PIONEERS IN MINIATURIZATION

SPECIAL CUSTOM BUILT POWER TRANSFORMERS & REACTORS

Exceptional quality and reliability is provided in all UTC designs. Over 30 years of engineering knowledge and experience backed by complete environmental testing and life testing facilities assure the highest standard in the industry. Full analysis and evaluation of materials are conducted in UTC's Material and Chemical Laboratories. Rigid quality control measures coordinated with exhaustive statistical findings and latest production procedures results in the industry's highest degree of reliability. Range covered in Power Transformers is from milliwatts to 100 KVA.

New designs for both military and commercial types custom built to YOUR specifications for transistor and tube applications.

SOME TYPICAL APPLICATIONS:

- Current Limiting
- Filament
- Isolation
- Plate
- Transistor Inverter
- Transistor Supply

Write for catalog of over 1,000 STOCK ITEMS with UTC High Reliability IMMEDIATELY AVAILABLE from your local distributor.

SPECIAL CUSTOM BUILT IRON CORE COMPONENTS FOR EVERY PHASE OF THE ELECTRONICS ART

POWER TRANSFORMERS • AUDIO TRANSFORMERS
REACTORS • PULSE TRANSFORMERS • ELECTRIC WAVE FILTERS • LUMPED CONSTANT DELAY LINES
HIGH Q COILS • MAGNETIC AMPLIFIERS

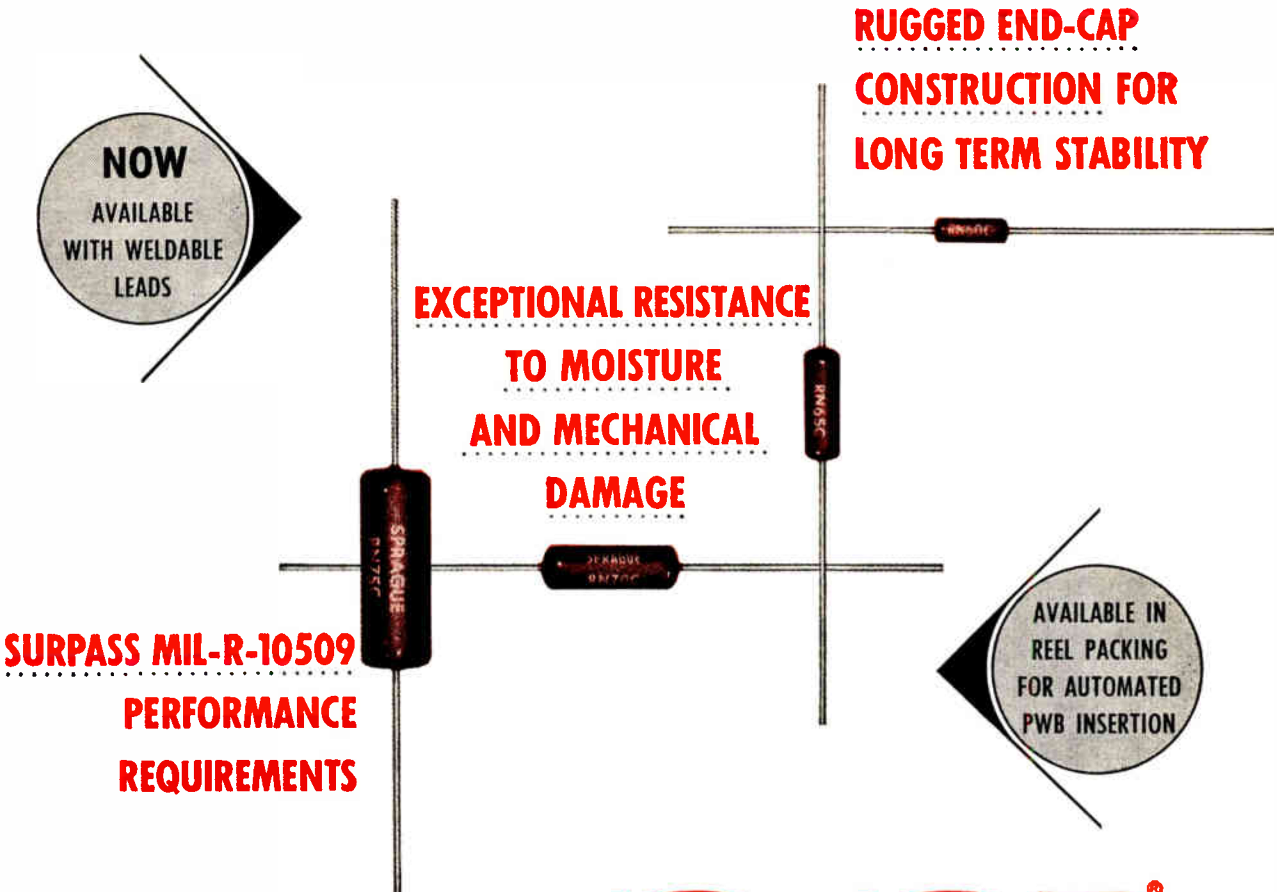
PROCEEDINGS OF THE IRE, published monthly by The Institute of Radio Engineers, Inc., at 1 East 79 Street, New York 21, N. Y. Manuscripts should be submitted in triplicate to the Editorial Department. Correspondence column items should not exceed four double-spaced pages (illustrations count as one-half page each). Responsibility for contents of papers published rests upon the authors, and not the IRE or its members. All republication rights, including translations, are reserved by the IRE and granted only on request. Abstracting is permitted with mention of source.

Thirty days notice is required for change of address. Yearly subscription price: members $9.00, one additional subscription $13.50; public libraries and colleges $13.50; non-members in the United States, Canada, and U. S. Possessions $18.00; abroad $19.00. Second-class postage paid at Menasha, Wisconsin, under the act of March 3, 1879. Acceptance for mailing at a special rate of postage is provided for in the act of February 28, 1925, embodied in Paragraph 4, Section 412, P. L. and R., authorized October 26, 1927. Printed in U.S.A.



FILMISTOR®

METAL FILM RESISTORS

OFFER 5 DISTINCT TEMPERATURE COEFFICIENTS TO MEET ALL CIRCUIT REQUIREMENTS

Providing close accuracy, reliability and stability with low controlled temperature coefficients, these molded case metal-film resistors outperform precision wirewound and carbon film resistors. Prime characteristics include minimum inherent noise level, negligible voltage coefficient of resistance and excellent long-time stability under rated load as well as under severe conditions of humidity.

Close tracking of resistance values of 2 or more resistors over a wide temperature range is another key performance characteristic of molded-case Filmistor Metal Film Resistors. This is especially important where they are used to make highly accurate ratio dividers.

Filmistor Metal Film Resistors, in ⅛, ¼, ½ and 1 watt ratings, surpass stringent performance requirements of MIL-R-10509D, Characteristics C and E. Write for Engineering Bulletin No. 7025 to: Technical Literature Section, Sprague Electric Co., 235 Marshall Street, North Adams, Mass.

For application engineering assistance write:
Resistor Division, Sprague Electric Co., Nashua, New Hampshire.

THE MARK OF RELIABILITY

On this fiftieth anniversary of the IRE, all of us look forward to the advances sure to be made in the next fifty years. But we thought it would be fun to look back fifty years and see what the world was like in the year that the IRE was founded.

Peg Salzberg, the wife of AIL's Chief Scientist, contributed the idea and most of the material for this ad. It is arranged in the format that THE NEW YORK TIMES *uses to summarize the news of the day.*

1912 NEWS SUMMARY

the year the IRE was born

International

U. S. Troops land in China. U. S. Marines land in Cuba, Honduras, and Nicaragua to maintain order and to protect American interests.

General Monteagudo, commander in chief of the Cuban Government troops, formally turns over the government of the province of Oriente to the civil authorities, declaring that the revolution is over.

Russian troops advance into Azerbaijan and northeast Khorosan.

The French General Gouraud defeats the Rogui of Sichtala, said to have been France's most troublesome enemy in Morocco.

War breaks out between Turkey and a confederation of Greece, Serbia, Bulgaria, and Montenegro.

Andrew Carnegie sends a letter to the heads of all leading nations, appealing for peace. "Get together often. Learn to trust each other."

Dr. Charles W. Eliot, former president of Harvard, returns from a trip around the world in the interests of universal peace. His conclusion: "International or national disarmament is not taken seriously by the leaders and thinking men of the more important peoples."

The Arbitration League (which includes such eminent Englishmen as Sir Arthur Conan Doyle, John Galsworthy, Sir William Osler, and Sir William Ramsay) issues a "memorial protesting against the use of aerial vessels in war" and appeals "to all Governments to foster an international understanding which shall prevent the world from what they think would add new hideousness to warfare. . . . To the argument that because men fight on earth and water they may just as well fight in the air, they reply that there has never yet been a moment when it was practically possible to ban war machines of the earth or the water, but there is a moment when it is practically possible to ban those of the air. That moment is now before us, before these machines have been proved and great vested interests have been formed."

The board of directors of the Nobel Institute announce that no Peace Prize will be awarded in 1912.

The Titanic, the world's largest passenger ship, strikes an iceberg on her maiden voyage and sinks—with a loss of 1500 lives. (Her wireless calls for help were heard by numerous ships, but the radio room of the California, only a few miles away from the sinking ship, had shut down for the night and did not receive the distress signal.)

Captain Robert Falcon Scott and four members of his British Antarctic Expedition reach the South Pole—only to find that Amundsen with a Norwegian party had arrived about a month earlier. (Scott's party suffered extremely severe weather, and on the way back their supplies ran short. Two men had already died when Scott made his last camp—only 11 miles from a supply depot. The death of his party was not known until 1913, when the rest of his expedition reached New Zealand. All subsequent expeditions were equipped with wireless.)

A survey of noted Englishmen revealed this list of "The Ten Greatest Living Men": Edison, Kipling, Roosevelt (Theodore), Marconi, Lister, Chamberlain, Taft, Roberts, William II, Metchnikoff. (Also rans: Wilbur Wright, Andrew Carnegie, J. Pierpont Morgan, John D. Rockefeller, Puccini.)

The population of the world is estimated at 1,623,300,000.

National

New Mexico and Arizona are admitted to the Union as the 47th and 48th states.

April floods in the Mississippi valley leave 30,000 homeless and cause damage of $50,000,000.

About 50,000 students will graduate from college this year; this represents about 66 percent more students than graduated ten years ago. . . . College tuition costs range from about $40 to $250; Harvard, Yale, and Princeton charge about $150.

A teacher sees the public school as "the most momentous failure in our American life. Can you imagine a more grossly stupid, a more genuinely asinine system tenaciously persisted in to the fearful detriment of over 17,000,000 children and at a cost to you of over $403,000,000 each year—a system that not only is absolutely ineffective in its results, but also actually harmful in that it throws every year 93 out of 100 children into the world of action absolutely unfitted for even the simplest tasks in life?"

There have been fewer lynchings in 1912 than in any previous year since 1884—64 (vs 71 in 1911). But suicides have increased from 12,242 in 1911 to 12,981 in 1912.

R. E. Olds, noted automobile designer, calls his Reo the Fifth his Farewell Car because he believes that it represents the ultimate in car design. The future, he says, will bring minor changes, folderol and fashion, but a 35-horsepower 4-cylinder car will doubtless remain the standard because greater power is unnecessary and expensive. In the future, just this one car will be made.

In six months, gasoline prices have increased from 6¢ per gallon to 16¢ per gallon. . . . "What do you know about mortgages?" "I know all about mortgages. The first mortgage is for the car; the second mortgage is for the upkeep."

Headline on front page of "The New York Times," December 28, 1912: "THE STOCK EXCHANGE IS TO REFORM ITSELF"

The 54-hour-a-week law becomes effective in New York State. . . . The Government sues the Erie Railroad for keeping firemen on duty more than 16 hours a day.

As a result of the showing of American moving pictures, American styles of hats, shoes, clothing, and haircuts have become very popular in Belgrade. The American ambassador suggests that all kinds of American products, including farm machinery, should be promoted in this fashion.

Commissions delegated to investigate vice conditions in many large cities have uniformly found the public dancehall next to the saloon in the potency of its influence for evil.

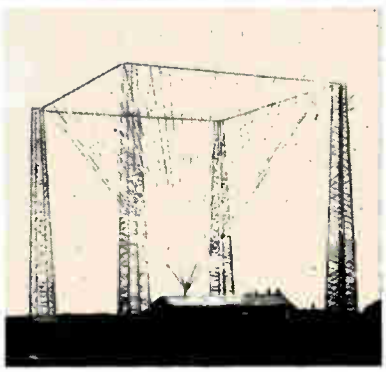
During 1912, Broadway showed 97 new plays, 36 new musical comedies, and numerous revivals. "Peg o' My Heart," "Little Women," and "Within the Law" were some of the plays: George M. Cohan, Weber and Fields, and Laurette Taylor were some of the performers. . . . The Metropolitan Opera stars include Tetrazzini, Mary Garden, Scotti and Caruso. Caruso earned about $90,000 in 1912 from "talking-machine records."

The Boston Red Sox win the World Series from the New York Giants. (Christy Mathewson was a Giant pitcher.)

The chestnut tree blight is spreading and affecting more and more trees. Scientists and tree experts have not been able to find any cure for it.

Wireless

In a new wireless telegraph system devised by Prof. Zehnder, no antenna is required.



Marconi Station at Glace Bay, Cape Breton Island

A law is passed (shortly after the Titanic disaster) requiring ships carrying more than 50 passengers to have wireless equipment capable of transmitting messages 100 miles or more, an auxiliary set with independent power supply, and at least two skilled operators.

A new law requires every station (operator) to obtain a license, to use special call letters, and to designate his normal sending and receiving wave lengths. (Fortescue, in a book written in 1912, describes the indiscriminate use of powerful transmitting apparatus by amateurs in the U.S.A. as resulting in chaos.)

Headline on front page of "The New York Times," February 1, 1912: "WIRELESS TO LINK ALL BRITISH EMPIRE" "Every part of the empire, on which it is the Briton's proud boast that the sun never sets, will be linked by an immaterial chain formed out of the encircled either. A new Puck will girdle the earth."

G. W. Pierce, a Harvard professor, demonstrates a "wireless telephone" with which he communicates between Gloucester and Cambridge, Mass.—a distance of about 35 miles.

The new wireless station of the Navy Department at Arlington, Va., which is one of the largest in the world, will send out time signals to all parts of the United States.

The Audion detector is coming into use, replacing crystals or the moving steel tape in a magnetic field which are often used on board ships.

Science and Industry

Headline in "The New York Times," February 4, 1912: "GREAT BIOLOGISTS UNITE TO SEEK A CANCER CURE" (Among them—Dr. Paul Ehrlich, Dr. A. von Wassermann, and Dr. Metchnikoff.)

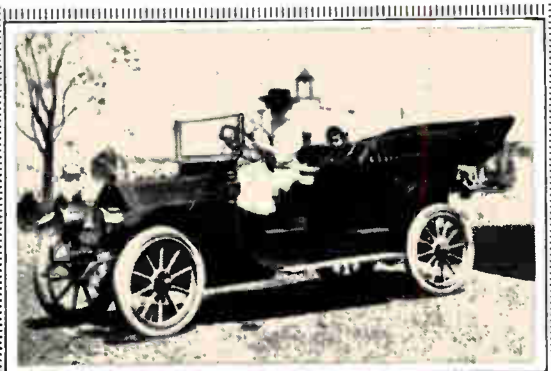
Headlines in "The New York Times," December 29, 1912: "DR. LEO LOEB MAKES BOLD EXPERIMENTS IN CANCER CASES. ST. LOUIS EXPERT ACHIEVES RESULTS FROM COLLOIDAL COPPER THAT ARE CONSIDERED REMARKABLE."

Dr. H. Glebeler reports "The discovery of radium, uranium and emanation radiations in the spectrum of Nova Geminorum."

Cutler-Hammer develops the "world's first practical, electrically-controlled, pushbutton-operated gear shift mechanism applicable to the sliding gear transmissions of the automobile." The picture shows Miss Claire Rochester in her Premier car, on which the C-H Magnetic Gear Shift is regular equipment. (Miss Rochester is the famous "Liberty Girl," who drove from coast to coast in 11 days, to procure funds to illuminate the Statue of Liberty.) Miss Rochester says she would not shift gears by hand any more.

To raise money for charity, Miss Rochester drove up the County Court House steps in San Antonio. Here is what she says about the C-H Magnetic Gear Shift: "For years I've shifted gears by hand. Now, I simply press a button on my Premier and electricity does the shifting for me. Today I wouldn't be bothered with the difficulty of shifting gears by hand. No other up-to-date motorist should and wouldn't if they saw the Magnetic Gear Shift of the Premier."

(In 1912, the 19-year-old Cutler-Hammer organization employed 250 people. The median age of the forty people who today make up AIL's senior staff was minus six years in 1912.)



Meetings with Exhibits

● As a service both to Members and the industry, we will endeavor to record in this column each month those meetings of IRE, its sections and professional groups, which include exhibits.

Δ

May 14-16, 1962

NAECON (National Aerospace Electronics Conference), Biltmore Hotel, Dayton, Ohio

Exhibits: Mr. Robert J. Stein, 19 Beverly Place, Dayton 19, Ohio

May 23-25, 1962

National Telemetering Conference, Sheraton Park Hotel, Washington, D.C.

Exhibits: Mr. L. H. King, Jansky & Bailey Co., Shirley Highway & Edsall Rd., Alexandria, Va.

May 24-26, 1962

IRE Seventh Region Conference on "Space Communications," Olympic Hotel, Seattle, Wash.

Exhibits: Mr. J. K. Schloss, 1520 N.E. 106th, Seattle 55, Wash.

June 12-14, 1962

Armed Forces Communications & Electronics Show, Sheraton Park Hotel, Washington, D.C.

Exhibits: Mr. William C. Copp, 72 W. 45th St., New York 36, N.Y.

June 18-19, 1962

Chicago Spring Conference on Broadcast and Television Receivers, O'Hare Inn, Chicago, Ill.

Exhibits: Mr. John H. Landeck, Admiral Corp., 3800 W. Cortland St., Chicago 47, Ill.

June 25-27, 1962

Sixth National Convention on Military Electronics, Shoreham Hotel, Washington, D.C.

Exhibits: Mr. L. D. Whitelock, 5614 Greentree Rd., Bethesda 14, Md.

June 25-27, 1962

Sixth National Conference on Product Engineering & Production, Los Angeles, Calif.

Exhibits: Mr. Lionel Crown, International Computer, 4301 Redwood Ave., Los Angeles 66, Calif.

August 21-24, 1962

Western Electronics Show and Conference (WESCON), Ambassador Hotel & Memorial Sports Arena, Los Angeles, Calif.

Exhibits: Mr. Don Larson, WESCON, 1435 La Cienega Blvd., Los Angeles, Calif.

(Continued on page 10A)

HYREL® ST Capacitors, developed and qualified for use in the Minuteman Missile, are NOW available to you in ALL RATINGS!

- Quality *100 times greater* than that of former high-reliability components! That's the ultra-high-reliability now demanded of electronic parts in the Minuteman missile's intricate guidance and control system.
- An unmatched test history of over 127 million unit-hours backs up the design of HYREL ST Capacitors to withstand the rigorous performance requirements specified for Minuteman components.
- The pioneer in solid tantalum capacitors, Sprague is one of 12 nationally-known manufacturers chosen to participate in the Air Force's Minuteman Component Development Program of Autonetics, a division of North American Aviation, Inc.
- All of the special processes and quality control procedures that make HYREL ST Capacitors the most reliable in the world can now help you in your military electronic circuitry. A tantalum capacitor engineer will be glad to discuss the application of these capacitors to your missile and space projects. Write to Mr. C. G. Killen, Vice-president, Industrial and Military Sales, Sprague Electric Company, 235 Marshall St., North Adams, Mass.

THE MARK OF RELIABILITY

Meetings with Exhibits

(Continued from page 8A)

August 29-September 1, 1962

Second International Conference on Information Processing, Munich, Germany

Exhibits: Dr. Heinz Billing, Max Planck Institute, Munich, Germany

September 3-7, 1962

National Advanced Technology Management Conference, Opera House, Seattle World's Fair Grounds, Seattle, Wash.

Exhibits: Mr. Hugh Fairclough, 1624 22nd Avenue East, Seattle 2, Wash.

October 1-3, 1962

Eighth National Communications Symposium, Hotel Utica & Utica Municipal Auditorium, Utica, N.Y.

Exhibits: Mr. Charles Glaviano, 45 Meadow Dr., Rome, N.Y.

October 2-4, 1962

Seventh National Symposium on Space Electronics & Telemetry, Fontainebleau Hotel, Miami, Fla.

Exhibits: Mr. Charles H. Doersam, Jr., Instruments for Industry, 101 New South Road, Hicksville, L.I., N.Y.

October 8-10, 1962

National Electronics Conference, McCormick Place, Chicago, Ill.

Exhibits: Mr. Rudy Napolitan, National Electronics Conference, 228 N. LaSalle St., Chicago, Ill.

October 15-18, 1962

Symposium on Space Phenomena & Measurement, Statler Hilton Hotel, Detroit, Mich.

Exhibits: Mr. J. B. Bullock, University of Michigan, Ann Arbor, Mich.

November 1-2, 1962

Sixth National Conference on Product Engineering and Production, Jack Tar Hotel, San Francisco, Calif.

Exhibits: Mr. W. Dale Fuller, Lockheed Missiles & Space Div., P.O. Box 504, Sunnyvale, Calif.

November 4-7, 1962

Fifteenth Annual Conference on Engineering in Biology and Medicine, Conrad Hilton Hotel, Chicago, Ill.

Exhibits: Professional Associates, Inc., 6520 Clayton Rd., Saint Louis, Mo.

Δ

Note on Professional Group Meetings: Some of the Professional Groups conduct meetings at which there are exhibits. Working committeemen on these groups are asked to send advance data to this column for publicity information. You may address these notices to the Advertising Department and of course listings are free to IRE Professional Groups.

HOW TO TORTURE A MICROWAVE COMPONENT

Metcom puts every one of the microwave components it manufactures through a very special kind of hell known technically as Dynamic Environmental Testing.

Here, for example, a beacon magnetron, hooked up to the barrel-shaped vibrator in the center of this picture, is about to receive, electronically, the shaking up of its life. When it has passed this particular test, it (and every other beacon magnetron with our name on it) will be placed in a vacuum, and alternately frozen and cooked at temperatures ranging from —54°C to 125°C. And that's not all. Some from each lot will be sterilized — some will be tested to ultimate destruction.

No part of our job is more important than subjecting our own products to this uniquely thorough dynamic environmental testing — to this very special kind of hell. Extra-rigorous testing is the best guarantee there is of extra-reliable performance.

Whatever your requirements in microwave components, *make sure they're by Metcom . . . because Metcom makes sure.*

Write for our folder containing brief specifications on over 300 microwave tubes and devices.

for better microwave tubes and devices . . . . METCOM INC.

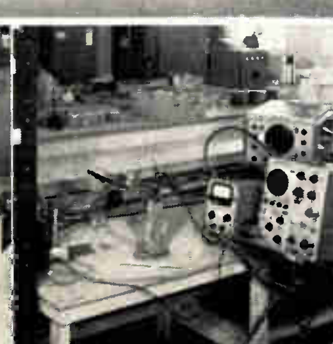
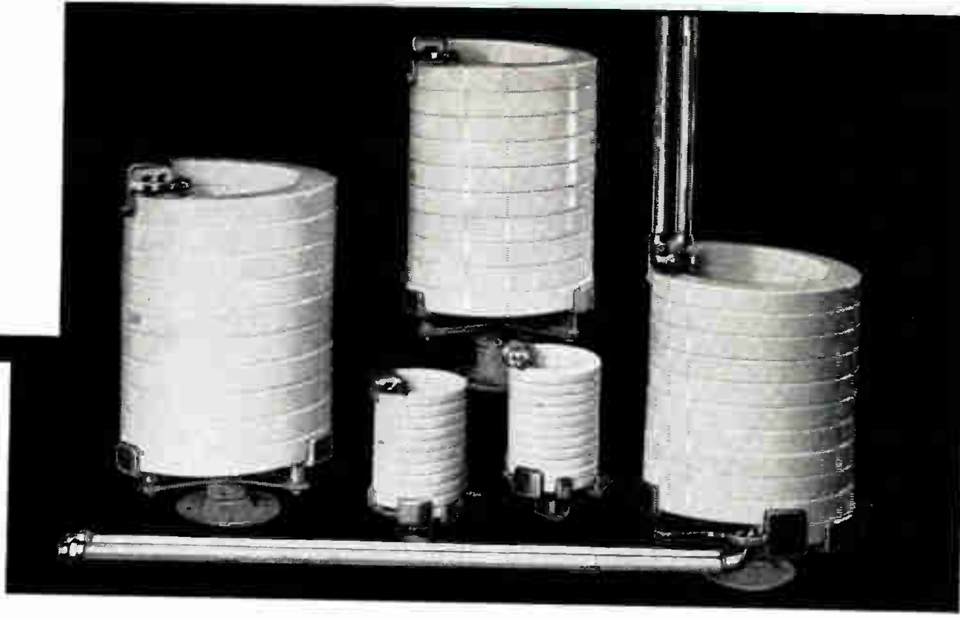
Magnetron aging



Magnetron life test

Magnetron acceptance test

Lapp

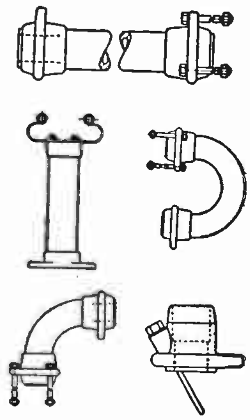


TUBE SUPPORTS
for air-cooled tubes

No longer is it necessary for equipment manufacturers to design supports for forced-air-cooled tubes. After producing many such special designs, Lapp has engineered and built a complete series of insulating supports for air-cooled tubes. Use of these supports facilitates design of transmitter and other high-power circuits. Simple, compact, efficient and attractive in appearance, in porcelain or steatite, they make for economical production, easy interchangeability, and availability of replacement units. Write for Bulletin 301, with complete description and specification data.

INSULATION FOR WATER-COOLED SYSTEMS

For carrying cooling water which must undergo a change in potential, use of Lapp porcelain eliminates troubles arising from water contamination and conductivity, sludging and electrolytic attack of fittings. Permanent cleanness and high resistance of cooling water is assured—for positive cooling and long tube life.



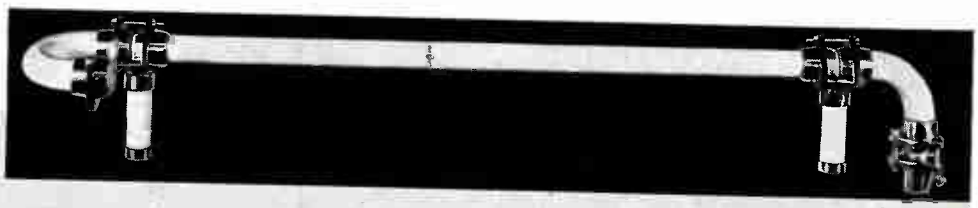
LAPP PORCELAIN WATER COILS

Twin-hole and single-hole models in sizes to provide flow of cooling water from 2 to 90 gallons per minute. Cast aluminum mounting bases, lead pipe or flexible metal hose for attachment.

LAPP PORCELAIN PIPE

Inside diameters ¾″ to 3″, in straight, 90° and 180° elbows, fittings. Swivel-type connections. Standoff insulators attach directly to fitting bolts.

Write for Bulletin 301 with specifications for Lapp Porcelain Water Coils and Porcelain Pipe.



LAPP GAS-FILLED CONDENSERS
Capacitance for high-voltage, high-current duty

The record of more than 18 years' service, in thousands of installations, proves the reliability of the Lapp Gas-Filled Condenser. For duty at high voltages and high currents, this unit offers the advantages of extreme compactness . . . low loss . . . high safety factor . . . constant capacitance under temperature variation . . . grounded tuning shaft . . . and rugged sturdiness. Units available in four tank diameters, 7″ to 18″ . . . in fixed or variable capacitance . . . capacitances to 30,000 mmf; current ratings to 390 amps at 1 mc; voltages to 85 Kv peak. Write for Bulletin 302.

ENTRANCE INSULATORS

To eliminate losses which occur in ordinary types of bushings at radio frequency, Lapp units use air as major insulation, porcelain path being lengthened by its "bowl" shape. In wide variety of types for most electrical and mechanical requirements.

STAND-OFF INSULATORS

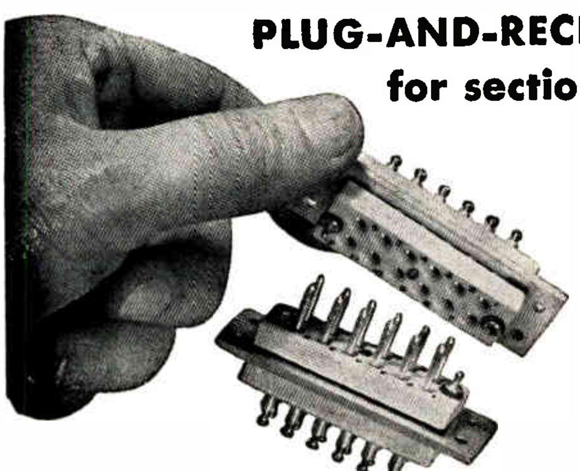
Dependable mechanical and electrical performance—and trim good looks. Hundreds of standard and special types available.

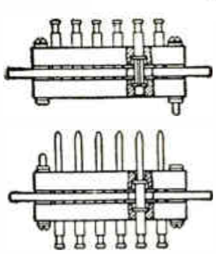
Write for Bulletin 301, listing entrance and stand-off insulators.

ANTENNA STRAIN INSULATORS

The largest of the porcelain rod insulators shown develops 12,000 lb. strength. Available, as specified, with rain shield and/or corona rings. Smaller units, in porcelain or steatite, for all strain or spreader use. Engineering and production facilities also available for special performance units See catalog 301.

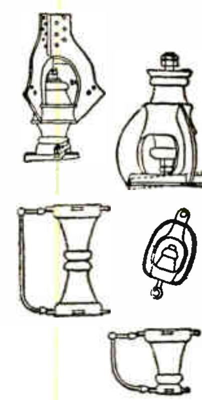
PLUG-AND-RECEPTACLE UNITS for sectionalizing circuits





For panel-rack or other sectionalized circuits, Lapp offers a variety of plug-and-receptacle units. Any number of contacts can be provided (in multiples of twelve). Male and female contacts are full floating, for easy alignment and positive contact. Contacts silver plated, terminals tinned for soldering. Insulation is steatite, the low-loss ceramic . . . non-carbonizing even under leakage flashover resulting from contamination, moisture or humidity. Write for complete electrical and mechanical specifications and recommendations.

ANTENNA TOWER INSULATORS



Most of the world's radio towers are supported by Lapp insulators, including the tallest guyed mast ever built. Through the Lapp "compression cone," immense loads can be carried by electrical porcelain. Write for data on Lapp footing insulators for self-supporting radiators, mast-base insulators, or guy insulators.

SPECIAL ASSEMBLIES

Lapp business is electrical porcelain, its application, design, manufacture, and assembly. Our skill is in our knowledge of the capabilities, and limitations, of ceramic insulation . . . in engineering ingenuity to meet specified requirements . . . and in efficient production. If you have need for insulating parts and associated sub-assemblies, we may be able to show you how they can be made most economically, to perform most efficiently.

NBS Offers Radio Propagation Course

The National Bureau of Standards will present a three-week course in Radio Propagation from July 16–August 3, 1962, at the Boulder Laboratories, Boulder, Colo.

The course, sponsored by the NBS Central Radio Propagation Laboratory in association with the University of Colorado, is designed to give scientists and engineers from universities, industry, and government agencies access to the latest advances in radio propagation research and show how this knowledge can best be applied to the design and development of communication systems. It will consider communication via the entire range of useable radio frequencies in the atmosphere, space, underground, and underwater, and will extend into the modes of propagation which are being explored for the future.

The Central NBS Radio Propagation Laboratory in Boulder conducts continuous studies designed to develop new methods of communication and more efficient use of the methods which now exist. This Laboratory is the central information agency of the government on the propagation of radio waves at all frequencies along the surface of the earth, in the atmosphere, and in space. The course is being offered as part of the Laboratory's responsibility to help industry and government design the most efficient communication systems possible.

To facilitate transfer of academic credit for students working on graduate degrees in areas related to radio propagation, the course will be included in the Graduate program at the University of Colorado. Such students must plan an additional half day at the end of the course to write a final examination.

The 1962 course will employ a unified approach to both ionospheric and tropospheric propagation stressing their similarities and differences. Increased emphasis will be given to both fundamental physics and to systems applications. Lectures will be supplemented by regularly scheduled informal discussions conducted by all lecturers within a particular topic group.

Prerequisites for the course are a Bachelor's degree in electrical engineering, physics, or other suitable academic or practical experience. A tuition is $300 for the entire course running from July 16 through August 3. A small additional University registration fee will be required of students who also desire academic credit.

Registration will be limited and early application should be made to ensure consideration. To facilitate local arrangements, registration will be closed July 1, 1962. Further details of the course and registration forms will be available March 1, 1962, from: Edmund H. Brown, Education Director, Boulder Laboratories, National Bureau of Standards, Boulder, Colo.

PGVC Presents Chapter of the Year Award

The Institute of Radio Engineers Professional Group on Vehicular Communications presented its Chapter of the Year Award for 1960–1961 to the Chicago Chapter. The award was presented at the 12th National Conference of the Professional Group Vehicular Communications held in Minneapolis, Minn., on November 30 and December 1, 1961. J. E. Farley, presently Chairman of the Chicago Chapter, accepted the award for Chicago.

This Chapter organized an active professional program covering the fast moving developments in the mobile radio field last year. Included in their program were papers and meetings on Satellite Communications, Airlines Radio, and a field trip of the new communication facilities at O'Hare Airport, Chicago, Ill.

1960–1961 PGVC Chicago Chapter Officers: *Left to right:* G. P. Schleicher (Membership), Jack Germain (Chairman), J. E. Farley (Vice-Chairman), F. Hilton (Secretary-Treasurer), B. D. Wickline (Arrangements).

Captain Kenneth M. Gentry, USN, (*left*) receiving his decoration "Cavialeri Ufficiale" of the Order "Al Merito della Repubblica Italiana," from Admiral Pecori Geraldi, Chief of Italian Naval Staff.

Captain Kenneth M. Gentry Receives Decoration

Captain Kenneth M. Gentry, USN, (Retired) has been decorated by the Italian government for his work in establishing a Supreme Allied Commander Atlantic anti-submarine warfare research center in Italy. The decoration, called "Cavialeri Ufficiale" of the Order "Al Merito della Repubblica Italiana," was presented by Chief of Italian Naval Staff, Admiral Pecori Geraldi, in Rome.

Captain Gentry served as Subcommittee Chairman of the Naval Research Advisory Committee which visited NATO countries to investigate organizing the NATO research laboratory. The recommendations of this subcommittee and the subsequent negotiations between nine NATO nations resulted in setting up the center in LaSpezia, Italy. Captain Gentry served as its first Military Director, and for his work as director was awarded a Letter of Commendation from SACLANT, and a Letter of Appreciation from the Scientific Advisory Council of the nine NATO nations.

At present, Captain Gentry is Associate Director of Research and Development for Undersea Warfare and Electronic Countermeasures for the Motorola Military Electronics Division, Chicago, Ill.

IEE-IRE Cooperate In London TV Conference

The International Television Conference will be held in London, England, May 31 to June 7, 1962. The Conference is organized by the Electronics and Communications Section of The Institution of Electrical Engineers in association with the Television Society, the British Kinematograph Society and the IRE. The association of the IRE in the Conference will provide an important example of Anglo-American cooperation in the professional electronic field, which, it is hoped, will set a pattern for the future.

The Conference will overlap the last three days of the International Instruments, Electronics and Automation Exhibition at Olympia, London, and arrangements are being made for those attending the Conference to attend the exhibition. The technical program will also include visits to various laboratories and industrial organizations.

The Chairman of the Conference Organizing Committee is Robert C. G. Williams who is also Chairman of the IRE Advisory Committee in the United Kingdom. Information and registration forms may be obtained by writing the Secretary, The Institution of Electrical Engineers, Savoy Place, London, W.C.2, England.

The provisional sessions of the Conference are as follows:

Thursday, May 31—Opening Session.

Friday, June 1 (morning)—Systems Standards; (afternoon)—Signal Pick-Up Tubes.

Monday, June 4 (morning)—Frequency-Assignment Problems, with a parallel session on Television Recording—Programme and Commercial; (afternoon)—Standards Conversion, with a parallel session on Medical Uses.

Tuesday, June 5 (morning)—Point-to-Point Links, with a parallel session on Outside-Broadcast Equipment; (afternoon)—Studio Design, with a parallel session on both Scientific Applications and Data Transmission.

Wednesday, June 6 (morning)—Wire Broadcasting for Domestic Television, with parallel sessions on Studio Design and Lighting, and Industrial Applications; (afternoon)—Broadcast Transmitter Equipment, with a parallel session on Low-Light-Level Applications.

Thursday, June 7 (morning)—Domestic Receiver Equipment, with a parallel session on Space Applications; (afternoon)—Color Television.

Calendar of Coming Events and Author's Deadlines*

(*Continued from page 14A*)

June 28–29: 4th Nat'l Symp. on Radio Frequency Interference, Town House Hotel, San Francisco, Calif.

July 17–18: Data Acquisition and Processing in Medicine and Biology, Whipple Aud., Strong Mem. Hosp., Rochester, N. Y.

Aug. 14–16: Internat'l Conf. on Precision Electromagnetic Measurements (former title: Conf. on Standards and Electronic Measurements), Nat'l. Bur. Standards, Boulder, Colo.

Aug. 21–24: WSCON (Western Electronics Show and Conf.) Los Angeles, Calif.

Aug. 27–Sept. 1: 2nd Internat'l Federation of Information Processing Societies Congress, Munich, Germany.

Sept. 3–7: Internat'l Symp. on Information Theory, Brussels, Belgium

Sept. 3–7: Nat'l Advanced Technology, Management Conf., Seattle, Wash.

Sept. 3–7: 4th Internat'l Congress on Microwave Tubes, Kurhaus Hotel, Scheveningen, Netherlands

Sept. 4–7: ACM Nat'l Conf., Hotel Syracuse, Syracuse, N. Y.

Sept. 13–14: 10th Annual Engineering Management Conf., Hotel Roosevelt, New Orleans, La.

