at Valdez within 3 months and was completed by October, 1904, to include 2650 miles of submarine cable and wireless systems and 1400 miles of land lines. Growth and modernization have been continuous to this day, with recent great achievement by the U. S. Air Force and the communications industry in extending communication to the rugged extremities of this great northern state to link the northern radar outposts.

These were important beginnings—important as a backdrop of understanding for what was to come and, doubtless, essential to recognition in the military services of the communication requirements of the future. This recognition, however, was never complete or adequate and resistance to change has imposed an endless succession of obstacles to be overcome.

Coming on the scene with great publicity and fanfare during this period was the fascinating but mysterious radio wireless. It appears certain that the interest, support, publicity and promotion given to this infant by the military services advanced in a major way the application of radio to both seagoing and point-to-point commercial radio-telegraph service.

Both the Navy and the Army had their Service inventors. A brilliant Navy pioneer was Lieutenant Brad-

[1] D. S. Muzzey, "A History of Our Country."

ley A. Fiske who early (1884?) recognized the naval need for a signal means independent of fog, darkness, daylight or distance. His studies led him to Prof. Dolbear's theories, to Dolbear himself in 1888, and thereafter, to devise a system which did succeed in communication from ship to ship over short distances without wires. Had he the means and the time to experiment consistently, the story of naval radio might have been advanced several years. In the Army Signal Corps experimenters were many. Picking up the trail of research blazed between 1892 and 1896 by Preece, Branley, Sir Oliver Lodge, Popoff and Marconi, the experimentation was noted in the New York *Herald*, December 4, 1899: "It is said there can be no infringement of patents as, with the exception of a few parts, the wireless telegraphy system is common property and the Signal Corps of the Army is now experimenting with instruments devised by its own officers." By this time the Signal Corps had assembled equipments and established radio communication circuits between Fire Island and the Fire Island Lightship and between Governors Island, N. Y., and Fort Hamilton, N. Y.[2]

During the turbulent next two decades of radio's growth Army pioneering efforts were continuous and significant but the major military influence during this period came from the U. S. Navy.

From the very outset the U. S. Navy adopted a deliberate and studied approach toward this new invention. With interest and expedition, but refusing to be swayed by newspaper criticism and pressure or by the rival claims of early proponents, in July, 1899, the Navy took note of the Royal Navy's tests of wireless; negotiated in August and September, 1899, with the Marconi Company for tests to be conducted aboard U. S. Naval vessels; observed Marconi's demonstration during the international yacht races in U. S. waters September–October, 1899; produced a set of requirements for service test; and in October–November, 1899, with Marconi presiding, conducted tests off the port of New York. The tests were generally successful but the Marconi Company's uncompromising insistence on a high-priced year-to-year lease to achieve its plan for a monopoly, caused both the Navy and the War Department to reject Marconi's proposal, to seek other sources of supply, and to encourage competitive tests of equipment developed by newly-emerging and highly-competitive groups of U. S. inventors. This decision was in fact a critical one because it gave strong support and encouragement to these small adventurous, imaginative U. S. wireless pioneers who saw visions of future greatness many years before major economic feasibility in the commercial communication field was attained. The Navy's careful study continued; it included the purchase from four European and two U. S. companies of experimental equipment which was ready for test by the end of 1902.

The manifestly sensible effort to explore the whole new field and select the best on a competitive basis immediately placed the Navy in the middle of a hot welter of negotiation, conflicting patent and performance claims, accusations of unfairness to U. S. firms and press criticism. Attack from within the Navy during 1904 on the dangers of relying on wireless in war raised the questions of enemy intercept and interference which were to remain and grow into the major research and operational fields of radio intelligence and radio countermeasures.

Meanwhile, in April, 1902, Admiral Bradford advanced proposals stating the importance of government regulation or control of radio stations established within the territorial limits of the United States. At the first International Radio Telegraphic Conference assembled in Berlin on August 4, 1903, the American delegates were Brig. Gen. A. W. Greely, CSO, U. S. Army; Commander F. M. Barber, U. S. Navy (Ret.); and Mr. John J. Waterbury, Department of Labor and Commerce.[3]

Historically significant was the action of the President in calling into session the first Inter-Departmental Board of Wireless Telegraphy, generally known as the Roosevelt Board, which met July 6, 1904. Despite previous interdepartmental competition, noncooperation and noncoordination, this Board unanimously recognized the Navy's paramount interest in this new field and recommended that

> The Navy be designated to provide efficient coastwise radio communication for the United States Government and when not in competition with commercial stations to receive and transmit all radio messages to and from ships at sea.
>
> The Army be authorized to erect such stations as deemed necessary provided they do not interfere with the coastwise radio system. . . .
>
> Legislation to prevent the control of radio telegraphy by monopolies or trusts should place supervision in the Department of Commerce and Labor.[4]

The story of the rapid development of naval and marine radio under Navy leadership is one of great interest to all.[5] Most of the contentions and problems of later times made their appearance promptly. Through this early period of strife and progress the Navy steered with good judgment, vision and achievement, to create the finest naval radio communication system in service

[2] G. H. Clark, "Radio in War and Peace," unpublished ms.
Note: DeForest (Autobiography), "Father of Radio," Wilcox and Follett Co., Chicago, Ill. p. 150; 1950. DeForest states his belief that the opening of radio telegraph service August 7, 1903, by the Signal Corps between Ft. Safety (near Nome, Alaska) and Ft. Michael, 107 miles south across Norton Sound as part of the Alaska Communications system was the first wireless system in the world operated regularly as part of a telegraph system handling commercial traffic.

[3] This meeting resulted from the 1902 incident when Prince Henry of Prussia, brother of the Kaiser, tried to radio from the Deutschland to President Roosevelt a message of thanks for the hospitality just extended. The Marconi Co. station at Nantucket refused to accept the message because the Deutschland carried competitor's equipment.

[5] It is to be published soon by the Department of the Navy.

during World War I. While accomplishing this primary mission, naval officers left a record of service to the radio industry, to maritime communications, and to the development of national and international radio communication policy.

Many Navy and Army officers representing our government at international radio conferences contributed importantly to the establishment of policies in international radio communication. For example, at the Second International Radio Telegraphic Conference, Berlin, October 3, 1906, the experience of both the U. S. Navy and Army was used to refute the claims and policies of the Marconi Company and others which held that only by restricting intercommunication to message exchanges between equipments of identical manufacture could satisfactory and reliable communications be conducted. The U. S. Delegation seeking to eliminate this barrier to the extension of maritime communication made a declaration which is worth quoting in part

> It has been fully demonstrated by the Government of the United States of America through experiments carried out in climates of every kind, that the different systems of radio telegraphy can be effectively used with the other. The United States Navy is actually using at present eight different systems in its coastal stations and its stations aboard ship; and during the three years in which it has been making these experiments it has reason to be entirely satisfied with the results obtained.

As a result of the determined crusade of the U. S. Delegation and despite strong opposition, the conference finally adopted a provision which stated that every ship station "shall be bound to intercommunicate with every other shipboard station without distinction as to the radio telegraphic system adopted respectively by these stations." One might think that this removed shackles not imposed by nature and freed maritime radio for rapid expansion to serve world needs. But an extended period of contention ensued and the Senate failed to ratify the convention for several years. At the Third International Radio Telegraphic Conference in London, June 4, 1912, the military services were again ably represented. The delegation was headed by Admiral Edwards, USN, and membership included Dr. Louis Austin, Head of the U. S. Naval Radio Laboratory and Majors George O. Squier, Edgar Russell, and Charles Saltzman, U. S. Army Signal Corps.

During this early period of the century both Army and Navy recognized the need for a regularly organized research, development and engineering function. The Army established a Development Division of the Chief Signal Officer's Office in 1902 under Captain E. Russell and the U. S. Navy established, in 1908, the U. S. Navy Radio Laboratory with facilities and help of the U. S. Bureau of Standards and under the direction of a noted Bureau of Standards physicist, Dr. L. W. Austin. This organization and its greatly expanded successors have through the years made achievements well recognized throughout the world. The Navy had started on the course of developing its own detailed specifications for communication equipment and later the Radio Test Shop at the Washington Navy Yard tested commercial equipment and designed naval receiving equipment. Later, 1923, these activities became part of the U. S. Naval Research Laboratory at Anacostia under Dr. A. Hoyt Taylor, whose outstanding leadership of naval research covered more than two decades.

During the period 1912–1945 the naval officer who most continuously and brilliantly contributed to the growth, expanding influence and effectiveness of U. S. naval radio was S. C. Hooper. Even as a midshipman and before his assignment as Fleet Radio Officer in 1912 he had shown great interest and ability in the new field. The influence he attained as a relatively junior officer in the policy councils of the Navy Department was remarkable to say the least and for many years he represented this country's government radio interests in virtually all international conferences. From 1915 to 1928 he was the guiding spirit in developing naval radio from an ambitious experiment to the efficient and reliable system which it became. He has come to be regarded as the father of naval radio and was credited by Owen D. Young as being the motivating force which led to the formation of the Radio Corporation of America.