Sept. 13–14: Nat'l Symp. on Engineering Writing and Speech, Mayflower Hotel, Washington, D. C.

Sept. 19–20: 11th Annual Industrial Electronics Symp., Hotel Sheraton, Chicago, Ill.

Sept. 28–29: 12th Annual Broadcast Symp., Willard Hotel, Washington, D. C.

Oct. 1–3: 8th Nat'l Communications Symposium, Utica, N. Y. (DL*: June 1, 1962, G. Baldwin, Paris Rd.-R.D. 2, Clinton, N. Y.)

Oct. 7–12: AIEE 1962 Fall General Meeting—3rd Ann. Symp. on Switching, Circuit Theory and Logical Design, Chicago, Ill. (DL*: Apr. 1, 1962, W. Semon, Sperry Rand Res. Ctr., North Rd., Sudbury, Mass.)

Oct. 15–18: Symposium on Space Phenomena and Measurement, Statler Hilton Hotel, Detroit, Mich.

Oct. 22–24: ECCANE, Emerson Hotel, Baltimore, Md. (DL*: June 4, 1962, W. C. Vergara, Dept. 466-2, Bendix Radio, Towson 4, Md.)

Oct. 30–31: Spaceborne Computer Engineering Conf., Disneyland Hotel, Anaheim, Calif. (DL*: June 15, 1962).

Nov. 1–2: Sixth National Conf. on Product Engineering and Production, Jack Tar Hotel, San Francisco, Calif. (DL*: June 11, 1962, G. F. Reyling, Varian Associates, 611 Hansen Way, Palo Alto, Calif.)

Nov. 4–7: 15th Annual Conference on Engineering in Biology and Medicine, Conrad Hilton Hotel, Chicago, Ill. (DL*: June 1, 1962, D. A. Holaday, Univ. of Chicago, 950 E. 59 St., Chicago, Ill.)

Nov. 5–7: Northeast Res. and Engineering Meeting, Boston, Mass.

Nov. 12–14: Radio Fall Meeting, King Edward Hotel, Toronto, Ont., Canada.

* DL = Deadline for submitting abstracts.

Tudor R. Finch (*right*), chairman of the 1961 International Solid-State Circuits Conference, presenting one of the annual conference awards to Hewitt D. Crane (*left*) for his outstanding paper on the Neuristor delivered during the 1961 meeting.

Solid-State Circuits Conference Digests Offered

Digests of Technical Papers for the 1962 International Solid-State Circuits Conference held at the University of Pennsylvania and the Sheraton Hotel, Philadelphia, Pa., February 14, are being offered. The digest (112 pages) includes illustrated condensations of all of the conference papers.

Copies are now available at $5.00 each and can be obtained from: H. G. Sparks, The Moore School of Electrical Engineering, University of Pennsylvania, 200 S. 33rd Street, Philadelphia, Pa. Remittance (payable in U. S. currency) should be made payable to the order of: Solid-State Circuits Conference.

University of California Presents Summer Course

The seventh annual summer Reliability and Statistical Methods in Industry Course will be presented at the University of California, Los Angeles, Calif., July 30, through August 24, 1962. The course will be jointly sponsored by the Dept. of Engineering and University Extension in cooperation with the Los Angeles Sections of the American Society for Quality Control, American Society of Mechanical Engineers, American Institute of Industrial Engineers, American Institute of Electrical Engineers, the Small Business Administration and the Society for Non-Destructive Testing.

The program will be divided into two sessions, each consisting of four courses of two weeks each. The courses are planned for key people whose responsibilities are concerned with improved production including inspectors, managers, engineers and others involved in research and development.

Staff for this program is specially selected from all parts of the United States and includes recognized experts in their respective fields.

For a brochure of this program giving full details of the above courses and other general lectures and special features, contact: Edward P. Coleman, Professor of Engineering, University of California, Los Angeles 24, Calif.

New Geoscience PG Announces Officers

At the first organizational meeting of IRE's newest Professional Group, No. G-29 on Geoscience Electronics, nine members of an anticipated 15-member administrative committee were elected. The meeting was held in Dallas, Tex., on February 15, 1962, under the guidance of Chairman pro-tem Robert W. Olson, Texas Instruments, Dallas. The committee members are, in addition to Chairman Olson (F): M. A. Arthur (SM), Humble Oil, Houston, Tex.; W. T. Born (F), Geophysical Research, Tulsa, Okla.; R. A. Broding (SM), Century Geophysical, Tulsa, Okla.; Sidney Kaufman (SM), Shell Development, Houston, Tex.; B. H. List (M), Texas Instruments, Dallas, Tex.; W. Harry Mayne (SM), Petty Geophysical, San Antonio, Tex.; F. C. Smith, Jr. (SM), Dannemiller-Smith, Houston, Tex.; H. W. Smith (SM), University of Texas, Austin, Tex.

The remaining six positions on the administrative committee will be filled at its next meeting to be held during the 1962 SWIRECO Convention, April 11–13, in Houston, Tex. It is planned for these to represent other geographical areas and different branches of the geosciences from those listed above. Interested members of the IRE are invited to attend.

Space Symposium Call for Papers

A Symposium on Space Phenomena and Measurement will be held in Detroit, Mich., October 15–18, 1962. Co-sponsors for the Symposium are the IRE Professional Group on Nuclear Science, the Atomic Energy Commission, and the National Aeronautics and Space Administration.

Space environments and measurements will be emphasized during the three-day meeting but, in addition, a parallel session will be presented on selected topics on space nuclear propulsion, energy conversion, nuclear instrumentation and radiation effects. Typical of the space exploration topics to be included are: Measurement in the Radiation Belts, Solar and Galactic Cosmic Ray Behavior, Electromagnetic Fields in the Solar System, and X-Ray and Gamma Ray Astronomy.

Papers are being accepted for both sessions of this meeting. One hundred word abstracts should be submitted before July 1, 1962 to: Mr. Michael Ihnat, AVCO Corp., 201 Lowell St., Wilmington, Mass. A rough draft of the paper should be submitted to the same address prior to September 1, 1962.

Further details relating to the Symposium can be obtained by writing: Dr. Harold E. DeBolt, AVCO Corp., 201 Lowell St., Wilmington, Mass.

Industrial Engineering Seminars Held at Cornell

Cornell University, Ithaca, N. Y., will hold Industrial Engineering Seminars from June 12 through June 15, 1962. The Seminars are being sponsored by the Dept. of Industrial and Engineering Administration, Cornell University.

Participants enroll in one of the following eleven groups and also attend general sessions: Industrial Management, Engineering Administration, Capital Investment Planning (Theory and Practice), Operations Management of the Smaller Company, Work Measurement, Applied Operations Research, Systems Simulation Using Digital Computers, Techniques of Mathematical Programming, Queuing and Inventory Theory, Statistical Decision Making (Theory and Practice), and Statistical Reliability Analysis (Theory and Practice).

The discussion leaders and speakers will be specialists from both industry and the staff of Cornell University.

The Seminars are offered to operating management personnel in line supervision and staff positions in industrial engineering, production engineering, engineering administration, operations research, research and development, quality control, production and inventory control, cost control, materials management, warehousing, purchasing, data processing, and the controller's function.

For additional information write: J. W. Gavett, Seminars Coordinator, Dept. of Industrial and Engineering Administration, Upson Hall, Cornell University, Ithaca, N. Y.

PANORAMIC "the pioneer is the leader"

dependable CERTIFIED SPECIFICATIONS for accurate data

SUMMARY OF SPECIFICATIONS

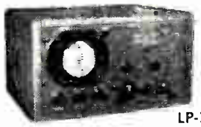
SPECTRUM ANALYZERS

½ cps to 44 kmc

BROADBAND SPECTRUM ANALYZERS 0.5 cps to 25 mc. Easy-to-operate direct reading analyzers display plot of signal amplitude vs. frequency on 5" CRT or chart. Features include: "quick look" wideband scans plus highly selective narrow scans. Center frequency, sweep width, and selectivity (resolution) are adjustable. Calibrated linear and 40-db log scales

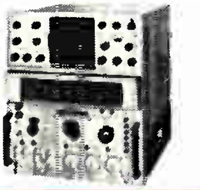
All these broadband spectrum analyzers are available with accessories and in systems (data on SY-systems available) which materially improve specifications and application versatility.

*This specification improved or adjustable with optional accessories.



LP-1a

Frequency Range	Model No.	Sweep Width	Resolution (I-F Bandwidth)	Sensitivity Range (Full Scale Linear)	Sweep Rate	Harmonic Products (Dynamic Range)
0.5 cps to 2500 cps	LF-2b (incl. chart recorder. 3" CRT optional)	Preset 2-500 cps on 2 ranges	0.1-20 cps	10 mv to 100 v	30 sec- 16 min/scan	—40 db
20 cps* to 22.5 kc.	LP-1a (5" CRT)	40 cps—20 kc log scan. Linear* 200, 1000,5000 cps	Automatic optimum. Best resolution 25 cps*	500 µv to 500 v	*1 cps	—60 db
200 cps to 300 kc	SB-7bZ (5" CRT)	0-200 kc	100 cps—2 kc	250 µv to 25 v	*6.7 cps.	—50 db
100 cps to 600 kc	SB-15a (5" CRT)	1 kc—200 kc	100 cps—4 kc + automatic optimum	200 µv to 200 v	*1-60 cps	—60 db
1 kc to 15 mc	SPA-3 (5" CRT)	0-3 mc	200 cps—30 kc	20 µv to 2 v	1-60 cps	—46 db
1 kc to 25 mc	SPA-3/25 (5" CRT)	0-3 mc	200 cps—30 kc	20 µv to 2 v	1-60 cps	—46 db



SPA-4a

MICROWAVE SPECTRUM ANALYZERS 10 mc to 44 kmc. Feature unsurpassed usable sensitivity and freedom from spurious effects for pulsed AM, FM and CW signals. Direct reading frequency dial ± 1%. They have adjustable dispersion, I-F bandwidth and adjustable sweep rate; 1-60 cps, free running or synchronized; 3 calibrated amplitude scales, linear, 40 db log, and power; calibrated frequency markers. Model SPA-1 has 2 interchangeable tuning heads; SPA-4a covers band to 44 kmc with 1 head.

Frequency Range	Model No.	Sweep Width (Dispersion)	Resolution (I-F Bandwidth)	Sensitivity (Signal = 2x Noise)	Other Features
10 mc to 44,000 mc 1 Tuning Head	SPA-4a (5" CRT)	2 swept oscillators 0 to 70 mc 0 to 5 mc	1 kc to 80 kc	L band —100 to —110 dbm.; S band — 90 to —100 dbm.; X band — 90 to —100 dbm.; K band — 70 to — 90 dbm.	All mixers built in • Dynamic range to —60 db. • Low residual FM • Synchroscope Output • Marker Modulation
50 mc to 4000 mc; (10 mc to 4000 mc. optional)	SPA-1 (5" CRT)	0 to 10 mc	9 kc to 80 kc	(With opt. internal preamp.) RF-2 head, 50-250 mc —100 dbm RF-3 head, 220-4000 mc 500 mc —100 dbm 1500 mc — 94 dbm 3000 mc — 76 dbm	Extremely low cost • Exceptionally stable • Available in 4 styles • Highly sensitive I-F preamp, optional.

FREQUENCY RESPONSE PLOTTERS

½ cps to 15 mc

COMPANION SWEEP GENERATORS FOR BROADBAND SPECTRUM ANALYZERS: Response to fundamental frequency only; discriminate against noise and hum; virtually unlimited dynamic range; single line plots. Accessories available for comparison testing, triangular scanning, and manual tuning.

Frequency Range	Sweeper Model No.	Used With Analyzer Model	Output Voltage (& Impedance)	Output Attenuator	Overall Flatness
0.5 cps to 2500 cps	G-5	LF-2a	0-5V (3000Ω)	0-60 db	±0.5 db (1-2500Ω)
20 cps to 22,500 cps	G-2a	LP-1a	50 mv-5v (1000,600, 3KΩ)	0-100 db	±1 db
200 cps to 300 kc	G-3a	SB-7bZ	250 µv to 2.5 v (600Ω)	0-80 db	±0.5 db (1-300 kc)
100 cps to 600 kc	G-15a	SB-15a	250 µv to 2.5 v (600Ω)	0-80 db	±1 db (0.2-600 kc)
1 kc to 15 mc	G-6	SPA-3 SPA-3/25	200 µv to 0.2 v (72Ω)	0-60 db	±2 db (1 kc-13.5 mc)

G-3a

SWEEP GENERATOR 20 cps-200 kc used with ext. scope (CRT scale furnished). Model SG1. Pre-set broad-band, log and adjustable linear scans. Built-in markers. SG-1R same as SG-1, plus synch pulse for testing tape recorder frequency response.

Frequency Range	Model	Scan Modes	Output Voltage (& Impedance)	Flatness	Sweep Rate
20 cps-200 kc	SG-1 SG-1R	40 cps to 20 kc log scan 400 cps to 200 kc log scan 0—200 kc lin. sweep widths	0-1 volt (600Ω)	±½ db	1 cps. Adjustable with TW-1a

COMMUNICATIONS SYSTEMS ANALYZERS

SSB, AM, FM

PANADAPTORS. For use with communications receiver with I-F = Panadaptor center frequency. Panadaptor response shaped to match receiver. Specify receiver model no. and I-F.

SUMMARY OF SERIES CAPABILITY

For Receivers With Intermediate Frequency of	Model Series	Sweep Width	Resolution	Sensitivity (At I-F)	Sweep Rate	Amplitude Scales	CRT Size
450 kc-30 mc	SA-8b (4 types)	0-100 kc to 0-10 mc	50 cps to 80 kc	150-2000 mv full scale	1-60 cps	Linear, 40 db log Power	5" (camera mount style optional)
450 kc-30 mc	SA-3 (10 types)	0-50 kc to 0-6 mc	2 kc to 50 kc	10 µv- 10 mv ¼" deflection	30 cps	linear (nominal)	3 inch

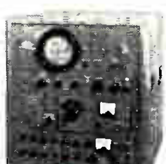
PANALYZORS scan through an adjustable sweep width about their center frequencies. An external VFO* is used for conversion of signals in Panalyzor input mixer. Mixer range up to 1000 mc.

*eg. Model RF-7a Panoramic VFO, 2-40 mc.

SUMMARY OF SERIES CAPABILITY

Model Series (Input Center Frequency)	Sweep Width	Resolution	Signal Sensitivity (VFO 0.1 volt rms)	Sweep Rate	Amplitude Scales
(†) SB-12b, 500 kc (or 455 kc)	0 to 100 kc + preset modes	10 cps-2.5 kc (see also SSB-3b)	2 mv full scale log	0.1-30 cps	linear 40 db log
SB-8b 3 types (500 kc-30 mc)	0 to 200 kc to 0 to 10 mc	50 cps-80 kc	10-100 mv full scale log	1-60 cps	linear 40 db log power
SB-3 5 types (500 kc-30 mc)	0 to 50 kc to 0 to 6 mc	2 kc-40 kc	1-10 mv, ¼" deflection	30 cps	linear (nominal)

(†) SB-12b also part of SSB-3b, (below)



SSB-3b

SINGLE SIDEBAND SPECTRUM ANALYZER—Model SSB-3b is a complete, compact unit for communications systems analysis. Advantages are 60 db dynamic range (at least 65 db upon request), selectivity for hum sidebands resolved down 60 db, and simple operation with preset modes and self-checking facilities.

SSB-3b Frequency Range	SSB-3B INCLUDES THESE COMPONENT INSTRUMENTS. Panalyzor Model SB-12b(s)	Model RF-7a Tuning Head	2 tone AF Gen. Model TTG-2	Resolution (I-F Bandwidth)	Sensitivity
2 mc to 40 mc (100 cps to 40 mc with Model REC-1 optional)	see SB-12b specs. above	2-40 mc Fast search + precise vernier tuning 1% accuracy	100 cps-10 kc (±2%) 0-4 volts rms metered outputs	(Same as SB-12b Minimum—60 db bandwidths = 50 cps)	2 mv full scale log, Virtually uniform from 100 cps-40 mc. 0-65 db input attenuator

TELEMETRY TEST INSTRUMENTS

(for IRIG FM/FM Systems)

TMI-1b

Model No.	Name	Features	Uses
TMI-1b (TMI-1b/120)	Telemetering Indicator	Analyzes 350 cps-85 kc band (to 120 kc optional) • Both Log & Linear Scans • Automatic optimum resolution • Internal markers	Subcarrier spectrum analysis • pre-emphasis • distortion measurements to —55 db • spillover • noise
TMC-1a	3 Point Calibration and Subcarrier Deviation Indicator	Xtal controlled ± 0.02%; + 7.5%, 0, —7.5%; also A to E • Special deviations available • Provides markers for uni-channel scans for TMI-1b analyzer (not used with TMI-1b/120)	Discriminator calibration ±0.02% With TMI-1b, monitors individual channels or VCO deviation linearity
TMC-411E	Simultaneous 11 Pt. Calibrator (also 3 pt. and 5 pt. optional)	Accuracy ± 0.002% • All ± 7½% channels + A to E • 18 channel outputs simultaneously or individually • auto./manual sequencing • special provisions available • all electronic, 7" high • distortion —40 db	Complete discriminator checkout in seconds! Multiple frequency reference source for data reduction and system calibration. With TMI-1b for VCO checks.

Specification subject to change without notice

Joint Conference On Automatic Control

The University of Texas, Austin, Tex. has been selected as the location of the fourth Joint Automatic Control Conference, June 19–21, 1963. The first invitation of papers will be made in February 1962, with abstracts due at the end of September and manuscripts by November 1. Such timing, an innovation with the 1962 JACC, will permit the mailing of complete preprints to pre-registrants as much as a month before the conference.

Since the 1963 congress of the International Federation on Automatic Control follows the JACC by only three months and should overlap it only slightly in attendance, authors of IFAC papers are being urged to submit them also for JACC presentation. Such dual submission is approved by the American Automatic Control Council, and is in fact encouraged for purposes of practice and criticism. Because of IFAC copyright restrictions, such papers will be preprinted in abstract only.

Of the five member societies of the sponsoring council, the American Institute of Chemical Engineers has prime responsibility for the 1963 JACC. Dr. Theodore J. Williams, of Monsanto Chemical Co., St. Louis, Mo., is General Chairman; Dr. Otis L. Updike, University of Virginia, Charlottesville, Va., is Technical Program Chairman; and Dr. William A. Cunningham, University of Texas, Austin, Tex., is Local Arrangements Chairman. Papers on control theory, applications, or components will be solicited through the sponsoring societies.

Pacific Energy Conversion Conference Set for August

The Pacific Energy Conversion Conference will be held at the Fairmont Hotel, San Francisco, Calif., August 13–16, 1962.

The Conference is being sponsored by the American Institute of Electrical Engineers. Its purpose is to bridge the gap between scientific investigation and practical application. Topics to be covered are: Energy Storage, Thermoelectric, Magnetohydrodynamics, Thermionic, Photovoltaic, and Fuel Cells.

Air Force MARS Announces Schedule

The schedule of broadcasts of the Air Force MARS Eastern Technical Net, operating Sundays from 2 to 4 P.M. EDST on 3295, 7540, and 15,715 kc, has been announced for May and early June:

May 6—"Rectifiers for Amateur Radio Power Supplies." A panel of rectifier engineers will discuss the theory, operation and application of germanium and silicon rectifiers. J. Mengenast, moderator.

May 13—"Presentation of the 1961 Edison Radio Amateur Award." Rebroadcast of ceremonies attendant to the presentation of the 1961 Edison Award to William G. Welsh, WISAD/6. Major General J. B. Bestic, Director of Telecommunications, U. S. Air Force, speaker.

May 20—"Novel Equipment for the MARS and Amateur Radio Station," R. Gunderson, Braille Technical Press.

May 27—"Applications of Drift Transistors to Radio Receivers," J. Englund, RCA Research Laboratories.

June 3—"Transistor Multivibrator and Logic Design Considerations," B. Lohman, RCA Semiconductor Products Division.

Group Travel Plan To IFIP Congress-62

IRE members planning to attend the IFIP Congress-62 may take advantage of the new reduced-fare group travel plan. This major international conference on information processing, which is organized by the International Federation for Information Processing, will be held in Munich, Germany, August 27–September 1, 1962. Papers and exhibits on computing and data processing will be contributed by experts from many countries.

The reduced fare applies to a group of 25 or more who travel together, round-trip, on the same regularly scheduled flights. For example, the fare from New York to Munich and back is $353.00 for each member of such a group, compared with the $568.80 individual fare on the same economy-class jet flights. This substantial saving is available to paid-up IRE members of any grade and accompanying members of their immediate family. Groups with various flight dates and routings will be arranged as interest warrants. For further information please write to: W. Buchholz, IBM Development Lab., P.O. Box 390, Poughkeepsie, N. Y.

Reservations should be made soon because seasonally heavy travel at the time of the Congress may limit the number of groups that can be organized.

National Advanced-Technology Management Conference Set

The National Advanced-Technology Management Conference will be held at the Opera House on the Seattle World's Fair Grounds, Seattle, Wash., September 3–7, 1962. The sponsors for the conference will be: the American Institute of Chemical Engineers, the American Institute of Electrical Engineers, the American Society of Civil Engineers, the American Society of Mechanical Engineers, the IRE, the Society of American Military Engineers, the Society for Advancement of Management, the Institute of Management Sciences, the National Society of Professional Engineers, and the University of Washington.

The theme of the conference is: An Exposition of Modern Systems Management . . . Its Development and Practical Application During an Era of Accelerating Technology. The conference is designed to create an atmosphere suitable for the exchange of ideas, both theoretical and practical, on this subject for advanced-technology program managers.

Panel subjects under consideration are: 1) Information Management in Both Civil and Military Science and Technology, 2) How to Organize our Forces to Compete with the Russians in the Military Area, 3) A Summary of the Conference—to allow the exchange of ideas about what the panel members have found most significant in what has been presented.

Workshop subjects under consideration are: 1) Planning the overall program, 2) Controlling the configuration of the end product, 3) Quality assurance, 4) Final system evaluation, 5) Allocation and control of resources, 6) "Exploding" technology.

The Proceedings of the conference can be purchased for $8.00 by writing to the: National Advanced-Technology Management Conference, 512 First Avenue North, Seattle 9, Wash.

Professional Group News

At its meeting held March 8, 1962, the IRE Executive Committee approved the following new chapters: Joint PG on **Audio and Broadcasting**—Montreal Chapter; PG on **Broadcasting** and **Broadcast and Television Receivers** to be combined to form one Joint Chapter—Philadelphia Chapter; PG on **Communications Systems** and **Vehicular Communications** to be combined to form one Joint Chapter—Philadelphia Chapter; PG on **Antennas and Propagation** and **Microwave Theory and Techniques** to be combined to form one Joint Chapter—Philadelphia Chapter.

Military Electronics Convention Proceedings

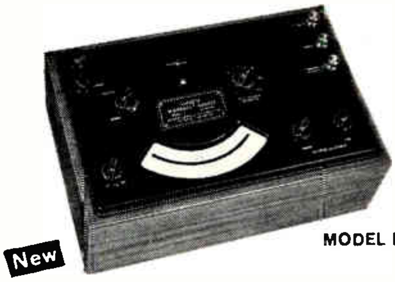
Convention Proceedings for the Third National Winter Convention on Military Electronics, held in Los Angeles, Calif., February 7–9, 1962, may be obtained from the IRE Business Office. Mark requests attention: Ray Banks, 1435 South La Cienega Boulevard, Los Angeles 35, Calif.

Schedule Changed for MAECON

The dates for the 1962 Mid-American Electronics Conference scheduled for November 13 and 14, at the Hotel Muehlebach, Kansas City, Mo., have been changed. The conference will be held instead November 19 and 20 at the Continental Hotel, Kansas City, Mo.

The conference's theme will be "Electronics and Automation." Technical Papers Chairman is Dr. J. N. Warfield, University of Kansas, Lawrence, Kan.

For information regarding booth space write: Charles E. Day, c/o R. W. Farris Co., Inc., 1715 Baltimore, Kansas City, Mo.



MODEL LE

10 NEW INSTRUMENTS

Lindeck Microvolt Source for use as:
• A comparator in the calibration of volt ratio boxes, saturated standard cells and similar instrumentation.
• A direct measuring instrument in the microvolt range.

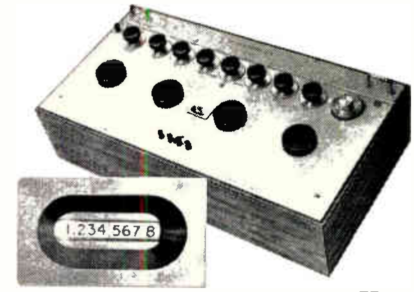
Ranges: 0-1/2/5/10/20/50/100/200/500 μv; 1/2/5/200 mv; 2 v.

Accuracy: ±.5% of full scale

Readout: SRIC Model C. 100 division, 6.3" hand-drawn scale. Accuracy .25%. Diamond pivoted!

Application is described in NBS Paper RP1419, "Testing and Performance of Volt Ratio Boxes". Copies available upon request.

Model PCM "Pocket-Pot." A new multirange, high sensitivity, miniature potentiometer, with self-contained galvanometer and battery operated standardization circuit. In-line readout. Continuous resolution on slidewire with 1 mv. divisions. Infinite resistance at null. Total measuring range 0-5.100 v. Plug in unit available to increase measuring range to 500 v. and 1 amp. (Model PC-S). Accuracy ±.05% of reading; ±.5 mv. on x1 range; ±.1 mv. on x.1 and x.01 ranges.



SINGLE WINDOW READOUT

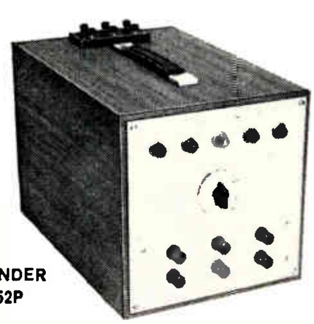
COMMANDER TYPE 9120

New **A 4 dial, 7 figure precision potentiometer** with single window readout and a resolution of 1 part in 20 million. Total measuring range of 2.099,999,9 volts in steps of .1 μv. is achieved without the necessity of switching ranges. **Accuracy ±(.0015% of reading +.1 μv.)**

Facilities are incorporated to enable the user to completely "Self Check" the potentiometer within its guaranteed accuracy. All positions on the measuring dials are calibrated steps (no slidewire). Thermal emf's are less than .1 μv.

SENSITIVE RESEARCH

ELECTRICAL MEASURING INSTRUMENTS SINCE 1927



COMMANDER TYPE 9152P

New **A portable constant temperature air bath** designed to eliminate the hazards involved in transporting saturated standard cells. It is an ideal transfer standard when direct intercomparison of saturated standard cells is desired between a calibration laboratory and NBS or between variously located calibration facilities of the same organization. Enclosure accommodates three saturated cadmium cells constructed with a porous partition to greatly improve portability. Cells can be certified to ±.0001%.

Weight (30 lbs.) and box size (18" L x 10" W x 10" H) are convenient for hand carrying. Provision is made for operation from a portable battery pack, a 110 volt AC line or a car cigarette lighter outlet. Enclosure is maintained at a nominal 32°C and is guaranteed not to vary more than ±.01C° even after continuous exposure to ambient temperatures down to 0°F (−17.4°C) in still air.

MODEL PC-R

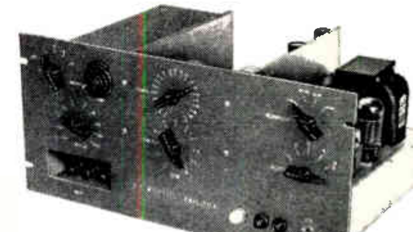
"Plug-in" Wheatstone Bridge for use with PocketPot to make DC resistance measurements from .1 Ω to 9.999 megohms. Accuracy is ±1% from .1 Ω to 10 Ω; ±.2% above 10 Ω to 1 megohm; ±2% above 1 megohm to 9.999 megohms.

New **COMMANDER Type 9770:** Constant current source for standardizing a DC potentiometer or supplying a stable current to any circuit in the range of 10 ma. to 100 ma. Current stability is ±(1 ppm + stability of reference cell).

New **COMMANDER Type 9180:** A 3 dial, 5 figure version of the Dauphinee Potentiometer. Accuracy ±.002% of reading. Range: −10μv. to +2.10100 v. in steps of 10 μv. on X1. Additional ranges of X.1, X.01 and X.001 with resolution to .01 μv. Thermal emf's less than .1 μv. "Self Checking".

New **COMMANDER Type 9174:** A dual range, 2 dial, 4 figure microvolt potentiometer. Thermal emf's less than .02 μv. Accuracy ±.01% of reading. Range: −10 μv. to + 1010 μv.

New **Model ESX:** AC/DC, 0-150 v., electrostatic voltmeter with DC scale expansion enabling practical readings down to 2 v. Input resistances from 1 x 10^{14} Ω.



COMMANDER TYPE 9790

New **A DC amplifier** for the measurement of low level voltages in the fractional microvolt range. Features are:

1. .03 μv. lowest range.
2. Immediate recovery from overloads of 1,000,000%.
3. .003 μv. stability over a 24 hour period.
4. Facility for compensation of stray thermal emf's.
5. Easy accessibility for maintenance purposes.

Output is 1 ma. into 1500 Ω, or 1 mv., 10 mv. or 100 mv. F.S. Input resistance of 50 Ω to 1000 Ω depending on input transformer selected. Continuously variable gain control. Calibration signals to the input (accuracy ±5%) are .03/.1/.3/1/3/10/30/100/300 μv. Response time is 2 to 5 seconds to 90% F.S.

SENSITIVE RESEARCH INSTRUMENT CORPORATION
New Rochelle, N. Y.

COMMANDER instruments are manufactured for Sensitive Research by Guildline Instruments, Ltd., Smiths Falls, Canada.

Conference on Self-Organizing Systems

Museum of Science and Industry, Chicago, Ill., May 22–24, 1962

Tuesday Morning, May 22

"The Organization of Organization," O. Selfridge, Lincoln Lab., Massachusetts Institute of Technology, Lexington, Mass.

"Self-Organizational Systems," M. D. Mesarovic, Case Institute of Technology, Cleveland, Ohio.

"Self-Organization in the Time Domain," D. M. MacKay, University College of North Staffordshire, Dept. of Communication, Keele, Staffordshire, Eng.

"Integrative Processes," J. D. Cowan, Warren S. McCulloch, Research Lab. of Electronics, Massachusetts Institute of Technology, Cambridge, Mass.

Tuesday Afternoon

"Information Input Overload," J. G. Miller, Mental Health Research Institute, University of Michigan, Ann Arbor, Mich.

"Learning Signal Detection," M. Kac, Rockefeller Institute, New York, N. Y.

"Optimization Through Evolution with Sexual Recombinations," H. J. Bremermann, University of California, Dept. of Mathematics, Berkeley, Calif.

The Automatic Formation of a Program which Represents a Theory," S. Amarel, Radio Corporation of America, Princeton, N. J.

Wednesday Morning, May 23

"Natural and Artificial Synapses," L. D. Harmon, Bell Telephone Labs., Murray Hill, N. J.

"Logical Aspects of Neuristor Systems," H. Crane, Stanford Research Inst., Menlo Park, Calif.

"Some Probabilistic Aspects of Automata with a Pushdown Memory," M. P. Schultzenberger, Harvard University Medical School, Boston, Mass.

"Efficient Adaptive Systems and their Realization," J. H. Holland, University of Mich., Ann Arbor, Mich.

"Empirical Laws and Physical Theories; Discussion of the Respective Roles of Information and Imagination," L. Brillouin, Columbia University, New York, N. Y.

Wednesday Afternoon

"Majority Logic," S. Muroga, International Business Machines Corp., Yorktown Heights, N. Y.

"Interaction Between a Group of Subjects and an Adaptive Automaton to Produce a Self-Organizing System for Decision Making," G. Pask, Systems Research Ltd., Richmond, Surrey, Eng.

"Cybernetic Ontology and the Transjunctional Operator," G. Gunther, University of Illinois, Urbana, Ill.

"Some Problems of Basic Organization in Problem-Solving Programs," A. Newell, Carnegie Institute of Technology, Pittsburgh, Pa.

"Training Sequences for Mechanized Induction," R. J. Solomonoff, Zator Co., Cambridge, Mass.

Thursday Morning, May 24

"Adaptive 'Neuron' Memory System," B. Widrow, Stanford University, Stanford, Calif.

"A Comparison of Several Perceptron Models," Frank Rosenblatt, Cornell University, Ithaca, N. Y.

"A New Class of Multi-Layer Series in Coupled Perceptrons," A. G. Konheim, International Business Machines Corp., Yorktown Heights, N. Y.

"Simple Tests for Linear Separability as Applied to Self-Organizing Machines," R. C. Singleton, Stanford Research Inst., Menlo Park, Calif.

Thursday Afternoon

"Remarks on the Algebra of Functors," K. Menger, Illinois Institute of Technology, Chicago, Ill.

"A Feedback Coding Theory of Learning and Cognition," H. H. Kantner, Armour Research Foundation, Illinois Institute of Technology, Chicago, Ill.

"Some Similarities Between the Behavior of a Neural Network Model and Electrophysiological Experiments," P. G. Farley, Lincoln Lab., Massachusetts Institute of Technology, Lexington, Mass.

"The Representation of Information by Neural Net Models," P. H. Greene, University of Chicago, Chicago, Ill.

1962 National Microwave Theory and Techniques Symposium

Boulder, Colo., May 22–24, 1962

Tuesday Morning, May 22

Session I—Microwave Frontiers

Chairman: *Dr. D. D. King, Electronic Communications, Inc., Timonium, Md.*

"Millimeter Wavelength Resonant Structures," *R. W. Zimmerer, M. V. Anderson, G. L. Strine, and Y. Beers, National Bureau of Standards, Boulder, Colo.*

"Superconducting Delay Line," *R. J. Allen, A. J. Cummings, and F. M. Kudo, Martin Marietta Corp., Baltimore, Md.*

"Ferroelectric Phase Shifters for VHF and UHF," *M. Cohn and A. F. Eikenberg, Electronic Communications, Inc., Timonium, Md.*

Tuesday Afternoon

Session II—Theory, Waveguide Properties

Chairman: *Prof. A. A. Oliner, Microwave Research Institute, Polytechnic Institute of Brooklyn, Brooklyn, N. Y.*

"Microwave Propagation in an Overdense Bounded Magnetoplasma," *B. Wieder, National Bureau of Standards, Boulder, Colo.*

"Measurements of Field Strength on Resonator Boundaries by Perturbation of Radiation Field," *I. Hefni, Lincoln Lab., M.I.T., Lexington, Mass.*

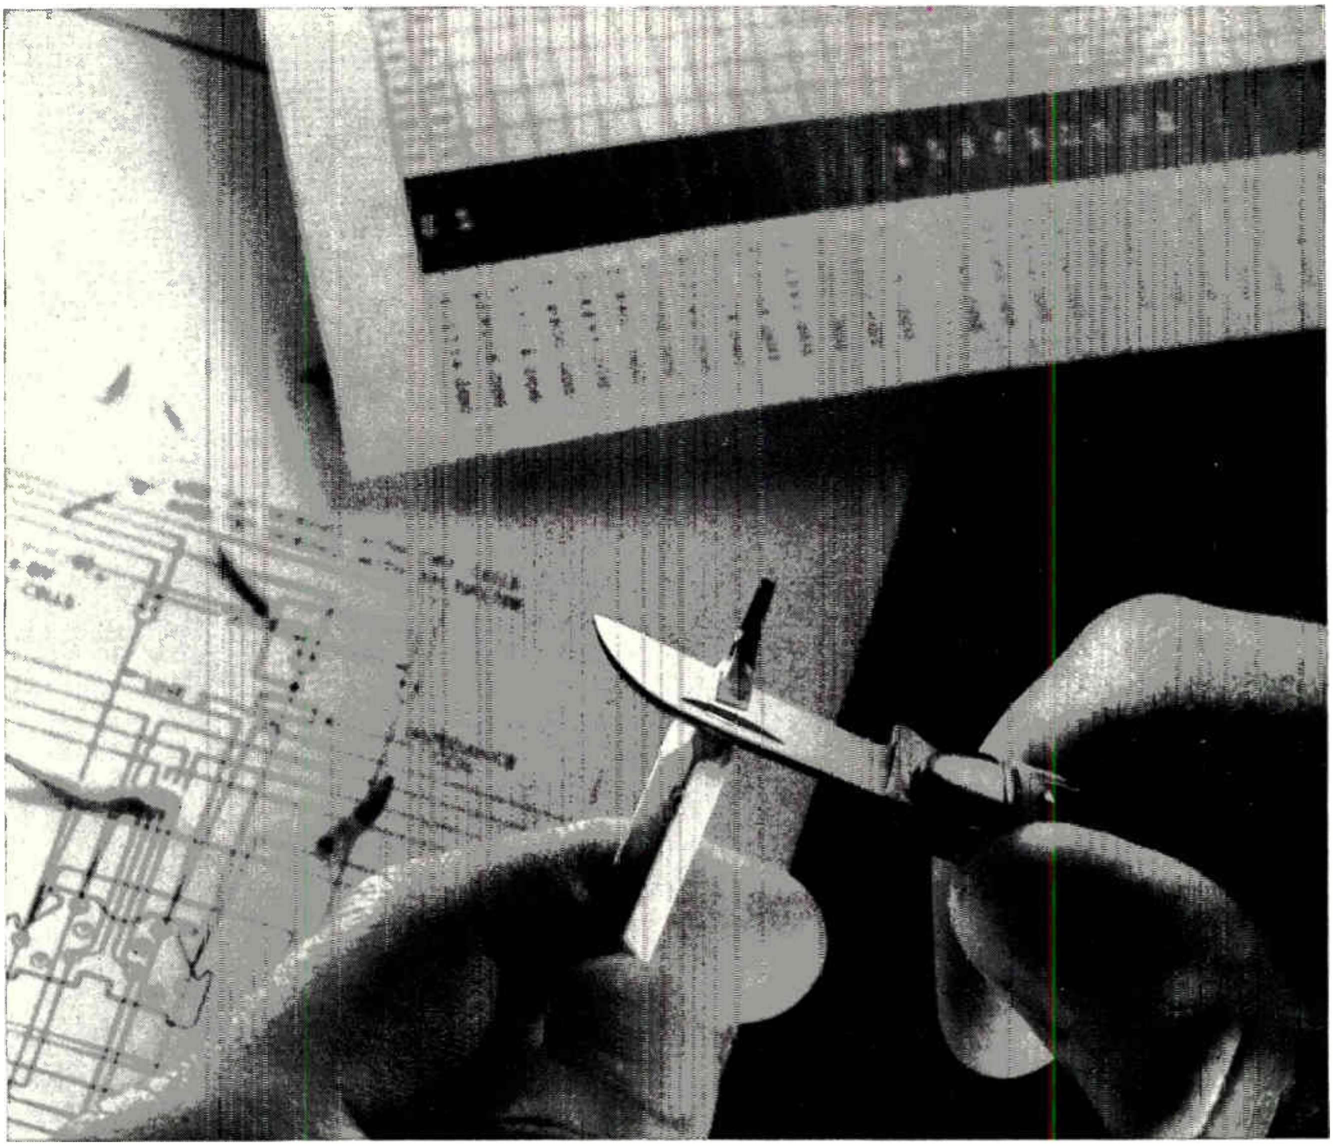
"General Power Loss Method for Attenuation of Cavities and Waveguides," *J. J. Gustincic and R. E. Collin, Case Institute of Technology, Cleveland, Ohio.*

Session III—Theory, Waveguide Discontinuities

Chairman: *Prof. A. A. Oliner, Microwave Research Institute, Polytechnic Institute of Brooklyn, Brooklyn, N. Y.*

"Perturbation Theorems for Waveguide Junctions, with Applications," *D. M. Kerns and W. T. Grandy, Jr., National Bureau of Standards, Boulder, Colo.*

"Investigations of the Reflection from a Junction of an Ideal Rectangular Waveguide with One Having Rounded Inside Corners," *W. J. Anson, R. W. Beatty, D. M. Kerns, and W. T. Grandy, Jr., National Bureau of Standards, Boulder, Colo.*



Sorry, but your resistor specs just went out of date

Now Corning supplies total ΔR less than 3% with no derating

Start a design with known limits of resistance deviation as tight as that and you can specify other components with more certainty and more freedom.