Just prior to and during World War I there was rapid and manifold expansion of communication activities in both services. The U. S. Navy expanded and perfected its Naval Radio Communication Service and was charged with management of U. S. Government Radio Communications. This included taking over such commercial facilities as were required for the U. S. Naval Communication System. The capacity and reliability of radio communication to Europe was increased by vigorous broad-front development of high-power, long-range systems and the heavy load of war traffic was effectively handled by transatlantic cable and the Naval Radio Service.

Army communication development during World War I required prodigious efforts. The Army Signal Corps had to expand its field signal units about fifty times in personnel strength—build an infant air arm into a major corps—and specify and procure signal equipment for the largest U. S. Army in history.

The primary Army communication problem was to support the AEF—first with the primary means, wire communication, and secondly, with the immature early tactical radio systems.

The Army's Chief Signal Officer sought and received massive support from AT&T, its operating companies, Western Electric, Western Union and many other U. S. companies. Affiliated units from telephone companies and Western Union bulked large in the ranks of units which constructed over 5000 line route miles of pole lines in France.

Tactical radio was pushed with great vigor but never became a major communication factor during World War I. Technical talent in the Army from civilian life was used to man laboratories which did notable work at Fort Monmouth, N. J., and in Paris where Major Edwin H. Armstrong, Fred Lack, William McDonald, Ralph Bowen and many other later famous men made significant contributions to radio—Armstrong's superheterodyne circuit for one.

The years between 1920–1937 became another period of general apathy toward the services and in communications research and development, the result was a loss of momentum in both services. Both were able to maintain research and development laboratories which even grew a little from the point of lowest ebb, but Naval R&D was so reduced around 1930 that the disestablishment of the Naval Research Laboratory was seriously considered. In the midst of and despite these struggles to remain effective both services developed the beginnings of radar in their communication laboratories.

The "cut to the core" budget reductions which followed the economic crash of 1929 almost caused the elimination of research and development in the services. But the Navy's major support heretofore of thermionic-tube development and other projects which had advanced the state of the art was greatly reduced and the Army had virtually no money which could be so employed. Frequently, service research and development was the object of charity from industrial firms who were better able to push forward the state of the art with larger corporate earnings derived from the rapidly expanding broadcast and communication markets. These firms hoped to recover these give aways by getting military production contracts, but few actually did so.

With the establishment of the Federal Radio Commission in 1927—first headed by a retired naval officer and later made permanent and renamed the Federal Communication Commission in 1934, the position of the Navy as government spokesman with the industry terminated after two decades of notable achievement.

Despite the paucity of resources available for the advancement of specialized techniques and the national strife over the role of military air power which characterized the two decades between the World Wars, the Army Air Corps achieved some measure of progress in communications. In 1934 General "Hap" Arnold, then a Lieutenant Colonel, led a flight of ten Martin B-10 bombers from Washington, D. C., to Alaska and back again. Careful advance preparations had been made along the route and the communications essential to navigation and the transmission of weather information were provided. However, a later training mission flight led by Arnold encountered a series of misadventures and inconveniences due to bad weather and unreliable communications. This experience gave impetus to the establishment in November, 1938, of the Army Airways Communications Service, which evolved ultimately into the present globe-girdling Air Force Communications Service.

Meantime the Air Corps had embarked on a program of spanning the continental U. S. with military airways connecting Air Corps fields and installing, in cooperation with the Civil Aeronautics Authority, the required radio ranges and the ground communications facilities required both for exchange of information on aircraft movements and for the air-ground communications. The establishment of the Signal Corps Aircraft Laboratory at Wright Field, Ohio, led to the joint development with the Air Corps of radio communications and navigational equipment designed specifically for military aircraft operations. Under the leadership of Air Corps officers, pioneer work in radio direction finding and instrument landing systems was accomplished.

Except for the radio industry's developments of side band and multiplex equipment and the adaptation of the Baudot code to radio transmissions, the services approached World War II with the major portion of their radio equipment rapidly approaching obsolescence.

Tactical communication techniques and equipment which were standard for the U. S. Army in 1937 were almost without exception inadequate to meet the new requirements of mobility, range and reliability for armor, motorized artillery, infantry and air-ground communication. Nor was development under way which could provide communications comparable to that of the modern, mobile Germany army. Tactical radio sustems of the time were not, in fact, serviceable or reliable communication systems. As late as 1941, wire-system development engineers competing for money against radio projects had a slogan: "Millions for radio but not one cent for communications." Fortunately, but almost too late, the situation was recognized and although beset by equally or more compelling requirements for radar and aircraft communication, a successful fight was waged for the funds to start a new program and a race with time. The technical advances which qualified tactical radio to add deservedly the word "communication" were the wholesale use of crystal control and the adoption of frequency modulation. These fateful decisions were made by Colonel, later Major General, R. B. Colton. Major E. H. Armstrong again threw his personal efforts into the effort to get superior radio communications for the Army, donating his time, his equipment and his patents voluntarily and without compensation. Over 100 U. S. manufacturing companies performed outstandingly in the development of this new equipment for the Army.

In preparing to start the air war against Germany, early dependence was placed on the communications systems of the United Kingdom, developed for the Royal Air Force to meet latest air war concepts. The plan was for U. S. air units to be based in the United Kingdom. Our aircraft were equipped initially with British supplied VHF radio equipment to meet the requirements for operation in a common ground environment. This required U. S. fighters to adapt to the British methods of air defense and the equipment was later manufactured in the United States. These initial adaptations had an impact on our world-wide forces to the extent that at the end of World War II all allied combat aircraft and associated ground units had been converted to VHF for air-to-air and air-ground communications in order to provide compatibility in air operations. The successful adaptation of the VHF to military air operations resulted subsequently in its adoption for commercial air operations.

To meet the requirements for communications electronics equipment in the U. S. Armed Forces in terms of both quantity and variety, the combined scientific, industrial, and military resources of the nation operating in concert were utilized. In the process, miracles were accomplished in the compression of lead times involving the development, manufacture and delivery of new equipments to combat units. Fateful decisions were made to press for delivery of new types of equipment utilizing advanced techniques rather than relying on obsolescent prewar types.

Some understanding may be obtained of the procurement task facing Army, Navy and industry in communication and electronics alone, by considering that March, 1942, estimates showed that 4.3 billion dollars would soon be available to the military services for radio and radar contract awards to an industry whose total annual output was 0.25 billion. The Army Signal Corps preliminary Fiscal Year 1941 budget estimate made in 1939 had been 9 million dollars. The Fiscal Year 1941 funds made available were 256 million. In May, 1941, the Fiscal Year 1942 Signal Corps budget submitted to Congress was 103 million dollars. There were no less than 30 different and enlarged budgets submitted during the year 1941. By the end of Fiscal Year 1942 over 2.6 billion dollars worth of contracts had been placed with U. S. and Canadian firms by the Army Signal Corps alone. Money alone, however, could not produce military equipment on command. Yet as early as June, 1942, the Army Signal Corps was accepting every two weeks as much equipment as it had procured during World War I. The Navy, between November 1, 1942 and September 1, 1945, accepted deliveries of electronics equipment amounting to 2.54 billion dollars.

Radio and wire system development continued during the war. From the Army's Fort Monmouth Laboratories came the development of FM radio relay producing a communications breakthrough which integrated radio into wire systems with equal transmission quality and dependability. From Western Electric Company came a high-speed spiral four-cable and carrier system, and in 1945 the first U. S. time division multiplexed microwave radio relay system which saw service in Europe in the final campaigns.

It is difficult to eliminate completely from this brief summation some mention of the vast field of electronics which developed slowly, then explosively, during the years 1930–1945, because this vast mushroom of electronically-controlled weapons systems grew out of the Service, industry, and university laboratory and engineering groups engaged in advancing the communications art. Radar-groundbased-shipborne-airborne-early warning-gunlaying; sonar; guidance for bombs-torpedos-missiles-drones; proximity V.T. fuse systems; electronic countermeasures—all started from communication beginnings and all were important and some were decisive factors in winning World War II.[6] The incredible progress in all these fields concurrently was made possible only by the establishment of the National Defense Research Committee, its unprecedented mobilization of scientists, the establishment of organizations such as the Radiation Laboratories and the industry-science-military team which resulted.[7]

The urgent requirements for hitherto undreamed of varieties and numbers of highly-skilled specialists created a rapidly increasing crescendo of training demands which swamped the school facilities of all services. Had the multiplying demands resulted solely from the unexpected expansions in communications, they would have seemed impossible. But requirements for training specialists for the needs of radar and other electronic specialties multiplied even faster and fell upon the same communication training establishments. These were required to split and split again and again to establish cadres for training schools throughout the country, some in newly activated military camps and stations, others in universities, in civilian training schools and in schools set up by our British allies within their radar and training establishments.

Of major consequence in filling these insatiable needs for radio- and electronically-trained men was the response of the radio amateurs of the nation. As in World War I, and in even larger numbers, they aided the training operation, and maintenance of electronic equipment in all the services.