Drop an amplifier stage? Use broader tolerance, cheaper tubes or transistors?

That's what our new *Corning Design Tolerances* are all about. They give you a percent deviation from nominal that includes the purchase tolerance, maximum ΔR due to TC, and maximum load-life drift. They're based on extended performance at full power and 70°C. ambient for over 30,000 hours.

Model		Resistance (ohms)	Corning Design Tolerance
NF (Meets Mil-R-10509D)	60 65	100 to 100K 100 to 348K	3%
N (Meets Mil-R-10509D)	60 65 70	10 to 133K 10 to 499K 10 to 1 meg.	3%
C (Meets Mil-R-22684)	20 32 42S	51 to 150K 51 to 470K 10 to 1.3 meg.	5% (plus purchase tolerance of either 2% or 5%)

We've assigned them to resistors that cover the 10 ohm—1 meg. range: the fusion-sealed NF, the precision N, and the low-cost, high-performance general purpose C. They're available fast, and at factory prices, from your local Corning distributor.

A new folder, "Design Tolerances for Tin Oxide Resistors," gives you full information. Write for a copy to Corning Glass Works, 542 High St., Bradford, Pa. . . . and sharpen your pencil.

CORNING
Electronic Components

"Electromagnetic Diffraction by a Planar Array of Circular Disks," *W. H. Eggimann and R. E. Collin, Case Institute of Technology, Cleveland, Ohio.*

"The Representation of Waveguides Containing Small Ferrimagnetic Ellipsoids," *L. K. Anderson, Bell Telephone Labs., Murray Hill, N. J., and H. J. Shaw, Stanford University, Stanford, Calif.*

Wednesday Morning, May 23
Session IV—Filters

Chairman: *Dr. S. B. Cohn, Rantec Corp., Calabasas, Calif.*

"Interdigital, Band-Pass Filters," *G. L. Matthaei, Stanford Research Institute, Menlo Park, Calif.*

"Microwave Bandstop Filters with Narrow Stop Bands," *L. Young, G. L. Matthaei, Stanford Research Institute, Menlo Park, Calif., and E. M. T. Jones, TRG-West, Menlo Park, Calif.*

"The Design of Branch-Guide Couplers, with Applications to the Suppression of Spurious Frequencies," *L. Young, Stanford Research Institute, Menlo Park, Calif.*

"An Electronically Turnable Band-Pass Microwave Filter," *I. Kaufman, Space Technology Labs., Inc., Canoga Park, Calif., and W. H. Steier, University of Illinois, Urbana, Ill.*

Session V—High Power

Chairman: *Dr. S. B. Cohn, Rantec Corp., Calabasas, Calif.*

"A New Technique for Multimode Power Measurement," *J. J. Taub and J. Goldberg, Airborne Instruments Lab., Deer Park, L. I., N. Y.*

"A Novel High-Power Harmonic Suppressor," *E. Wantuch and R. M. Maines, Airtron, Inc., Morris Plains, N. J.*

"Layered Media as High Power Microwave Absorbers," *S. R. Steele and R. J. Briggs, Raytheon Co., Burlington, Mass.*

"Fine Grain Spectrum Analysis of Pulsed Microwave Amplifiers," *R. F. Koontz, Radio Corp. of America, Moorestown, N. J.*

Wednesday Afternoon
Session VI—Measurements

Chairman: *R. W. Beatty, National Bureau of Standards, Boulder, Col.*

"Subtle Differences in System Noise Measurements and Calibration of noise Standards," *T. Mukaihata, B. Walsh, M. F. Bottjer, and E. B. Roberts, Hughes Aircraft Co., Culver City, Calif.*

"An Accurate Millimeter Wave Loss and Delay Measurement Set," *M. B. Chasek, Bell Telephone Labs., Murray Hill, N. J.*

"Microwave Phase Comparator," *J. A. Kaiser, H. B. Smith, Jr., W. H. Pepper, and J. H. Little, Diamond Ordnance Fuze Labs., Washington, D. C.*

"Waveguide Perturbation Techniques in Microwave Semiconductor Diagnostics," *K. S. Champlin and D. B. Armstrong, University of Minnesota, Minneapolis, Minn.*

Session VII—Components

Chairman: *R. W. Beatty, National Bureau of Standards, Boulder, Colo.*

"Further Developments in Dielectric Waveguide Devices for Millimeter Wavelengths," *C. E. Barnes, Bell Telephone Labs., Murray Hill, N. J.*

"Phase Shift Characteristics of Dielectric Loaded Waveguide," *G. F. Bland and A. G. Franco, International Business Machines, Yorktown Heights, N. Y.*

"Ferrite Switches in Coaxial or Strip Transmission Line," *C. E. Fay, Bell Telephone Labs., Murray Hill, N. J.*

"A 6 KW Peak Power Varactor Duplexer," *J. C. Hoover, Sperry Microwave Electronics Co., Clearwater, Fla.*

Thursday Morning, May 24
Session VIII—Limiters

Chairman: *M. T. Lebenbaum, Airborne Instruments Lab., Deer Park, L. I., N. Y.*

"Bandwidth of Tem Diode Limiters," *R. V. Garver and J. A. Rosado, Diamond Ordnance Fuze Labs., Washington, D. C.*

"Frequency-Selective Limiting," *K. L. Kotzebue, Watkins-Johnson Co., Palo Alto, Calif.*

"Operation of a Microwave Garnet Limiter," *R. L. Comstock and L. J. Varnerin, Bell Telephone Labs., Murray Hill, N. J.*

"A Coincidence Region Power Limiter Using Monocrystal Lithium Ferrite at 6500 Mc," *S. Okwit, Airborne Instruments Lab., Deer Park, L. I., N. Y.*

Session IX—Parametric Amplifiers

Chairman: *M. T. Lebenbaum, Airborne Instruments Lab., Deer Park, L. I., N. Y.*

"Multiple Pumped Parametric Amplifiers," *G. Spacek and R. Brewster, General Motors Corporation Defense Systems, Santa Barbara, Calif.*

"Broadband Parametric Amplifiers," *R. Pettai, Micro State Electronics Corp., Murray Hill, N. J., and B. B. Bossard, Radio Corp. of America, N. Y., N. Y.*

"Large Signal Properties of Non-Degenerate Varactor Parametric Amplifiers," *D. Jackson, Boeing Co., Seattle, Wash.*

"Design of a Wideband Tunnel Diode Preamplifier for Phased Array Radars," *D. W. MacGlashan, Bendix Corp., Baltimore, Md.*

Thursday Afternoon
Session X—(Invited Session) Future of Microwave and Solid State

Chairman: *Dr. K. Tomiyasu, General Electric Co., Schenectady, N. Y.*

"Masers and Millimeter Waves," *Prof. F. S. Barnes, University of Colorado, Boulder, Colo.*

"Microwaves and Solid State," *Dr. B. Lax, Lincoln Lab., M.I.T.., Lexington, Mass.*

"Coherent Wave Optics, New Frontier of the Microwave Art," *A. G. Fox, Bell Telephone Labs., Holmdel, N. J.*

IRE Seventh Region Conference

OLYMPIC HOTEL, SEATTLE, WASH., MAY 24–26, 1962

"Space Communications" is the theme of the 1962 IRE Seventh Region Conference which will stress the impact of electronics on the cultural and social life of the future.

All hotel reservations are being handled only through the Seventh Region Conference Housing Bureau. The bureau will hold hotel space until April 23. Your request must be accompanied by a deposite of $15.00 a room, payable to "IRE Seventh Region Conference." Acknowledgment will be made by the hotel. Cancellations must be received by May 8 for any refund.

The Board of Directors of the IRE and of WESCON are also meeting during the period of the Seventh Region Conference.

The program will be as follows:

Thursday Morning, May 24
Session 2A—Antennas

Moderator: *Dr. N. Yaru, Hughes Aircraft Co.*

"Giant Aperture Antennas for Space Applications," *C. J. Sletten and P. Blacksmith, Jr., Electromagnetic Radiation Lab. AFCRL.*

"Antennas for the Naby Space Surveillance System," C. A. Bartholomew, Space Surveillance Group NRL.

"Cassegrain Design Procedure," P. A. Jensen, Hughes Aircraft Co.

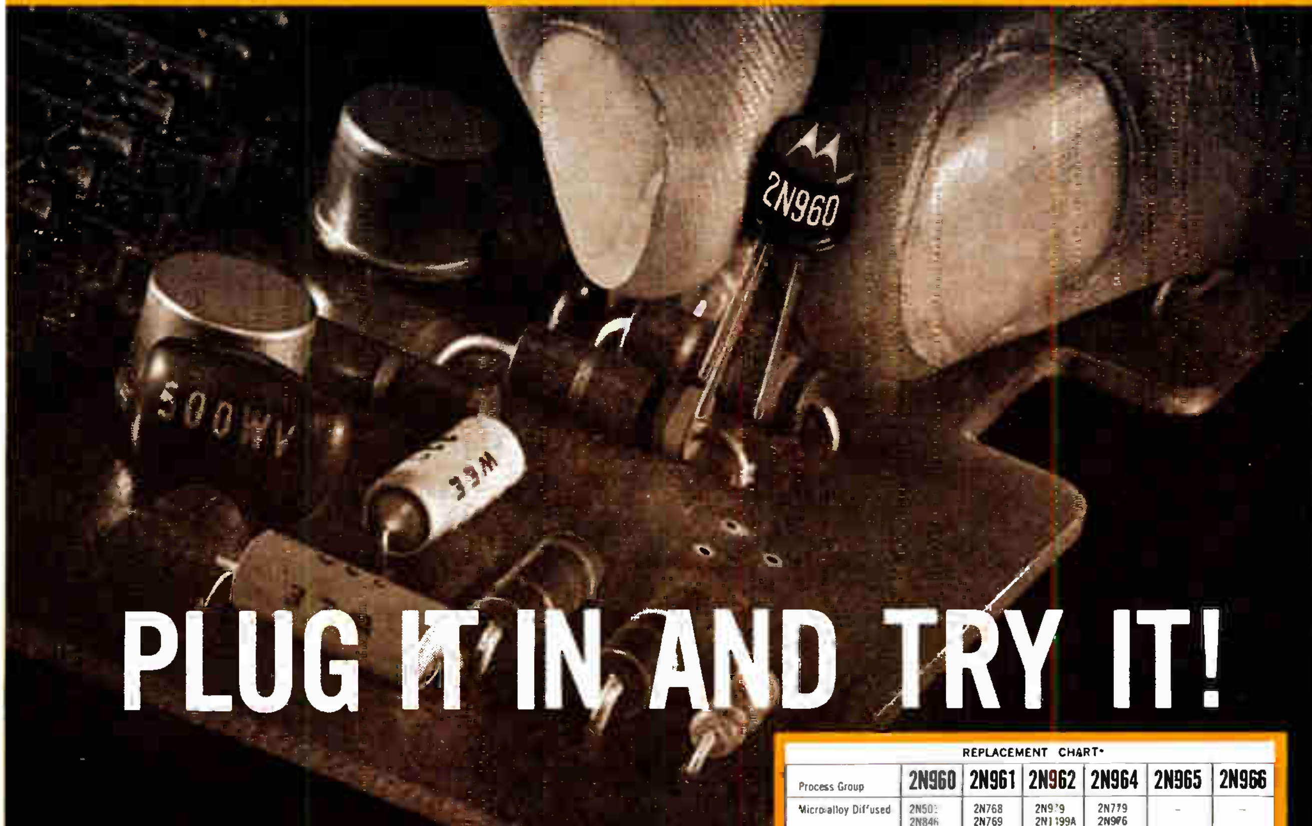
"High Power Dual Polarized Monopulse Feed," E. D. Burnett, Hughes Aircraft Co.

Session 3A—Electronics in Education

Moderator: *T. L. Martin, Dean, College of Engineering, University of Arizona.*

Panel members: *Prof. W. W. Harman, Electrical Engineering Dept., Stanford University.*

How much better is MOTOROLA'S 2N960 Series Epitaxial Mesa?



REPLACEMENT CHART*						
Process Group	2N960	2N961	2N962	2N964	2N965	2N966
Micro-alloy Diffused	2N502 2N846 2N984	2N768 2N769	2N979 2N1199A 2N1200	2N779 2N976 2N982 2N983	–	–
Mesa	2N705 2N710 2N711B 2N781	2N711 2N711A	2N782	2N795 2N934 2N994 2N1301	2N796 2N1683	2N1309 2N794
Micro-alloy	2N1122A	2N1122	2N1411 2N1427	–	–	2N393
Alloy	2N583	–	–	2N582 2N584	–	–
Drift	–	2N643 2N644 2N645	2N602 2N1450	–	2N609	2N603

*Interchangeability of types shown is on the basis of performance in most switching circuit applications.

Is it true that Motorola's germanium, epitaxial, 2N960 switching series will supplant nearly all other germanium micro-alloy, drift, mesa, and other transistor types for high-speed switching applications? And is it true that the Motorola series is even faster and performs better than advertised? The best way to find out is to try it!

Use the adjacent Replacement Chart and Specifications as a guide, and try any of these six remarkable new Motorola devices in your circuits. Judge for yourself what the advantages are. Samples are available from your local Motorola District Office. Ask also about Motorola's low prices – in many cases, they are considerably lower than those for old type devices.

Some of the Published Advantages of the Motorola 2N960 Series:

- faster switching time
- guaranteed minimum Beta over a wide current range . . . specified at 10, 50, and 100 mA
- low saturation even at 100 mA
- rugged Motorola mesa construction
- the most comprehensive *and conservative* published specifications of any similar switching transistors
- proven reliability from the world's largest manufacturer of germanium epitaxial transistors

MOTOROLA GERMANIUM EPITAXIAL SWITCHING TRANSISTORS							
	2N960	2N961	2N962	2N964	2N965	2N966	UNITS
h_{FE} (MIN) 10, 50, 100 mA	20	20	20	40	40	40	—
V_{CE} (SAT) MAX @ 10 mA	.20	.20	.20	.18	.18	.18	Volts
@ 50 mA	.40	.40	.40	.35	.35	.35	Volts
@ 100 mA	.70	.70	.70	.60	.60	.60	Volts
f_T (MIN) I_E=20 mAdc V_{CB}=1.0 Vdc	300 mc all types						
Q_T (MAX) I_C=10 mAdc I_B=1 mAdc	80	80	90	80	80	90	pc
I_C=100 mAdc I_B=5 mAdc	125	125	150	125	125	150	pc
τ_{RE}	0.6 nsec typical all types						
τ_{FE}	0.5 nsec typical all types						
All types have 150 mW dissipation in free air. 300 mW at 25°C case temperature							

For more information on this important new mesa series, contact your Motorola District Office, or call or write: Motorola Semiconductor Products Inc., Technical Information Department, 5005 East McDowell Road, Phoenix 8, Arizona.

Prof. D. K. Weaver, Director of Electronics Research Lab., Montana State University.

Prof. A. V. Eastman, Chairman, Electrical Engineering Dept., University of Washington.

Prof. D. O. Peterson, Director of Electronics Research Lab., University of California, Berkeley, Calif.

Thursday Afternoon

Session 1A—Propagation and Ionospheric Physics

Moderator: *R. A. Helliwell, Radio Science Lab., Stanford University.*

"Topside Sounder," *R. W. Knecht, National Bureau of Standards.*

"Measurement of Ion Composition Above the F_2 Peak," *T. W. Flowerday and D. D. McKibbin, Lockheed Missile and Space Co.*

"Interpretation of VLF Propagation-Measurement on the LOFTI Satellite," *R. L. Smith, Radio Science Lab., Stanford University; L. H. Rorden, Stanford Research Institute; R. A. Helliwell, Radio Science Lab., Stanford University.*

Session 1B—Satellite Communication

Moderator: *Dr. G. H. Keitel, Philco Corp., Palo Alto, Calif.*

(Title to be announced), *S. H. Reiger,* The Rand Corp.

"A Review of Defense Communications Satellite Program," *R. L. Clark, Department of Defense, Washington, D. C.*

"The Impact of Communication Satellites on Civilian Communications," *R. T. Haviland, General Electric, Philadelphia, Pa.*

Session 2C—Advanced Circuit Packing Techniques

Moderator: *Lt. Col. J. K. Schloss, USAF (Ret.)*

"Principles, Practices and Problems of Protective Packaging of Semi-conductor Devices," *Dr. S. S. Flaschen, Semiconductor Product Div., Motorola Inc., Phoenix, Ariz.*

"Protection and Interconnection of Space Quality Microcircuits," *G. J. Selvin, Microelectronics Lab., Sylvania Electric Products.*

"Packaging of Miniaturized Electronics," *E. C. Singletary, Texas Instruments Inc., Dallas, Tex.*

"System Packaging with Molecular Electronics," *J. McKinley, Air Arm Division, Westinghouse Electric Corp.*

Friday Morning, May 25

Session 2B—Devices

Moderator: *W. G. Shepherd, Head of Electrical Engineering Dept., University of Minnesota.*

"High Power Linear Electron Beam Tube for Space Communication." *C. M. Veronda, Sperry Electronic Tube Div.*

"The Solid-State Traveling-Wave Maser," *Dr. R. W. DeGrasse, Microwave Electronics Corp.*

"MM Wavelength Vacuum Tube Development," *G. Convert, Compagnie generale de telegraphie Sans Fil, Paris, France,*

"The Design of Optical Masers," *Dr. J. C. Axtell, The Boeing Co.*

Session 3C—Electronics in Business

Moderator: *H. W. Haines, Vice President Finance, The Boeing Co.*

"Impact of Electronics on Suppliers of Equipment," *W. Hume, President of I.B.M. Data Processing Div.*

"Impact of Electronics on Systems and Methods of Applying Electronics in Business," *N. Ream, Director of System and Procedures, Lockheed Co.*

"Impact of Electronics on Business in European Market," *H. Reinoud, Director in Chief, Netherlands Postal and Telecommunications Services.*

"Impact of Electronics on Finance, Banking and Stock Market." *J. H. Moller, Director Merrill Lynch, Pierce, Finner and Smith.*

Session 3E—Student Papers

Moderator: *Prof. I. J. Sandorf, University of Nevada.*

"Impact of Electronics on People Business and Management in Century 21," *J. Diebold, President John Diebold and Associates.*

Friday Afternoon

Session 1D—Space Experiments and Communication

Moderator: *S. H. Reiger, The Rand Corp.*

"Ranger III Lunar Impact Television Experiment," *R. C. Heyser, Jet Propulsion Labs.*

"JPL Venus Radar Experiment," *M. H. Brockman, Jet Propulsion Labs.*

"Influence of the Sun on Space Communication," *D. W. Swayze, Philco Corp., Palo Alto.*

"An Approach to Space Craft Data Handling and Experiment Control," *R. W. Waller, Chief Engineer, Western Div., Computer Control Co.*

"A Microwave Radiometer for a Venus Fly-By Probe," *D. Jones, Jet Propulsion Labs.*

Session 2D—Secondary Power

Moderator: *W. C. Scott, Chief, Space Power Technology Program, NASA.*

"Solar Thermo—Mechanical Power," *J. A. Rudy, New Devices Labs., Thompson Ramo-Wooldridge.*

"Solar Photovoltaic Devices," *A. Klammer, Jr., Power Sources Unit, The Boeing Co.*

"Biological Fuel Cell," *Commander F. W. Anders, Bureau of Ships, U.S.N.*

"Nuclear Radioisotope Power," *Capt. R. T. Carpenter, Auxiliary Power Branch, U. S. Atomic Energy Commission.*

Session 3D—Electronics in 2012 AD

Moderator: *Dr. L. Fields, Manager, Microwave Tube Div., Hughes Aircraft Co.*

"Automatic Handbook," *N. Rochester, I.B.M.*

"Electronic Nirvana," *D. E. Noble, Executive Vice President, Motorola, Phoenix.*

"Electronic Mastering of Ship," *Rear Adm. Bennett, Vice President Director of Engineering, Sangamo Electric Co.*

(Title to be announced), *W. O. McGuigan, Assistant General Manager Engineering, Stanford, Research Institute.*

"Electronics and Health Care," *V. K. Zworykim, Vice President and Technical Consultant, David Sarnoff Research Center RCA Research Labs., Princeton, N. J.*

Saturday Morning, May 26

Session 1C—Radio Astronomy

Moderator: *R. S. Lawrence, National Bureau of Standards.*

"Jupiter Radiation," *Dr. J. D. Warwick, University of Colorado.*

"University of Illinois Radio Telescope," *Dr. G. W. Swenson, University of Illinois.*

"Radar Reflections from the Solar Corona," *Dr. J. M. Chisolm, Lincoln Labs.*

"The 300 ft. Transit Radio Telescope at the National Radio Astronomy Observatory," *Dr. J. W. Finley, National Radio Astronomy Observatory.*

Session 2E—Radiation Effects on Electronic Equipment

Moderator: *W. L. Brown, Bell Telephone Lab.*

"Radiation Environment for Space Electronics," *Prof. S. F. Singer, University of Maryland, JPL.*

"Radiation Effects on Solar Cells," *Dr. J. M. Denny, Space Technology Labs.*

"The Implication of Nuclear-Powered Space Systems to the Radiation Effects Problem," *Dr. J. C. Lee, Lockheed Missiles and Space Div.*

"Prediction of Transient Radiation Effects on Electronic Equipment," *Dr. G. L. Keister, The Boeing Co.*

Chicago Spring Conference

O'HARE INN, DES PLAINES, ILL., JUNE 18–19, 1962

The Chicago Spring Conference will be held at the O'Hare Inn, Des Plaines, Ill., June 18 and 19, 1962. R. W. Galvin of Motorola will be the guest luncheon speaker.

The tentative program for the conference follows:

Monday Morning, June 18
Session I

"Cross-Modulation and Modulation Distortion of RF Transistors," *G. E. Theriault, Radio Corp. of America.*

"A New UHF TV Local Oscillator," *L. R. Maguire, Sylvania Electric Products, Inc.*

"Transistors in UHF Television Tuners," *S. M. Weaver, Texas Instruments Incorporated.*

"Gamma Distortion in the TV System," *G. W. Fyler, Zenith Radio Corp.*

Monday Afternoon
Session II

"A High-Performance Silicon Transistor Television Receiver," *J. A. MacIntosh, S. A. Schwartz, P. J. Bénéteau, Fairchild Semiconductor, Division of Fairchild Camera and Instrument Corp.*

"Recent Developments in Deflection Circuits," *K. W. McGlashan, Advance Ross Electronics Corp.*

"Transistor Failure Modes in High Power Switching Operation," *J. W. Mathews Philco Corp.*

"Highlights of Stabilized TV Deflection," *J. Sennik, Dominion Electrohome Industries Ltd.*

"A New Silicon High Performance Video Output Transistor," *R. Gudis and C. Kile, Lansdale Division, Philco Corp.*

Tuesday Morning, June 19
Session III

"A Four-Transistor Line Operated Receiver," *S. H. Kuehler and K. G. Cherry, Texas Instruments Incorporated.*

"Ferrite Antennas for AM Broadcast Receivers," *H. J. Laurent and C. A. B. Carvalho, Bendix Radio Division, Bendix Corp.*

"Television Stereo System," *R. B. Dome, General Electric Co.*

"A Mechanical Ultrasonic Signal Source for Remote Control Systems," *L. J. Sienkiewicz and H. T. Goldstein, Westinghouse Electric Corp.*

Tuesday Afternoon
Session IV

"Practical Design Considerations for Low-Cost FM Stereophonic Receivers," *R. J. Nelson and O. P. Hart, Radio Corp. of America.*

"A Two-Transistor FM Broadcast Band Tuner for a 12-Volt Automobile System," *W. F. King, Amperex Electronic Corp.*

"New Capacitor Products for Use in Radio and Television Receivers," *W. M. Robinson, Cornell-Dubilier Electronics Division, Federal Pacific Electric Co.*

"The Design of a Low Cost, High Sensitivity FM Tuner," *D. Ruby, Zenith Radio Corp.*

"A Self-Protecting Transistor Power Amplifier," *G. Randolph and N. Kramer, Knight Electronics Corp.*

Professional Groups*

Aerospace and Navigational Electronics (G-11)—G. M. Kirkpatrick, Electronics Equipment and Systems Lab., GE Co., Syracuse, N. Y.; H. R. Mimno, Cruft Lab., Harvard Univ., Cambridge 38, Mass.

Antennas and Propagation (G-3)—Dr. H. Fine, Applied Propagation Branch, Technical Research Div., FCC, Washington, D. C.; S. A. Bowhill, Pennsylvania State Univ., University Park, Pa.

Audio (G-1)—C. M. Harris, Electronics Res. Labs., Columbia Univ., New York 27, N. Y.; M. Camras, Armour Res. Foundation, Tech. Ctr., Chicago 16, Ill.

Automatic Control (G-23)—J. M. Salzer, Ramo-Wooldridge, 5500 E. Segunda, Hawthorne, Calif; G. S. Axelby, Westinghouse Air Arm Div., Friendship Airport, Baltimore 3, Md.

Bio-Medical Electronics (G-18)—G. N. Webb, Dept. of Medicine, Biophysical Div., Johns Hopkins Hospital, Baltimore 5, Md.; L. B. Lusted, Dept. of Radiology, Univ. of Rochester, Rochester 20, N. Y.

Broadcast and Television Receivers (G-8)—J. F. Bell, Zenith Radio Corp., 6001 W. Dickins Ave., Chicago 39, Ill.; C. W. Sall, RCA, Princeton, N. J.

Broadcasting (G-2)—R. F. Guy, 264 Franklin St., Haworth, N. J.; W. L. Hughes, School of Elec. Engrg., Oklahoma State University, Stillwater, Okla.

Circuit Theory (G-4). Dr. J. H. Mulligan, Jr., College of Engrg., New York Univ., University Heights, New York 53, N. Y.; M. E. Van Valkenburg, Dept. of E.E. Univ. of Illinois, Urbana, Ill.

Communications Systems (G-19)—R. L. Marks, Rome Air Dev. Ctr., Griffiss AFB, N. Y.; E. J. Baghdady, Elec. Engrg. Dept., M.I.T., Cambridge 39, Mass.

Components Parts (G-21)—F. E. Wenger, Headquarters, ARDC, Andrews AFB, Washington 25, D. C.; G. Shapiro, Engineering Electronics Sec., Div. 1.6, NBS, Connecticut Ave. and Van Ness St., Washington 25, D. C.

Education (G-25)—G. E. Moore, Westinghouse Elec. Corp., East Pittsburgh, Pa.; W. R. LePage, Dept. of E.E., Syracuse Univ., Syracuse 10, N. Y.

Electron Devices (G-15)—W. A. Adcock, Texas Instruments, 6000 Lemmon Ave., Dallas 9, Tex.; G. Wade, Spencer Lab., Raytheon Co., Burlington, Mass.

Electronic Computers (G-16)—W. L. Anderson, 1408 Lexington Rd., Falls Church, Va.; Prof. N. R. Scott, Dept. of Elec. Engrg., University of Michigan, Ann Arbor, Mich.

Engineering Management (G-14)—T. W. Jarmie, Engineered Electronics Co., 1441 E. Chestnut Ave., Santa Ana, Calif.; A. H. Rubenstein, Dept. of Indus. Engrg., Northwestern Univ., Evanston, Ill.

Engineering Writing and Speech (G-16)—J. M. Kinn, Jr., *IBM Journal*, 17th Floor, 545 Madison Ave., New York, N. Y.; H. B. Michaelson, IBM Res. Ctr., Box 218, Yorktown Heights, N. Y.

Geoscience Electronics (G-29)—R. W. Olson (Acting Chairman), Texas Instruments, Inc., Dallas, Tex.; Editor to be advised.

Human Factors in Electronics (G-28)—R. R. Riesz, Bell Telephone Labs., Murray Hill, N. J.; J. I. Elkind, Bolt Beranek and Newman, Inc., 50 Moulton St., Cam-Bridge, Mass.

Industrial Electronics (G-13)—J. E. Eiselein, RCA Victor Div., Camden, N. J.; R. W. Bull, Coleman Instruments, Inc., 42 Madison St., Maywood, Ill.

2 PEAS IN A POD?

no guarantee of similarity!

One pea may be damaged by insects or disease . . . or may be quite different simply through a caprice of nature.

THERE IS A DIFFERENCE IN DEFLECTION YOKES

TYPE Y58
Highest Resolution Stator Yoke

TYPE Y25
Compact Rotating Yoke

TYPE Y16
Low Capacity Push-Pull Yoke for Speed

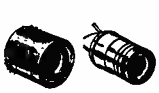
TYPE F10
Precision Electro-magnetic Focus Coil

Specialists in yokes, Syntronic's team of experts knows more about yoke design, engineering and quality control than anyone else. A solid record of leadership for over 10 years—acknowledged throughout the industry.

This specialized experience means more to you than you may know. "Little" things make a big quality difference . . . like fast spot recovery time . . . smallest, roundest dots . . . geometrical precision . . . rapid settling time . . . least spot growth from center to edge . . . smallest residual magnetism. Mighty important, actually. Syntronic cares enough to make them right. You can depend on it.

Syntronic claims—and delivers—the most precise yokes that can be made. Every time. Year after year. To your exact requirement. And Syntronic's team of experts can help solve your yoke problems.

Since there is a difference, benefit from it. Get the most from your display.



TYPE Y15
Precision Low Current Yoke

TYPE Y57
1" I.D. Push-Pull Yoke

TYPE Y59
7/8" I.D. Transistor Yoke

TYPE F40
Dynamic-static Focus Coil

FABRICATING MICROMODULES TO MOBILE ROOMS

Magnetic Shields Custom Fabricated to Any Size or Shape

The industry's widest range of production facilities . . . in 3 factories:

PRESS FORMING AND DRAWING • HYDROFORMING • SPINNING • HAND FABRICATION OF PROTOTYPES

Already Tooled for Samples or Production

- Simple designs to elaborate complexes.
- Single or multiple laminae constructions.
- Micromodule size to a completely prefabricated mobile shielded room weighing 5 tons which can be transported anywhere — an achievement unique with Magnetic Shield Division.*

ALSO AVAILABLE

- Processed stock for fabrication in your own plant.
- Co-operative design facilities.

Use this SINGLE CONVENIENT SOURCE for all magnetic shielding requirements. Saves you countless design hours . . . helps speed your project . . . lowers your costs.

We recommend NETIC and CO-NETIC magnetic shielding materials because they are non-shock sensitive, non-retentive, do not require periodic annealing and provide completely effective shielding for optimum results.

NETIC and CO-NETIC are widely specified for satellite, missile, protecting recording tapes, data processing and for innumerable other military, scientific and laboratory applications as well as for commercial applications.

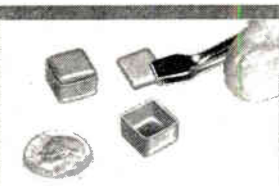
MAGNETIC SHIELD DIVISION

Perfection Mica Company

1322 N. ELSTON AVENUE, CHICAGO 22, ILLINOIS

ORIGINATORS OF PERMANENTLY EFFECTIVE NETIC CO-NETIC MAGNETIC SHIELDING

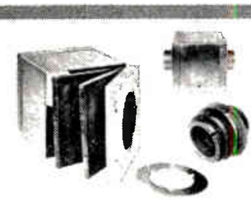


Micro miniature shield and cover, punch press operation.

Sequence of shield cans, punch press or spinning.

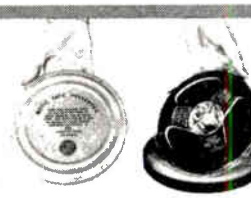
Complex configuration multi-lamina shield, hydroformed.

CRT shield illustrating combination of hand fabrication, spinning and sizing.

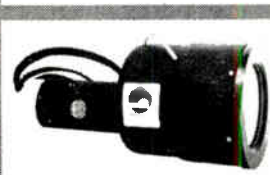


Backward wave tube shield assembly design, involving hand fabrication and hydroform or spinning.

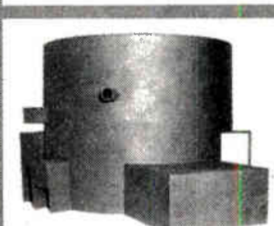
Special purpose shield, hand fabrication (levitated gyro).



Tape preserver can be spun, hydroformed or punch press fabricated.



Data storage tube shield, hydroform or spinning, plus hand fabrication.



Large fabricated special structure (shaker table shield), approx. 60" dia. and 57" high.

Composite photo demonstrating that magnetic shielding qualities of NETIC alloy material are not affected by vibration, shock, (including dropping), etc.

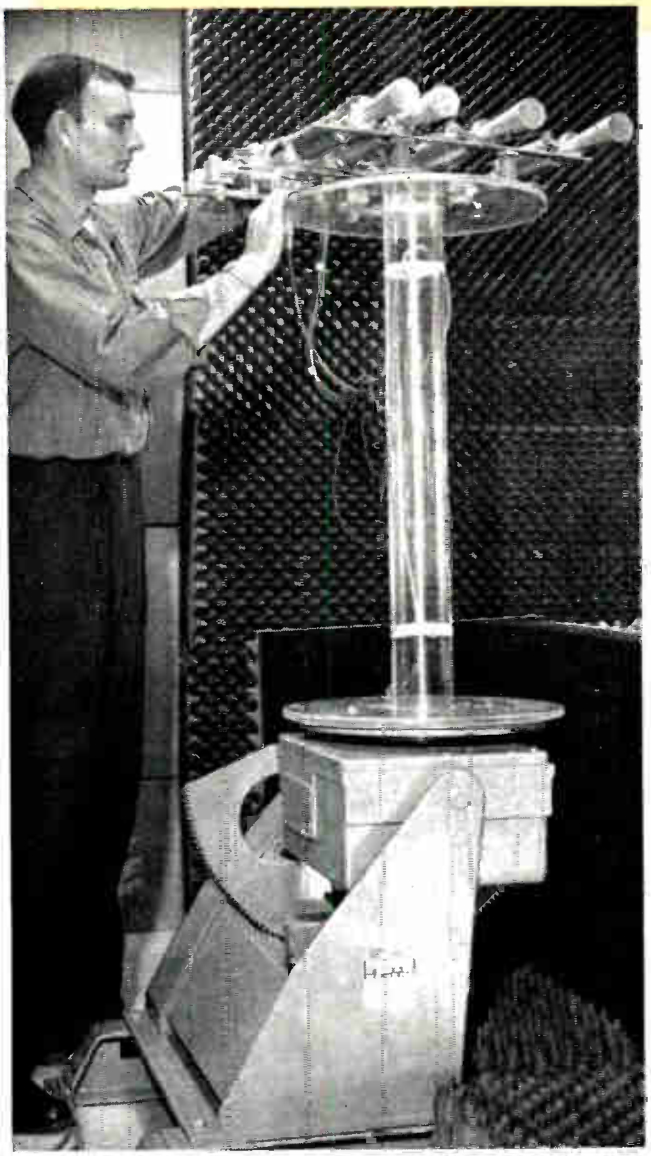
AT TEXAS INSTRUMENTS:

New capabilities in antenna research

WITH THE AID OF SCIENTIFIC-ATLANTA EQUIPMENT



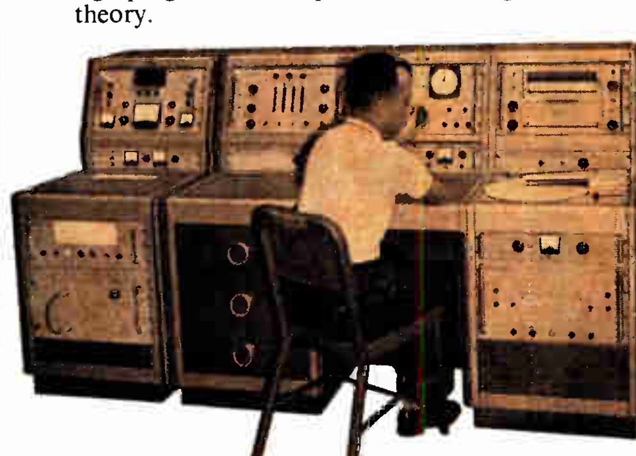
Antenna positioner installed in Texas Instruments' anechoic chamber (microwave darkroom) is one part of the Scientific-Atlanta instrumented facility.

Recently the Apparatus Division of Texas Instruments Incorporated built a new antenna research laboratory to allow more advanced work on a wide range of applications. These include radar equipment and systems for airborne early warning, submarine detection, and airport and airborne surveillance. Scientific-Atlanta supplied the antenna pattern instrumentation consoles and positioning equipment which includes the following major items:

a wide range, low noise receiving system (model 402A); an antenna pattern recording system (model APR 20/30); an antenna pattern integrator (model API-1); and an azimuth over elevation antenna positioner (model PAE 5).

This instrumentation, along with signal sources from S through K_u bands, a complete line of standard test equipment, an anechoic chamber, an inside test range, and 150 acres of outside test ranges, gives Texas Instruments one of the most sophisticated antenna test facilities in the country.

Texas Instruments engineers report that their Scientific-Atlanta equipment enables them to make quick, accurate and reliable one-way pattern/gain measurements, antenna backscatter experiments, and studies of advanced methods of electronic scanning, all contributing to missile antenna design programs and experiments relating to antenna theory.



Texas Instruments' installation uses a completely equipped Scientific-Atlanta console.

For more details on the Texas Instruments facility and how Scientific-Atlanta can design, construct and install an antenna test facility that suits *your* needs, please write to:

SCIENTIFIC-ATLANTA, INC.

2162 Piedmont Road, N.E. Atlanta 9, Georgia Phone: 875-7291

Challenging opportunities for electronic engineers with five to ten years' circuit design experience. Please send complete resume to Personnel Manager. An equal opportunity employer.

16

IRE People

Univac Military Operations, St. Paul, has hired two new engineers to supervise the electronic design of advanced micro-miniature aerospace computers.

W. C. Timm

T. M. Sammis

They are: **Theodore M. Sammis,** (SM'61), supervising development engineer, and **Walter C. Timm** (S'53–A'55–M'60) principal development engineer, both former senior group engineers at McDonnell Aircraft Corp., St. Louis, Mo.

Mr. Sammis supervised the design of miniature aerospace digital equipment at McDonnell. He previously was a supervising engineer at Hazeltine Electronics Corp., Little Neck, N. Y.

Before joining McDonnell, Mr. Timm was on the technical staff of Bell Telephone Laboratories, Whippany, N. J. He is a member of the American Institute of Electrical Engineers.

❖

Joseph D. Schantz (S'33–A'35–SM'44) has been appointed manager of the ZMAR program at the eastern operation of Sylvania Electronic Systems, Waltham, Mass., a major division of Sylvania Electric Products, Inc.

J. D. Schantz

Since July 1960, Mr. Schantz has served as Director of Engineering at the division's Waltham Laboratories, which recently combined with the Data Systems Operations at Needham, Mass., to form the eastern operation. Previously, he served successively as Chief Electronics Engineer, Assistant Manager of the avionics division, and finally as Director of Plans and Programs for Bell Aircraft Corp., Buffalo, N. Y. Mr. Schantz also served as a research engineer with RCA and as manager of the military projects division of Farnsworth Television and Radio Corporation.

He received his Bachelor's degree in electrical engineering from Gettysburg College and his Master's degree from the University of Michigan.

John D. Smith (M'59) has been appointed head of the Mechanical Engineering Department at the Data Systems Division of Litton Systems, Canoga Park, Calif.

Mr. Smith was graduated from the University of Denver in 1941 with a B.S. degree in electrical engineering, and from the University of Southern California in 1955 with an M.S. degree in electrical engineering.

In the newly-created post Mr. Smith will be responsible for mechanical engineering for the advanced command and control systems developed and manufactured by the division. Before joining Litton systems he was manager of the displays laboratory at the Hughes Ground Systems Division, Fullerton.

Mr. Smith is a member of the AIEE.

❖

It was recently announced that **Dr. Thomas E. Tice** (S'46–A'50–SM'55–F'61) has been appointed to the position of Chief Engineer of the Antenna and Microwave Group, at Motorola Inc., Military Electronics Division, Scottsdale, Ariz.

T. E. Tice

Dr. Tice, a native of Florence, Ala. was prior to this appointment the director of Ohio State University's Antenna Laboratory, Columbus, Ohio, and was responsible for research in microwave circuits, wave propagation, antennas, and electromagnetic field theory. Concurrently, Dr. Tice held the rank of Professor, OSU Department of Electrical Engineering.

He was a former communications officer with the U. S. Army Signal Corps and was responsible for the installation and maintenance of Army airways communications equipment and air navigational aids in North Africa and Arabia.

Dr. Tice served as Editor-in-Chief for McGraw-Hill's "Techniques for Airborne Radome Design" in 1957.

Dr. Tice is a member of Sigma Xi, Tau Beta Pi, Eta Kappa Nu, and Chi Beta Phi. He is also a member of the Air Force Advisory Group on Passive Satellite Communications, the IRE Seventh Region Student Paper Competition Committee, and the IRE Phoenix Section Awards Committee.

A SIGNIFICANT BREAK-THROUGH IN TRANSISTOR TECHNOLOGY...

ECDC*

The Best High-Power, High-Speed Switching Transistors Ever Developed Provide the Optimum Combination of Voltage, Power, and Speed

The Sprague ECDC Transistor is the first to combine the optimum features of the electro-chemical precision-etch techniques and diffused collector techniques in one highly-mechanized process.

The ECDC Transistor meets these 7 conditions for an "ideal" transistor:

1. Very low collector-to-case thermal resistance through the utilization of high thermal conductivity material as the collector body, resulting in high power dissipation.
2. Thin base width for high radiation resistance and lower storage time.
3. Precision-etched emitter pit permits placement of emitter junction at proper resistivity for optimum breakdown voltage and frequency response.
4. High conductivity surface surrounds emitter pit and close emitter-to-base spacing results in extremely low base resistance.
5. Precision-etched collector provides optimum control of collector series resistance with attendant low saturation voltage, low storage time, and high breakdown voltage.
6. Low collector series resistance as a result of the use of high conductivity material for the mass of the collector area.
7. The structure and manufacturing processes are suited for automated production equipment with immediate in-process feedback.

*Trademark of Sprague Electric Co.

TYPES 2N2099 & 2N2100

These P-N-P Germanium Electro-Chemical, Diffused-Collector Transistors are especially designed for core and film memory driver applications. They feature excellent beta linearity from less than 1 ma to over 400 ma, high frequency response, and low saturation resistance. The low-height TO-9 case is ideally suited to meet equipment designers' needs.

TYPES 2N2096 & 2N2097

Types 2N2096 and 2N2097 are electrically identical to Types 2N2099 and 2N2100, respectively, except for their TO-31 Case, with its threaded stud mounting.

For complete information on ECDC Transistors, write Product Marketing Section, Transistor Division, Sprague Electric Company, Concord, New Hampshire.

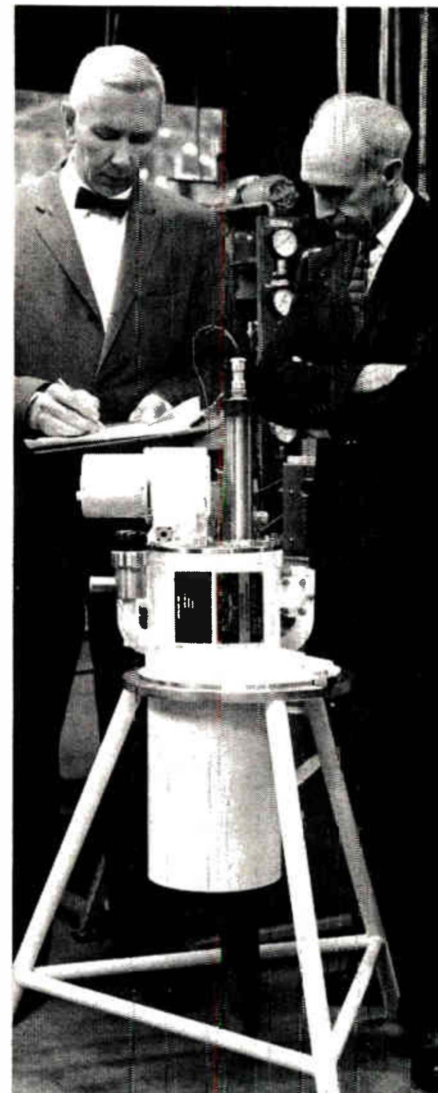
THE CRYODYNE® HELIUM REFRIGERATOR

a new milestone

now from ADL



Albert Hatch (left) and Dr. Howard McMahon discuss the results of a test run. Dr. McMahon and William E. Gifford, now Professor of Mechanical Engineering at The University of Syracuse, were co-inventors of the refrigeration cycle used in the CRYODYNE Refrigerator. Albert Hatch is in charge of engineering development of the Refrigerator at ADL.

Closed-cycle refrigeration at liquid helium temperatures is now available in proven hardware. Arthur D. Little, Inc. — under the initial sponsorship of International Business Machines Corporation and continuing sponsorship by the U.S. Army Ordnance Corps through Bell Telephone Laboratories, Inc. — has extended the development of its patented Gifford-McMahon cycle to produce the ADL CRYODYNE HELIUM REFRIGERATOR. The Refrigerator will provide up to 250 milliwatts of refrigeration at liquid helium temperatures and will function normally regardless of physical orientation. A number of units were completed in 1961 and by December 31st had accumulated, in aggregate, more than 10,000 operating hours. A CRYODYNE Refrigerator on one endurance test run exceeded 1500 hours of continuous operation without maintenance or control manipulation.

Because of its demonstrated reliability, its compact size and simplicity of design, the CRYODYNE Refrigerator lends itself to a wide range of application in cooling superconductive, quantum electronic, and IR devices. For complete technical data and price information, write: CRYOGENIC EQUIPMENT, Arthur D. Little, Inc., 20 Acorn Park, Cambridge 40, Massachusetts.

Here is MEASURED RELIABILITY!

DUR-MICA CAPACITORS TYPE M2DM

Ten thousand EL-MENCO high reliability dipped mica capacitors were put on life test at 85°C with 225% of the rated DC voltage applied–After 26,500,000 actual test unit-hours no failures of any type occurred.

The accumulated 26.5 x 10^6 test unit-hours without any failures can be used to calculate many different failure rates depending upon the confidence level desired. However, we shall explore the meaning of the results at a 90% confidence level.

Assuming no acceleration factor for either temperature or voltage, we have verified a failure rate of less than 0.01% per 1000 hours. (Actually, there is a temperature effect and it has been found that, with the DC voltage stress remaining constant, the life decreases approximately 50% for every 10°C rise in temperature. There is also a voltage effect such that, with the temperature stress remaining constant, the life is inversely proportional to the 8th power of the applied DC voltage.)

Assuming no temperature acceleration factor and assuming the voltage acceleration exponent is such as to yield an acceleration factor as low as 100, we have nevertheless verified a failure rate of less than 0.0001% per 1000 hours.

Assuming no temperature acceleration factor and assuming the voltage acceleration factor is on the order of 250 (test results are available to confirm this) we have accumulated sufficient unit-hours to verify a failure rate of less than 0.00004% per 1000 hours!

Note that all the above failure rates are calculated at a 90% confidence level!

Only 1 Failure in 14,336,000 Unit-Hours for 0.1 MFD Capacitors

Life tests have proved that El-Menco Mylar-Paper Dipped Capacitors — tested at 105°C with rated voltage applied—have yielded a failure rate of only 1 per 1,433,600 unit-hours for 1.0 MFD. Since the number of unit-hours of these capacitors is inversely proportional to the capacitance, 0.1 MFD El-Menco Mylar-Paper Dipped Capacitors will yield ONLY 1 FAILURE IN 14,336,000 UNIT-HOURS.

MINIMUM LIFE EXPECTANCY FOR 1.0 MFD MYLAR-PAPER* DIPPED CAPACITORS AS A FUNCTION OF VOLTAGE & TEMPERATURE**

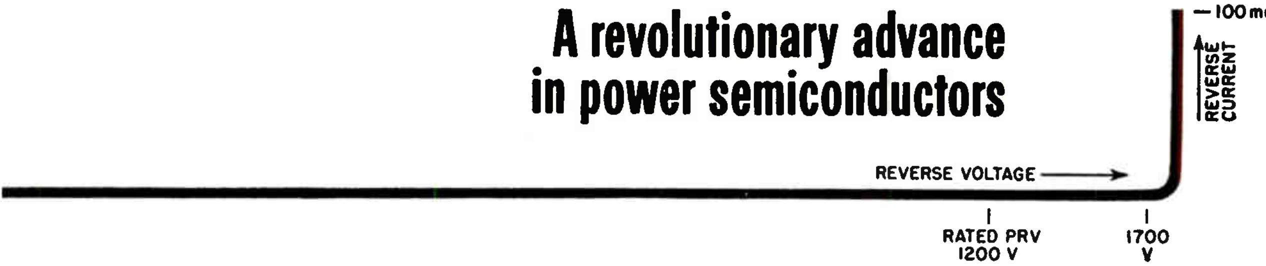
THE CONTROLLED RECTIFIER

For complete technical information, call your G-E Semiconductor Products District Sales Manager. Or write Rectifier Components Department, Section 23E62, General Electric Company, Auburn, New York. In Canada: Canadian General Electric, 189 Dufferin Street, Toronto, Ontario. Export: International General Electric, 159 Madison Avenue, New York 16, N. Y.

GE ELECTRONICS
PROGRESS IN RECTIFIER COMPONENTS

A revolutionary advance in power semiconductors



AVALANCHE

A NEW 12 AMPERE RECTIFIER WITH PEAK REVERSE RATING OF 1200 VOLTS, AND A SELF-PROTECTIVE REVERSE "AVALANCHE" POWER DISSIPATION RATING UP TO 3900 WATTS

The most important step forward in rectifier technology since General Electric introduced the SCR, the ZJ218 Controlled Avalanche Rectifier is the first of a new generation of G-E power semiconductors which eliminate a *fundamental* silicon rectifier limitation. Carefully controlled *non-destructive* internal avalanche breakdown *across the entire junction area* protects the junction surface, eliminates destructive local surface heating that permanently impairs or destroys the conventional rectifier's reverse blocking ability. In effect, ZJ218 has built-in "zener" diode protection, even well beyond 1200 volts. 600, 800, 1000 and 1200 PRV types are now available . . . *all* with these outstanding features:

SELF-PROTECTION AGAINST VOLTAGE TRANSIENTS

PRV	AVALANCHE VOLTAGE @ 25°C	
	Min.	Max.
1200	1500	1930
1000	1250	1550
800	1000	1290
600	750	1030

- *self-protection against voltage transients . . . dissipates up to 3900 watts peak power in reverse direction*
- *new high reliability standards at PRV's up to 1200 volts (as well as lower voltages)*
- *protection of other circuit components (including transformers) from overvoltage through rigidly spec'd max./min. avalanche characteristics*
- *simplified rectifier series operation in high voltage applications . . . eliminates need for shunt resistors*
- *permits continuous operation in avalanche breakdown region at high voltage . . . unharmed by hi-pot and megger tests*

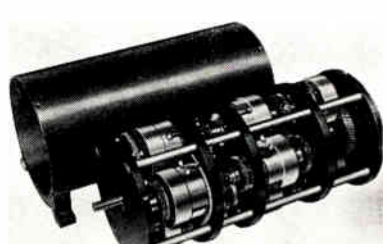
Burnell Dedicates Guillemin Laboratory

Science and industry joined in the dedication (Oct. 26, 1961) of **Burnell & Co., Inc.'s,** new Guillemin Research Laboratory in Cambridge, Mass. Honoring Dr. Ernst A. Guillemin, eminent M.I.T. scientist who is also vice president in charge of research of Burnell & Co., the lab is believed to be the first facility of its kind devoted exclusively to research in electronic filters and networks.

Above, Dr. Guillemin (center) is shown in a discussion with Dr. Lan J. Chu (right), professor of electrical engineering at M.I.T., and Lewis G. Burnell, executive vice president and director of engineering of Burnell & Co., who were among the guests at the dedication. The firm's main plant is located at 10 Pelham Parkway, Pelham, N. Y.

Multi-Speed Reversible Transmission

With continuous running input, this transmission, designed by **Autotronics, Inc., Dept. T.,** P. O. Box 208, Florissant, Mo., delivers eight binary ratio output speeds in both directions plus an electromagnetically actuated instant brake. Output torque is in excess of 45 lb. in. at each speed.



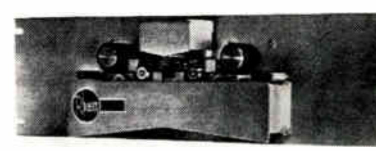
With 1800 rpm input, the output speeds are 360, 180, 90, 45, 22.5, 11.25, 5.625, and 2.8 rpm in both clockwise and counterclockwise directions. Speed and/or direction change takes place within 25 milliseconds.

Size is 3.6″ diameter by 7.3″ long excluding shaft extensions. Transmission is shown in picture with cover removed.

Price dependent upon specifications and quantity ordered. Contact: Art Lee, Sales Manager, for additional information.

Photocell Punched Tape Reader

A high speed unit is the newest addition to the line of Photocell Punched Tape Readers, according to an announcement of **Rheem Manufacturing Co., Electronics Div.,** 5200 W. 104th St., Los Angeles, Calif. The new model, the RR-1000, is nominally a 1,000 character per second unit, and features completely transistorized circuits, photovoltaic sensing cells and rugged two speed motor drives.



This new high speed unit is believed to be the lowest priced high speed tape reader currently being marketed. The uni-directional model is priced at **$1,450.00** and the bi-directional model at **$1,590.00.**

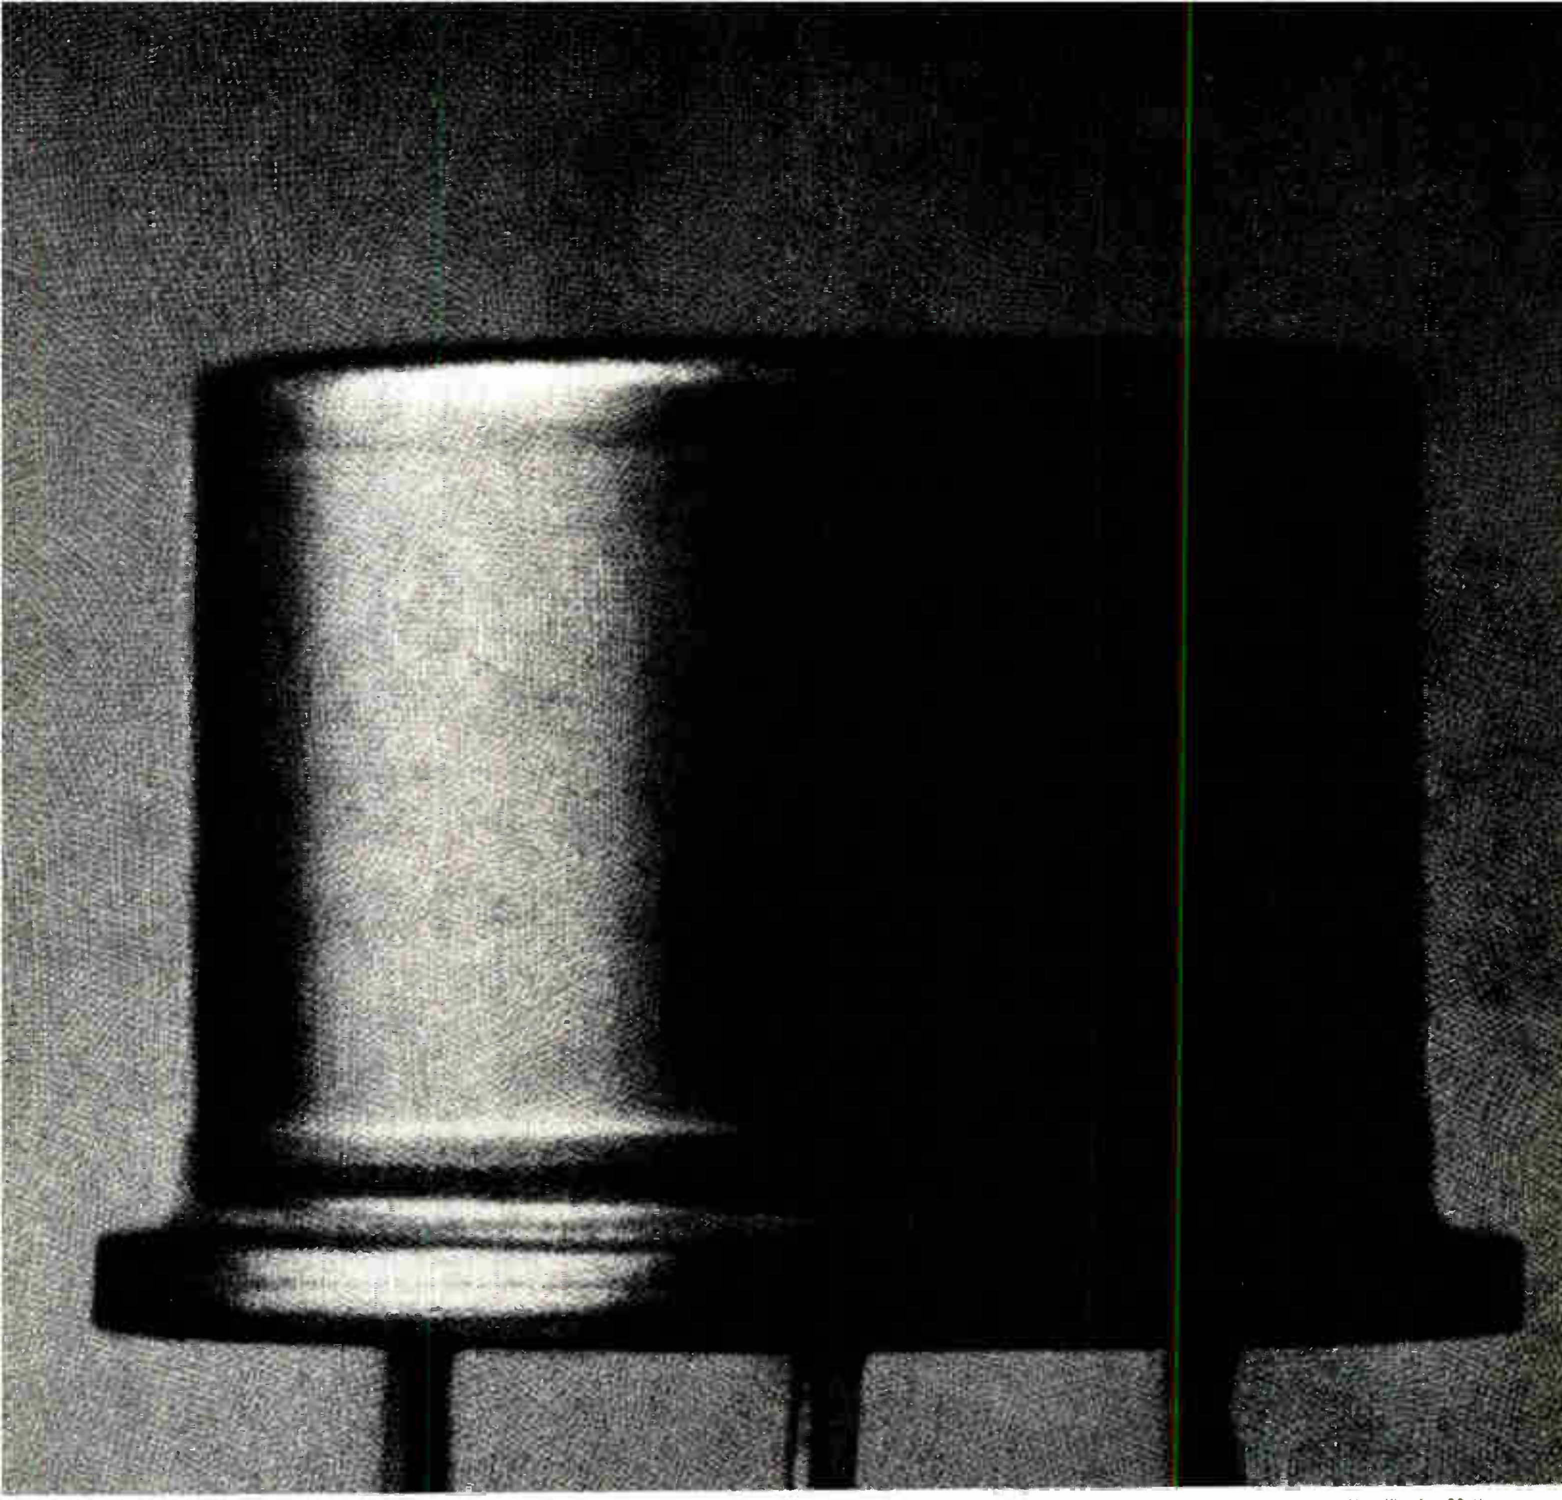
The standard model includes 2:1 speed ratio selectable with low level input, and 5, 7, and 8 level tape selection. Outputs can be selected for positive or negative logic and positive or negative voltage level. The reader is $5\frac{1}{4}$ inches high and 19 inches wide for rack mounting.

For details contact Dr. Wm. Leone at the firm.

Mechanical Filter

A new low cost mechanical filter for commercial and amateur communications equipment is available from **Collins Radio Co., Components Div.,** P. O. Box 1891, 19700 San Joaquin Rd., Newport Beach, Calif.

(Continued on page 46A)



Magnification: 20 times

Old hat

Six months ago this Fairchild transistor was the newest thing on the market. Now there's a better one. Made by Fairchild. Meeting the challenge of your own products is a criterion of leadership in this fast-moving, fast-changing industry. That's why the search to make it (1) work better, (2) do more and (3) cost less—goes on 24-hours a day at Fairchild.

FAIRCHILD SEMICONDUCTOR

FAIRCHILD SEMICONDUCTOR / 545 WHISMAN RD., MOUNTAIN VIEW, CALIF. / YORKSHIRE 8-8161 / TWX: MN VW CAL 853 / A DIVISION OF FAIRCHILD CAMERA AND INSTRUMENT CORPORATION

NEWS New Products

Based on innovations in design and manufacturing, the new 455 kc mechanical filter will be available at cost reductions of as much as 35 per cent under the standard version of the same filter.

The new filter has steep skirted selectivity with a 6 db bandwidth of 2.1 kc and a 60 db bandwidth of 5.3 kc—a shape factor of just over 2.5 to 1. One of the most widespread applications of the new filter is expected to be in single sideband transmitters and receivers.

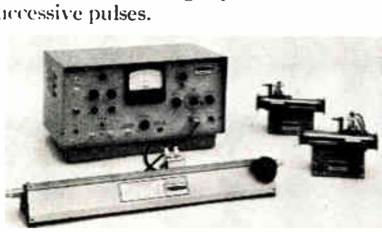
The filter is packaged in a phenolic case and is suited for circuit board manufacturing techniques involving dip soldering. The filter is 2½ inches long, and slightly more than ½ inch wide and ½ inch high, not including mounting studs and terminals.

Production quantities will be available with 120-day delivery after May, 1962. Specific application, price and delivery information can be obtained from the firm.

Phase Meter For Pulsed Microwaves

Wiltron Co., 717 Loma Verde Ave., Palo Alto, Calif., has developed a phase meter for pulsed microwave signals.

This new phase measuring capability is of importance to microwave tube manufacturers, radar and communication system designers, transmitter designers and other users of microwave pulsed signals. It means that for the first time there is an instrument for measuring the RF phase characteristics during a pulse and between successive pulses.



The meter takes a μs sample of the pulsed signal being measured. After calibration, the average phase during this sample is presented on a direct reading meter in degrees. The point of sampling can be progressively moved through a pulse to achieve a plot of phase for each portion of the pulse. In addition, the entire pulse phase pattern can be read out on an oscilloscope. This permits the observation of dynamic phase changes, with a response time of about 0.2 microsecond.

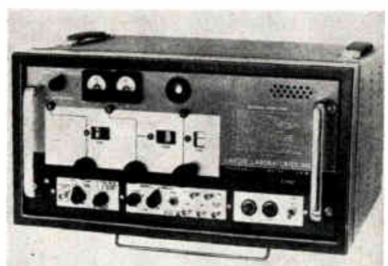
The Model 305 sells for $2,450.00 and must be used with one of Wiltron's Phase Detectors which are in the range of $950.00 and above. Delivery is 7 weeks.

(Continued from page 44A)

These manufacturers have invited PROCEEDINGS readers to write for literature and further technical information. Please mention your IRE affiliation.

VHF Frequency Meter

The LA-70B VHF Frequency Meter, designed by **Lavoie Laboratories, Inc.,** Morganville, N. J., can measure from 10 kc to 3,000 mc with an accuracy of 0.0001% between 20 mc to 3000 mc. In addition, it is capable of generating frequencies from zero to 3000 mc. Using an oven-mounted 1 mc quartz crystal for frequency control, the instrument has a stability of 0.001% and resetability of 0.000025%.



It is a direct reading meter, no temperature correction curves or calibration book is required, and the instrument operates in an ambient temperature range of 4°F to 130°F.

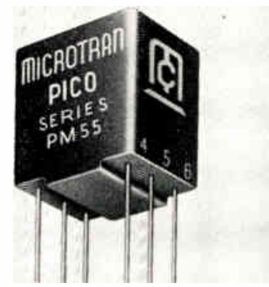
Useful for any frequency measurement task, and particularly mobile radio service, the instrument is useful in input, oscillator and intermediate or harmonic frequency measurements and any frequency encountered in VHF receivers. Since any desired single frequency over the entire range of zero to 3,000 mc is available as an active output, alignments of VHF receivers and other passive elements can also be performed.

The LA-70B also features: output frequencies of zero to 3000 mc with output levels in the order of a few tenths of a volt; internal impedance (as a generator) 3000 ohms; internal impedance (as a frequency meter) 50 ohms; with power requirements of 115 v, ±10%, 60 cps, 130 watts maximum during warmup to 105 watts during operation.

Transformers and Inductors

Microtran Company, Inc., Valley Stream, N. Y., has produced several new lines of products.

Among these are a new line of PICO miniaturized transformers for miniaturized printed-circuit board applications, and a new stock line of toroid inductors.



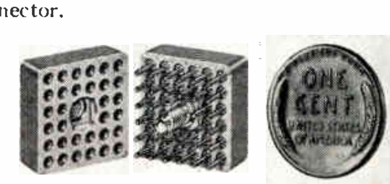
The new PICO series with leads on 0.1″ grids is 5/16″×13/32″×15/32″ high and weighs 0.1 ounce. Gold-plated, high-strength nickel alloy leads permit both reliable soldered joints and high-density welded packaging. Epoxy molded construction per MIL-T-27, Grade 5, Class R, 10,000-hour life. The 20 different items in the PICO series are available in impedance ratings from 3.2 ohms to 200,000 ohms.

The line of toroid inductors is available in a wide choice of frequency ranges and inductances. Types of construction available are: open frame, plastic dipped, molded with lugs. The inductors are hermetically sealed with a standard accuracy of inductance of ±2%.

Detailed information, specifications, comprehensive catalogs, pricing, and list of distributors may be obtained from the firm.

High Density Contact Connector

Winchester Electronics, Inc., 19 Willard Rd., Norwalk, Conn., has announced a new subminiature high density connector.



Named the SRD series, the connector is designed for use with instrumentation employing small modular packages. Extremely suitable for logic units in computors, and allied applications, the connector, 0.6″ square, has center jackscrew for engagement and disengagement and is readily adapted for potting.

The component has 32 contacts; solder dup and dip solder terminals; pin contact brass, socket phosphor bronze—gold plated over silver. Polarization is by pins in place of contacts. Standard molding is diallyl phthalate. Contact spacing is 0.094″.

(Continued on page 48A)

NEWS New Products

(Continued from page 46A)

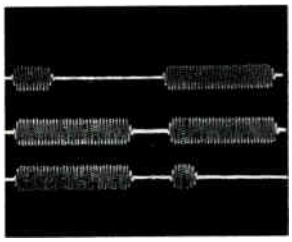
High Power Pulsed Oscillator

Oscillator, PG-650C, an improved version of the original model, manufactured by **Arenberg Ultrasonic Laboratory, Inc.**, 94 Green St., Jamaica Plain 30, Mass., is used as a variable frequency pulse modulated RF source for applications requiring high power as well as extreme stability. Its chief application has been in all phases of ultrasonic testing, nuclear magnetic resonance and transient analysis.

The standard units provide 0 to 300 v peak to peak pulses into 93 ohms from 5 mc to 90 mc. The pulse length is continuously adjustable from 1½ to 20 μsec and provision is made for external or internal triggering from 50 to several thousand cps. Three calibrated delay ranges cover 20 to 120, 100 to 1100, and 1000 to 11,000 μsec. In addition, fine controls giving a 1% change of the coarse controls on pulse length, prf and delay are provided.

The pulse length can be reduced to a minimum of ½ μsec and on special units extended to 50 or 100 μsec with a small increase in the minimum continuously variable range.

The rise time is 0.4 μsec or 3 cps, whichever is greater, on standard units and the fall time is shorter. Provision can be made for increasing the rise or shaping the envelope. The RF pulse is phase stable with respect to the trigger and jitter can be held to 0.005 μsec. Droop or overshoot is less than 5%. Because of the push-pull gated oscillator action, the total harmonic content is less than 10% consisting mainly of the third harmonic and no noise or background is generated between pulses. RF leakage is detectable only with great difficulty.



Variable Pulse Output

The unit is contained in a shielded aluminum box with a rack mounting front panel. The output may be taken either from a balanced or unbalanced shielded U.H.F. receptacle.

The RF tuning is easily adjusted via a wide band spread vernier dial and read on a straight line chart. The range can be extended from 300 kc to 150 mc on the standard unit with extra coils, or from 12 kc to 210 mc on a modified unit.

Other features of the standard unit now are:

(1) Gated output for blanking or intensifying purposes available during the RF pulse.

(2) Provision for two pulses of the same frequency and amplitude separated by a variable delay initiated by the same trigger. A modification will allow these to have different widths.

(3) External modulation of the RF pulses from a gate to allow any sequence of variable pulse widths and spacings. The application is mostly for nuclear magnetic resonance work but external modulation will allow pulsing up to a 110 kc repetition rate for accurate measurements of sound velocity.

(Continued on page 52A)

Patents and the Electronics Company

The basis for Patent Law in the Constitution of the United States reads: "The Congress shall have power . . . to promote the progress of science and useful arts, by securing for limited times to authors and inventors the exclusive right to their respective writings and discoveries."

Patents Are Needed!

In the early days of the patent law, individual inventors obtained patents on their inventions and benefited in proportion to their commercial successes. Today the individual has much less opportunity to work out successful ventures alone and more often combines forces with others. At the other extreme is the large corporation with an elaborate system for exploiting the inventions of its engineers even to the point of license pools some of which have been knocked down by application of Anti-Trust Laws. With serious difficulties at both ends of the scale, the small company has come into its own in patent matters. The small company with proper handling can reap great rewards from the skillful use of the Patent Laws of this and foreign countries. Some of these rewards are set forth below:

Worth Patenting?

1. The growth and stability of a small electronics business depends on many factors such as marketing, management, financing, but fully as important is its technical ability. Technical ability means, among other things, a certain amount of development. This development requires good engineers and good ideas. Many of these good ideas are worth patenting.

Stimulant to Engineers

2. The patenting of new ideas is one of the best stimulants to more and better ideas. This is really the heart and core of the intent of the Constitutional provision for patents and it really works. New products require new ideas. New ideas flow readily from creative engineers in the right environment. One of the ways to help create this environment is to give the engineer the recognition that the proper handling and patenting of his ideas provides. A well integrated and competent patent department can provide much of this stimulating environment for the engineer. In a small company in the electronics field a competent patent engineer/attorney can provide this patent department at a nominal and predictable cost.

Patents Stabilize

3. Patents held by small electronics companies provide a strong stabilizing influence on the company's operations and its standing and recognition in the field. Patents help establish a field of priority. This established field of priority may be most valuable in its implicit warning to competition. This is especially true of competition from other companies who recognize the value of patents and ask and give respect for the fields of priority which they establish. This valuable aspect of patents grows with the growth of the patent coverage obtained, but requires the obtaining of good patents. All this usually takes place, when properly handled, without patent suits and only with the warnings which are implicit with the issuance of carefully drawn and apparently valid patents.

Patents Are Assets

4. Patents are property and have asset value. There is a striking contrast between the company which after years of operation has no patents and the one which has gathered many. Many businesses are sold or obtain financing on asset values greatly augmented by their patents. Sometimes the patents are themselves sold at considerable profit. A company which might otherwise be an empty shell, when provided with a patent folio can show substantial values. Patents are an equity accumulated over the years which might otherwise become almost completely lost in the normal course of business. This asset value alone makes patents an extremely good business practice. There are other important ways in which the asset value of patents may be used. The licensing of patents especially for noncompetitive uses may be a source of considerable revenue. Patents which are not being worked may be sold. The patent department should be aware of these possibilities and bring them to the attention of management for decision.

Patents Do Protect

5. Finally, and this section is made the last for good reason, patents may be used to sue others. The small company is admittedly at a disadvantage here with respect to the large corporation since patent suits are expensive. However, with careful management and the proper attitude with regard to patents, suits are a last resort. This is a subject with too many implications to be discussed fully here. It is merely suggested that patents may be dealt with and many important and real values realized without resorting to patent suits. The statement that a patent is only a right to sue, glosses over the many advantages and values set forth above, which may be had without even considering suing others.

A Patent Is Insurance

A patent program may be regarded as an insurance program; insurance that full value will be received for contributions to advancement of the electronics art.

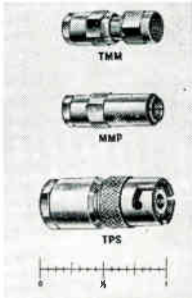
(4) Provision for use as a pulsed amplifier in order to use an external CW source of greater frequency stability than is possible with a gated single stage oscillator. This mode can be extended to several gated stages of amplification.

(5) Operation as a CW oscillator of 10 to 20 watts output in the standard frequency range.

Connectors

Automatic Metal Products Corp., 314-323 Berry St., Brooklyn 11, N. Y., announces the development of five new series of micro-miniature connectors. These new series are as follows: TMM (Threaded) 50 ohm; TMM (Threaded) 75 ohm; MMP (Push On) 50 ohm; MMP (Push On) 75 ohm and, TPS (Bayonet) 50 ohm.



In style and configuration, these connectors closely parallel the present sub-miniature connectors as shown in the firm's brochure #sub min-1-660-5M. They have improved electrical and environmental characteristics, and are recommended for the most severe applications at frequencies up to "X" band.

Standard cable clamping in all of these series is Wedge-Lock/Captive Contact. Optional cable clampings are Wedge-Crimp/Captive Contact, or an external crimp type clamp. These cable clamping techniques are said to cut assembly time as much as 70% over previous methods. As an optional extra, neoprene or silastic strain relief boots in either black or standard RETMA colors may be supplied.

All connectors have Teflon insulation. They may however, be supplied with alternate insulation materials for special applications such as radiation resistance, etc.

In the Threaded and Push-on series, plug members contain the female contact and jack members contain the male contact. In the Bayonet series, contacts are reversed. Optional polarization of all of these connectors may be obtained by reversing the male and female contacts. Additional polarization may be obtained by reversing both the contacts and insulators. (By utilizing the various polarization methods, three connectors may be placed side by side on a panel without the chance of accidental mismating.)