The achievement of this literally incredible task is another story which deserves adequate book-length treatment. It resulted after the war in the release to civilian life of the largest influx of technically-trained men ever available in so short a time.

For example, during World War II, the Army Signal Corps alone supervised the training of 432,000 officers and enlisted men. In all, 34,000 officers graduated from 50 courses, most of which had high technical content. If one adds the specialists trained by the Navy, the Air Corps and other branches of the Army, the number of men and women receiving communications or electronics training could be estimated at over a million. Their rapid absorption by a growing electronics industry was a major factor in its postwar growth.

From the brief sidelong glance above at the wartime birth of the electronics industry, a return to communications requires that the growth of military global

[6] J. B. Dow, "Navy radio and electronics during World War II," Proc. IRE, vol. 34, pp. 284–287; May, 1946.

[7] J. P. Baxter, III, "Scientists Against Time," 1945. Other laboratories of outstanding importance and achievement were formed at Harvard, Columbia, Illinois, Chicago, Brooklyn Polytechnic, Stanford and many other universities.

systems be noted as concurrent with the beginnings of U. S. responsibility, first, for war on a global scale and later as the primary trustee of free-world security and peace.

The establishment of U. S. bases, theaters of operation, Army Airways Ferry and Air Transport routes literally all over the world and into combat zones created communication requirements on a scale not hitherto experienced or foreseen. The Army Airways Communications System and the Army Command and Administrative Network owe their growth to these requirements.

The station names stretched out in all directions, with great speed in the perspective of normal actions but with painful slowness from the standpoint of the need.

From Honolulu—the names included New Caledonia, Melbourne, Brisbane, Port Moresby, Noumea, Espiritu Santo, Hollandia, Wake, the Philippines, Okinawa, Japan and Korea. As the U. S. Navy made it possible by control of ocean areas, MacArthur set a record for island hopping and his signal officer, Major General S. B. Akin, developed new concepts for massive use of high-frequency radio to substitute for nonexistent wire communication. The AACS and ACAN followed with long-distance radio circuits.

Over the South Atlantic Ferry Route and beyond, it was Miami, Puerto Rico, Georgetown, Belem, Natal, Ascension, Accra, Dakar, Marrakech, Casablanca, Algiers, Cairo, Asmara, Abaden, Karachi to name only a few.

Over the North Atlantic Ferry Route names like Presque Isle; Goose Bay, Labrador; Gander, Newfoundland; Greenland, Reykjavik, Iceland and Prestwick, Scotland, were most familiar.

Systems development passed rapidly from wide use of hand-keyed and partial use of Boehme speed-tape equipment to an over-all system using 60-wpm radio teletype plus radio telephone with newly developed ciphony equipment between the Pentagon and most important theater headquarters. Both Air Corps and Army personnel had major responsibilities for building these systems.

After the war the Army Command and Communication System was retailored to meet the cold war requirements, U. S. military deployments in 73 different foreign areas and the Korean War, but its speed reliability, flexibility and mobility would soon be inadequate to meet rapidly changing conditions.

The Army Airways Communications System was also retailored progressively to meet the operational needs of a U. S. Air Force deployed on a global scale.

By the end of World War II, the Navy had improved its fleet communications by employment of the latest developments in equipments and techniques which stressed the requirements of time and reduction of distances and the electronic coupling of detection on, above and below the sea. Its shore system had been modernized to share the large volume of joint communications generated by the joint actions of three services.

Communication lessons of the war were major. In addition to the primary realization that equipment rapidly becomes obsolete, it was clear that as the mobility, firepower and complexity of modern war increased, the quantity and quality of communication support must also increase. In World War II the trend was exponential. It was clear also that the advance conceptual planning of the operational nature of the war had been inadequate. Military and industry were unprepared for the large increase in quantity and performance requirements of communication equipment. Organizationally, technologically and production-wise there was surprise; this emergency was met by costly improvisation—some considerable warm-up time had been granted by circumstance. It was made painfully clear at Pearl Harbor that the communication system must be ready to meet the first shock of war and that nothing less than instant readiness of an adequate system in being and in use meets minimum modern defense requirements.

The two most significant features of World War II which dictated the scope and complexity of the communication systems required were:

1) The global nature of the conflict.
2) The advent of Air Power as a decisive influence on the conduct of war.

The operation of the U. S. Armed Forces in far-flung corners of the globe required immediate establishment by the Army and Navy of world-wide communications centering upon Washington, D. C., for strategic direction, intelligence, administration and logistic support and for the considerable load of press traffic generated in the areas of combat operations.

The advent of Air Power resulted in a struggle by each combatant side to achieve air superiority. The inevitable outgrowth of this struggle was the perfection of radar as a basic tool of air defense. The disposition of radars in depth in the combat area required the operation of combat centers, in the ground forces and aboard ship, whose function was to direct the defensive operations of fighter aircraft and anti-aircraft guns. Adequate, accurate and timely information and direction dictated the pattern, quantity, reliability and types of communications installed, an unprecedented requirement. Communications for transmission of weather data and aircraft movements in the area had to be provided. The demands of mobility in a mechanized ground war had to be satisfied by mobilizing heavy radar equipment, communications terminals equipped for a complex of point-to-point and air-ground operations and message centers operating in conjunction with similarly mobilized fighter and anti-aircraft direction centers. In landing operations involving both Air Force and Navy combat aircraft, additional facilities were required for coordinated direction of air operations. The communications systems and facilities thus provided attained an order of accuracy and speed in the handling, assimilation and use of combat data never previously attained. However, in terms of postwar air weapon developments to come, even this complex was soon to become obsolete.

If for the sake of brevity the several phases of the period 1945–1962 must be treated as one, the summarization might be:

In research and experimentation it is the story of a long search by the three services for new capabilities in both strategic global and in tactical communications. As time passed the search was intensified.

In operational achievements it became a period of massive U. S. Air Force, Navy and Army programs to meet the threat of nuclear attack on the North American continent and to extend and increase the effectiveness of our retaliatory delivery. It was also a period of major new system extensions and major advances by all three services.

In appraisal it was a period of progressive realization that the requirements for military communication were changing so drastically and so rapidly as to render obsolete the basic systems and techniques which by 1944 were proving satisfactory for World War II. Part of this recognition was that the new requirements could not be met by adaptation or extension of the current art; that new capabilities must be found.

To outline the search for new technical communication capabilities in such a summary fashion as follows is unsatisfactory to say the least. The major contributions of the National Bureau of Standards, the National Aeronautics and Space Agency, Canadian and British research and our many university and scientific groups should be adequately interwoven into the story and they are not. The role of the military in this search varied in degree and nature: financial supporter, participant, innovater, exploiter and frequently first user.

Communication by earth-moon relay, ionospheric scatter, tropospheric scatter, meteor trail reflection, communication by active or passive relay from satellites, and reflection from orbiting dipole belts—all have been achieved and exploited or are in development.

This 17-year time span has seen the development of weapons which have progressively annihilated the World War II military operational concepts of time and space. The speeds of aircraft have advanced into the supersonic region. The missile age was suddenly achieved. With each new weapon development the effort to provide for more speed, capacity and, most important, reliability in military communications, has been given more impetus.

In this period, the perimeters of U. S. Air Defense were progressively thrust forward to the northernmost reaches of the Arctic, into the North Atlantic and the Pacific and tied to the air defense of NATO in order to cope with the potential air threat. The Soviet missile threat dictated the installation of a Ballistic Missile Early Warning System (BMEWS) capable of surveying the space over the Soviet land mass. The U. S. Strategic Air Command, assigned a deterrent role, acquired a global mission capability from bases in the United States which called for centralized direction and control of SAC units and recently has been engaged in building a capability for operation of intercontinental ballistic missiles.

Each progressive extension of these Air Defense and Strategic Air capabilities has been accompanied by increasingly demanding requirements for communications. The distinction between communications and weapons and radars as separate systems with human operating links began to disappear and each progressively became a subsystem which taken with the others comprised the Air Defense System in which the important objective was to annihilate time as a factor in operations. To accomplish this, a new subsystem was introduced, the electronic computer, which for purposes of compatibility with the communications subsystem resulted in the development of associated data-processing, conversion and transmission equipment. The resulting system was called the Semi-Automatic Ground Environment or SAGE. Gradually the human functions in the system were being reduced to maintenance and decision making by the electron tube and transistor and through a common system language of digital data.

Both in Continental Air Defense and SAC operations reliability in the operation of communications continued to loom large as a problem in the face of the long distances and the difficult Arctic and sub-Arctic environment that had to be spanned. Demands for information handling capacity and versatility increased beyond the capability of techniques available in the immediate post-war period. To satisfy these demands, the U. S. Air Force embarked on a program of installing ionospheric and tropospheric circuits. With the collaboration of the National Bureau of Standards, in 1951, a simplex test circuit (FPIS) of 1000 statute miles was established in 1952 from Goose Bay, Labrador to Sondrestromfjord, Greenland, to determine the feasibility of this technique. Soon after (May, 1952) a decision was made to proceed with a three-circuit multichannel telegraph system known as "Bittersweet" connecting Maine, Goose Bay, Sandestrom and Thule, Greenland, to meet pressing operational requirements. In November, 1953, "Bittersweet" was completed and by 1954 the FPIS system had been extended to the United Kingdom via Iceland.