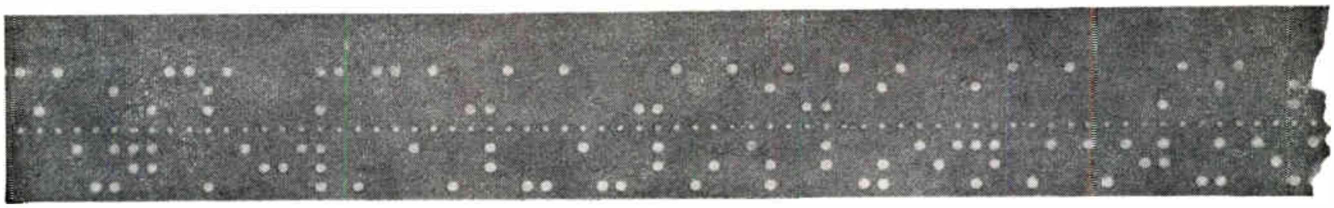
RFI ANALYSIS & PREDICTION BY COMPUTER!



Any equipments or components you are producing for missile weapons systems can be analyzed for Radio Frequency Interference by Capehart's INTERDICT* Group. Under our analysis procedures, RFI is computer-predicted on finished products, prototypes, or preliminary designs. Every item of electronic equipment which produces radiated or conducted RF signals is considered a transmitter, and every electronic equipment which is subject to malfunction as a result of exposure to conducted or radiated spurious signals is considered a receiver. We will make specific recommendations and provide design changes to bring your equipment within the RFI specifications or inform you if it is already within standards. Capehart's INTERDICT Group performs this same service for any other type of installation, site or system where RFI may be a potential problem. Our approach in RFI diagnosis of over-all operational requirements utilizing computer programming has been proven on a number of electronic equipments, missile systems and military sites including Cape Canaveral and Vandenberg AFB.

** Interference Detection and Interdiction by Countermeasures Team*

COMPLIANCE WITH CURRENT MIL SPECS: MIL-I-26600 • MIL-I-6051 • MIL-I-6181D

Engineers interested in joining Capehart's INTERDICT Group, or in other opportunities at Capehart, are invited to contact our Professional Recruiter, at the address below.

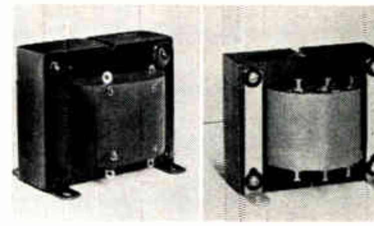
(Continued from page 52A)

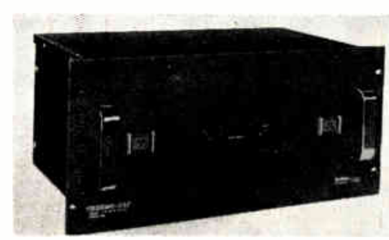
Transformers and Chokes



A new stock line of high current rectifier transformers and chokes with ratings from 9 to 56 volts at 1 to 200 amperes is now available from **Signal Transformer Co.**, 1661 McDonald Ave., Brooklyn 30, N. Y. Primarily designed for low voltage, high current applications, these items find extensive use in power supplies for transistor circuits, computers, magnets, battery charging and electro-plating. Units can be obtained for 50 or 60 cps operation in both open frame and encapsulated types. Available for immediate shipment from the firm.

Solid State Temperature Reference

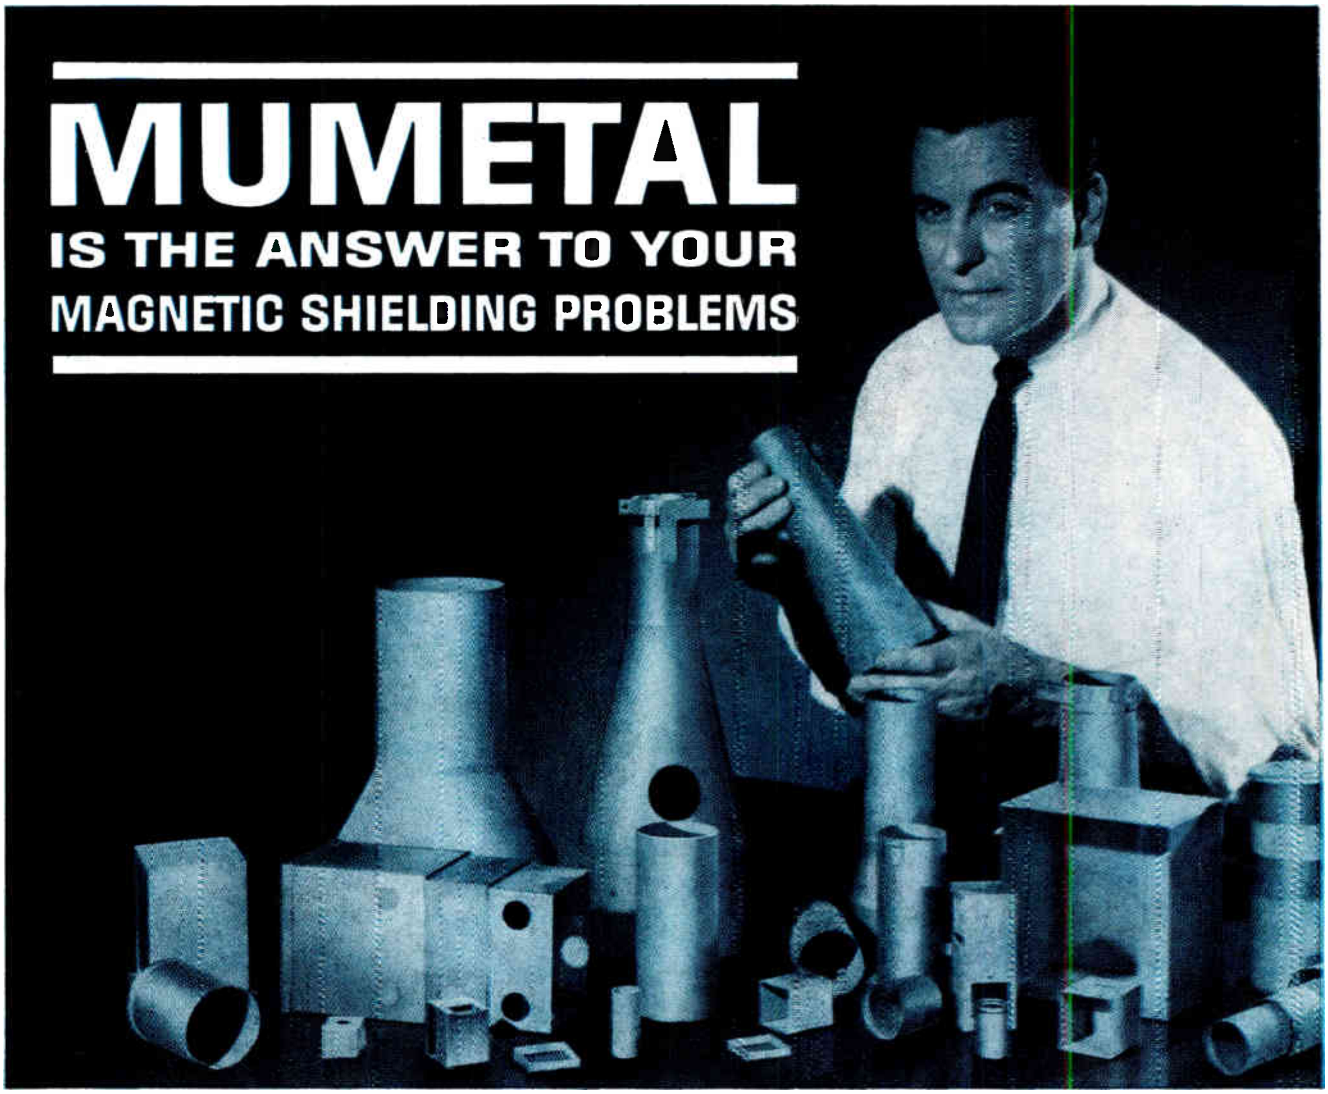
A rack-mounted version of the Thermo-Ref solid-state temperature reference is now available from **Genistron, Inc.**, 2301 Federal Ave., Los Angeles 64, Calif., from all applications requiring close temperature measurement tolerances and field ruggedness with laboratory accuracy.



Two 40-channel configuration of the Genistron unit provides a choice of junction materials—chromel-alumel in the Thermo-Ref Model 4010 and copper-constantan in the Model 4020, and other materials as specified.

Reference temperature is 212°F (100°C) with a special scale, visual calibrator, indicating meter for voltage check point. Junction uniformity and temperature stability are both ±.2°F over the standard operating range of −20°F to +150°F which allows laboratory accuracy in typical applications. Power requirements are 10 watts maximum at 115 V, 60 cps with nominal 15-minute warmup. TC channel to channel isolation is in excess of 50 megohms. Custom modifications can be supplied to meet specific requirements. The Thermo-Ref meets applicable military environmental specifications. Designed for

(Continued on page 56A)



Instant relief to interference caused by extraneous magnetic fields is the net result of shields made of Allegheny Ludlum's Mumetal. These shields protect components against stray external fields or prevent neighboring parts from being affected by a field-generating component inside the shield. In electronics, Mumetal and shielding are practically synonymous terms.

To develop its optimum shielding properties, Mumetal must be properly annealed in a pure, dry, high temperature hydrogen atmosphere after fabrication. When properly annealed, Mumetal has extremely high permeability and is capable of attenuating stray fields to negligible proportions.

In general, high permeability, shielding excellence and strain sensitivity go hand in hand. In the optimum condition, Mumetal is relatively soft. Shields in this condition should be handled with care in order to preserve optimum shielding efficiency.

In many applications, fabricating or field conditions are encountered which make it impossible to avoid straining the material after the high temperature hydrogen anneal. Even when strained, Mumetal shields remain extremely effective.

The inherent ductility of Mumetal offers fabricating advantages in forming, drawing, and spinning operations.

For all your shielding requirements, insist on Allegheny Ludlum Mumetal. And for more information, ask for a copy of EM12, a 20 page technical Blue Sheet describing Mumetal, its properties, annealing details, etc. Write ***Allegheny Ludlum Steel Corporation, Oliver Bldg., Pittsburgh 22, Pa., Address Dept. IRE-5***

(Continued from page 54A)

standard 19-inch rack mounting, the unit is 10 inches deep.

Typical usage includes rack-mounted Thermo-Ref models as an integral component of temperature monitor systems in missile test stand operations, and other applications when temperature accuracy is important.

For additional information, contact the firm.

Octave Amplifiers

A new series of packaged octave amplifiers is now available from **LEL, Inc.**, 75 Akron St., Copiague, N. Y. These low noise, broadband RF amplifiers cover a range of frequencies from 40 mc to 640 mc.

The Model OMP-5-160 has a gain of 30 db minimum, ±0.5 db ripple and a linear output of greater than 1 volt over the range of 160 to 320 mc. It is available as a self-contained rack-mounted unit as shown or as an amplifier only, Model OMX-5-160.* The rack mounted units employ a solid state regulated power supply. Price and delivery upon request.

* Average noise figure is 6 db.

Miniature Preamplifier

Quanta Dyne, P.O. Box 252, Menlo Park, Calif., has introduced its Model Q-63 miniature amplifier. This ruggedized, ultrasensitive, low-noise, solid-state preamplifier can be used for original equipments or test bench. Included among its many uses are microwave crystal boosting and video preamplification.

The Q-63 provides nominally 50 db gain over the bandwidth of 30 cps to 100 kc and 40 db gain over the bandwidth of 10 cps to 600 kc, measured with typical input impedance of 7 kohms, output impedance of 4 kohms, source impedance of 1 kohm, and load impedance of 1

MICRO-MESH SIEVES DETERMINE PARTICLE SIZE DISTRIBUTION-Accurately

Set of Buckbee Mears Co. Micro-mesh sieves, standard sizes from 20 to 90 microns. Smaller sizes to order. Background: Enlarged evaporation mask for Mesa transistor.

Buckbee Mears research in subminiature mesh has solved many problems for the industry. A few current items are—

EVAPORATION MASKS—Mesa Transistors

SHADOW MASKS—Color TV

STORAGE MESH—Radar Tubes

CALIBRATED DIALS—Test Equipment

Anything that can be drawn can be reproduced. Send us your problems

SETS FROM 20 TO 90 MICRONS

The accurate measurement of particle size distribution of cracking catalyst has become practical. Buckbee Mears has developed screen sets which have been thoroughly tested as reported on by Ketjen N. V. Amsterdam*, and ASTME*. One comment "micro-mesh sieve method produces data with great accuracy and reproducibility." Another "the sieves made by Buckbee Mears Company appear especially attractive."

According to these papers, previous methods had disadvantages and results by different methods varied considerably. Now BMC sieves are recommended as a primary standard for testing size distribution of dry materials (cracking catalyst).

**Copies of these papers will be sent on request also complete sieve information.*

(Continued from page 56A)

megohm (high input impedance module to work in conjunction with the amplifier is also available).

The noise of the Q-63 is nominally 3 microvolts, measured with a source impedance of 1 kohm and a load impedance of approximately 6 K.

Mechanical specifications list the size at $\frac{3}{4}'' \times \frac{3}{4}'' \times 2''$ less the BNC 1094/U connectors, and the weight at 2 oz.

The external power supply requirements of 9 volts at approximately 3 ma may be met by a Quanta Dyne miniature battery pack, Model Q-630.

Ferrite Isolator

A new ferrite isolator is now being manufactured by **Instrument Systems Corp., Microwave Div.,** 129-07 18th Ave., College Point 56, N. Y.

Model 3005-I is an X Band, medium power waveguide isolator, operating on the Faraday rotation principle, having substantial isolation characteristics coupled with minimum insertion loss.

In normal applications, it is placed between the microwave source and its transmission line to improve the stability and reliability of the generator. The nonreciprocal characteristic prevents impedance variations, due to long line effects and load mismatches, from appearing at the source, thus providing broad band operation in addition to the elimination of frequency pulling.

Constructed of aluminum, the isolator operates into a 3:1 VSWR mismatched load. The device has been qualified under applicable government specifications for Naval and Air Force environments. Cost per unit is $210.

More information on isolators and microwave ferrite components of all kinds may be obtained by writing to Manager, Microwave Division, at the firm.

AC Power Supply

A portable ac power supply that provides an adjustable output voltage from 1 to 140 volts has been developed by **Industrial Timer Corp.,** 1407 McCarter Highway, Newark 4, N. J., for a wide variety

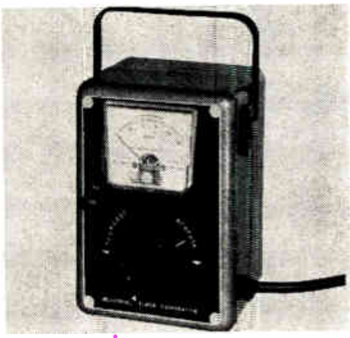
(Continued on page 60A)

NEWS New Products

These manufacturers have invited PROCEEDINGS readers to write for literature and further technical information. Please mention your IRE affiliation.

(*Continued from page 58A*)

of applications in both laboratory and production installations.



Called Model VVS, the unit is basically a package comprising a variable transformer capable of controlling loads up to 5 amperes, voltmeter, input line and output receptacle. Model VVS features a large voltmeter showing the output voltage, which is adjusted with a knob on the front of the unit.

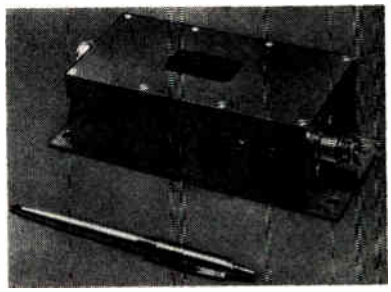
The portable unit is self-contained, with a carrying handle, heavy duty line cord and plug, and a convenient two-prong build-in receptacle for output voltage.

Applications for Model VVS are numerous, including laboratory testing and production control.

List price of the Model VVS is $55.00, subject to Industrial Timer's standard quantity discount schedule.

Solid State Frequency Multiplier

A high efficiency, passive solid state frequency multiplier was exhibited at the IRE show by **Microwave Associates, Inc.**, Burlington, Mass.



The MA-8028 multiplier can be driven with 3 watts CW power at about 36 to 40 mc and will deliver 200 mw at the 32nd harmonic in the L-band range. The bandwidth is 1.25%.

Three stages, featuring a compact lumped-circuit design, are incorporated in this multiplier, two of which are quadruplers and the third stage a doubler. A total of 5 varactors are used. No external bias is required.

29 Fields of Special Interest-

The 29 Professional Groups are listed below, together with a brief definition of each, the name of

Aerospace and Navigational Electronics

Annual fee: $3.

The application of electronics to operation and traffic control of aircraft and to navigation of all craft.

Mr. George M. Kirkpatrick, Chairman, General Electric Co., Syracuse, N.Y.

42 Transactions, *9, Vol. 1, No. 3; Vol. 2, No. 1-3; Vol. 4, No. 1, 2, 3; Vol. 5, No. 2, 3, 4; Vol. 6, No. 1, 2, 4; Vol. 7, No. 1, 2, 3, 4; Vol. 8, No. 1, 2, 3, 4

Antennas and Propagation

Annual fee: $6.

Technical advances in antennas and wave propagation theory and the utilization of techniques or products of this field.

Dr. Harry Fine, Chairman, Applied Propagation Branch FCC, Washington, D.C.

47 Transactions, *Vol. AP-2, No. 2; AP-4, No. 4; AP-5, No. 1-4; AP-6, No. 1, 2, 3, 4; AP-7, No. 1, 2, 3, 4; AP-8, No. 1, 2, 3, 4, 5, 6; AP-9, No. 1, 2, 3, 4, 5, 6.

Audio

Annual fee: $2.

Technology of communication at audio frequencies and of the audio portion of radio frequency systems, including acoustic terminations, recording and reproduction.

Dr. Robert W. Benson, Chairman, Elec. Eng. Dept., Vanderbilt University, Nashville 5, Tenn.

61 Transactions, *Vol. AU-1, No. 6; *Vol. AU-2, No. 4; Vol. AU-3, No. 1, 3, 5; Vol. AU-4, No. 1, 5-6; Vol. AU-5, No. 1, 2, 3, 4, 5, 6; AU-6, No. 1, 2, 3, 4, 5, 6; AU-7, No. 1, 2, 3, 4, 5, 6; AU-8, No. 1, 2, 3, 4, 5, 6; AU-9, No. 1, 2, 3, 4, 5.

Automatic Control

Annual fee: $3.

The theory and application of automatic control techniques including feedback control systems.

Mr. John M. Salzer, Chairman, 909 Berkeley St., Santa Monica, Calif.

16 Transactions, PGAC-3-4-5-6, AC-4, No. 1, 2, 3; AC-5, No. 1, 2, 4; AC-6, No. 1, 2, 3.

Bio-Medical Electronics

Annual fee: $3.

The use of electronic theory and techniques in problems of medicine and biology.

Mr. George N. Webb, Chairman, Dept. of Med. Biophysical Div., Johns Hopkins Hospital, Baltimore 5, Md.

23 Transactions, 8, 9, 11; ME-6, No. 1, 3, 4; ME-7, No. 2, 3, 4; BME-8, No. 2, 3, 4.

Broadcast & Television Receivers

Annual fee: $4.

The design and manufacture of broadcast and television receivers and components and activities related thereto.

Mr. John F. Bell, Chairman, Zenith Radio Corp., 6001 W. Dickens Ave., Chicago 39, Ill.

30 Transactions, *7, 8; BTR-1, No. 1-4, BTR-2, No. 1-2-3; BTR-3, No. 1-2; BTR-4, No. 2, 3-4; BTR-5, No. 1, 2; BTR-6, No. 1, 2, 3; BTR-7, No. 1, 2, 3.

Broadcasting

Annual fee: $2.

Broadcast transmission systems engineering, including the design and utilization of broadcast equipment.

Mr. Raymond F. Guy, Chairman, 264 Franklin St., Haworth, N.J.

21 Transactions, No. 10, 11, 12, 13, 14; BC-6, No. 1, 2, 3; BC-7, No. 1, 2, 3, 4

Circuit Theory

Annual fee: $4.

Design and theory of operation of circuits for use in radio and electronic equipment.

Dr. James H. Mulligan, Jr., Chairman, College of Eng., New York University, New York 53, N.Y.

35 Transactions, CT-4, No. 3-4; CT-5, No. 1, 2, 3; CT-6, No. 1, 2, 3, 4; CT-7, No. 2, 3, 4; CT-8, No. 2, 3

Communications Systems

Annual fee: $2.

Radio and wire telephone, telegraph and facsimile in marine, aeronautical, radio-relay, coaxial cable and fixed station services.

Mr. Ralph L. Marks, Chairman, Rome Air Dev. Center, Griffiss AFB, N.Y.

23 Transactions, CS-5, No. 2, 3; CS-6, No. 1, 2; CS-7, No. 1, 3, 4; CS-8, No. 1, 2, 3, 4; CS-9, No. 1, 2, 3.

Component Parts

Annual fee: $3.

The characteristics, limitation, applications, development, performance and reliability of component parts.

Mr. Floyd E. Wenger, Chairman, Headquarters ARDC, Andrews AFB, Washington 25, D.C.

25 Transactions, CP-4, No 1, 2, 3, 4; CP-5, No. 2, 3, 4; CP-6, No. 1, 2, 3, 4; CP-7, No. 1, 2, 3, 4; CP-8, No. 1, 2, 3

Education

Annual fee: $3.

To foster improved relations between the electronic and affiliated industries and schools, colleges, and universities.

Mr. George E. Moore, Chairman, Westinghouse Electric Corp., East Pittsburgh, Pa.

15 Transactions, Vol. E-1, No. 3, 4; E-2, No. 1, 2, 3, 4; E-3, No. 1, 2, 3, 4; E-4, No. 1, 2, 3.

Electron Devices

Annual fee: $3.

Electron devices, including particularly electron tubes and solid state devices.

Mr. Willis A. Adcock, Chairman, Texas Instruments Co., Dallas 9, Tex.

36 Transactions, *Vol. ED-1, No. 3, 4; ED-3, No. 2, ED-4, No. 2, 3, 4; ED-5, No. 2, 3, 4; ED-6, No. 1, 3; ED-7, No. 2, 3, 4; ED-8, No. 1, 2, 3, 4, 5, 6.

Electronic Computers

Annual fee: $4.

Design and operation of electronic computers.

Dr. A. A. Cohen, Chairman, Remington-Rand Univac, St. Paul 16, Minn.

40 Transactions, EC-6, No. 2, 3; EC-7, No. 1, 2, 3, 4; EC-8, No. 1, 2, 3, 4; EC-9, No. 1, 2, 3, 4; EC-10, No. 1, 2, 3, 4

Engineering Management

Annual fee: $3.

Engineering management and administration as applied to technical, industrial and educational activities in the field of electronics.

Mr. T. W. Jarmie, Chairman, Engineered Electronics, 1441 East Chestnut Ave., Santa Ana, Calif.

23 Transactions, EM-4, No. 1, 3, 4; EM-5, No. 1-4; EM-6, No. 1, 2, 3; EM-7, No. 1, 2, 3; EM-8, No. 1, 2, 3.

Engineering Writing and Speech

Annual fee: $3.

The promotion, study, development, and improvement of the techniques of preparation, organization, processing, editing, and delivery of any form of information in the electronic-engineering and related fields by and to individuals and groups by means of direct or derived methods of communication.

John M. Kinn, Jr., Chairman, IBM Journal, 545 Madison Ave., New York, N.Y.

10 Transactions, Vol. EWS-1, No. 2; EWS-2, No. 1, 2, 3; EWS-3, No. 1, 2; EWS-4, No. 2, 3.

THE INSTITUTE OF RADIO

IRE's 29 Professional Groups

the group chairman, and publications to date.

* Indicates publications still available

Geoscience Electronics

Annual fee: None

Research and development in electronic instrumentation for geophysics and geochemistry, especially gravity measurements, seismic measurements, magnetics, well-logging, space exploration, meteorology, oceanography, etc.

Human Factors in Electronics

Annual fee: $2.

Development and application of human factors and knowledge germane to the design of electronic equipment.

Mr. Robert R. Riesz, Chairman, Bell Tel. Labs, Murray Hill, N.J.

4 Transactions, HFE-1, No. 1, 2; HFE-2, No. 1, 2.

Industrial Electronics

Annual fee: $3.

Electronics pertaining to control, treatment and measurement, specifically, in industrial processes.

Mr. J. E. Eiselein, Chairman, RCA Victor Div., Camden, N. J.

16 Transactions, *PGIE 1, 3, 5, 6, 7, 8, 9, 10, 11; IE-7. No. 1, 2, 3; IE-8, No. 1, 2.

Information Theory

Annual fee: $4.

The theoretical and experimental aspects of information transmission, processing and utilization.

Dr. George L. Turin, Chairman, Dept. of E.E., Univ. of California, Berkeley 4, Calif.

31 Transactions, PGIT-4, IT-1, No. 3; IT-2, No. 3; IT-3, No. 1, 2, 3, 4; IT-4, No. 1, 2, 3, 4; IT-5, No. 1, 2, 3, 4; IT-6, No. 1, 3, 4, 5; IT-7, No. 1, 2, 3, 4.

Instrumentation

Annual fee: $3.

Measurements and instrumentation utilizing electronic techniques.

Mr. Harvey W. Lance, Chairman, Natl. Bureau of Standards, Boulder, Colo.

21 Transactions. PGI-4, Vol. 1-6, No. 2, 3, 4; Vol. 1-7, No. 1, 2; Vol. 1-8, No. 1, 2; Vol. 1-9, No. 1, 2, 3; Vol. 1-10, No. 1, 2.

Microwave Theory and Techniques

Annual fee: $3.

Microwave theory, microwave circuitry and techniques, microwave measurements and the generation and amplification of microwaves.

Mr. Tore N. Anderson, Chairman, EMT Corp., Syosett, Long Island, N.Y.

40 Transactions, MTT-4, No. 3; MTT-5, No. 3, 4; MTT-6, No. 1, 2, 3, 4; MTT-7, No. 2, 3; MTT-8, No. 1, 2, 3, 4, 5, 6; MTT-9, No. 1, 3, 4, 5, 6.

Military Electronics

Annual fee: $2.

The electronics sciences, systems, activities and services germane to the requirements of the military. Aids other Professional Groups in liaison with the military.

Mr. Willie L. Doxey, Chairman, EC Dept., USASRDL, Fort Monmouth, N.J.

14 Transactions, MIL-1, No. 1; MIL-2, No. 1; MIL-3, No. 2, 3, 4; MIL-4, No. 2-3, 4; MIL-5, No. 1, 2, 3, 4.

Nuclear Science

Annual fee: $3.

Application of electronic techniques and devices to the nuclear field.

Mr. Louis Costrell, Chairman, N.B.S., Washington 25, D.C.

22 Transactions, NS-1, No. 1; NS-4, No. 2; NS-5, No. 1, 2, 3; NS-6, No. 1, 2, 3, 4; NS-7, No. 1, 2-3, 4; NS-8. No. 1, 2, 3, 4.

Product Engineering & Production

Annual fee: $2.

New advances and materials applications for the improvement of production techniques, including automation techniques.

Mr. Alfred R. Gray, Chairman, Astrodyne Reliability Inc. Orlando, Fla.

10 Transactions, No. 3, 4, 5, 6; PEP-5, No. 1, 2, 3, 4.

Radio Frequency Interference

Annual fee: $2.

Origin, effect, control and measurement of radio frequency interference.

Mr. Harold E. Dinger, Chairman, Naval Research Lab., Washington 25, D.C.

3 Transactions, RFI-1, No. 1, RFI-2, No. 1, RFI-3 No. 1.

Reliability and Quality Control

Annual fee: $3.

Principles and practices used in reliability and quality engineering of electronic products.

Mr L. J. Paddison, Chairman, Sandia Corp., Sandia Base, Albuquerque, N.M.

22 Transactions, *3, 5, 10, 11, 12, 13, 14, 15, RQC-9, No. 1. 2, 3; RQC-10. No. 1, 2, 3.

Space Electronics and Telemetry

Annual fee: $3.

The control of devices and the measurement and recording of data from a remote point by radio.

Mr. Kenneth V. Uglow, Chairman, Electro-Mechanical Research Inc., Sarasota, Fla.

20 Transactions, TRC-1, No. 2-3; TRC-2, No. 1; TRC-3, No. 2, 3; TRC-4, No. 1; SET-5, No. 1, 2, 3, 4; SET-6, No. 1, 2, 3-4; SET-7, No. 1, 2, 3, 4.

Ultrasonics Engineering

Annual fee: $2.

Ultrasonic measurements and communications, including underwater sound, ultrasonic delay lines, and various chemical and industrial ultrasonic devices.

Dr. Vincent Salmon, Chairman, Stanford Research Inst., Menlo Park, Calif.

10 Transactions, PGUE, 5, 6, 7; UE-7, No. 1, 2; UE-8, No. 1.

Vehicular Communications

Annual fee: $3.

Communications problems in the field of land and mobile radio services, such as public safety, public utilities, railroads, commercial and transportation, etc.

Mr. Richard P. Gifford, Chairman, General Electric Co., Lynchburg, Va.

18 Transactions, 5, 8, 9, 10, 11, 12, 13; Vol. VC-9, No. 1, 2, 3; Vol. 10, No. 1, 2.

(Continued from page 60A)

The body, of aluminum construction, is $5\frac{3}{8}''$ long, $2\frac{3}{4}''$ wide and 2" deep excluding mounting pads and connectors. Total weight is less than two lbs. The nominal input impedance is 50 ohms with type "N" input and output connectors.

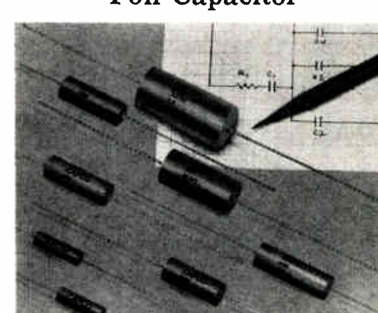
The multipliers are particularly useful in telemetering or beacon transmitters, antenna alignment, signal generation, radar or fixed-frequency communications driver stages, or in local oscillator service. A major advantage is that precise frequency control can be achieved in microwave channels using crystal-controlled drivers at frequencies under 100 mc.

These units are now in production and are available within six weeks after receipt of order. Prototypes are priced at about $1600 with substantial price reduction on quantity orders.

Bouldin New V. P. For Westronics, Inc.

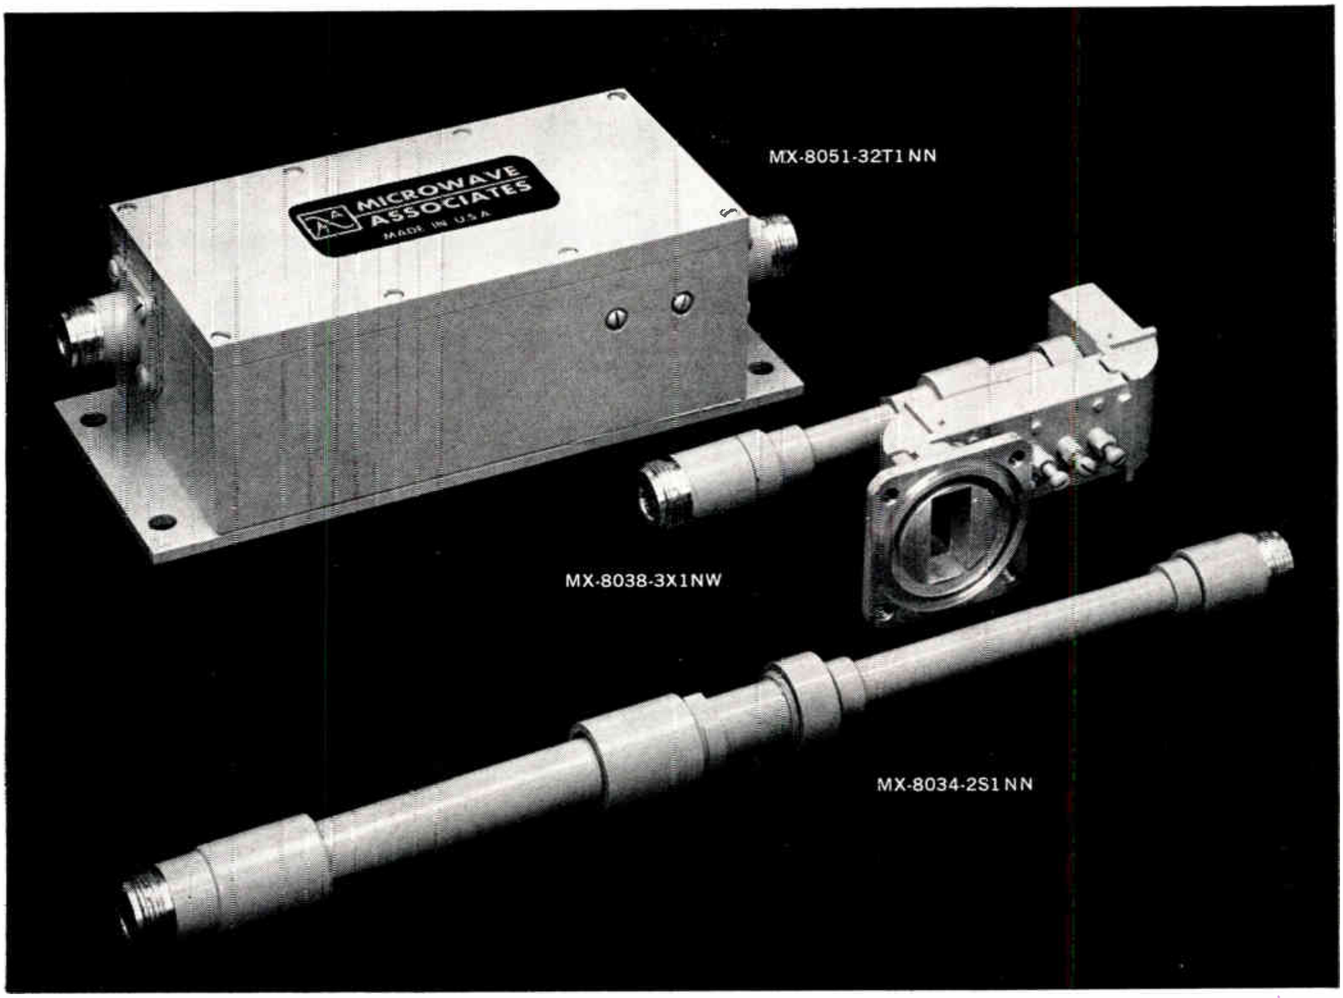
Wood W. Bouldin has been elected vice president in charge of sales at **Westronics, Inc.**, 3605 McCart, Ft. Worth, Texas. He joined the firm as a sales engineer in March 1959, having previously served three years in the USAF as a B-36 pilot and two years at Chance Vought as a flight test engineer. He is a graduate of John Reagan High School, Houston, and Texas A&M where he earned his B.S. degree in 1954 in Industrial Technology. Westronics, Inc. specializes in its own proprietory line of industrial electronic recording and indicating instruments for both domestic and foreign markets.

Mylar and Foil Capacitor



A Mylar and foil capacitor, Type MW, has been announced by the **Capco Div., Texas Research and Electronic Corp.**, 6612 Denton Dr., Dallas 35, Texas. These capacitors are specifically designed for low drift requirements. Fully stabilized, they

(Continued on page 66A)



Harmonic Generators for Microwave Power

AVAILABLE models of varactor harmonic generators can now provide outputs over most of the microwave spectrum. Microwave Associates' several years of experience in designing and building a wide range of varactor harmonic generators make possible a standard line of which several typical units are described here.

These solid-state sources of microwave power provide precise frequency multiplication, lightweight, small size, and have low power requirements.

We would like to discuss with you how these units can serve your requirements for highly reliable, fixed-frequency RF power sources. If you have special environmental or space requirements, modifications of units in our standard line will most probably save you considerable time.

Model	Application	Input Frequency (Mc)	Output Frequency (Mc)	Input Power (Nominal) Watts	Output Power (Nominal) Watts
MX-8052-16T1 NN	VHF — L	60	960	10	2
MX-8052-24T1 NN	VHF — L	40-43	960-1025	12	1
MX-8051-32T1 NN	VHF — L	40	1280	4	0.2
MX-8034-2S1 NN	L — S	1125	2250	2	1
MX-8057-128X1MW	VHF — X	64	8192	10	0.175
MX-8045-2X1WW	C — X	4500	9000	1.2	0.5
MX-8038-3X1NW	S — X	2800-3100	8400-9300	0.25	0.010

The above units are representative of our current line of over 60 standard harmonic generators. Write for our new four page short form Harmonic Generator Catalog.

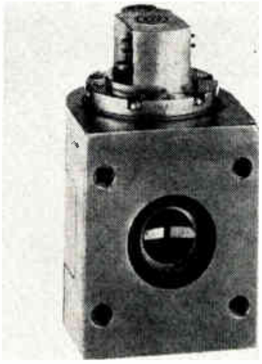
are available from stock in 1% capacity tolerance. The high moisture resistance of the epoxy-impregnated wrap eliminates the need for encapsulation. These capacitors have a positive temperature coefficient with dissipation factors of less than 0.45% for values under 1.0 mfd and less than 0.75% for higher values at 25°C. Available in standard ratings from 0.0005 to 2.00 mfd at 200, 400 and 600 volts dc, they are priced from $.30 to $1.20 in 100 lots.

Tunable Magnetron



Metcom, Inc., 76 Lafayette St., Salem, Massachusetts, offers for the first time a waveguide output 2 KW X Band tunable magnetron. The MXM-28 has been designed to withstand missile type environmental conditions in addition to working under pure vacuum atmosphere. In addition, the MXM-28 has been designed to undergo sterilization under customer's specification for space environs.

The MXM-28 offers 2 KW peak power at 3 KV and 3 amperes input under extreme shock, vibration, and temperature environs.

The MXM-28 is available 60–90 days.

Magnetic Shields For Dewar Flasks

Magnetic Shield Div., Perfection Mica Co., 1322 No. Elston Ave., Chicago 22, Ill., offers a new line of diversionary Netic and Co-Netic magnetic shields which minimize effects of the earth's magnetic field as well as all other low level fields on samples being tested under cryogenic conditions in any size dewar flask. Two, three or four concentric cylindrical shields can be used, one inside

the other. The shield illustrated is 36″ high and 15″ OD. It consists of three inner shields of high permeability Co-Netic alloy and one outer shield of heavy gauge

(Continued on page 68A)

NEWS New Products

These manufacturers have invited PROCEEDINGS readers to write for literature and further technical information. Please mention your IRE affiliation.