In this same period the U. S. Air Force turned to tropospheric scatter as another promising solution to its communications problems. Although tests conducted and theoretical data calculated by the National Bureau of Standards, Lincoln Laboratories and Bell Laboratories indicated that the exact degree of reliability and channel capacity to be expected from tropospheric scatter circuits could not be predicted, the consensus among the scientists was that reliable communication with minimum channel capacity could be expected.

Data also indicated a requirement for high power and large antennas. Success in the application of this technique was confirmed with the installation of circuits connecting radar stations in the rugged terrain of the Labrador-Newfoundland Air Defense System which was placed in operation two years after initiation of the Air Force study. Since 1954 tropospheric scatter facilities have been extensively installed to connect the radars of the Distant Early Warning Line (DEWLine), BMEWS and the Alaskan Air Defense System (Project White Alice). This technique has also been extensively applied to military requirements in Europe. Under sub-Arctic and Arctic conditions where other means of radio communication could not be depended on, tropospheric scatter provided a system reliability of better than 99 per cent. Moreover circuits were provided to operate with design capacities of 36 to 72 voice channels depending on antenna size and transmitter power. The effort to date has been toward application of techniques which would increase reliability to the ideal goal of 100 per cent.

During this post-war period the demands of the national economy for space in the VHF portion of the radio spectrum and the needs of the three services for equipment with greater operational flexibility resulted in adoption of the UHF band (225–400 Mc) for short-range military aircraft communications, airborne and ground and land-based radio relay. Equipment was developed which permitted rapid selection of a large number of channels. Use of the UHF band was extended to NATO aircraft and their associated ground facilities so that all Allied military aircraft would be capable of operating in a common communications environment.

In the search for more reliable communications to meet the operational requirements of its global mission, the Strategic Air Command (SAC), in mid-decade 1950–1960, converted its long-range high-frequency equipment from the World War II mode of double-side amplitude modulation to single-sideband modulation and started to increase the power of its ground stations. New records in maintaining long-range communications contacts with Strategic Air Commmand aircraft were achieved as a result. The SAC decision to convert to single-sideband equipment was based in no small part on the distance records achieved by U. S. amateur operators, through the use of this type of equipment. The increasing missile threat was met with a decision to equip SAC with an airborne command capability to offset the vulnerability of ground-based command posts. New techniques to improve this capability in terms of traffic capacity and reliability continue to be applied.

In the Army, Navy and Air Force, recognition of the vanishing time dimension, the need for instantaneous national reaction to military or political perturbations occurring in any part of the globe, the vulnerability of the Army command and communication network and its lack of mobility, led to major action. Programs were carried out for new antenna-transmitter-receiver design and installation and for new modulation techniques. System capacity and speed was increased—the communication system throughout the Pacific and Far East areas was augmented by the most extensive ionospheric scatter system in existence. Mobility was increased by immediate airborne readiness of complete van-mounted stations. During the Lebanon emergency a complete van-mounted station was flown in and communication into what had been called the Army command network was established. Extended and redesigned, the system is now called STARCOM—Strategic Army Command Network.

But even this optimization of current capabilities fell short of meeting requirements for bandwidth, capacity and flexibility. Therefore, Army planning started in 1955 for development of satellite relay systems. Early results were the ARPA-Army Air Force-Industry experimental project "Score," the talking satellite and its experimental successor, "Courier," "Advent," the synchronous active satellite, "Syncom," a NASA-ADVENT experiment and "Westford," a Massachusetts Institute of Technology-Air Force experiment for orbiting a band of reflecting dipoles, are programs which will shortly give birth to new communications capabilities urgently needed to fit the pattern of current and future military needs.

Recognition of the present unsatisfactory variety of analog and digital material now diversely affecting systems design requirements led both the Army and Air Force to contract with industry for new systems concepts. The Army concept is "Unicom," a universal system using one common digital language, accepting all types of signal content and meeting unique military requirements for security and reliability.

The Air Force, in extending its weapons systems management concept to include supporting electronics systems, initiated a series of "L" system projects many of which required associated communications, some on a global scale. Examples of such projects are 413L, extension of the DEWLine; 425L, NORAD Combat Operations Center; 433L, Weather Observation and Reporting; 466L, Electromagnetic Intelligence System and 477L, Nuclear Detection and Reporting System. Experience with such projects as DEWLine and BMEWS led the Air Force to the conclusion that the communications for these and other systems to be implemented might better be engineered within the existing over-all Air Force global communications system and project 480L was established as an over-all framework.

During the mid 1950's there was realization also among the management and membership of the Institute of Radio Engineers of the rapid growth and importance of communication electronics, and the Professional Group on Military Electronics was formed to promote increased IRE assistance, participation and support to the military effort.

During this period all three services pioneered in exploiting electronic computers and computer communications to solve logistical, supply, personnel and administrative problems of these large complex organizations. Punch-card requisitions were now possible direct from overseas commands to depot complexes in the U. S. This revolution is still very much in progress in inventory-stock control—and to provide capabilities for quick reaction to supply-service needs throughout globally deployed military forces. In addition industry developed for the Army van-mounted mobile "Mobidic" computers to accompany and serve units in the field.

The U. S. Navy, faced with all the communication problems of the other two services, had some which were unique to that service. One of these was the problem of communicating to and from submerged submarines scattered throughout the oceans of the world. Besides making communication advances comparable to the other services, the Navy established a system of superpowered (2 Mw) VLF transmitters to cover world ocean areas and reach submerged submarines. The Navy's Marine Corps developed an air-ground support communication system that was unexcelled.

In land warfare, previous maximum artillery ranges of less than a few tens of miles were suddenly expanded by modern missiles to thousands of miles without available observation and communication means to support them. The advent of tactical nuclear weapons suddenly required a revolutionary increase in troop and headquarters dispersions with concurrent increase in range and speed of communication systems. Wholly new concepts for area coverage systems became urgent; also development of new equipment capabilities was required.

As responsible military communication executives have sought to meet the urgent pressures of increasing requirements, the cost of development, implementation and operation of these new systems has increased to constitute a significant percentage of the military budget. Therefore, budgetary and defense management has increasingly questioned the communication programs of the services. Are the requirements realistic? Are new capabilities really needed? Is there unreasonable duplication among the services? Is military communications as a business efficiently managed?

Increasingly the services have examined their requirements more searchingly and in greater detail. Advisory councils of scientific and industry leaders have been constituted in the services to give broader perspective than that of military personnel alone. Contracts have been placed with nonprofit analysis organizations to determine the basis of and reasons for increasing communication requirements. Particular emphasis has been placed on determining organizational and procedural methods for satisfying future needs with maximum efficiency and economy. What can be done to better organize and utilize the systems we now have? Further, the joint chiefs of staff have continually exercised greater supervisory and coordinating influence. The Secretary of Defense has also progressively enlarged his supervisory and decision making role in military communications. To meet the common communication needs of the widely spaced unified and specified commands which are made up of combat elements of all services, there has recently been organized the Defense Communication Agency staffed by communication personnel of all the services. This Agency also has a responsibility for evaluation and coordination of service communication programs. Its scope, authority and effectiveness are growing and should continue to grow.

Looking back over this panorama of some hundred years of U. S. military communication raises questions as to possible recurring patterns or trends. Some appear to be present.

Although given little mention in this fast sweep through time, the most important recurring pattern has to do with people. Fortunately, within the services the challenge of communications has attracted a fraternity of men, with basic military interests, who in addition had strong pioneering interests in providing, maintaining and improving communications. Aboard combat naval vessels, aircraft and in tactical Army and Marine Corps combat units, communicators of whatever rank or branch of service overcame obstacles, shared common hazards, gave dedicated service both as communicators and as fighting men. Their contributions have consistently been a major factor in achieving needed communications throughout this period.[8] Nor can the dedicated service and achievements of civil service men and women in the services go unmentioned.

It seems clear that military communication requirements consistently have preceded and exceeded the communication capabilities available to satisfy them. It appears that primary military emphasis over this period on weapons systems, ships-tanks-guns-aircraft-missiles has not been accompanied by sufficient and concurrent emphasis on the communication systems, equipment and organization to make the weapons employable with adequate effectiveness. Communications have been in the usual position of trying to catch up with needs and the needs were frequently late in being recognized.[9]

Another consistent pattern that emerges is that before each of our major wars of the past there have been periods of warning and warm-up when there was some considerable opportunity to reduce our unreadiness for the

[8] The authors' most serious dissatisfaction with this article is that brevity requires almost complete omission of the names of major outstanding leaders in military communications. The contributions of Army Chief Signal Officers, Chiefs of Naval Communication, Directors of Air Force Communication, Directors of Communication of the Joint Chiefs of Staff and of the Defense Communication Agency—all have been unmentioned—but not overlooked.