(Continued from page 66A)

Netic alloy. Shield sections are symmetrically separated by rectangular aluminum spacers positioned around the shield's periphery parallel to its axis. This multi-sectional air gapped construction was selected because attenuations of 1,000 times or better were required. Conduction of external magnetic fields to the inner low level area is minimized by progressively shortening the inner Co-Netic shields and extending the outer Netic shield beyond the inner shields at the open end.

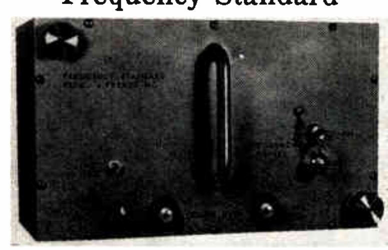
A multi-section viewing port is provided. This consists of four sliding panels, one in each shield section, which can be manually opened or closed sequentially by inserting a hand hook in the panel holes. (See illustration.) The entire shield can be parted at the middle of its length on a butt joint junction seam with overlapping flange.

In addition to dewar flask application, the shield's basic design permits general laboratory usage for a wide variety of other magnetic shielding applications. Although designed specifically for dc magnetic fields, the shield will prove even more effective in medium or low level ac fields. Electrostatic shielding is also provided by simply grounding the outer shield.

Low retentivity and low shock sensitivity are inherently displayed by the Netic and Co-Netic alloys used. All shields have been annealed and require no further heat treating.

Delivery is four to six weeks. Prices are subject to design complexities and size, and range from $150.00 to $1500.00.

Crystal-Controlled Frequency Standard



The model S1455, a 4.999600-mc crystal-controlled frequency standard, was designed by **Reeves-Hoffman Div., Dynamics Corp. of America,** Cherry and North Sts., Carlisle, Pa., as an aid to precise navigation and for use as a master oscillator of "TRANSIT" operational test equipment. Operating ambient-temperature range is from 0 to 60°C. Frequency is 5 mc or frequencies nearby; aging, 1 part 10^8 per week; short-term stability 5 parts 10^{11} per second. Output is 55 millivolts, sine wave; power required, 2.7 watts at 12 volts dc regulated to 1% or better, or 33 watts at 28 volts dc regulated to 5%. Output impedance is 50 ohms.

The oscillator measures 5 by 5 by 8½ in., including hardware, and weighs 8 lb. Mounting is by two captive ¼-inch screws.

In the *complete* BUSS line...

you can quickly find the right fuse and fuseholder to meet every demand!

Dual-element "slow-blowing", single-element "quick-acting" and signal or visual indicating type fuses . . . plus a companion line of fuse clips, blocks and holders . . . are available from one source — BUSS. You'll save time and trouble by turning first to BUSS when you need fuses and fuseholders.

To safeguard against 'kicks' or complaints, every BUSS fuse is tested in a sensitive electronic device. Any fuse not correctly calibrated, properly constructed and right in all physical dimensions is automatically rejected to assure dependable protection under all service conditions.

Save engineering time on special problems in electrical protection. At your request, the BUSS fuse engineers are at your service to help you determine the fuse or fuse mounting best suited to your needs.

In many cases it is possible to find, in the complete BUSS line, a fuse and fuse mounting already available in local wholesalers' stocks, so that your device can be easily serviced.

For more information on BUSS and FUSETRON small dimension fuses and fuseholders . . . Write for bulletin SFB.

Industrial Engineering Notes*

Association Activities

The Military Relations Department has been asked to gauge the interest of EIA member companies in participating in a program of exchanging abstracts of electronic data processing programs aimed at solving EDP problems. Abstracts would be limited to computer techniques, excluding electronic accounting machine procedures. Each abstract would consist of a one-page written explanation of the purpose, scope, and frequency of the system being abstracted, together with a brief description of the system. This would be accompanied by a skeleton schematic diagram of the system. The purpose of the program is to exchange useful information and assist management in effectively applying EDP techniques. Any participant could contact other participants directly if additional information were desired, but there would be complete discretion in each company as to how much it revealed. The abstracts would not be made available to EDP manufacturers for propaganda purposes. To insure mutual benefit, all participants would be required to submit at least two abstracts before receiving any from other companies. Firms interested in participating may contact Manager, Military Relations Department, EIA Headquarters. . . . **The Federal Communications Commission should freeze assignments of television channel 14 until engineering standards can be established to forestall interference to land mobile radio frequencies, EIA told the FCC last week.** EIA pointed out that UHF channel 14 (470-476 Mc) lies immediately adjacent to the land mobile allocation (450-470 Mc). "If the Commission were to permit unrestricted allocation of channel 14 in these areas, serious harm could be caused to land mobile users by the TV side bands," the Association declared. "Furthermore, it is conceivable that interference could be caused by mobile users to TV reception. This interference would be existent even with the use of vestigial side band filters, which (the Commission) proposes to eliminate." The comments on channel 14 were among a number by EIA in a filing in FCC Docket 14229, "Fostering Expanded Use of the UHF Television Channels." Comments on individual proposals in the docket reflected the views of several industry groups, represented in the Association by the TV Broadcast Equipment Section and the Land Mobile Communications Section, both of the Industrial Electronics Division; and the Consumer Products Division. EIA declared it supported the move by the Commission to expand use of UHF television channels. Specifically, it made the following points: 1) UHF TV transmitting equipment can be designed and built for remote control operation, and requirements proposed by the FCC appear adequate for remote control and monitoring. 2) Elimination of restrictions on antenna directivity for UHF stations, as proposed by the FCC, will permit greater flexibility in station location and the possibility of meeting market coverage requirements with lower transmitter power. 3) On the FCC's recommendation to eliminate the vestigial side band attenuation for all UHF receivers, EIA restated an earlier comment that attenuation should be a function of transmitter power and recommended a formula for attenuation to replace one proposed by the Commission. The Association also said the recommended elimination of the vestigial side band filter might result in degraded performance in some existing receivers having significant response in the lower side band region. 4) The proposed reduction of the ratio of visual-to-aural power should not be made, EIA declared, because reduction in sound power results in deterioration of receiver performance and a reduction in service coverage.

Governmental and Legislative

The President last week established the long-expected Director of Telecommunications Management to administer Government radio frequencies. The new post was placed in the Office of Emergency Planning (OEP), which took over the telecommunications functions of the Office of Civil and Defense Mobilization when that agency's responsibilities were split between the Defense Department and OEP last year. Concurrent with his Executive Order establishing the position, President Kennedy disclosed the impending appointment of Dr. Irvin Stewart as Director of Telecommunications Management. The 63-year-old Texan is a former member of the Federal Communications Commission and a past President of West Virginia University. Dr. Stewart will coordinate telecommunications activities of the Executive Branch of the Government and will be responsible for formulating its telecommunications policies and standards. He will also have authority to assign radio frequencies to Government agencies. The White House emphasized the move will not affect the authority of the FCC to regulate non-Federal use of radio or other communications. From 1934 to

ANSWERS...with CRAM and Remote Inquiry

provided by the NCR 315 Computer System

The NCR 315 CRAM (Card Random Access Memory) Computer System is more than just another back-office electronic accounting machine . . . it is a vital electronic tool which contributes to a higher-quality of management and personnel effectiveness.

For example: in a bank, Inquiry Units placed in the various departments enable authorized personnel to interrogate the computer files at will . . . to promptly answer requests for balances . . . to quickly obtain valuable credit information . . . to obtain current, up-to-the-minute reports on investments, trusts, loans, and other essential data.

In industry, Inquiry Units can be located at dozens of remote locations, enabling people to communicate with the computer files . . . even from hundreds of miles away. With the NCR 315 you will be able to keep a "current-finger" on the pulse of your business . . . to get immediate answers to questions about inventories, production, sales . . . and a host of other timely facts people must have to effectively manage . . . and to act while the "iron is hot."

The NCR 315 CRAM System provides many exclusive advantages for Remote Inquiry, Data Processing, On-Line Accounting, Operations Research, Engineering and Scientific Applications. For more information, call your nearby NCR representative or write to Data Processing Systems and Sales, Dayton 9, Ohio.

Industrial Engineering Notes

(Continued from page 70A)

1937, Dr. Stewart was a member of the Federal Communications Commission and Chairman of the FCC Telegraph Division. He was Director of the Commission on Scientific Research from 1937 to 1946 and in the latter year was elected President of West Virginia University, a position he held until 1958. Dr. Stewart joined the State Department in 1930 as head of electrical communications for the Treaty Division. In this post, he was a member of various American delegations to international radio conferences in Washington, Copenhagen, Madrid, and Mexico City.

Industry Marketing Data

Electronics output and employment will reach another all-time high in 1962, the Business and Defense Services Administration of the Department of Commerce reported last week. Because of increasing defense procurement, accelerating space exploration programs, and greater industrial demand, total output of systems and equipment is expected to exceed $7.2 billion in 1962, about 7 per cent more than in 1961, BDSA said. Total output of components should exceed $3.7 billion. The projections do not include the value of electronic research, development, evaluation, and test expenditures or distribution, service, installation, and operating revenues, the agency pointed out. Manufacturers' shipments of consumer products are expected to increase modestly in value, mainly because of new product promotion of color television receivers, stereophonic sound equipment, electronic toys and kits, and other products. Output of commercial and industrial electronic equipment will be stimulated by increased capital goods expenditures, including plant modernization programs and rapidly expanding space activities. Substantial increases in defense expenditures for advanced weapons systems of high electronic content may be partially offset by cutbacks and cancellations of new programs. Because most electronic components are used in the manufacture of new equipment, output of components will increase proportionately. Both domestic and foreign competition will be more intense; thus profit levels may not keep pace with rising output, BDSA said. Electronic research, development, test, and evaluation activities—a major part of total electronic effort—will continue to increase rapidly and may exceed $2.8 billion in 1962, according to BDSA. The major impact of advanced weapons and space programs will be felt in the research and development area. Electronics output in 1961 generally followed expectations, it was reported. Factory value of electronics production reached an all-time high of $6.7 billion—about 5 per cent above the 1960 level of $6.4 billion. Output of consumer electronic products declined in

(Continued on page 74A)

Industrial Engineering Notes

(Continued from page 72A)

the early months of 1961 but increased rapidly in the latter part of the year. The volume of production of most consumer electronic products in 1961 exceeded that in 1960, but the total value of shipments declined almost 4 per cent. This was attributed to a general shift in consumer buying to less expensive models and a decline in phonograph sales. Production and sales of consumer electronic products are now at high levels, and output is expected by BDSA to increase about 7 per cent in 1962 . . . **Japan's exports of electronic products to the United States during the first nine months of 1961 totaled $78.4 million, an increase of 24 per cent over the same period in 1960, according to Japanese statistics, the Electronics Division of the Commerce Department's Business and Defense Services Administration disclosed last week.** Radio receivers and chassis together with sound recorders and reproducers accounted for 76 per cent of the total value, compared with 81 per cent of the total during January-September 1960, it was reported. BDSA said products registering substantial gains were sound recorders and reproducers, up $6 million; tube-type radios, up $5.7 million; and radios with less than three transistors, up $3.6 million. Exports to the United States of radios with three or more transistors declined $7.3 million, while shipments of this type radio to the rest of the world increased. During January-September 1961, Japanese exports of television receivers to the United States totaled nearly a million dollars. Exports of transistors doubled in dollar volume—from $0.8 million to $1.6 million—while tripling in quantity over exports for January-September 1960 . . . **Factory sales of transistors totaling more than 18 million a month during the last quarter of 1961 boosted the year's total to 190,916,354, a whopping 62,987,768 more than the 127,928,586 sold the previous year, according to the EIA Marketing Data Department's year-end compilation.** But while sales volume was up by an impressive margin, sales value dipped from $301,432,285 in 1960 to $299,538,760 last year, a drop of $1,893,525. December transistor sales at the factory remained relatively stable compared to the previous month. In December, 18,166,839 units worth $24,883,538 were sold, against 18,342,285 valued at $24,034,703 sold the month before.

Engineering

Two new recommended technical standards have been completed by EIA engineering committees and published by the Engineering Department. They are: 1) RS-255—*Simulated Life Test Circuit for Semiconductor Rectifier Diodes* (25 cents). Defines a simulated life

BRAINCHILD (it figures!) **ONLY $125** (it doesn't figure!)

This smart little machine weighs only six pounds, yet does just about everything the big, expensive machines do...and a couple of things they can't.

The big machines add, subtract, multiply, divide.

So does the Bohn Contex.

Here's what the expensive calculators *can't* do.

They can't double as high-speed 10-key adding-subtracting machines.

The Bohn Contex can.

They can't be operated by anyone after just a few minutes instruction.

The Bohn Contex can.

Most important of all, the Bohn Contex is the first compact, 10-key machine that's truly portable. Goes to work anywhere.

Businessmen, salesmen, engineers, architects, students, housewives find the Bohn Contex the easiest, fastest way to figure bills, invoices, percentages, extensions, estimates, income tax..........................All this for **$125***

For hour-after-hour use, the Bohn Contex *Electric*. Same size, same features, but greater speed and ease because the motor does the work.....................Only **$235***

To a businessman who pays $500 to $1,000 for an office calculator, the price of our Brainchild seems too good to be true. Our suggestion: *borrow a Bohn Contex and see how it figures to save you money*. Any dealer listed below will lend you a hand (or electric) model. If the dealer in your city is not listed, or you're not in a borrowing mood, just mail the coupon.

*PLUS F. E. T. CARRYING CASE $14.95

Bohn Business Machines Inc., Dept. BY-10
444 Park Avenue South, New York 16, N. Y.
Send detailed "specs" on your Brainchild ☐ *manual* ☐ *electric.* ☐ *Send name of nearest dealer.*

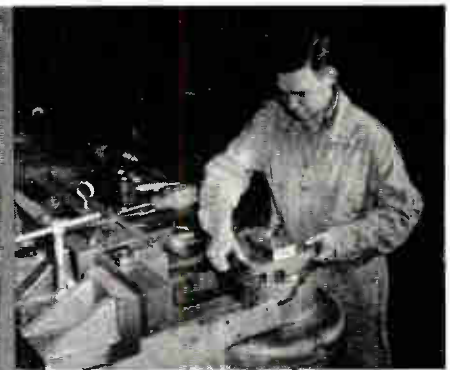
here's how a four-bend waveguide is processed at specialty automatic

Waveguide, taken from stock . . . is first cut to proper length . . . and then annealed for bending.

Special laminated shims must now be inserted into the waveguide to prevent its collapse during the bending process.



The proper die is then placed in position in the automatic bending machine preparatory to making the first bend.

Here the waveguide is shown still in the bending machine just after the first of the four bends has been made.

The shims are now removed in preparation for the next step in the bending process.

After each bend the waveguide is sized and the angle is checked to assure that all tolerances are correctly maintained.

Prior to each of its subsequent bends the waveguide must be properly positioned to give accurate register of the next bend (illustration left). The second, third and fourth bends are shown here as each has been processed on the automatic bending machine.

After the final bend has been made, sized and checked, rigid inspection takes place, assuring accuracy of the completed waveguide.

Whatever your needs — bends, twists, offsets, coils, transitions, fabrications, complete assemblies — SPECIALTY AUTOMATIC is ready to precision manfacture to your prints.

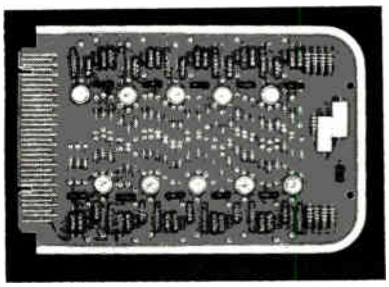
Octal/Decimal Decoder

Computer Control Co., 983 Concord St., Framingham, Mass., announces the recent addition of the Model OD-30 Octal /Decimal Decoder to its compatible series of dc to 1 and 5 megacycle S-PAC digital modules.



The OD-30 contains a prewired binary-to-octal decoder plus additional circuitry to expand the matrix for BCD-to-decimal decoding. Three additional inputs are provided to permit the matrix to be expanded

(Continued on page 82A)

NEWS New Products

These manufacturers have invited PROCEEDINGS readers to write for literature and further technical information. Please mention your IRE affiliation.

(Continued from page 81A)

to 16, 32, or 64 outputs by connecting additional decoders. One or more of these additional input lines may be used for strobing or sampling the matrix.

The BCD-to-decimal decoder uses the octal matrix for the "zero" through "seven" output lines, and two additional independent gates, included on the PAC, for output lines "eight" and "nine." The two independent gates are standard NAND gates and may be used as such if BCD-to-decimal decoding is not required. One of these gates has six inputs, the other has two. Both gates have modes for expanding the fan-in to a maximum of ten. Each output will drive the specified number of standard S-PAC loads plus stray capacitance.

Packaging features include a $4\frac{1}{2}'' \times 7''$ glass-impregnated epoxy card, etched wiring, an anodized aluminum frame, and a 34-terminal hermaphroditic type connector designed for insertion into a standard, prewired 19- or 28-connector S-BLOC housing.

APD Data Acquisition System

Sampling rate of 200 channels per second is now available in a new high speed version of an analog to pulse duration (APD) data acquisition system for process control applications developed by Genisco, Inc., 2233 Federal Ave., Los Angeles 64, Calif.

The new unit adds the advantages of high speed sampling to the accuracy and stability of the original APD. The system directly converts a low level electrical input signal to a pulse linearly related in duration to the input signal amplitude. It is applicable with DC-voltage, low impedance sensing instrument sources such as thermocouples, resistance thermometers, strain gage transducers.

The pulse duration output is digitally measured for display, recording, or for further processing for input to digital computing equipment. The system retains the permanent "sample and hold" feature of the original APD and can be designed to operate either in sequential or parallel data sampling modes. (Output values can be in engineering units.) Modular design permits systems of several hundred channels to be built.

Operational characteristics include 5-

GIVE YOUR YOUNG ENGINEERS A HEAD START

Send today for this professional development kit prepared by successful engineers

The first five years after graduation are the most important years of an engineer's career. That's why this carefully planned program of professional development can help your engineers—just as it is now helping so many others.

This kit, sponsored by eight of the foremost engineering societies provides a framework for planning, focuses attention on six vital areas:

1. Starting your career
2. Education after college
3. Professional identification
4. Responsible citizenship
5. Selected reading
6. Personal appraisal

The complete kit contains a 48-page reference manual, a statement of the responsibilities and ethical principles of the engineering profession, a selected reading list, a personal appraisal booklet, and a brochure outlining the complete six point program.

Start now to help your engineers plan their careers with professional help . . . send in the coupon today.

COMPLETE KIT $2.00—*quantity discounts on request*

ENGINEERS COUNCIL FOR PROFESSIONAL DEVELOPMENT
345 East 47th Street, New York 17, N.Y.

Gentlemen: Please send me ______ *First Five Years* Kit (s) for which $_____ is enclosed.

millisecond sampling time for each channel, resolution of 0.1% (1 part in 1000), repeatability of ±0.1% ± one output count per 1000; linearity of ±0.1% of full scale input, sensitivity of 5 millivolts minimum full scale input. Source impedance is a nominal 100 ohms for thermocouples. Converter output is 10-volt pulse with less than 2 microsecond rise and fall times, output impedance of 1800 ohms. Power requirements: Approximately 1 watt /channel, 110 volts, 60 cps. Special sampling rates from 5 to 500 samples/second are available on order. For additional information, contact the firm.

Dual Preset Counter-Controller

A new all transistorized 100 kc dual preset counter-controller has been announced by **Computer Measurements Co.**, 12970 Bradley Ave., San Fernando, Calif.

The 780 Series counters are designed to solve control problems, such as motor overspeed, shearing to length, high speed coil winding, weighing, sorting, batching, func-

(Continued on page 85A)

tion programming and timing, and variable pulse generation. CMC offers this instrument with a two-year free service warranty.

The counter-controller is a direct-reading solid state electronic counter providing output information in the form of pulses and relay closures at any two preselected counts within the capacity of the unit. Capable of operating at rates up to 100,000 counts per second, the instrument accepts input information from any standard transducer such as a photocell, tachometer, flow and pressure pickups, switch closures, and so forth. Selection of the preset numbers is accomplished by thumb wheels adjacent to each decade. Input sensitivity is 0.1 volt.

The series is available in two-through six-decade models. Power consumption is 40 watts. The unit measures $5\frac{1}{4}''$ H $\times 17''$ W $\times 12''$ D and weighs 21 pounds. It is available in either rack or cabinet mounting. Prices range from \$975.00 to \$1350.00. Delivery 60 days.

For complete technical information, please address Bob Steele, sales manager at the firm.

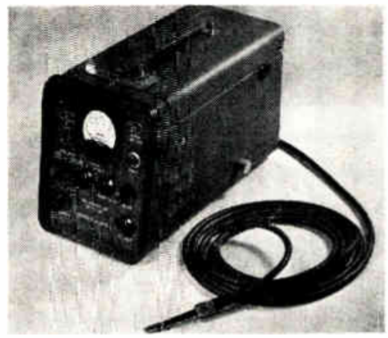
Halogen-Sensitive Leak Detector

General Electric of Schenectady, N. Y. has introduced a new halogen-sensitive, electronic leak detector specifically designed for use in halogen-contaminated atmospheres. Designated the H-5P and featuring a new proportioning probe, this detector is sensitive enough to detect halogen leaks as small as 1/100 ounces Refrigerant-12 per year even when contamination levels reach 1000 parts R-12 per million parts air.



The H-5P leak detector can be used to test pressurized enclosures by manually probing seams, joints and welds. When a leak is detected, an audible alarm sounds.

In operation, the H-5P draws air from the atmosphere and from a pure air filter in the control unit. The proportioning probe rations the amount of air coming from both sources. By adjusting the probe's proportioning valve, the operator can reduce the amount of contaminated air entering the detector and increase the amount of pure air coming from the filter. As a result, the effects of contamination are neutralized and the H-5P operates at full sensitivity.

Because of the new proportioning probe, the detector's sensitive element is protected against exposure to large amounts of contamination. General Electric engineers say that this will result in minimum maintenance of the unit and longer sensitive element life.

High Power TWT Supply

A TWT supply designed specifically for high power TWT's is available as a standard unit. Developed by **The Narda Microwave Corp.**, Plainview, L. I., N. Y. and designated Model 15101, the unit is available in eight weeks.

The beam supply is continuously variable from −2 to −12 kv by means of both coarse and fine controls on the front panel. The DC bias supply is also continuously variable from 0 to 250 V negative with respect to the cathode, and it floats at the beam voltage. The DC filament supply can be varied between 0 and 10 V and is connected to float at the cathode voltage. The grid pulser, which provides for complete control of the pulse width, amplitude, and repetition rate, is referenced to the bias supply and, therefore, also floats at approximately the beam voltage. In all cases, each of these voltages is completely controllable from ground level at the front panel.

Meters are provided to monitor both voltage and current of the filament and bias supplies, and the high voltage power supply. The filament and bias meters are located behind a shielded viewing panel. An output is also provided for viewing the performance of the grid pulser.

Other features included are a vac-ion power supply, and a provision for external synchronization at any repetition rate compatible with the 0.005 maximum duty cycle and pulse width range.

The price is $9,925. For additional information and more complete specifications, write directly to Narda.

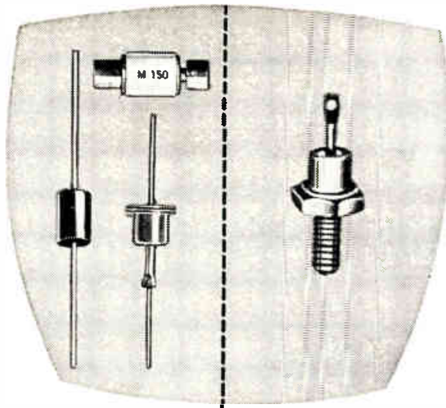
Magnetic Tape Adapter

A magnetic tape adapter unit which provides IBM 1401 computer users with read/write capability from GE/ERMA

(Continued on page 88A)

Low Current Silicon Rectifiers

22 types, with ratings from 0.15 amps to 1.50 amps; 100 to 2800 piv.

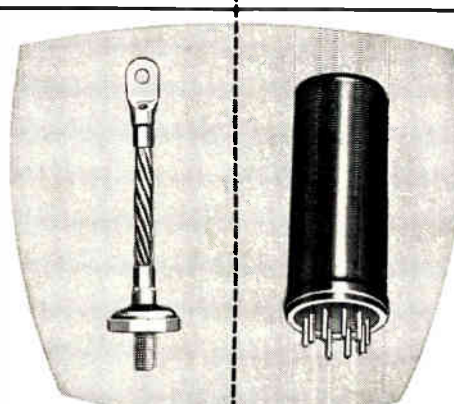


Medium Current Silicon Rectifiers

36 types, with ratings from 2 amps to 35 amps; 100 to 600 piv; many with choice of positive or negative base polarity.

High Current Silicon Rectifiers

36 types, with ratings from 50 amps to 1000 amps; 100 to 600 piv; most with choice of base polarity.

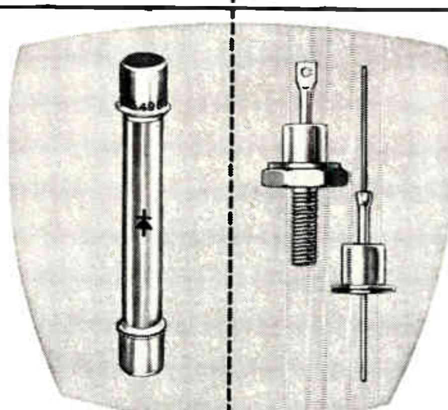


Tube Replacement Silicon Rectifiers

Long life, cool-operating, compact units replacing 95% of all popular vacuum tube rectifiers. PIV ratings from 1600 to 10,400; dc output current ratings, 250 to 750 ma.

High Voltage Cartridge Silicon Rectifiers

Ferrule mounted and axial lead series, each in 18 different types; 600 to 16,000 piv.



Silicon Voltage Regulators

Regular series: 93 types in ¼, 1, and 10 watt classifications; 5.6 to 100 volts breakdown. Special series: 17 types, 1 watt, 6 to 105 volts breakdown; excellent performance at low cost.

7 invitations

or GE 210 to IBM format and vice versa, is now available from **Electronic Engineering Co. of California,** Box 58, Santa Ana, Calif.

The 754 magnetic tape adapter operates as a program control input/output unit of IBM 1401 and ties to it in place of one IBM 729 Tape Unit. Data may be edited or updated during the conversions as programmed by the IBM 1401. The complete ERMA and IBM error detection circuitry are provided in the system. All data translated to and from the EECO 754 is in IBM coding and format. All normal capabilities of the IBM 1401 are available to process data.

The 754 is housed in two equipment cabinets 69" high, with a total width of 48", a depth of 24", and weighs 800 lbs. All active components in the system are solid state construction.

Price is $85,000 and delivery is 120 days after receipt of order.

For additional information write Data Processing Section, Sales Department, of the firm.

Ionization Gage

A new, low-cost, cold cathode ionization gage (referred to as a Philips or Pennings gage), designed for industrial applications and capable of vacuum measurements from 10^{-2} to 10^{-7} mm Hg, has been announced by **The Fredericks Co.,** Bethayres, Pa. Designated the Televac Model 7A Cold Cathode Ionization Gage, this instrument is of particular value in such applications as vacuum metallurgy, electron beam welders, vacuum welding, vac-

(Continued from page 88A)

uum brazing, vacuum evaporating, vacuum sintering, vacuum annealing, vacuum heat treating, particle accelerators, vacuum jacketing for liquid oxygen and hydrogen, and missile launch instrumentation.

Sensing tubes are metal, and include a removable anode assembly for ease of cleaning and inspection of inside of sensing tube. Tubulation is of one-inch ID to permit rapid response to pressure changes. The Televac Model 7A permits operation in either single, dual or three range scales from 10^{-2} to 10^{-7} mm Hg.

By adding a thermocouple vacuum gage as an integral part of the Model 7A, complete and independent coverage of the range from 1 to 10^{-3} mm Hg can be provided.

The Model 7A has no measurable drift or meter oscillation and can be coupled with an automatic controller for indication, remote alarm or external control. Terminals can also be provided for driving a 10 millivolt, full scale, potentiometer-type recorder.

Several explosion-proof versions for use in liquid oxygen and hydrogen vacuum dewar-type tanks are available.

The instrument is produced in cabinet panel, chassis and rack mounted configurations. Dimensions of the cabinet mounted unit are: Height, 7⅜″; width, 14¼″; and depth, 10″. The rack mounted unit measures 7″ high (other heights available upon request), 19″ wide and 11¾″ deep. For details write to the firm.

Motor Generator

Thirty-five per cent more space and a reduction of 23 per cent in weight, is made available through the use of the motor generator designed and developed by **The Bendix Corp., Eclipse-Pioneer Div.,** Teterboro, N. J. Designated as the FV-6000-1-A1, the new unit is 1.375 inches long in a size 10 frame, as compared to the conventional length of 2.1 inches. The unit is comparable in operating characteristics to the Eclipse-Pioneer FV-100 series motor generators, and is being made available in the same variety of shaft configurations.

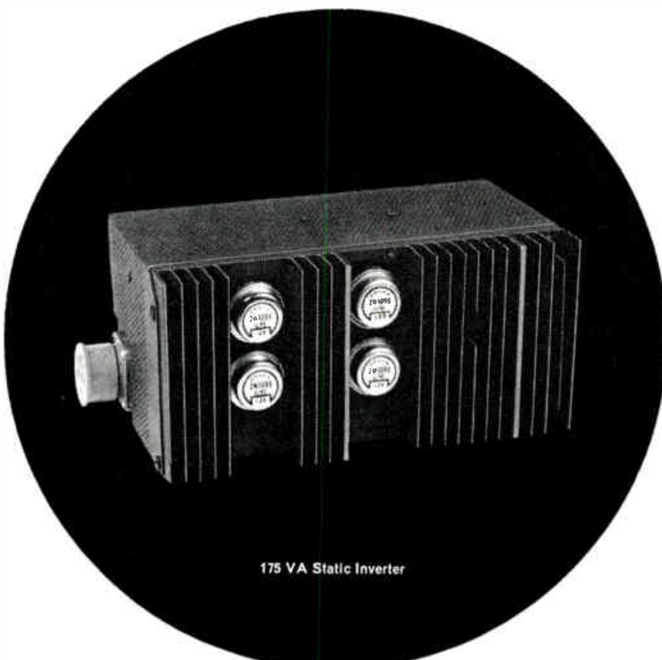
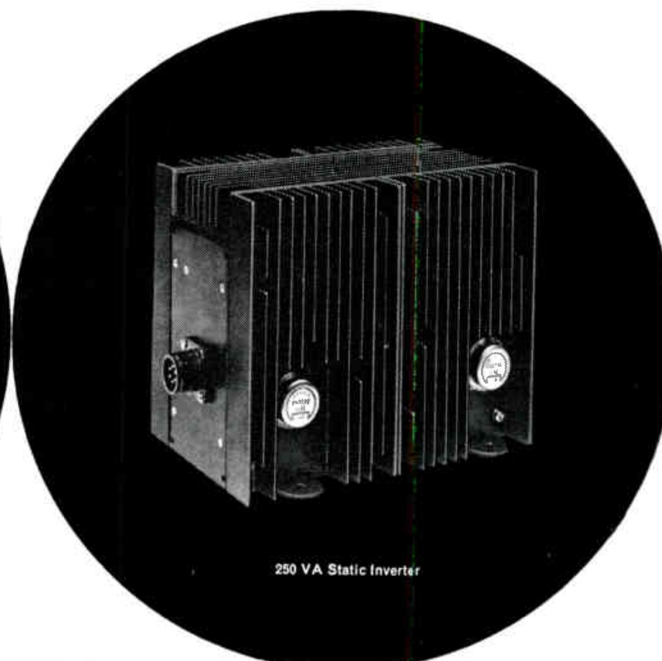
PRECISION WITH SIMPLICITY
FROM DELCO RADIO

That's the big feature in Delco Radio's new 175 VA and 250 VA static inverter power supplies. These *all-transistor* units offer increased reliability through simplified circuits. Both static inverters are designed for either airborne or ground applications and will withstand overload and output short circuit conditions indefinitely, delivering at least 110% of rated output before going into overload protection. Units automatically recover to full output upon removal of overload and short circuit. Units are designed to meet the environmental requirements of MIL-E-5272C. For further information on military electronics write Delco Radio's Military Sales Department.



175 VA Static Inverter



250 VA Static Inverter

ELECTRICAL SPECIFICATIONS

175 VA STATIC INVERTER

Input

Voltage: 27.5 VDC ± 10% per MIL-STD-704

Output

Power:	175 VA single phase 0.5 lag to 1.0 power factor
Voltage:	115 V adjustable from 110 to 120 volts
Regulation:	1-volt change for any variation of load between zero and 110% of full load, and input voltage between 25 VDC and 30 VDC
Frequency:	400 ± 1 cps. Frequency changes less than 1.0 cps. for all environment, load and input voltage variation
Distortion:	Less than 5% total harmonic
Efficiency:	80% at full load

250 VA STATIC INVERTER

Input

Voltage: 27.5 VDC ± 10% per MIL-STD-704

Output

Power:	250 VA single phase 0.6 lag to 1.0 power factor
Voltage:	115 V adjustable from 110 to 120 volts
Regulation:	0.7 volt for any variation of load between zero and 110% of full load, and input voltage between 25 VDC and 30 VDC
Frequency:	400 ± .5 cps. Frequency changes less than 1.0 cps. for all environment, load and input voltage variation
Distortion:	Less than 5% total harmonic

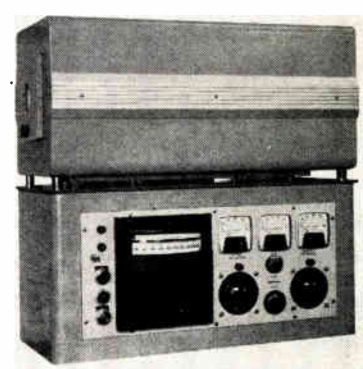
(Continued from page 90A)

In existing installations, the FV-6000-1-A1 can replace conventional units with comparable operating characteristics, resulting in additional space for expansion. In designing new installations, the unit will provide for an overall reduction of the space envelope.

The unit consists of a two-phase, four-pole, 400-cps induction motor and a single-phase generator, the rotors of both elements being mounted on a common shaft in a single housing. One motor phase is center-tapped, while the other has a split winding for either parallel or series operation. The generator produces a single-phase output, proportional to speed, of 0.42 volt at 1000 rpm, with a linearity of ½ of 1% up to 4000 rpm. Stainless steel bearings and laminations assure resistance to corrosion. The component weighs 2.3 ounces, and has an operating temperature range of −55 to +125°C.

Bench Size Diffusion Furnace

A bench size precision diffusion furnace has been introduced by **Sutherland Macklem, Inc.** The 16″×16″×36″ furnace is mounted on a power and control console only 15 inches high. In one to four 2¼″ alumina muffles it provides thermal flats within ±0.8°C over 10 to 14 inches long, at any temperature between 500°C and 1300°C. At maximum operating temperature, the case temperature remains under 95°C.



The wound heating elements are operated in three sections, with single-point, three-mode, millivoltmeter temperature control. Eight-point profile adjustment and continuous differential end-section controls set the thermal flat uniformity over a wide range of operating conditions. Two, three, and four tube models have separate heating elements, with individual adjustment for each.

The control system is based on silicon-controlled-rectifier ac power modulators, and fail-safe magnetic Transphasers® with error-rate damping control and reset vernier. Digital set-point, temperature re-

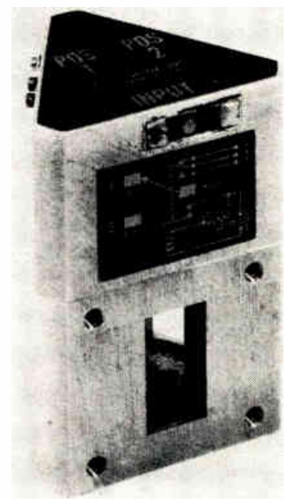
cording, multi-point control, and other features, are available as modifications to the basic unit. The basic (single tube) unit, complete, is priced at $3500 (packing and shipping extra). Delivery 2 to 4 weeks, or from stock as available.

Microwave Switch

Production of a new group of microwave switches, which are now standard items, is announced by **Waveguide, Incorporated,** 851 W. 18th St., Costa Mesa, Calif.



These high speed switches are designed to meet the environmental conditions of MIL-E-5272. For reliability micro switches are used for both position indicating and solenoid control circuit. Precision instrument bearings are used at all friction points to insure maintenance of operating characteristics. They may be supplied for return to either outlet port upon failure of external circuit. They are of light-weight aluminum construction with maximum body width of 1.865" and are suitable for airborne, missile, space and shipboard application.

Additional specifications are as follows: VSWR, maximum 1.08:1; Insertion Loss, 0.2 db maximum; Isolation, 50 db minimum; Maximum Pull-in current, 900 M. Amperes ma at 28v dc; Maximum Hold-in current, 200 M. Amperes ma at 28v dc; Frequency Range of Line, 7.05—18.0 kmc; RF connectors: Mate with Standard Waveguide flanges; Life, Design-tested to greater than 200,000 cycles.

Westinghouse electronic tube leadership

Westinghouse leadership in electronic tubes dates back to the first dry battery WD-11 tube made in 1920. In the great progress of tube advances that followed, Westinghouse engineers have contributed hundreds of improved tube types, and many entirely new ones. Today, Westinghouse continues to stay ahead of the field by creating new electronic tube capabilities that give design engineers dramatic increases in systems and equipment performance. The four tubes illustrated are only four examples of recent Westinghouse tube developments:

Microwave switching tube WX-4405 is a C-band, high-power, fast recovery time crystal protector featuring 0.1 to 0.2 microseconds recovery time.

Image intensifier orthicon for extremely low-light level viewing gives threshold pictures at 10^{-9} ft. candles illumination on the photocathode. Provides highest known sensitivity with good resolution.

Astracon—new 150,000X photon image amplifier tube—displays sufficient electron gain to display single photoelectron phenomenon.

High performance **neutron detectors** exemplified by the new ECONOLINE WL-8105 ionization chamber. In neutron detector production and development Westinghouse today has world-wide leadership—more Westinghouse neutron detectors are in use today than all other makes combined.

These tube developments are typical of Westinghouse leadership in electronic tubes for: atomic energy; commercial, industrial and military communications; radar; imaging systems; information storage and display; industrial processing; military aircraft and aerospace systems.