[9] "The methods of modern warfare and its wide deployment of forces make effective communications one of the vital elements of victory. . . . Actually war laid far greater demands on Signal Troops and equipment than the War Department had anticipated and the rapid development of electronic devices continued to multiply these demands. Foreword by Major General Albert C. Smith, U.S.A., Chief of Military History to U. S. Army in World War II, *The Signal Corps: The Test* by G. R. Thompson, D. Harris and others in the U. S. Army in World War II historical series.

test of war. Yet each war did in fact find us unready from a communication point of view. The degree of the unreadiness and its cost seems to have become higher as war became more mechanized, complicated, long range and rapid.

Finally, it seems certain that the important relationship of command-control-communications to the effectiveness of all military operations and weapons systems has been consistently misunderstood and undervalued.[9]

Perhaps it may be appropriate in concluding this brief backward look to ask some questions about what lies ahead in military communications. Have the lessons of the past been learned? Is our recognition and evaluation of future needs in military communications now adequate? Do we have realistic answers to the question of what leadership at all levels must do in meeting and after suffering the next shock of whatever type of war may come so that we may plan now and have ready the communications necessary to permit the exercise of this leadership? How can we provide the essential survivability of this system without unnecessary expense? From whom and by what method can the right answers be obtained?

These questions grow more complex with each passing year. The strength of the effort is growing to find better answers for the future than we have had in the past. In the success of these efforts the nation has a vital stake. By what standards can their adequacy be measured? Are there additional ways in which the great technical strengths of this Institute of Radio Engineers can be brought to bear in support of these efforts?

Achievements and Prospects of Artificial Earth Satellites*

S. F. SINGER†

Summary—**In less than half a decade astronautics has developed from crude satellites to systems of unbelievable sophistication. Probes to Mars and Venus and a manned expedition to the moon are well into the planning and design stage. Weather and communication satellites as well as military monitoring satellites will soon be fully operational; navigation satellites are at this stage already, as are manned earth satellites. Elaborate lunar probes and complex astronomical satellites are just around the corner. However, practically all of the scientific achievements so far have been in the field of geophysics. Although some areas still remain to be investigated, many fundamental results have been gathered about the earth and its environment; briefly discussed here are findings about the figure of the earth, the density, temperature and constitution of the upper atmosphere, the nature of the radiation belt and auroral particles, and disturbances of the geomagnetic field.**

THE SCOPE of the present paper is confined mainly to the applications of earth satellites and space probes to space science, *i.e.*, to geophysics and astrophysics. That is not to say that satellites have not been used for other purposes, and certainly in future years and even future months we shall see an increasing application of satellites to important areas of human enterprise, such as communication, navigation, and weather reconnaissance. (The military applications of satellites, embodied in the MIDAS and SAMOS satellites, are also concerned with reconnaissance, but their construction and operation is quite different from a weather satellite.)

* Received by the IRE, February 5, 1962.

Some More Immediate Prospects for Space Technology

We want to speak briefly about these applied satellites. Articles have appeared, of course, which point out the impact that they will have on human affairs and on the way of life of the "man in the street." But it seems impossible to do them complete justice because in their final form, and after their outputs are fully integrated into our economy, they may indeed lead to quite revolutionary (and unpredictable) changes.

Everyone by now is familiar with the importance of a communication satellite. Some pioneer experiments have been made, the initial one by the Army Signal Corps in the SCORE satellite which in 1958 transmitted a message from the President of the United States all over the world.

Communications satellites fall into two major classes: passive satellites and active satellites. A prototype of the *passive* reflector is the ECHO satellite, which is essentially a large sphere of thin balloon material; its purpose is to present as large a cross-sectional area as possible for a minimum weight. Its main advantage is its utmost reliability since it carries no receiving and transmitting equipment. A second advantage is the fact that it can be used to communicate at *any* frequency; its bandwidth is limited only by the opaqueness of the earth's atmosphere and ionosphere. Its only disadvantage, really, is the fact that one requires powerful transmitters and receivers on the earth and high-gain antenna systems in order to communicate with a good signal-to-noise ratio.

A special subclass of passive satellites is represented by the WEST FORD project which consists of a belt of orbiting dipoles. It is effective only for frequencies near the dipole resonant frequency (8000 Mc).

For this reason much attention has been paid to *active* satellites which carry both receivers and transmitters to relay the information sent to them. They may even carry more elaborate equipment, for example, tape recorders, to store and receive information and transmit on command or by preprogramming when they reach a certain location over the earth. In addition, they have the facility, of course, of receiving on one frequency and transmitting on another one. In general they have advantages which are complementary to those of passive satellites. Therefore, it seems likely that both systems will find eventual application.

Two types of active satellites are being pursued: 1) A relatively low altitude satellite, or rather a system of satellites in order to cover the earth; its prototype is the COURIER launched in 1960. 2) In addition, we have the so-called hovering satellite, at an altitude of 22,300 miles, whose orbital period is 24 hours. It, therefore, remains synchronous with the earth, and by suitable minor adjustments can be made to remain almost stationary over a given point on the earth's surface. Three satellites could cover the earth; the system is exemplified by the SYNCOM and ADVENT prototypes now being constructed.

It is too early at this stage to review in detail the manifold activities concerning communication satellites. In particular, their mode of operation has not been conclusively settled, *i.e.*, to what extent individual companies and government agencies participate, how a civilian and military network is to be set up, to what extent foreign countries or associations of foreign countries will participate or compete, etc. It is in the field of the communication satellite where the European community has chosen to make its entry into space technology, and precisely for the reason that it offers hope of a great economic return. One factor which is often not appreciated is the very low cost of the satellite relative to the cost of the ground station facilities which must be built in order to utilize the satellite communication system to the fullest extent.

By contrast, the *navigation satellite* is almost operational as the Navy TRANSIT satellite system. A complete analysis of the Doppler shift of the received radio signal fixes the position of the observer relative to the satellite, and if the latter's orbit is precisely known, then the position of the observer is determined. A review article covering all aspects of the system, from the theoretical point of view to the operational point of view, has recently been prepared.[1] The accuracy of the navigational function depends on how elaborate the receiving equipment is; it can be as good as 100 ft.

Weather satellites are not yet operational, but the time is drawing near when they will be used for weather studies and prediction in a routine way. The TIROS series has been successful as a test of instrumentation, and the forthcoming NIMBUS and AEROS satellites promise to be the prototypes of a complete weather system. The U. S. Weather Bureau has already made immediate operational use of satellite data to forecast severe storms and to check ice conditions in northern shipping lanes.

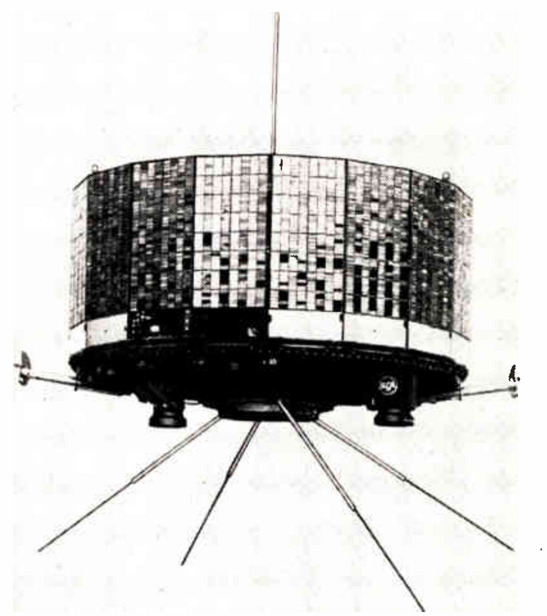

Fig. 1—TIROS III weather satellite, launched July 12, 1961.

Technical Features of Satellites

From the point of view of space science, artificial satellites have turned out to be a tool whose scope probably extends further than any other technique. As we shall see, it has been used to investigate phenomena from the interior core of the earth, extending through the crust and atmosphere all the way into interplanetary space. We shall base our review here, in structure

[1] A. M. Stone and G. C. Weiffenbach, "Radio Doppler method of using satellites for geodesy, navigation and geophysics within the planetary system," in "Progress in Astronautical Sciences," S. F. Singer, Ed., North Holland Publishing Co., Amsterdam, vol. 1; 1962. Wherever possible in this article references will be given to books and review papers in which original publications will be found cited.

at least, on a review published about six years ago,[2] which described the type of research which *might* be done with artificial earth satellites; it gave the theory and the *rationale* for many experiments, but, of course, it gave no results. It may, however, be consulted to illustrate the thinking which prevailed at that time and also as a source for references up through 1956.

Some of the technical features described for satellites in 1956 seem antiquated in modern terms; however, many ideas current at that time have been adopted in actual satellite systems. For example, it was surmised that an inert earth satellite would be scientifically useful since its orbit could be used to measure the figure of the earth as well as atmospheric density. Satellites with telemetering aboard are, of course, much more useful. But in addition to a multichannel telemetering system and telemetering storage which was then anticipated, we have now data-handling systems of great complexity. They automatically select the instrument whose information is to be transmitted, turn off certain instrumentations when the data become less useful and will change the transmitting setup automatically as required by external conditions or by command.

As far as attitude control is concerned, not only has use been made of gravitational torques and of spin stabilization, but also magnetic torques have been found useful for a number of satellites, and automatic attitude-control systems based on horizon scanning have been adopted in many cases.

As anticipated, solar batteries have been found fully useful for at least the present generation of earth satellites. It seems likely, however, that nuclear power supplies will be of increasing importance for many applications where the power demands are great. A nuclear power supply based on the SNAP system, *i.e.*, the use of radioactive isotopes, has already been flown in 1961 on a TRANSIT satellite.

Advantages for Scientific Work Peculiar to Satellites

The chief distinguishing features of a satellite are several: 1) Primarily its location which leads to the possibility of continuous observations above the absorbing effects of the atmosphere. In order to maintain itself the satellite must be located above the appreciable atmosphere which in practice means in the exosphere, about 500 km, well above the ionospheric regions. 2) The uniform coverage of the earth which a satellite can furnish if it is in a suitable orbit.

From these major points follow many minor points in which a satellite may be superior to earth-bound instrumentations:

a) It is capable of nearly simultaneous measurements over the whole earth and, therefore, can give an instantaneous picture of the phenomenon under study.

b) It can make a large number of these simultaneous measurements one after the other, and so average out transient effects.

c) By being at high altitudes it can often de-emphasize disturbances which exist near sea level and are caused by local anomalies.

d) Finally, a satellite measurement may often be less expensive from the point of view of effort and cost than equivalent measurements with other tools such as sea-level expeditions, airplanes, balloons and rockets.

In the following discussions these advantages of the satellite will become evident, but by far the most important characteristic of the satellite is that it is capable of performing some measurements which *cannot be conducted by any other means.* It is therefore a *unique* tool as well as a most convenient one.

The Interior of the Earth

Surprising as it may seem at first glance, satellites are capable of making refined measurements of the interior of the earth which are quite difficult by other means. These refer to the main magnetic field, and therefore to the dynamics of the liquid core, and to the distribution of matter in the earth. While it is possible to made these measurements at lower altitudes, or even at sea level, the advantages of the satellite which have been enumerated above provide an overwhelming argument for its use.

The Earth Magnetic Field and Its Secular Variations

The central problem is to explain the origin of the earth's magnetic field. Sea-level observations over the last decades have shown that the field is complicated, containing in addition to the main dipole also higher-order components, as well as local anomalies; in addition, the field exhibits a slow variation with time, the so-called secular variation, consisting of a westward drift of the nondipole components, as well as a change in the dipole field.[3]

These observations of the secular variation have been handicapped by the fact that the time scale of the observations themselves has a spread on the order of a few years, since simultaneous observations over the earth cannot yet be made. Therefore, it is likely that a satellite survey will reveal quite a different picture concerning the geomagnetic field and its time variation.

[2] S. F. Singer, "Geophysical research with artificial earth satellites," in "Advances in Geophysics," H. Landsberg, Ed., Academic Press, New York, N. Y., vol. 3; 1956.

[3] E. H. Vestine, L. Laporte, C. Cooper, I. Lange and W. C. Hendrix, "Description of the Earth's Main Magnetic Field and Its Secular Change, 1905–1945," Carnegie Inst. Wash. Publ. No. 578; 1947.
E. H. Vestine, L. Laporte, I. Lange and W. E. Scott, "The Geomagnetic Field: Its Description and Analysis," Carnegie Inst. Wash. Publ. No. 580; 1947.

In fact, there are indications today which would show that the sea-level field (as we believe it to be) must contain a large contribution from external current systems, greater than the 1 per cent which is usually assumed.

In spite of the obvious advantages of a satellite for the geomagnetic mapping job, this has not yet been carried out.[4] There are, of course, technical difficulties; for example, satellite magnetometers can be constructed which have an accuracy of 10^{-5} gauss. However, in order to keep the field variation due to altitude changes within this limit, the altitude must be determined to within 20 m for a 500-km orbit.

The Figure of the Earth and Gravitational Anomalies

The determinations of the shape of the earth and of the distribution of matter in its interior are of considerable interest not only in geophysics but also for geodetic applications. The subject had its start with Newton's estimate of the nonsphericity of the earth; this allowed him to give a satisfactory explanation of the phenomenon of the precession of the equinoxes which had been discovered much earlier. Subsequent advances are associated with names of Clairaut whose treatment of the subject proved that in order to satisfy the equilibrium equations, the figure of the earth must be that of an oblate spheroid. However, the earth departs at places by several miles from the shape of a perfect oblate spheroid. It is more closely approximated by the "geoid," an assumed equipotential surface which coincides with the mean sea-level surface over the oceans and is perpendicular at every point to the direction of gravity. The deviations of the geoid from the spheroid normally do not exceed about 100 m. These irregularities are caused by the attraction of land masses, but are partially compensated by isostasy.

The size and shape of the geoid as determined by geodetic data has been reviewed by Heiskanen. Another approach to obtain information on the geoid is from the precession of the moon and from its slow nutation, as shown by Jeffreys.[5]

Earth satellites can be used to measure the geoid by studying changes in their orbits. As is well known the equatorial bulge of the earth leads to two effects on the orbits of satellites:[6,7]

1) A rotation of the orbital plane in space or "regression of the node," *i.e.*, the line on which the orbital plane interesects the equatorial plane of the earth rotates in space at a certain rate, given approximately by 10.0 $(R/a)^{3.5}$ cos i degrees per day, where R is the earth's radius, a the semimajor axis of the orbit, and i the orbit's inclination to the earth's equator. 2) In addition, the line of apsides rotates within the orbital plane, *i.e.*, the perigee moves around the ellipse, at a certain rate given by 5.0 $(R/a)^{3.5}$ $(5 \cos^2 i-1)$ degrees per day. Additional perturbations result from the fact that the earth is not a perfect spheroid.

An analysis of the results has given a more accurate measurement of the equatorial bulge. It has also been found that the northern and southern hemisphere differ slightly in shape, leading to what has been called a "pear-shaped" distribution of the earth. In addition, it seems that the earth is slightly tri-axial, *i.e.*, that it does not possess perfect symmetry about its axis of rotation. This tri-axiality would have an important effect on a 24-hour synchronous satellite.

The results on the shape of the geoid have been discussed in great detail by King-Hele[8] and by O'Keefe.[9] A simplified version of the background is given by Singer[2] and a simplified discussion of the results by Rossi and Jastrow.[10]

The Earth's Surface and Lower Atmosphere

A satellite can be used to study the atmosphere below it primarily by (passive) optical means. It either receives electromagnetic radiations which are *emitted* from the surface and various atmospheric layers, or it observes solar radiation *scattered* from the layers below it. In the radio spectrum, however, the satellite may take an active part in the measurement by emitting radio waves whose modification in traversing the ionosphere gives information about the ionospheric layers. We shall discuss, in order, the earth's surface, troposphere, stratosphere, chemosphere, and ionosphere.

Albedo and Its Relation to Weather

One of the simplest and at the same time one of the most important from a meteorological point of view is the observation of the amount of reflected sunlight. It can be carried out with simple photocells, or when more detail is desired, with television cameras. One can obtain rather detailed information about the distribution of the albedo, and therefore about the distribution of clouds, ice, and snow fields, all of which have a very high value of specific albedo.

Such information is useful from two points of view. The *detailed* distribution of albedo, in particular, therefore, the distribution of clouds, provides one of the

[4] It would seem that the geomagnetic mapping experiment might be a suitable one for the forthcoming POGO (polar orbiting geophysical observatory) series of satellites.

most direct means of observing "weather" and can be used for forecasting. On the other hand, the albedo *integrated*, for example, as a function of latitude, is useful for climatological studies and for providing an input to the problem of describing the large scale circulation of the atmosphere.[2]

Finally, there is the problem of measuring the albedo on a long-term basis. The possibility exists that climatic changes are due to long-term changes of the earth's albedo, because of an increase in cloudiness or increased atmospheric turbidity, produced, *e.g.*, by volcanic dust. This point of view has been worked out especially by Wexler; it may be that satellites will provide an answer to this question, but probably not in the near future.

Infrared Emission and Temperature of Atmosphere, Ground, and Oceans

It is well known that the infrared emission from the earth to space can be thought of in terms of two components: 1) the black body emission from the earth's surface with a peak near 10–12 microns; 2) the emission from the upper atmosphere which takes place at a very low temperature of $-50°$ to $-60°$C.[2] Thus, an infrared detector sensitive near 10 microns measures the surface temperature of the earth, while infrared detectors sensitive outside of the atmospheric "window" measure the temperature of the emitting layers at higher altitudes. Both of these possibilities are being followed up in the current meteorological programs.