For the future, electronic tubes by Westinghouse have a planned place in systems developments. As micro-electronics, cryogenics, light frequencies, space explorations, new environments and technologies become common accomplishments, Westinghouse will provide electronic tube components to perform system functions that will advance the "state of the art." Whatever function your system has to perform, work with Westinghouse . . . for special system needs. Westinghouse Electric Corp., Electronic Tube Division, Elmira, N. Y. *You can be sure . . . if it's*

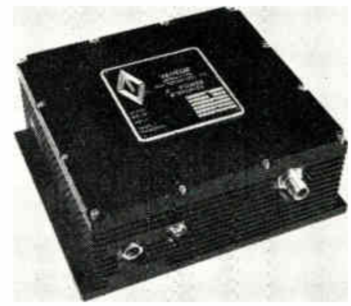
NEWS New Products

These manufacturers have invited PROCEEDINGS readers to write for literature and further technical information. Please mention your IRE affiliation.

(Continued from page 94A)

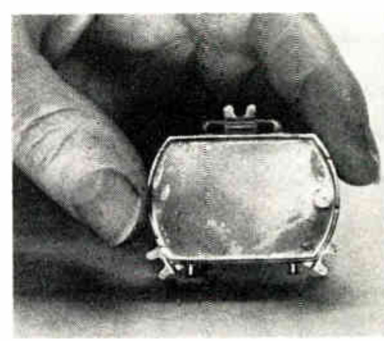
VHF telemetry power amplifier with an output of 50 watts. Using a unique innovation in circuitry, the anode is mechanically and electrically connected to the housing, thereby providing a superior thermal connection for vacuum tube cooling.



This 6 lb. amplifier of 115 cubic inches is designed for application in FM telemetry systems in the 215 to 260 mc range. The unit features compactness and excellent overall efficiency (typically 35%) with a power gain of 10 db, and operates from a standard 28 volt dc source.

RFI Filter

Efficient and economical filters to keep spurious incident RF energy from triggering sensitive U. S. Air Force cameras are now being produced by **Astron Corp.**, 255 Grant Ave., East Newark, N. J. The filters, designated AF-1637, are used to keep the line which controls the indexing of the film in airborne cameras free of accidental or intentional RF interference.



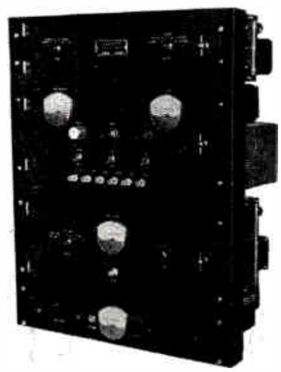
The AF-1637 filter operates conventionally, by presenting a very high impedance across the circuit but a low impedance to ground, thus trapping out signals at other than the operating frequency. The unit is a stabilized multiple-pi filter comprising four capacitors, two of which are single and two double, making six capacitive constants in all. It also contains two center-tapped inductors. The entire circuit was designed and fabricated to fit inside a housing less than $1\frac{3}{4}$ inches long, $1\frac{1}{4}$ inches wide and $\frac{1}{2}$ inch high including its standoff lugs.

NEWS New Products

The AF-1637 filter meets the environmental requirements of Department of Defense specification MIL-F-1573D. Electrical specifications are 50 ma and 28v dc.

Universal Transmitter

The 637 transmitter, a fixed frequency, crystal controlled unit, was designed by **Erco Radio Laboratories, Inc.**, 637 Stewart Ave., Garden City, N. Y., as a universal application transmitter. It can be used for any air-ground service in the 225–400 mc communications band.



Modular construction features permit plug-in multiplier strip and I.P.A. strip to form a complete 10 watt RF unit in an $8\frac{3}{4} \times 19''$ rack panel construction for low power applications. It requires the addition of a modulator panel unit which is completely solid state and requires $3\frac{1}{2}''$ of panel space. This unit features individual drawer-type modules with a low distortion compressor and low power drain.

The power amplifier unit, when added to the above combination together with its power supply, completes the 50 watt AM package. This unit can then operate in Class AB_1 mode as above

(Continued on page 98A)

(Continued from page 97A)

for AM, or can be switched to Class C condition for use as an amplifier for FM applications. It may also be used with a high level modulator for Class C AM operation at increased power specifications: Carrier Power is 50 Watts A3 in AB_1 mode. Frequency Range is 225 to 400 mc. Frequency Control is with an oven regulated CR32/U crystal for 0.002% stability. Output Impedance is 50 ohms unbalanced. Input Impedance is 600 ohms balanced. Frequency Response is 300 to 400 cps ±3 DB. Distortion is less than 6% at 1000 cps for 95% modulation. Carrier Noise is at least 40 db below full modulation. Control may be local or remote. On remote, up to 3000 ohms of loop resistance may be tolerated.

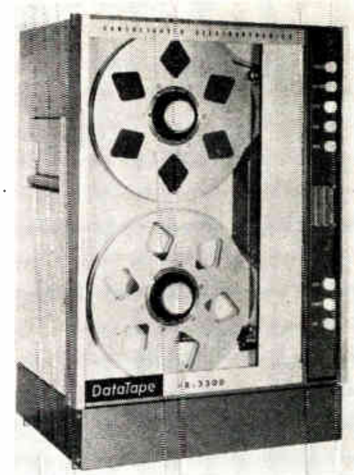
Power Source is 115 volts 50/60 cps single phase or 220 volts 50/60 cps can be provided on special order.

Panel Space Required is standard 19" relay rack; 28 inches is required for the 50 watt A3 model.

Technical Bulletin 637-T is available on request.

Portable Solid-State Recorder

A low cost precision portable, solid-state magnetic tape recorder/reproduce system has been introduced by the **Data Recorders Div., Consolidated Electrodynamics Corp.,** a subsidiary of Bell & Howell, 360 Sierra Madre Villa, Pasadena, California.



The Type PR-3300 unit can record and/or reproduce up to 14 channels of direct, FM or PDM data. Frequency response is 100 cps to 100 kc direct and 0 to 10 kc FM. Maximum cumulative flutter is 0.3% peak-to-peak up to 300 cps and 0.55% peak-to-peak up to 10 kc at 60 ips.

The aluminum carrying case is 22⅝ inches high by 18⅝ inches wide by 15⅛ inches deep.

Six standard speeds are available in pairs of 60, 30; 15, 7½; and 3¾, 1⅞ ips. Speed pairs are selected electrically by HIGH-LOW pushbuttons on the front panel. All control functions are relay op-

(Continued on page 99A)

(Continued from page 98A)

erated to permit remote operation.

The PR-3300 accepts either 1-mil or 1.5-mil mylar base tape or 1.5-mil acetate base tape. Reels up to 10½ inches in diameter with EIA-type hubs can be accommodated. CEC precision reels are supplied as standard equipment.

Operating power requirements are 115 volts ±10 v, 60 cps single phase. Power consumption is approximately 500 watts for a complete 14-channel system; 450 watts for a 7-channel system. Details are given in document 106-60.

Transistorized Pulse Generator

Pulse generator Model 521 is the latest addition to the line of digital equipment produced by **Digital Electronics Corp.**, 161 Sullivan Lane, Westbury, L. I., N. Y.

The generator is a low-cost, versatile, general-purpose fully transistorized unit designed to meet the requirements for research, development, and testing of low- and high-frequency pulse and digital equipment. A circuit in the Model 521 makes it possible to vary the frequency and width in a single multivibrator circuit as opposed to two in other types.

Supplying a pulse repetition rate from cps to 500 kc in five bands, the generator has a pulse width from 0.8 to 120,000 microseconds, a rise time of 50 nanoseconds, and a fall time of 200 nanoseconds. The amplitude is either positive or negative, 15 volts maximum, 5 volts into a 100-ohm load. For other pulse generators with dual polarities, a separate amplifier is needed for each polarity, with the Model 521, only one is needed. To produce the two polarities, a different voltage is applied to the amplifier with a switch on the panel.

Short-circuit protected, this unit operates with a nominal duty factor of 80%. With full amplitude at all loads and at all frequencies, the minimum duty factor is 60%. A synchronizing output pulse (−5 volts, 1 microsecond wide) is available at terminals on the front panel. To ensure synchronization with associated equipment, this signal is constant and is independent of the frequency and amplitude variations of the pulse output.

Weight is 2 pounds, dimensions are 8.25″ wide by 5.0″ high by 5.75″ deep. Power required is 115 volts, 60 cps, 5 watts.

Price is $89.50 f.o.b. Westbury, L. I., N. Y.

Availability is 30 days. For details contact E. Wiseman, at the firm.

Miniature DC Amplifier

The new Model 611 Plug-In dc Amplifier developed by **Wilson Greatbatch, Inc.**, 10647 Main St., Dept. IR, Clarence, N. Y., features small size, $\frac{3}{8}'' \times \frac{3}{4}'' \times \frac{7}{8}''$ high; light weight, $\frac{1}{4}$ oz.; better than 0.02%/°F zero stability, 150 K input impedance, better than 0.3% linearity. Any dual power supply from ± 6 V to ± 28 V dc may be used. This amplifier is suited for bridge inputs. Over 500 amplifiers will fit on a square foot of chassis space.

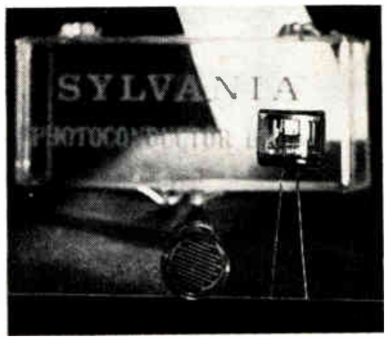
Gain may be set between 5 and 100 by means of an external resistor. Flat from dc to over 6 kc.

The Model 611 is suitable as a gain element for high-density physiological telemetering systems. One amplifier suffices for body temperature, GSR, respiration or pO_2 measurements. Two amplifiers cascaded suffice for EKG, EMG or Ocularmotor measurements. Three amplifiers cascaded suffice for EEG brain wave measurements.

Available from stock at $225 each.

Cadmium Sulfide Photoconductors

Two new cadmium sulfide photoconductor cells were displayed at the 1962 IRE Show by **Sylvania Electric Products Inc.**, a subsidiary of **General Telephone & Electronics Corp.**, 730 Third Ave., New York.



(Continued on page 102A)

(Continued from page 100A)

The new units, Types 8142 and 8143, have an outside bulb diameter of 0.5 inch and are end aluminated. They feature high sensitivity and hermetically sealed-in-glass construction. The cells are gaseous back filled for a high dissipation safety factor and include a special confidence feature, a blue dot compound which turns pink if the cell envelope becomes damaged.

Ultra-Fast Rise Time Delay Line

Ad-Yu Electronics Lab., Inc., 249 Terhune Ave., Passaic, N. J., has introduced a new type of delay line with bandwidth over 30 mc. The ratio of rise time can be made less than 2%, yet the maximum attenuation is less than 3 db. Chiefly, this is due to utilization of a new principle of network for linear phase shift, and adoption of a new method to achieve correct amounts of second and third order of mutual coupling among sections. Two or more units of this delay line with identical impedance, may be connected in tandem. In this case, the total time delay will be the sum of each individual unit, and the rise time will equal approximately the square root of the sum of the squares of the rise time of each unit.

There are a number of features for this series: Phase linear beyond 30 mc; rise time less than 2% of the total delay; distortion less than 2% of the signal amplitude; light weight, small physical size, and rugged construction.

The specifications are: Attenuation per microsecond is less than 0.5 db minimum; 1 db maximum. Maximum input voltage, 500 volts for most types. The cutoff frequency is 0.35 **n/Td** and the 3 db bandwidth is at 0.175 **n/Td**, where **Td** is total delay and **n** is the number of sections. Temperature coefficient is 0.005%/°C. Accuracy of delay is ±2%; and accuracy of characteristic impedance is ±10% (better accuracy can be supplied on request). Delay can be made from 0.2 μs up to 18 μs. Impedance available in the following values: 50, 75, 93, 150, 220, 280, 320, 400, 500 and 700 ohms. Price: $49.00 and up. Delivery: 2–3 weeks.

Amperex®

announces a significant step toward *instantaneous* electron emission . . .

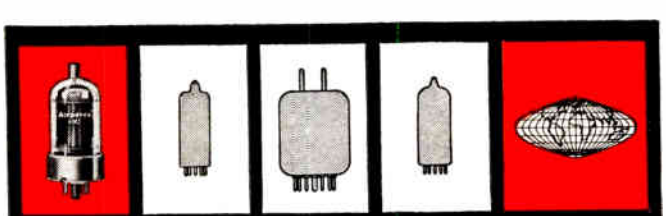
The

HARP CATHODE

Amperex sought the best means of producing the world's fastest heating electron tube; found it in the **Harp Cathode.** As developed by **Amperex, Harp Cathode** tubes permit warm-up in as little as 100 milliseconds. This major advantage, combined with low cathode inductance, low operating voltage, and extreme ruggedness—make Harp Cathode tubes the logical choice for transistorized mobile and airborne communications, and any other application where instantaneous response is a necessity.

Described simply, the Harp Cathode is a flat rectangle, strung harp-fashion with many superfine wires. Its unique advantages are largely a function of this physical arrangement. Thus, the minute wire size provides a high surface-to-volume ratio, resulting in instantaneous availability of thermal energy at the emissive surface. The quantity of electrically parallel, directly heated wires assures low cathode inductance. The low (1.6V) filament voltage affords the closest approach to the "unipotential" cathode. Moreover, in actual tests, tubes incorporating the Harp Cathode have given longer service life than tubes with conventional cathodes.

The **Amperex Harp Cathode Type 8042 Power Amplifier** (25 watts plate dissipation; 175mc ICAS) is available in pre-production quantities. It is the forerunner of **Amperex** Instant Heating Harp Cathode mobile transmitting tubes which will include versions of the types 6360, 6939, 6907 and 5894 push-pull tetrodes.



ask Amperex about the instant heating tube best suited to your particular application.

Counter-Timer Frequency Meter

Transistor Specialties, Inc., Engineers Hill, Plainview, L. I., N. Y., announces the availability of the Model 373 Counter/Timer, for the measurement of frequencies up to 10 megacycles, and time intervals (period measurements) from 1 microsecond to 10 seconds. By restricting the crystal "clock" circuitry to 1 mc, and employing only a single signal channel, very significant economies are effected, as are simplification of the panel controls and manipulations associated with each test setup.

The Model 373 is, according to the manufacturer, the most compact, lowest-priced all-solid-state 10 mc counter available. The level-sampling circuit, with 85 mv sensitivity, is used in the amplifier channel, and the readout is the superior 7-Nixie in-line type used on the most versatile and expensive counters.

The same high stability and accuracy (± 1 count, ± 3 parts in 10^7/week) are achieved in the Model 373, as in the most complex and advanced counters in its class. As in all TSI Counter/Timers, the instrument provides full self-testing, as well as frequency-standard output, consisting of every decade of frequency from 1 mc to 0.1 cps, derived from the crystal "clock."

Reliability is enhanced by the use of NOR-logic to reduce the semiconductor count, and generous derating guarantees a long, trouble-free life. Power consumption is only 35 watts.

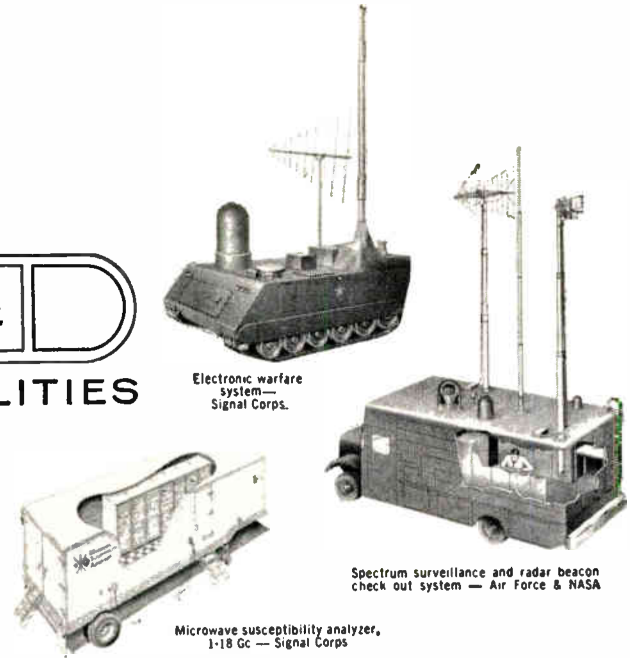
The 373 is illustrated in the attached photograph. The cabinet measures $8\frac{3}{4}'' \times 10\frac{1}{4}'' \times 12\frac{1}{2}''$. The unit weighs 19 lbs.

Additional information can be obtained from the manufacturer. Price is $1,880 (single units), delivery within 30 days.

Taut Band Measuring Instruments

A full new line of electrical measuring instruments featuring highly compact taut band suspension systems—interchangeable with conventional movements—has been

(Continued on page 106A)

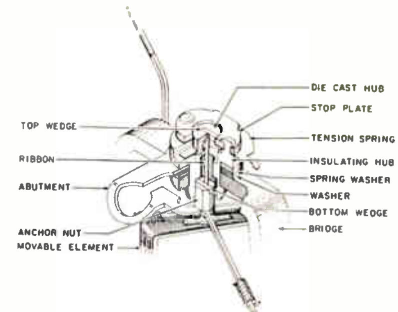


NEWS New Products

These manufacturers have invited PROCEEDINGS readers to write for literature and further technical information. Please mention your IRE affiliation.

(*Continued from page 104A*)

introduced by **Weston Instruments Div., Daystrom,** 614 Frelinghuysen Ave., Newark 4, N. J.



First instruments offered by Weston are 3.5, 4.5, 5.5, and 7.5-inch taut band models which, in external appearance, are exactly like the standard Weston rectangular 1900 series line in these sizes. Successful engineering design of taut band instrument movements, which are dimensionally interchangeable with conventional pivot-and-jewel movements, has made this possible.

In taut band instruments, the sensitive moving element is suspended by 2 slender metallic ribbons above and below the moving coil. When current is applied to the instrument, the rotation of the moving coil twists the suspension ribbons. When the current is removed, the ribbons return the movement to its original position.

The taut band method has the advantage of eliminating the friction encountered between pivots and jewels, and thereby increases repeatability. Sensitivity is also about five times greater than that of conventional instruments. The taut band suspension is extremely rugged and its stability is said to be superior to that of pivot-and-jewel instruments.

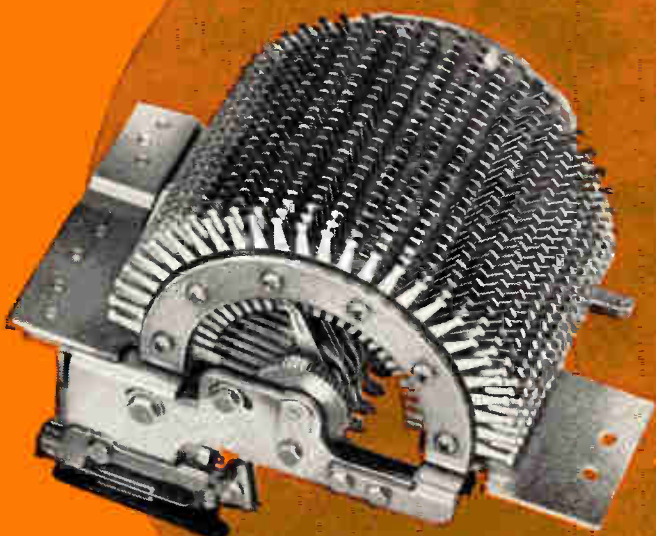
CLARE Stepping Switches

give designers—

- *more levels per switch*
- *more levels in less space*
- *more simplified circuitry*
- *NO synchronization problem*

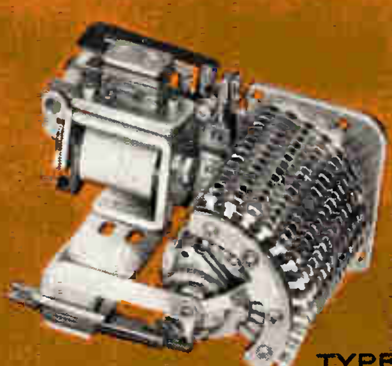


TYPE 26

Type for type, CLARE Stepping Switches provide more levels per switch . . . more levels per inch of height. The 12-level, 52-point, switch shown (CLARE Type 26), for instance, is 4$\frac{11}{16}$ in. high. It has four more 52-point levels than comparable 52-point switches, yet it is but $\frac{13}{16}$ in. higher than a comparable 8-level, 52-point switch. The smaller (Type 211), five-level, 33-point switch provides twice the levels of any comparable 33-point switch.

This greater working capacity per switch . . . and per inch . . . of CLARE Stepping Switches permits more simplified circuitry and avoids synchronization problems which arise when multiple stepping switches are necessary to do what is often a one-switch job with these high-capacity CLARE units.

CLARE Stepping Switches include a full line of spring-driven cam-operated or direct-drive switches with capacities from 10 to 52 points. CLARE engineering will cooperate with designers to develop special switches to meet unique requirements.



TYPE 211

For precise stepping switches famous for long life, high capacity and freedom from maintenance

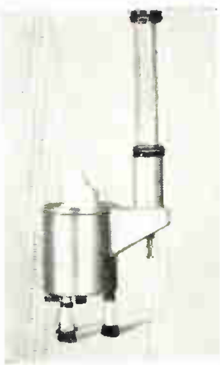
BOILING FOR "COOL" PERFORMANCE

This tube, the new ITT F-7832 Power Triode is in an open glass tank to demonstrate the new evaporative cooling method. Cooling water is shown boiling at the segmented copper cooling fins. Bubbles are rising off the surfaces and steam is escaping. Normally the tube is enclosed in a boiler (photograph at right) which, in conjunction with an external condenser, becomes a complete system.



Conventional water cooling is capable of dissipating 450 watts/sq. in. Forced air cooling dissipates 150. The ITT Evaporative Cooling System will dissipate in excess of 800 watts/sq. in. It will operate in an overload condition at 1600 watts/sq. in. with no damage. In addition, ITT Evaporative Cooling offers the advantages of noiseless operation, absence of rotating parts such as blowers and pumps, minimum servicing, self cleaning of tube, and minimum liquid coolant. ITT Evaporative Cooled Tubes feature ceramic construction. The new rugged, mesh cathode, another design innovation, provides improved emission per watt, quick heating and excellent temperature stabilization.

The appointment of **Harold G. Caldine** (M'58) as Manager of the New England District of HRB-Singer, Inc., was announced recently. In his new position he will be engaged in applications engineering and development liaison. He will also be responsible for general customer activities and will perform market research.

As an applications engineer for HRB-Singer during the past three years, Mr. Caldine was responsible for the application of company products to Air Force and Army needs. As an engineer at the Rome Air Development Center for seven years prior to this, he was responsible for the development of electronic equipment by private contractors, and was project engineer for the development of such units as selective calling systems, teletype and voice multiplexing and cryptographic equipment, and digitalized closed circuit television systems. His previous experience includes several years in the broadcast industry.

Mr. Caldine holds a B.A. degree in physics from Syracuse University. He attended Capital Radio Engineering Institute, Washington, D. C., and the Armed Forces Radio School, Ft. Knox, Ky. He belongs to the Armed Forces Communications and Electronics Association, as well as various professional groups for licensed pilots, and radiotelephone operators.

❖

The appointment of **Charles C. Camillo** (A'50–SM'55) to the post of Vice-President, Engineering, of FXR, Danbury, Conn., has been announced.

C. C. Camillo

Mr. Camillo, who joined Amphenol-Borg in 1948, was a member of the American delegation to the IEC Convention earlier this year in Geneva, Switzerland. He was Vice-President, Engineering, of Amphenol-Borg's RF Products division.

Mr. Camillo has contributed many technical papers and articles on various aspects of RF transmission theory and technology.

He was educated at Illinois Institute of Technology and the University of Illinois, from which he holds a B.S. degree in physics. He is active in a number of technical and scientific organizations, including ARRL, IEC, and NEMA.

NEW 10-AMP P&B RELAY IS DESIGNED FOR COST-SAVING INSTALLATION METHODS

Fast, labor-saving power screwdrivers can be used to hook up lead wires to the extra stout screw terminals of our new AK Series relays. Thus you save time and money on your production lines.

This new relay is sturdy throughout: its expected mechanical life is 3 million operations and the ¼" diameter contacts are rated at 10 amps at 115V AC non-inductive. Available for either AC or DC power.

Get all the facts today from your P&B representatives or call us direct.

AB SERIES

SIMILAR RELAYS HAVE U/L & CSA LISTING
The AB and the ABC have ¼" quick-connect terminals which can be used for printed circuits. Screw terminal adapters available. U/L and CSA listed for 10 amps at 115V 50/60 cycles.

ABC SERIES

ENGINEERING DATA, AK SERIES

GENERAL:

Insulation Resistance: 100 megohms min.
Breakdown Voltage: 1500 V. rms between all elements.
Temperature Range: AC and DC, $-55°C$. to $+45°C$.
Weight: Approx. 5 ozs.
Pull-In:
AC 78% of nominal voltage.
DC 75% of nominal voltage.
Terminals: Heavy-duty screw type.

CONTACTS:

Arrangements: Up to DPDT.
Material: ¼" dia. silver.
Rating: 10 amps @ 115 volts or 5 amps @ 230 volts, AC non-induc.

COILS:

Resistance: 35,000 ohms max.
Power: 6.4 volt amps (AC), 2.0 watts (DC).
Duty: Continuous AC or DC (DC coils will withstand 6 watts at $+25°C$.

P&B STANDARD RELAYS ARE AVAILABLE AT YOUR LOCAL ELECTRONIC PARTS DISTRIBUTOR

Dr. William M. Hall (A'23–M'44–SM'45) is the first member of Raytheon's staff to achieve the "Consulting Engineer, Consulting Scientist, or Scientific Fellow" level, a new professional level created by the Raytheon Co., Lexington, Mass., for its outstanding nonsupervisory engineers and scientists. Dr. Hall has been a member of Raytheon's technical staff for the past twenty-one years.

W. H. Hall

This new level permits the firm's specialists to contribute their best talent to advanced technologies while advancing their careers without need for accompanying administrative responsibilities.

Dr. Hall was awarded the Bachelor's, Master's and Doctorate degrees in science from Massachusetts Institute of Technology. He has written numerous papers and holds about twenty-five patents in the fields of sound measurements, infrared, instrument landing and radar.

❖

Reed E. Holaday (A'56) has been named senior scientist in Litton Industries' Electron Tube Research Laboratory, San Carlos, Calif.

Mr. Holaday has been associated with Litton Industries for the last three years, most recently as a senior engineer in charge of high power pulse crossed field devices. He was also klystron engineering manager during this period. He previously was employed at the Stanford Electronics Laboratory and the Sylvania Electronic Microwave Tube Laboratory.

In 1955 Mr. Holaday earned his Master's degree in electrical engineering at Purdue University. In 1959 he received an engineer's degree in electrical engineering at Stanford University.

❖

Hazeltine Electronics Division has announced the appointment of **John P. Hansen** (SM'58) as Manager of its Greenlawn, L. I., Laboratory. In this position he will have complete administrative and operational responsibility. He will also head the Greenlawn Project Administration Department.

Mr. Hansen, who is an assistant vice president of Hazeltine Electronics Division, joined Hazeltine in 1948 after serving as a product and sales engineer with the Sperry Gyroscope Co.

Mr. Hansen holds an engineering degree from the Polytechnic Institute of Brooklyn, Brooklyn, N. Y.

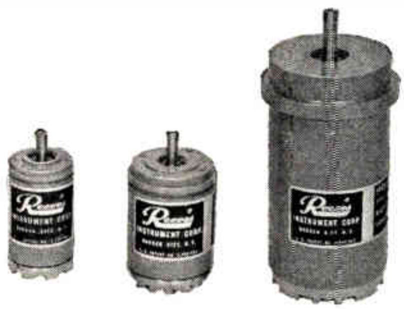
Reeves HIGH *Precision*

RESOLVERS, SYNCHROS and PHASE SHIFTERS

For data transmission; coordinate transformation and conversion; computer chain; and sweep applications. Write for data file 805.



STANDARD RESOLVERS

Reeves produces a full line of both compensated and uncompensated resolvers in standard BuOrd size 23, 15 and 11 cases. The size 23 series has a functional accuracy of 0.05%; resolvers in the other two series have an accuracy of 0.1%.

HIGH PRECISION SIZE 23 RESOLVERS

A new series of extremely accurate resolvers, which include a 0.01% functional accuracy computing resolver with 100% compensation; and a data transmission resolver with 20 second accuracy. They represent the ultimate in precision for resolvers of this case size.

30-SECOND SIZE 23 SYNCHROS

These three wire synchros are the most accurate units available in a standard BuOrd size 23 case. Both transmitters and control transformers can be supplied, designed for either 400-cycle or 60-cycle input.

PRECISION PANCAKE RESOLVERS

0.005% functional accuracy computer resolvers with 100% compensation; and 10-second accuracy data transmission resolvers. Integral bearing design permits direct mounting to gimbal structure. Beryllium housings provide highly stable operation under conditions of extreme temperature variation.

BOOSTER AMPLIFIERS

A complete line of vacuum tube and transistorized booster amplifiers, for use in conjunction with compensated resolvers. Transistorized units contain two fully encapsulated amplifiers in a single case.

Now—Micro Magnetics for the Space Age!

"MICRO MAG MOD"®
MAGNETIC MODULATORS

For Absolute Reliability . . .

Infinite Standby and Service Life . . .

New "MICRO MAG MODS" are complete micro miniaturized magnetic modulators featuring an essentially drift-free circuit with superior phase and gain stability over extremely wide environmental ranges. All the ruggedness, dependability, wide dynamic range and stability that are characteristic of the larger "MAG MOD" Magnetic Modulators are engineered into this magnetic circuit.

For complete information, request Bulletin MM 101. Bulletins also available on "MAG MOD" Miniaturized Standard and Multiplying Magnetic Modulators, and GMO Series High-Stability Oscillators.

FUNCTIONS –

"MAG MODS" provide four quadrant operation, extreme stability, with negligible change of phase, gain and zero position over a wide temperature range. Design is simple, rugged with no vacuum tubes, semiconductors or moving parts to limit life. "MAG MODS" offer infinite design possibilities and impedance levels — are adaptable for algebraic addition, subtraction, multiplying, dividing, raising to a power and vector summing.

APPLICATIONS –

Specify "MAG MOD" for magnetic amplifier components of proven reliability. These dependable instruments are widely employed in satellites, automatic flight systems, fire control, analog computers, guided missiles, nuclear equipment, antennas, gun turrets, commercial power amplifiers and countless control systems.

% Harmonic in Output Product Wave	15%	10% to 15%	5%	20%
Temperature Range	−55°C to +125°C	−55°C to +125°C	−55°C to +125°C	−55°C to +125°C
Frequency Response	5 K Series, 108 cps	Over 200 cps	Over 5 KC	Over 100 cps
Approximate Weight (in Ounces)	0.2	0.1	0.2	0.3

- Electrical zero point and gain, repeatability and stability over entire service life
- Extremely broad bandwidth
- Carrier frequencies as high as 1 megacycle
- Input signal current resolution better than 0.01μa
- Repeatable data over years of continuous, unattended operation
- High shock, vibration proof
- Low milliwatt power consumption
- May be mounted directly on printed circuit cards
- Light in weight

All "MAG MODS" conform to MIL-T-27A and MIL-E-5400

There is no Substitute for Reliability

joining Omni Spectra. He had been with Bendix from 1952 to 1955. From 1955 to 1956 he was a systems engineer for the Burroughs Corporation working on the development of the prototype Sage computer. After rejoining Bendix in 1956, he headed a group working on the development of a wide range of microwave components. He has five patent applications outstanding in the microwave field.

Mr. Cheal received his B.S. degree in electrical engineering from Michigan State University.

❖

The appointment of **Harvey Cohen** (S'55–M'55) as Eastern District Manager for the Systems Division of Beckman Instruments, Inc., Fullerton, Calif., was announced recently. In the new post, he will supervise the systems field engineering staff in the eastern half of the U. S.

Formerly a field engineer, Mr. Cohen has been a member of the Beckman organization since 1957.

He was graduated from the University of Manitoba, Winnipeg, Canada, with a BSc degree in electrical engineering, and received a Master's degree in business administration from Harvard University.

❖

The appointment of **Charles W. Hosterman** (M'56) as Manager of Planning of the Eastern Operation of Sylvania Electronic Systems, has been announced.

C. W. HOSTERMAN

Mr. Hosterman has served as Manager of Planning of the Data Systems Operations since January, 1961. He joined Sylvania in 1943 as an assistant supervisor of personnel at the company's Altoona, Pa., electronic tube plant. In 1944, he was transferred to the Proximity Fuse Tube Operation, Huntington, West Va., as supervisor of personnel, and subsequently was named Manufacturing Superintendent there.

Between 1950 and 1958, Mr. Hosterman served successively as the plant manager of the Sylvania receiving tube plant, Shawnee, Okla., assistant general manager of the company's Electronics Division, Woburn, Mass., and general manager of the Semiconductor Division, Woburn, Mass.

In 1958, with the formation of the Data Systems Operations, Needham, Mass., Mr. Hosterman was named Business Manager of that facility and later served as acting Marketing Manager.

A graduate of Pennsylvania State University, he is a member of the American Management Association, Professional

Those *non-conformists* at Burnell's engineering laboratory aren't satisfied with just producing the broadest range of crystal filters, toroids and communication networks: through their constant efforts to satisfy tomorrow's space age electronics problems, they have developed a whole new family of sophisticated crystal filters, with exceptional and unusual characteristics, contributing to increased circuit flexibility as graphically demonstrated above.

Those same *non-conformists* have also made considerable progress solving other electronics/space age problems. A typical example of this has been their work with the application of Time Domain Synthesis; producing an unlimited inventory of wave forms for new applications, and resulting in substantial reductions of size and weight, eliminating the need for complex active circuitry for its support.

*Join the *non-conformists*—write today for your free *Non-Conformist* paper weight and Crystal Filter Catalog XT-455. Yes! Your circuits *can* profit today from tomorrow's research.

The American Electronic Laboratories has announced the appointment of **Joseph R. Jahoda** (S'50–A'51–M'54–SM'58) as Vice President in charge of the newly formed Washington Division, Fairfax, Va.

J. R. Jahoda

Mr. Jahoda received his B.E.E. degree from the College of the City of New York in 1950, and his M.E.E. degree from Polytechnic Institute of Brooklyn in 1954.

He was employed by the EDO Corp. from 1953 to 1954. Prior to this Mr. Jahoda was employed by Polytechnic Research and Development Test department.

He did work on advanced ECM system design and development for the Sperry Gyroscope Co. from 1954 to 1956. During this period he served as evening Staff Instructor at the Polytechnic Institute of Brooklyn.

From 1956 to 1961, Mr. Jahoda worked with Melpar, Inc. as a project engineer in research and development of advanced electronic countermeasure systems. He served as a consultant in Medical Electronics to the George Washington University, Washington Institute of Biophysical Research, Inc. and Med Electronics, Inc. from 1957 to 1961. In 1961 he served as director of International Research Organization, Inc.

Mr. Jahoda is a member of the IRE Professional Groups on Ultrasonic, Microwaves and Medical Electronics.

❖

Everett LeGette (M'60) has been promoted to Regional Sales Manager in the Western United States by Motorola Communications and Electronics, Inc.

E. LeGette

In this capacity, Mr. LeGette will direct the design and sale of FM two-way radio and other communications systems and equipment to industrial, governmental and business organizations throughout a six-state area, which includes Colorado, Western Kansas, Western Nebraska, New Mexico, Southeastern Wyoming and Northern Texas. His headquarters are located in Denver.

(Continued from page 128A)

He brings to his new position 18 years of experience in radio communications. Previously, he was Sales Manager for Motorola in Southern California. He joined Motorola in 1950 as a radio communications representative, after managing a Motorola service station in San Luis Obispo, California for three years. He operated a radio common carrier system for three years.

Mr. LeGette is a charter member of the National Mobile Radio System.

❖

Maurice W. Horrell (A'37–M'44–SM'50) has been appointed Director of engineering and manufacturing centers for the UNIVAC division of the Sperry Rand Corp. He will be responsible for direction and coordination of all UNIVAC engineering and manufacturing.

M. W. HORRELL

Mr. Horrell was general manager of the computer division of Bendix Corp. prior to joining UNIVAC.

A registered professional engineer, Mr. Horrell received his Master's and Bachelor's degrees in electrical engineering from Kansas State University. He is a member of the Association for Computing Machinery, and the American Ordnance Association.

❖

Robert B. MacAskill (S'48–A'50–M'55–SM'56) has been named Director of Engineering of the J-V-M Division of Fidelitone Microwave, Inc., Brookfield, Ill.

R. B. MACASKILL

In his new position, Mr. MacAskill will direct the Research/Development and Systems Design Groups, and be responsible for new products.

Mr. MacAskill's previous experience includes microwave antenna and product development for The Hallicrafters Co., and Mark Products. Previous to that, he was a research and development consultant in the microwave field, specializing in antennas, systems and components.

Mr. MacAskill earned his degree in electrical engineering at the University of Illinois. At present he is business manager of "Scanfax," the publication of Chicago Section of the IRE. He also holds several patents covering design and applications of microwave components, and is the author of many technical papers.

Shortening Shadows

Alfred N. Goldsmith
Anniversary Editor

THE LIFE of a man or an organization has been aptly compared to the sequence of lights and shades during one day on earth. In the early morning, long shadows lie to the West as the sun rises. Then these shadows shorten as the day advances until no shadows are visible in the noonday blaze of light. And later, the shadows lengthen as the sunlight wanes, and twilight and night approach.

The Institute of Radio Engineers is fortunate in that it is still in its early morning amid the slowly shortening shadows. Its career is young and promising. Its hopes and accomplishments, while great and inspiring, are as yet only partly fulfilled. It has the cheerful stimulus of still being far even from the noon of its life, not to mention the evening.

Yet even at this early stage of the career of the Institute, an assessment of its accomplishments and an estimate of its future may be attempted. To this end, let us return in imagination to 1912, the year of the Institute's formation. It was a very different world from that of today. Knowledge of the communications and electronics field was limited. Vistas now clear were then dim or obscure. Professional standing and cooperation were not at today's encouraging levels. And the number of persons skilled in the electronics field was small indeed.

It was our privilege to be associated at that time with the other two founders of The Institute of Radio Engineers. Great tribute should be paid to these farsighted pioneers. Robert H. Marriott, President of the Wireless Institute (one of the merged societies which formed our Institute of Radio Engineers) was ever resourceful, determined, questioning, and analytic. And above all, he was an indefatigable worker and a thoughtful planner. John V. L. Hogan was a highly skilled, inventive, and forceful pioneer. He was that rare combination: a man both human in his reactions and humane in his instincts. Without the broad understanding and generosity of these men, our Institute might never have come into being.