The measurement of infrared flux leaving the earth is of two-fold importance: 1) it furnishes an important datum for the energy balance calculations of the atmosphere; 2) it allows measurement of ground temperatures. The latter may have an interesting application to oceanography. With sufficient resolution it would allow the tracking of certain ocean currents, *e.g.*, the Gulf Stream, by virtue of their temperature differential with respect to the surrounding ocean surface.

As of this date this application to oceanography has not yet been actively pursued. Neither has the application of satellites for the study of atmospheric electricity and for a measurement of the world-wide distribution of thunderstorms. Again, such applications may be anticipated for the future, perhaps as a part of a full-scale weather satellite program.

The Chemosphere

Solar radiation, particularly in the ultraviolet, can produce excitation and dissociation of atmospheric molecules such as O_2, H_2O, NO, etc., leading to complicated de-excitation and recombination reactions. Often new molecules are formed, such as ozone, having strong absorption characteristics by which they can be detected. Often too, the reaction emits visible radiation which can be observed on the ground as the "airglow."

Ozone Content and Distribution

A method for measuring the vertical distribution of ozone in the atmosphere, as well as the total amount of high-altitude ozone at various places over the earth, has been worked out and operates as follows:[2] ultraviolet light from the sun is partly scattered and partly absorbed in the earth's atmosphere, the absorption in the region of 2600 Å to 3000 Å being principally due to ozone. Therefore, a detector which looks down and measures the spectral distribution of scattered ultraviolet can in this manner determine the altitude distribution of ozone. Interestingly enough, this particular method may be applied to the planet Venus almost before it is applied to the earth.

Light Emission from Airglow and Aurorae

Various emissions can be studied by means of photocells with filters, or similar detectors of restricted bandwidth. The important measurements would be the forbidden oxygen transitions at 5577 and 6300 Å, the OH emissions in the near infrared, and ultraviolet emissions in the airglow which are not observable from the ground. Such measurements would serve to give a synoptic picture of the distribution of the airglow, and therefore some ideas of the state of motion of the upper atmosphere. Measurements by Roach and colleagues have indicated the patchiness of night airglow and its drift, but no world-wide measurements of the phenomenon have as yet been carried out.

Of special interest would be observations of auroral light emissions. They would provide accurate information about the geographic distribution of aurorae and of their time variations. Data obtained from ground measurements appear to be quite exciting. A group at the University of Alaska under the leadership of C. T. Elvey has deduced important information about the morphology of the aurora, while Soviet scientists, principally Lebedinsky and colleagues, have shown the existence of continuous auroral arcs which they suspect may extend not only over the Asian hemisphere but extend into the North American continent as well.

However, no concerted effort has been made to carry on satellite experiments in this field, and no data of any significance are therefore available.

The Ionosphere

Electron Density

Initial observations of the ionosphere were carried out through the Soviet SPUTNIKS, which used a transmitter frequency of the order of 20 Mc, low enough to be affected by the ionosphere. Measurements were made of the appearance and disappearance of the signal, refraction effects, fading, and Faraday rotation, to obtain synoptic information about the ionosphere.[11] However, it was found to be more satisfactory to carry out more specific experiments, and at the present time efforts are being directed towards the development of "topside"

[11] One would like to mention, however, the existence of an ionospheric retardation effect, first described by Berning, which is clearly observable for example in the TRANSIT program.[1] It manifests itself as a frequency shift and is produced by the varying phase shift of the wave as it passes through a varying amount of the ionosphere.

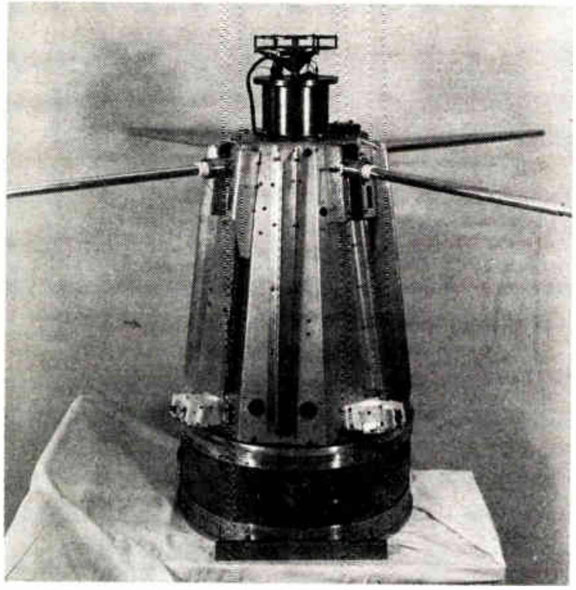

Fig. 2—P-21 Electron Density Profile Probe for upper ionospheric research.

sounders. This device is analogous to the usual ionospheric sounder, except that it is mounted on a satellite and will receive reflections from an electron layer located below the satellite.

A different aspect of ionospheric physics has been stressed in experiments in which LF waves are being received in satellites.[12] The purpose here is two-fold: 1) to measure the transmission of LF waves through the ionosphere which normally reflects the largest fraction of their energy back to the ground; and 2) to study radio whistlers.

No special effort will be made to review these techniques and results in the present survey since many of the papers are published in the PROC. IRE and are therefore available in their original form.[13]

THE EXOSPHERE

Since a satellite spends practically all of its useful life above 200 km, it is well suited to carry out direct physical observations in this region. Above 200 km the atmosphere is assumed to be in diffusive equilibrium, with each component falling off according to its own scale height as determined by its molecular weight. As a result N_2 molecules begin to be unimportant at around 200 km and by the time an altitude of 530 km is reached only oxygen atoms, some nitrogen atoms and a small percentage of helium and hydrogen atoms are present. The altitude of 530 km is generally taken to be the *base* of the exosphere, the region from which gas can escape from the earth's gravitational field without making any further collisions.

From theories of the exosphere it follows that oxygen is the most important constituent just above 500 km, and that hydrogen eventually predominates above about 2000 km. It seems possible from recent evidence that there is an intermediate region, around 1500 km, where helium is most abundant.

The important parameters that a satellite can determine are, in order of increasing difficulty: the density of the atmosphere, time variations in this density and to some extent latitude variations; and finally the composition, state of ionization, and energy distribution of free electrons.

Atmospheric Densities Deduced from Satellite Orbit

Measurement of upper atmosphere densities can be made even with an inert satellite; it is only necessary to observe its orbit. The collisions with atmospheric atoms produce a frictional force which is proportional to the density. The effect of this tangential drag force will be to change the energy of the orbit and therefore its shape and size. A very simplified discussion of the expected changes is given in Singer.[2] The subject has been studied in much greater detail by a number of authors; a recent review has been produced by King-Hele who also gives the currently accepted values of upper atmospheric densities, the day-night variation, seasonal effects, and an indication of a possible solar cycle effect.[6]

So-called "standard atmospheres" have been prepared from time to time. The most recent one is the COSPAR atmosphere of 1961; however, it should be realized that even this compilation is not likely to be the final answer concerning upper atmosphere densities. In fact, if a solar cycle variation does exist (as one would expect from a theoretical viewpoint), then the subject may be much more involved, and a single set of values may not suffice. On the other hand, in many cases it is permissible to deal with an average atmosphere.

More refined methods for measuring atmospheric density have been suggested from time to time but have not been generally used. They are the observations of an angular acceleration produced by aerodynamic torques; a measurement of ram pressure by means of sensitive gauges; and the observation of upper winds, temperature and turbulence by the production of artificial sodium trails.[2] No trails have been produced from a satellite as yet, but in one of the Russian probes sodium vapor was used to pinpoint the position of the probe. In geophysical rockets in the USSR sodium has been used by Shklovsky and Kurt to deduce upper atmospheric densities and temperatures.

Probe Measurements

Among the most active approaches to the study of the ionosphere is the use of probes of various types. We shall discuss the results here in some detail. The subject was pioneered mainly by Gringauz and colleagues, who flew ion traps in SPUTNIK III and more refined instruments in later Russian space probes. In principle, probes

[12] An additional purpose of these studies, not connected with the ionosphere, is the extension of radio astronomy to lower frequencies.

[13] See special issue on "The Nature of the Ionosphere—An IGY Objective," PROC. IRE, vol. 47; February, 1959. See also J. P. Leiphart, *et al.*, "Penetration of the onosphere by very-low-frequency radio signals—Interim results of the LOFTI I experiment," PROC. IRE, vol. 50, pp. 6–17; January, 1962.

can measure the complete properties of the medium in which the satellite or rocket is moving, *i.e.*, the ionic composition and energy spectrum of the electrons. In addition, it is possible to measure such subsidiary quantities as the collision frequency for electrons, and the electric potential of the vehicle with respect to the surrounding plasma.

In practice, however, many of these measurements have been difficult to make. Energetic ions can be studied in a fairly direct way after provisions are made to suppress the photoelectric effect due to solar ultraviolet. For example, Bridge and Rossi have used probes in EXPLORER X to measure some properties of the interplanetary plasma and deduced the existence of "clouds" or "layers" containing very energetic protons (plasma) alternated by layers which do not produce a detectable signal. These observations correlated extremely well with magnetic studies by Heppner in which the magnetic field was found to be turbulent whenever a plasma probe was seeing the hot plasma.

More down-to-earth measurements have been made in EXPLORER VIII and in a large number of research rockets. Bourdeau and colleagues from the Goddard Space Flight Center have measured the energy spectrum of electrons at satellite altitudes and find it to be the same as that of the ions.[14]

The altitude distribution of electrons has been measured through propagation experiments by Berning in the USA and by Alpert in the USSR, but the plasma probes give information which leads to a somewhat different interpretation. From the altitude distribution measured by Hale (as interpreted by Hanson) it is concluded that helium ions form the most abundant species of ions at around 1500 km. Similarly, the results of Gringauz, *et al.*, show that the scale height above 1500 km is extremely long. Before any detailed conclusions are drawn from these data, one must be quite certain that the *potential* of the vehicle is in no way affecting the measurements.[15]

Effects of Satellite Potential

The question of the *potential* of the vehicle is of considerable importance from many points of view. If the vehicle carries an electric charge, this charge will interact with the ions and electrons of the surrounding plasma through which the vehicle is moving, and produce an electric drag. This drag does not affect a large satellite to any considerable extent, but becomes quite important for a very small body, particularly one whose dimension is less than the Debye screening distance, *e.g.*, meteoric dust particles. In fact, the theory of Coulomb drag was first developed in order to deal with meteoric particles in interplanetary space and in the vicinity of the earth. More recently this theory has been applied to calculate the drag of the WEST FORD needles. It was concluded that the needles are likely to have an rms potential of -3.6 v, which in turn limits their lifetime to a few months. If their potential is of the order of 10 v, then the lifetime will be a matter of a few days or a few weeks.[16]

Among the most puzzling of observations have been the unusual radar echoes which are sometimes observed in connection with satellite passes. These were originally described by Kraus, who received bursts of WWV and concluded that somehow plasma clouds were produced in the ionosphere by a passing satellite. The existence of such clouds has not been accepted by all workers in the field, and in fact no detailed theoretical explanation has been produced so far. The writer has been partial to a mechanism which he calls a "plasma compression." It is assumed here that the satellite, because of its electric charge, will affect the plasma; because of the geomagnetic field a condensation of plasma can be produced in the vicinity of the satellite. For further detail concerning the observations by Kraus and others, and concerning possible explanations of these effects the reader is referred to Singer.[16]

Geomagnetically Trapped Radiation and the Earth's Radiation Belts

The motion of charged particles in the earth's magnetic field had been understood for many years, but the existence of particles in trapped orbits was hypothesized only as recently as 1956. Yet the discovery of trapped particles at low altitudes near the equator, in EXPLORERS I and IV by Van Allen and colleagues in 1958, came as a surprise. An interpretation was quickly put forward; the particles were identified as high energy protons even before their nature was experimentally established by Freden and White in 1959. The existence of trapped particles at higher latitudes and altitudes deduced from SPUTNIK III data by Vernov, Lebedinsky, Krasovsky, *et al.*, was similarly interpreted as a component of trapped radiation, but of lower energy and produced by a different mechanism than the equatorial inner belt.

A great deal of experimental effort has been devoted in the past 4 years to the study of trapped particles, unfortunately often with very crude instruments. It turns out that experiments in rockets carrying photographic emulsions have contributed most of the detail concerning the nature of the radiation, while satellite experiments, particularly EXPLORERS VI, VII, and XII, have elucidated the time variations and spatial distribution.

The experimental results may be summarized as follows: There is an inner region of trapped particles beginning at an altitude of about 500 km, at which point the intensity rises very sharply, increasing to a maximum at about 3000 km and reaching a minimum again at about

[14] From theoretical arguments, however, one would expect the electrons to contain a high energy tail since all of them are originally produced by quite high energy photons in a photo-ionization process.

[15] Results of EXPLORER VIII indicate that the potential of the vehicle is very close to zero, within 0.1 v. But this result is at variance with what one would expect from theory. The writer therefore reserves judgment concerning the ultimate interpretation of probe data.

[16] S. F. Singer, Ed., "Interaction of Space Vehicles with an Ionized Atmosphere," Plenum Press, New York, N. Y.; 1962.

6000 km. This inner belt contains high-energy protons with energies up to 700 Mev. The maximum flux is of the order of 3×10^4 per cm^2 per second in the heart of the belt. The falloff beyond 3000 km is thought to be due to the fact that the magnetic field begins to lose its trapping ability for high-energy particles; as a result the radiation becomes progressively softer with increasing altitudes.

The outer belt extends out to about 4 earth radii, and is known to consist of electrons having energies generally below 1 Mev, with perhaps a small fraction above that value. Quite recent information indicates that it also contains protons of the order of 1 Mev. Hence the outer belt is very soft and can easily be screened off with only a small amount of shielding. The fluxes involved are of the order of 10^8 per cm^2 per second and show very large time variations. It is quite clear that the outer belt is closely connected with magnetic storms and aurorae.

As far as interpretation is concerned, the most fruitful approach has been in terms of the so-called neutron albedo theory. Cosmic rays incident on the earth's atmosphere create neutrons, a fraction of which will be emitted in the upward direction. Being uncharged they can travel through the magnetic field without any deviation and will decay along the way. High energy neutrons will pass their kinetic energy to their decay protons, and thus it becomes possible to inject into the earth's magnetic field protons having energies of several hundred Mev. Even very-low-energy albedo neutrons will give an energy of the order of $\frac{1}{2}$ Mev to the decay electron; therefore, both protons and electrons can arise from the neutron albedo. A detailed review has been undertaken[17] and the results may be summarized as follows: Every observed fact about the high-energy protons (>10 Mev) can be explained so far on the basis of the neutron-albedo theory. But in the case of the low-energy particles, electron and proton, it would appear that the neutron albedo only contributes a part of it. It is possible that the largest fraction of high-energy electrons (>200 kev) arise from neutron albedo. But the lower energy electrons are almost certainly due to other causes, most likely a local acceleration mechanism within the earth's magnetic field in which energy contained in solar corpuscular streams is somehow converted to the kinetic energy of trapped particles.

Magnetic Storms and Aurorae

Measurements of the magnetic field were first undertaken in SPUTNIK III and LUNIK rockets, and carried on most fruitfully in PIONEER V and EXPLORERS VI and X. They indicate that the geomagnetic field terminates at about 10 to 15 earth radii, with a "quiet-day" magnetic perturbation existing at altitudes of 7 to 10 earth radii. During a magnetic storm, however, the perturbation is greatly enhanced and also moves inward; its magnitude during the "main phase" decrease of the storm correlates closely with sea-level values. It is generally considered likely that these magnetic perturbations are produced by the magnetic effects of trapped particles. A review article giving the theoretical development of these magnetic effects and a comparison with the observations has recently been published.[18]

Some disagreement exists among the experimenters; for example, the existence of the quiet-day ring current is not generally accepted. Further, a peculiar magnetic variation at 3 to 4 earth radii seen in LUNIK I has not been observed in other vehicles. It is likely, of course, that large fluctuations of the field may exist on a short spatial and temporal scale. In fact, what may be magnetic "shock waves" have been directly observed by Sonett near the boundary of the geomagnetic field.

Cosmic Radiation

Cosmic rays are corpuscular radiations of extremely high energies. The primary cosmic rays consist mainly of protons, but contain also (~15 per cent) helium

[18] J. R. Apel, S. F. Singer and R. C. Wentworth, "Effects of trapped particles on the geomagnetic field," in "Advances in Geophysics," H. Landsberg, Ed., Academic Press, New York, N. Y., vol. 9; 1962.

nuclei and to a smaller extent (~1 per cent) the nuclei of heavier elements. They arrive at the top of the atmosphere with almost the speed of light and with energies ranging from a few billion volts (Bev) up to a billion times as much. They constitute the highest energy phenomenon known in nature; but because of the small number of cosmic rays which are received here, the energy they bring is about equal to the energy of starlight. Nevertheless, the effects of cosmic rays on the earth and the earth's atmosphere are important: they account for the production of C^{14}, H^3, and He^3 isotopes, among others, as well as for the ionization below the ionospheric layers.

One of the important means of studying the properties of the cosmic radiation has been through geomagnetic effects. A survey of cosmic ray intensity over the earth is therefore of real interest. Such surveys have been undertaken in the Soviet manned spaceships and published by Vernov and his colleagues. In the United States a lesser emphasis has been placed on cosmic ray measurements in satellites; many of the important results are still being obtained by balloons and high altitude rockets.[19]

Among the most interesting of the investigations are those related to increases of "cosmic" rays associated with solar flares.[20] Satellite data give, generally speaking, the spatial and time distribution of the increase. More detailed studies relating to the energy spectrum and composition of the SHEP radiation, however, have been done in high altitude rockets launched at high latitudes. Worth mentioning is the analysis of recovered satellite material from two DISCOVERER vehicles which were exposed to SHEP radiation. An analysis showed an anomalously large amount of tritium in the skin of the satellite whose origin has not been satisfactorily explained.