The original builders of the IRE were certainly no example of squatting on their hunkers.

They were strong exponents of a much more logical creed that work conquers all. And work they did, over the passing years, and in the face of many obstacles.

Yet they were fortunate as the years went on in encountering an ever more favorable and respected environment. There were numerous fortuitous helpful events, and there were also many planned and logical campaigns. The founders and their many associates were able to function partly because of three major factors. One factor was the dependable and increasing devotion and effort of the membership. It would be impossible to exaggerate the sacrifices and labor which the membership readily gave the succession of officers of the Institute over the years. The second factor was the continued and friendly cooperation of the communications and electronics industry. Industry fully understood the work of the Institute and enthusiastically backed its efforts and expansion. And the third factor was the truly explosive growth of electronics, which provided an opportunity and a challenge which were gladly accepted and turned to the advantage of the Institute. And the Institute in turn contributed greatly to that expansion over the years. Thus the membership, industry, and the expansion of the electronics field offered the Institute its opportunities. Nor should it be forgotten that governments showed a clear understanding of the worth of the activities of the Institute and encouraged their officials, scientists, and engineers to affiliate with the Institute and to aid in its upbuilding. To all of these forces recognition must be given and gratitude expressed.

Yet growth itself, from a numerical viewpoint, is not enough to ensure the basic success of any professional organization or learned society. It must retain its personality. It must maintain its ideas and ideals. It must display continuing vitality. It must avoid entangling alliances or deviations from its true purpose. Accordingly it became necessary for the IRE carefully to plan its growth along statesmanlike lines to the end that it would remain as youthful and vigorous as in its earliest days. It would be too lengthy a recital to go into the details of the appropriate measures adopted by the Institute to accomplish its aims. Some of these measures have become classic and have blazed the trail for other engineering organizations which have wisely seen fit to adopt them. The IRE established its Sections to meet the needs of members in a city and its environs. It established subsections to fulfill the needs of smaller numbers of members in suburban sections or in smaller population centers. It coordinated the activities of Sections and subsections over large territories through the formation of Regional administrations. It coordinated Regional activities through National divisions or their equivalent.

And, in addition to these "horizontal organizations," the Institute established vertical organizations of all persons among its membership interested in a particular specialty. This led to the formation of Professional Groups and of their local Chapters. Undoubtedly the end is not yet. Additional organizations or administrations, and new forms of publication may in time be needed to meet the ever-increasing desires of the membership. And, if the past is any index to the future, the necessary statesmanship will be found to meet any current needs.

The IRE has carefully avoided such measures as would lead to its grounding on the shoals of disaster which often lie in the path of learned societies as they expand toward maturity. These pitfalls include insufficient interest in the organization by the individual member, of local geographic groups of members, of larger or regional groups of members, and of members imbued with a sense of the national dignity of their compatriot members. Also avoided was the development of insufficient interest resulting from the diverse activities of individual members of the Institute—a situation which was well met by the Professional Groups. More broadly, the Institute has also avoided the dangers of involvement with political, sectional, partisan, commercial, or personal viewpoints and activities which were not of a definitely engineering and scientific nature. It is easy for a learned society to forget its basic purpose of a search for truth, or for an engineering institute to forget that the practice of its profession for the benefit of humanity is its basic aim. The membership of the IRE may be proud in reviewing the past of the Institute and noting its complete detachment from purposes alien to its basic aims.

However, the Institute has not established itself in a guarded ivory tower and without contact or collaboration with others. One of its aims is continued cooperation and even coordinated activity or a suitable degree of integration with other engineering and scientific organizations. Wherever the IRE could help in the organization, operation, or publication activities of conventions, conferences, or symposia in collaboration with other engineering societies of standing, it has done so unhesitatingly and, at times, with considerable sacrifice. Since the establishment of the IRE Professional Groups, this type of cooperation has been greatly broadened. In fact, the roster of joint meetings or the like in which the IRE is engaged is almost startling in its dimensions.

One very important aspect of The Institute of Radio Engineers is its international nature, prescribed by its charter and consistently carried out in its activities. It has been said that science knows no country and that truth is universal. Such fields as communications and electronics are peculiarly adapted to the application of such doctrines, to the utmost practical limits.

Speaking more lightly, the techniques of communications and electronics might even make it logical that the scope of the IRE should ultimately become cosmic. We might look forward to the establishment of lunar and planetary Regions and Sections of the Institute in due course. And after that, who knows? But who would dare place finite limitations on the activities and studies which reach outward with the speed of light toward the infinite?

It may not be amiss also to emphasize that The Institute of Radio Engineers has sought and achieved a unique form of leadership in its dedicated field. In the world there are indeed many types of leadership. Some men, political parties, or nations maintain important positions of power or influence by brute force and iron discipline. Some organizations hold their eminence through guile, subtle persuasion, empty promises, or deceptive practices. But The Institute of Radio Engineers, the mental child and professional expression of its membership, holds its leadership only by service and accomplishment. Its sole aim is ever to give more to humanity and to its members. Its accomplishments require little recital or egotistical praise. They speak for themselves, and win hearty approval of all candid observers.

Thus the Institute will remain as a symbol of an epoch—the age of the approaching welfare, comfort, and health of every man on earth, and of man's conquest of space. And so, in the spirit of selfless aspirations to serve the interests of the people of the world and to express the best professional aims and accomplishments of its membership, The Institute of Radio Engineers looks forward through the decades and centuries toward ever wider, more useful, and more enlightening accomplishments.

The Fiftieth Anniversary Issue

MAY 13, 1962, marks the Fiftieth Anniversary of the founding of The Institute of Radio Engineers.

At this special moment the IRE finds itself poised precisely at the midpoint of a 100-year span where, in the fashion of Janus, it can watch simultaneously the gates of one half-century closing behind it and the gates of a new half-century opening before it. It is a time when we become more appreciative of the past, more aware of the future, and more conscious of the fact that they both converge upon the present.

It is a time also for remembering that the founding of the IRE 50 years ago coincided within a very few months with two other historic developments: the conversion of the three-element audion detector tube into an amplifier and into an oscillator, momentous events in which an IRE Charter Member, Lee de Forest, and IRE's first Vice President, Fritz Lowenstein, played leading roles. Thus, in a very real sense this occasion also commemorates the fiftieth anniversary of the beginnings of modern electronics and communications.

It is with these thoughts in mind that the IRE has assembled, in the month of its golden anniversary, an issue of its PROCEEDINGS of unprecedented scope, size, and distinction. Its pages carry the reader through a full century in time, from 1912 to 2012; its papers embrace the fields of all 28 Professional Groups of the IRE; its 180 contributors were chosen from among the leaders of the profession; its contents were written in their entirety by special invitation.

The reader will note from the table of contents in this issue that the material in the following pages falls into three major groupings. The subject of the first group of articles is the IRE itself. In the opening paper, an IRE fellow, who himself has been a member for 46 years, discloses many interesting facts about the origins, early history, and later growth of the IRE. This is complemented by special commentaries by the President, Past President, Secretary, and Executive Secretary, which provide a panoramic view of the position of the IRE today and its role in the future.

The unusual nature of the second group of contributions in the issue is indicated by its title, "Communications and Electronics—2012 A.D." In this section forty-eight Fellows of the IRE, in a series of brief essays, take the reader on a unique journey fifty years into the future, and describe to him the likely state of the art in 2012 A.D. as they envision it. As far as is known, never before has such a concerted assault on the barriers of time been attempted by so eminent an assembly of engineers and scientists.

The third group, which makes up the bulk of the issue, consists of 113 papers in which leading authorities take up in turn the fields of each of the 28 IRE Professional Groups and concisely summarize the evolution, present status and probable future trends of each. This portion of the issue presents a wealth of material concerning both past and current developments in a form that has never been published before. In a sense it comprises 28 condensed special issues in one.

In spite of the large size of the issue, the reader will have no difficulty in finding those articles that are of greatest interest to him. He will find that the second part of the issue, "Communications and Electronics—2012 A.D.," carries its own subject and author index at the end of that section. (Indeed, the subject index itself makes interesting reading.) The third part of the issue, dealing with Professional Group fields, is its own index. It has been divided alphabetically by subject into 28 sections, one section for each Professional Group field. In addition, an author index for the entire issue appears at the end.

Because of the special nature of this issue, the regular monthly features which PROCEEDINGS readers are accustomed to seeing at the back of the issue have been omitted. These include Correspondence, Books, Scanning the TRANSACTIONS, Abstracts of IRE TRANSACTIONS, and Abstracts and References. The May editions of these features will appear in the June issue.

The appearance of this issue represents the culmination of a two and one-half year effort. The issue was initiated late in 1959 when the Board of Directors asked Dr. Alfred N. Goldsmith, Editor Emeritus and co-founder of the IRE, to serve as Anniversary Editor and to assume responsibility for the conception, planning, and execution of an Anniversary Issue of the PROCEEDINGS. During the months that followed, the Anniversary Editor received helpful advice and assistance from many individuals and groups, including especially the Editorial Board, former Editor Ferdinand Hamburger, Jr., the Executive Secretary, and the Managing Editor.

In connection with the Professional Group section of the issue, particular thanks are due the 28 Professional Groups and their respective specially-formed Anniversary Committees, whose valuable suggestions of topics and authors and generous assistance in reviewing papers contributed greatly to the success of this undertaking. In particular, we are indebted to the following Professional Group representatives for the valuable service they rendered:

Batcher, Ralph (PGPEP)
Breiding, Eugene J. (PGRQC)
Elias, Peter (PGIT)
Fagen, M. D. (PGUE)
Felch, E. P. (PGI)
Grace, J. N. (PGNS)
Grobowski, Zigmund V. (PGRFI)
Gruenberg, Eliot (PGSET)
Hechtman, Harold (PGEM)
Herold, E. W. (PGED)
Hobbs, L. C. (PGEC)
Huggins, W. H. (PGCT)
Hughes, Wm. L. (PGBC)
Jackson, Albert S. (PGHFE)
Johnson, J. Kelly (PGBTR)
Liddell, Urner (PGBME)
McElwee, Eleanor (PGEWS)
Macdonald, Angus P. (PGVC)
Martin, D. W. (PGAU)
Minno, Harry (PGANE)
Mittleman, Eugene (PGIE)
Pritchard, W. L. (PGMTT)
Rhodes, Donald (PGMIL)
Rogers, A. W. (PGCP)
Smith, Phillip H. (PGAP)
Truxal, John G. (PGE)
Wallace, J. D. (PGCS)
Ward, John E. (PGAC)

The typesetting, printing and binding of more than 100,000 copies of a 1200-page volume, without disrupting the monthly flow of other issues of the PROCEEDINGS, requires not only a well-equipped and competently-run printing establishment, but also the wholehearted cooperation of a dedicated organization. We are especially pleased on this anniversary occasion to acknowledge the important contribution which the George Banta Company in Menasha, Wisconsin, has made to the IRE, not only in the production of this voluminous issue but in maintaining an unbroken record of devoted service to the PROCEEDINGS for a period of thirty-five years.

Our final thanks have been reserved for the 180 prominent engineers and scientists who, upon the invitation of the Anniversary Editor, so willingly accepted and so ably carried out the onerous task of preparing the outstanding contributions which comprise this issue. So skillful are their presentations that the average reader may not fully appreciate the difficulty of the assignment which each author faced, namely, to compress into a few pages a lifetime of knowledge and experience. It may be of some interest to note that among the contributors to this issue are 43 IRE officers and Directors, including 15 Presidents, and 119 IRE Fellows.

Thus the reader may be confident that this issue, in chronicling the past, assessing the present and interpreting the future, is presenting the judgments of those who are acknowledged as spokesmen for our profession.

—*The Managing Editor*

The Institute of Radio Engineers —Fifty Years of Service*

LAURENS E. WHITTEMORE†

FELLOW, IRE

A PREDICTION

(From an IRE information booklet, dated January 1, 1913, at which time the IRE had 109 members.)

The form of government of the Institute is thoroughly democratic and each member is given full opportunity to participate in all the advantages and privileges of the Institute. It is confidently expected that the already considerable membership will grow to the point where the greatest possible benefits will be extended to the greatest possible number of those interested in the development of radio-transmission.

INTRODUCTION

FOR THE INFORMATION of the members of the IRE, and especially those who are included in the one-third of the members who have joined during the past five years, there are here presented an outline of the beginnings of the Institute of Radio Engineers and some significant facts as to its organization, aims and recent accomplishments. Some statistics are included to show the growth of the Institute and the expansion of its activities over the 50 years of its existence. A perusal of these statistics shows how rapidly the Institute's activities are moving forward geographically, technically, professionally and in education.

This paper is in some respects a revision, and in some respects a repetition, of portions of the review of the first 45 years of IRE's service to its members, prepared under the sponsorship of the History Committee of the Institute and published in 1957.

Readers who are interested in more details of events, organization changes, etc., during the first 45 years of existence of the Institute, may refer to that paper which appeared in PROCEEDINGS OF THE IRE, May, 1957, pp. 597-635. As an appendix to both papers there is given a list of previous publications of significance relating to IRE history.

*Received by the IRE, November 17, 1961.

† Short Hills, New Jersey.

FORMATION OF THE INSTITUTE OF RADIO ENGINEERS

The Beginning

Radio people, apparently from the outset, have been characterized by a combination of two desires—1) to talk with one another about their accomplishments and their hopes, and 2) to write and read about the things which they and their technical "brothers" have been doing. The desire to present papers about "wireless" and to hear and discuss them resulted in the establishment of two organizations, one in Boston in 1907, and one in New York in 1908, whose members became the nucleus of the Institute of Radio Engineers in 1912.

Society of Wireless Telegraph Engineers

The Society of Wireless Telegraph Engineers (SWTE) was formed in Boston, Mass., on February 25, 1907, by John Stone Stone as an outgrowth of seminars held by engineers on the staff of the Stone Wireless Telegraph Company. Membership was eventually opened to men from Fessenden's National Electric Signaling Company and some other organizations. Members of this society were familiarly known as "swatties." John Stone Stone was the first President of this society.

The Wireless Institute

Robert H. Marriott made what appears to have been the first specific attempt to form a radio engineering society composed of members from any and all companies. On May 14, 1908, he sent a circular letter to some two hundred persons interested in wireless asking their opinions regarding the formation of such a society. On January 23, 1909, a temporary organization was formed to draw up a constitution. The name of the new society was "The Wireless Institute."

Robert Marriott was elected first President of The Wireless Institute, and served in that capacity during the three years of its existence.

By 1911 the Stone Wireless Telegraph Company had gone out of existence and the National Electric Signaling Company had moved to Brooklyn so there was very little left of the SWTE. The Wireless Institute was also struggling to hold its membership and to keep out of debt.

Institute of Radio Engineers

It was early in 1912 that Robert H. Marriott and Alfred N. Goldsmith, representing The Wireless Institute, with John V. L. Hogan, who was very active in the Society of Wireless Telegraph Engineers, held an informal meeting to discuss the plights of both societies. Out of their discussions there developed a meeting on the night of May 13, 1912, at which members of TWI and SWTE gathered in Room 304 of Fayerweather Hall at Columbia University in New York City. A constitution was approved and an election of officers was held at which the following were chosen: Robert H. Marriott, President; Fritz Lowenstein, Vice-President; E. D. Forbes, Treasurer; E. J. Simon, Secretary; Alfred N. Goldsmith, Editor; and Lloyd Espenschied, Frank Fay, J. H. Hammond, Jr., John V. L. Hogan, and John Stone Stone, Managers.

As a name for the organization "The Institute of Radio Engineers" was chosen. The original membership roster of the IRE consisted of 46 members, 22 from SWTE and 25 from TWI. One member, Greenleaf W. Pickard, was the only charter member of IRE who had been affiliated with both of the preceding organizations.

* Member of the IRE as of January, 1962.

After about a year, it was decided to incorporate the society. A meeting to decide details of this move was held at Sweet's Restaurant on Fulton Street in downtown New York on June 23, 1913. Those members with a more legal mind in the make-up of the Institute, drew up Articles of Incorporation, and on August 23, 1913, the organization was incorporated under the laws of the State of New York.

In brief, the expressed aims of the new association were:

"To advance the art and science of radio transmission, to publish works of literature, science and art for such purpose, to do all and every act necessary, suitable and proper for the accomplishment of any of the purposes or the attainment of any of the powers herein set forth, either alone or in association with other corporations, firms or individuals to do every act or acts, thing or things, incidental or appurtenant to or growing out of or connected with the aforesaid science or art, or power or any parts thereof, provided the same be not inconsistent with the laws under which this corporation is organized, or prohibited by the State of New York."

Growth of Membership of the Institute of Radio Engineers and its Predecessors, 1907–1914

	SWTE	TWI	IRE
February 25, 1907	11		
January 1, 1908	17		
January 1, 1909	27		
March 10, 1909		14	
January 1, 1910	36	81	
January 1, 1911	36	99	
January 1, 1912	43	27	
May 13, 1912	(22)	(25)	46
January 1, 1913			109
January 1, 1914			231

One of the most important functions of the Institute was to preserve its technical papers, and the remarks made regarding them, in published form. One of the early decisions of the Institute, therefore, was to publish a technical magazine which was named The Proceedings of the Institute of Radio Engineers. The first issue was dated January, 1913.

By the end of 1912, the Institute's membership had risen to 109 and during the succeeding year it more than doubled. The rapid increase in membership after consolidation, compared with the slow rate of growth of SWTE and TWI, bore out the wisdom of the founders who suggested the merger.

The original ledger book of the Institute, in which the names and dues payments of early members were recorded, constitutes a veritable *Who's Who* in the early history of radio. The names of many radio pioneers can be seen in the accompanying illustration showing the first few pages of the list of these members who joined the Institute during the first year.

Name of the Institute

In considering a name for the new organization the founders felt that something should be preserved from the names of both of the two component societies. The word "Institute" was borrowed from The Wireless Institute, and "Engineers" from the Society of Wireless Telegraph Engineers. Because the word "radio" was gradually supplanting "wireless," the title "The Institute of Radio Engineers" suggested itself. There was considerable temptation to add "American," particularly since TWI and IRE were modeled after the American Institute of Electrical Engineers in certain other respects. However, the temptation was resisted because it was expected that the IRE, as the only radio engineering society in existence, would be international in scope, an expectation that was promptly realized.

The Emblem or Symbol of the IRE

Neither of the emblems of the predecessor societies seemed readily adaptable to the new IRE. The SWTE emblem pictured a simple form of spark oscillator. The membership badge of TWI showed a spark gap functioning in the center of a dipole surrounded by a circular resonator provided with a micrometer gap for reception.

The founders of IRE decided not to use a representation of any specific form of equipment or physical structure but to devise a more general and perhaps perpetual symbol. It was realized that the Institute would always deal with electromagnetic energy, guided by conductors or passing through space, and that the distinguishing character of the transmission process was the existence of electrical forces and of their correlative magnetic forces. A representation of these forces

was adopted as part of the symbol; the electrical force being represented by a vertical arrow and the magnetic force by a circular arrow surrounding the electrical line and in the conventional relationship to it. The shape of the resulting drawing lent itself to a triangular placement of the letters, I, R, and E. This, in turn, led to the selection of a triangular emblem. Incidentally, the letters I, R, and E also symbolize the fundamental quantities, current, resistance and electromotive force, as well as the name, Institute of Radio Engineers.

Officers

The officers of the IRE from the beginning have been President, one or more Vice-Presidents, Secretary, Treasurer, Editor, and Directors with the infrequent addition of an Assistant Secretary or an Assistant Treasurer. The President and Vice-President(s) have always been elected by the IRE membership as have part of or all the members of the Board of Directors. Beginning in 1915, the elected members of the Board were authorized by the Constitution to choose several additional persons to complete the Board membership. The Secretary and Treasurer have for many years been elected by the Board.

An accompanying table shows, for each year since the formation of the IRE, the names of the Officers who served during that year.

Beginning in 1930, it became the custom for the Vice-President of the IRE to be a member who resides in a country other than the United States. In 1957 neither the President nor the Vice-President was a resident of the United States. In 1960, the IRE established two Vice-Presidents. Initially, one resided in North America and the other resided outside of North America. In 1962, the former was replaced by a Vice-President, elected by the voting members, whose function is to assist the President. Also a new Vice-President, elected by the Annual Assembly, was created to serve as a coordinator between the Professional Groups and the Executive Committee. The office of the Vice-President residing outside North America will terminate at the end of 1962.

As the IRE membership increased in numbers and geographical distribution, there developed an appreciation by the members of the Board that some specific measures should be adopted, possibly of an organizational nature, to make more certain that the contacts between the Board and the IRE membership would always be close and continuous and that the Board would comprise a truly democratic representation of the IRE membership. After several years of consideration of this problem, the Board of Directors recommended an amendment to the Constitution which was adopted by the Institute membership in 1947, providing for Regional Directors, selected specifically to represent designated regions of the United States and Canada from which they came and whose memberships had elected them.

Membership

Growth in Numbers

It is fitting to consider as the "Charter Members" of the IRE those members of the two parent societies who became the first members of the IRE when it was organized on May 13, 1912. The formal charter of the Institute of Radio Engineers, however, was granted on August 23, 1913.

The 1914 Year Book gives an analysis of the geographical distribution of the 271 Members and Associate Members of the IRE as of March 1, 1914, showing that there were members in eight countries other than the United States. The 1916 Year Book shows that the membership of the Institute immediately began to increase and by January 1, 1916, was only slightly under 1000.

The Constitution, as adopted in May, 1912, provided that the names of applicants for membership in the IRE should be sent out to each member of the Institute, prior to their acceptance as members. The members who were elected were required to subscribe personally to the Constitution of the IRE.

From the beginning, membership was open not only to radio engineers (Member grade) but also to those who had a real interest in radio engineering even though they were not professionally engaged in this field (Associate Member grade).

In 1914 the grade of Junior Member was established for persons under 21 years of age.

One of the outstanding aspects of IRE membership is the substantial number and generally increasing proportion of its membership living in countries outside of the United States. The IRE has taken special steps from time to time to recognize outstanding members living in other countries and to stimulate membership in such areas. At the end of 1961 the IRE had members in 90 countries outside of the United States.

Significance of Membership Grades

In the IRE, as is customary in professional societies, the several grades of membership are intended as a basis for giving recognition to the experience and achievements of the members in radio engineering and the related technical fields.

From the beginning, the Fellow grade has been intended to represent high attainment.

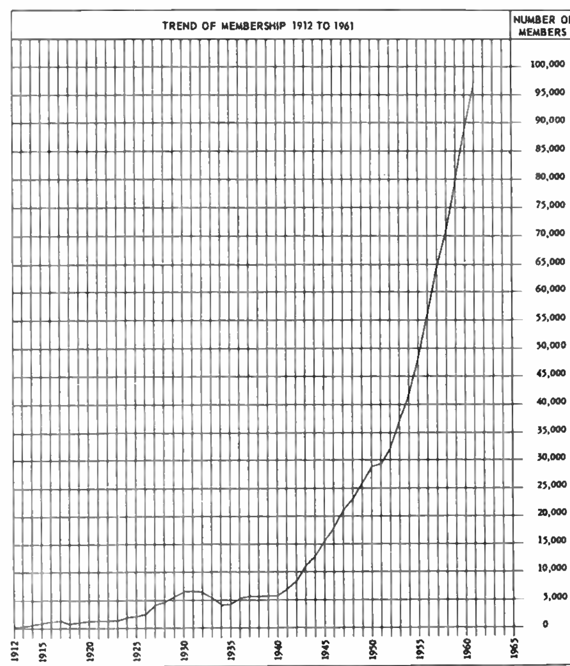
Beginning with the year 1940, all entries to the Fellow grade have been by invitation rather than upon application. The custom has been established of presenting the Fellow awards at meetings of the local Sections of which the recipients are members, and 78 persons were being honored in this way in the early part of 1962. About one per cent of the IRE's total membership of over 96,000 are of the Fellow grade.

Membership Growth in U.S.A., Canada and Abroad

Year	U.S. and Possessions	Canada	Abroad	Total
May 13, 1912	46			46
Dec. 31, 1927	3550	184	476	4210
" 1936	3975	178	1042	5195
" 1946	15,898	978	1278	18,154
" 1956	51,551	2085	1858	55,494
" 1961	88,956	3758	3837	96,551

The Senior Member grade was established in 1943 as a means of providing a higher grade than the Member grade into which members of the IRE might advance on the basis of their experience and training. This enabled the Institute to keep the Fellow grade as a special recognition.

Recognizing the desirability of encouraging engineering students to become affiliated with the Institute of Radio Engineers, a Student grade of membership in the IRE was established by constitutional amendment effective in 1932.



Membership Growth by Grades

Date	Junior	Student	Associate Non-Voting	Associate Voting	Member	Senior Member	Fellow	Total
May 13, 1912				46				46
Dec. 31, 1936	34	299		4092	637		133	5195
Dec. 31, 1946		2252	9890	1701	2330	1763	218	18,154
Dec. 31, 1956		10,384	18,491	388	19,110	6486	635	55,494
Dec. 31, 1961		19,167	13,566		52,284	10,570	964	96,551

The previously existing grade of Junior Member was dropped in 1943.

It was a natural development for the Student Members at a given college to meet together to discuss radio engineering questions among themselves or to hear addresses by visiting engineers, and a number of informal Student groups or "branches" came into existence.

The IRE Bylaws provide that every member who has attained the age of 65 years, and who has been a member of the IRE for 35 years or more, is eligible for Life Membership with waiver of payment of further dues. As of December 31, 1961, there were 272 Life Members of the IRE.

Standardization

From the beginning of its existence, the officers of the IRE have recognized that standardization is necessary for the orderly exchange of information and for effective progress in a technological field.

The Standardization Committee in 1913 published a report dealing with definitions of terms, letter and mathematical symbols, and methods of testing and rating equipment.

The current IRE standards are 89 in number. Of these 44 standards deal with terminology, symbols, and definitions of terms, and 45 standards deal with testing or measurement methods. Most of these standards have appeared in the Proceedings and all of them are available in reprint form. A list of the current standards is published from time to time in the Proceedings. As of the end of 1961, 18 current IRE standards have been adopted by the ASA as American Standards.

Until recently, the IRE Standards have been published either in separate pamphlets or singly in issues of the Proceedings. Now the Standards dealing with terminology and symbology have been gathered together in one "IRE Dictionary" of 50 pages containing 3700 technical terms and definitions and five standards of letter and graphical symbols.

Sections

Formation

The activities of the IRE, originally confined to the New York area, quickly spread to other cities as the membership increased. Small groups of members in various localities began to hold their own local meetings and elected their own officers for organizing and running these meetings. These groups of members were called Sections.

The first local Section of the IRE was organized at Washington, D.C., in January, 1914. Section meetings were held each month for the benefit of the group of perhaps a score of engineers, then described as "a large number of members residing in the vicinity of the capitol."

Following the formation of additional Sections, an approved form of a Constitution for Sections was made mandatory in 1930, by action of the Board of Directors.

The New York Section, as such, was established in 1942. Before that time the meetings held in New York were considered meetings of the Institute.

Effective January 1, 1946, the Board made a change in the method of assigning territory to Sections. Instead of assigning a small territory around a city as the area of each Section it was decided that the entire area of the United States should be assigned to one Section or another. This meant that every member of the IRE in the United States would automatically be on the membership list of a Section and would receive notices of Section meetings.

Sections in Other Countries

On October 2, 1925, the first Canadian Section was formed in Toronto at a meeting attended by fifty-three IRE members and guests. Now, thirty-six years later, the IRE has a membership in Canada of over 3700 members of all grades. Meanwhile in 1945 the Canadian Council of the IRE had been formed to coordinate the activities of various Canadian Sections on a national basis. This plan formed the basis of the organization that later became effective in the eight IRE Regions of North America.

The first Section of the IRE formally established outside the United States and Canada was the Buenos Aires, Argentina, Section established in 1939.

By the end of 1961, the IRE had 14 Sections in Canada and also 12 Sections outside North America as follows: Benelux, Buenos Aires, Chile, Colombia, Egypt, France, Geneva, India, Israel, Italy, Rio de Janeiro, and Tokyo.

Growth Under Regional Plan

The Sections were tied in more closely with the administration of the IRE in 1946 when the Sections were grouped into eight Regions and each Region was given representation on the IRE Board of Directors, each Regional Director being elected on a biennial basis by the membership of the respective Region. Since then the Regional Plan has provided an effective channel of communication between the Board and the membership of the local Sections. The growth of this important "grass roots" activity has continued unabated so that, at the end of the year 1961, there were 99 Sections and 31 Subsections in the United States and Canada, as well as the twelve Sections in other parts of the world. A list of Sections and their officers appears bimonthly in the PROCEEDINGS OF THE IRE.

TOTAL PAID MEMBERSHIP OF IRE PROFESSIONAL GROUPS

At End of Year	No. of Groups	Total Paid Members
1948	2	
1949	8	
1950	10	8500*
1951	16	13,000*
1952	17	12,482
1953	20	21,797
1954	21	28,158
1955	23	36,562
1956	24	53,015
1961	29	87,060

* Estimated; includes both paid and unpaid members.

PROFESSIONAL GROUP SYSTEM

The most basic change in the structure of the IRE which occurred during its half-century of growth was the establishment in 1948 of the Professional Group System, providing for Groups within IRE along lines of technical specialization of the members. The successful development of the Professional Group System is proving to be an effective means of counteracting the centrifugal tendencies that otherwise might have accompanied the rapid expansion of the Institute.

The first two Professional Groups were authorized by the Board on September 9, 1948. These were Groups known as "Audio," and "Broadcast Engineers."

The subsequent establishment of other Groups has brought the list to 29 at the end of 1961. A list of the Professional Groups appears bimonthly in PROCEEDINGS OF THE IRE.

The procurement of papers for national symposia and management of these symposia are now entirely in the hands of the Professional Groups. The wide scope of activity of the members of the IRE is indicated by the variety of subjects of the Symposia sponsored by the various Professional Groups, either solely or jointly with organizations having related interests. Here are some rather interesting examples:

Joint Automatic Control Conference, Cambridge, Mass., September, 1960
National Symposium on Space Electronics and Telemetry, Washington, D.C., September, 1960
Symposium on Electromagnetics and Fluid Dynamics of Gaseous Plasma, New York, N.Y., April, 1961
Fifth National Symposium on Global Communication, Chicago, Ill., May, 1961
National Symposium on Engineering Writing and Speech, East Lansing, Mich., October, 1961.

Professional Group Chapters

There were 303 Professional Group Chapters, organized by Group members in 57 IRE Sections, as of December, 1961. Chapter growth is continuing at a healthy rate. The Chapters are meeting regularly and sponsoring meetings in the fields of interest of their associated Groups.

As of the end of 1961, about one-half of the IRE members had, on the average, joined two Professional Groups, for a total Professional Group membership of 87,060. Over one-third of the Student Members of the IRE, numbering nearly 7400, had, by the end of 1961, joined one of the Groups covering their particular field of interest.

The comment was once made by John V. L. Hogan, one of the Founders and past Presidents of IRE, that "the Institute of Radio Engineers can well be considered to be the federal body which unites an increasing number of autonomous professional groups."

"Affiliate" Plan

In January, 1957, the Board took a step which bids fair to be a notable one in IRE history. Based on a need which had developed especially in the case of the Professional Group on Medical Electronics, it adopted a plan which enables non-IRE members whose main professional interests lie outside the sphere of IRE activities to become affiliated with certain of the IRE Professional Groups in whose activities they wish to share without having to join the IRE. To be such an "Affiliate" of a Group a person must belong to an accredited organization approved by that Group and by the IRE Executive Committee. Participation in the Affiliate Plan is at the option of each Professional Group. On payment of the regular assessment fee of his Group, plus $4.50, the Affiliate is entitled to receive the TRANSACTIONS of the Group. The Affiliate Plan is intended to recognize and provide for the rapidly spreading influence of electronics in every walk of scientific and technological life, and to enable the IRE further to fulfill its aim—that of advancing radio engineering and related fields of engineering and science.

PUBLICATIONS

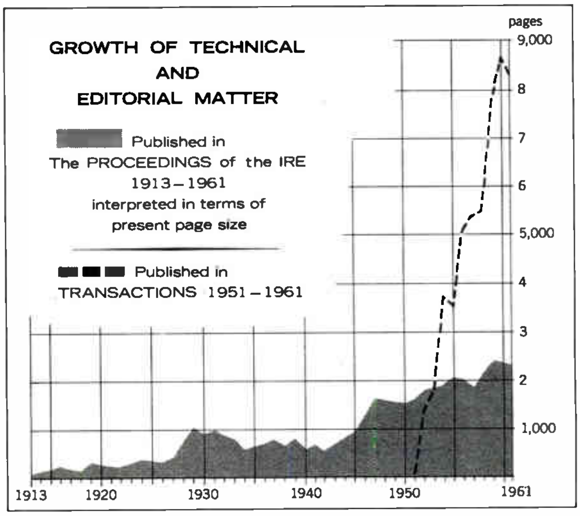
Proceedings of the IRE

In meeting the IRE objective of promoting the exchange of radio engineering knowledge, its publication program is perhaps the most important single activity of the Institute.

The PROCEEDINGS OF THE INSTITUTE OF RADIO ENGINEERS was established originally as a quarterly publication in 1913. An amendment to the IRE Constitution, effective in 1916, authorized the publication of six issues of the PROCEEDINGS per year instead of four. Beginning in 1927, the PROCEEDINGS has been published monthly. In 1939 the name of the journal was shortened to PROCEEDINGS OF THE IRE.

The first Editor was Alfred N. Goldsmith, one of the three Founders of the IRE. It is under the stimulus of his inspired leadership that, through the ensuing years, the IRE has turned out a publication which has been generally recognized as the leading technical magazine in the radio field.

At the outset, the contents of the PROCEEDINGS consisted of certain papers and discussions



as presented at meetings in New York and other cities. During the year 1913, thirteen technical papers were published and a total of 268 pages were occupied, an average of 67 pages per issue, size 6½ by 9 inches. The scope of the PROCEEDINGS was soon broadened to include more technical papers, and also lists of newly elected members, personal notes, reports of meetings and committees, and other information pertaining to the Institute.

To accomplish a balanced publication program, the IRE must supplement the contributed papers by invited papers, either to fill gaps in the coverage of new technical developments or to present a general review of a given field in a way which is helpful to a reader who is not a specialist in that field.

Beginning in 1951, there have been published, from time to time, numerous unusually large issues of the PROCEEDINGS, each devoted exclusively to a single subject. The first of these was the October, 1951, Color Television Issue. This issue consisted of 400 pages and was the largest single issue of the PROCEEDINGS ever published up to that time.

The expanding field dealt with in these special issues during the past few years is indicated by the following illustrative titles:

Radio Astronomy Issue, January, 1958
Transistor Issue, June, 1958
Ionosphere-IGY Issue, February, 1959
Government Research Issue, May, 1959
Infrared Issue, September, 1959

Bio-Medical Issue, November, 1959
Space Electronics Issue, April, 1960
Computer Issue (Second), January, 1961
Plasma Issue, December, 1961

As of January 1, 1954, Dr. Goldsmith was relieved of active editorial responsibilities and "in recognition of the invaluable service he has rendered the Institute and his monumental contributions to the growth and high standards of its publications" was appointed Editor Emeritus. Since January 1, 1954, five other person have successively served as Editor. Previously, however, the Institute had established the position of Managing Editor which is filled by a full-time employee of the Institute.

The drop in the membership of the Institute during the depression of the early 1930's led the Board of Directors to search for additional ways by which the members could reap value from the various services of the Institute. An immediate step was the expansion of the "Institute Notes" section of the PROCEEDINGS. This was so well appreciated that since then, from time to time, additional features have been added or the material published has been recognized. As a result, the PROCEEDINGS OF THE IRE now carries, in addition to its main body of technical papers, more than a dozen regular features and "Departments," most of them monthly.

Transactions of Professional Groups

The first major broadening of the IRE publication program was the appearance of the TRANSACTIONS issued by the Professional Groups. They immediately proved to serve a very useful purpose as a quick, practical method of providing Professional Group members with technical papers in their particular fields of interest. As early as 1951, six issues of such TRANSACTIONS were issued by the Audio Group and two issues of TRANSACTIONS by the Airborne Electronics Group.

The growth of the Professional Group TRANSACTIONS is indicated by the fact that in 1961, 102 issues of TRANSACTIONS were published by 28 Professional Groups containing a total of over 1200 papers. The TRANSACTIONS have circulations ranging from 1500 to 11,000 per issue. Publication varies with the Group, from one to six issues per year. Over-all distribution is about 360,000 annually. The total annual TRANSACTIONS output now exceeds that published in the PROCEEDINGS.

Convention Record

The papers that were presented at the National Conventions of the IRE in New York from 1953 to 1961, inclusive, have been published as Volumes I to IX, respectively, of what is now known as the IRE INTERNATIONAL CONVENTION RECORD.

From 1957 to 1960 the IRE also published the papers presented at the Western Electronics Show and Convention in an annual volume called the IRE WESCON CONVENTION RECORD.

Student Quarterly

In September, 1954, a new publication of the IRE was launched. It was the IRE STUDENT QUARTERLY which is sent free to all Student Members of the IRE as part of a program of increased service to students. It contains news of Student Branches, articles of technical value, and papers of significance to students who are interested in considering carefully whether to devote themselves to an engineering career.

The IRE STUDENT QUARTERLY is now in its eighth year of publication and now ranks second in circulation of IRE's 31 periodicals. The articles which it contains are so worthwhile and so readable that it is the subject of an increasing circulation on a subscription basis among other than Student Members.

Indexes to IRE Publications

With the increasing quantity of material published by the Institute, and in view of the widening areas of subject matter dealt with, it became apparent that a general cumulative index should be prepared and made available to all subscribers to the PROCEEDINGS. Several such indexes have been compiled from time to time. The four indexes which now cover this material are:

Cumulative Index, 1913–1942 (Part II of PROCEEDINGS, June, 1943)
Cumulative Index, 1943–1947 (Part II of PROCEEDINGS, June, 1948)
Cumulative Index of IRE Publications, 1948–1953

Cumulative Index of IRE Publications, 1954–1958

This latter index, printed as a separate pamphlet, includes references to the PROCEEDINGS OF THE IRE, the IRE TRANSACTIONS, the IRE INTERNATIONAL CONVENTION RECORD, the IRE WESCON RECORD and the STUDENT QUARTERLY.

Year Book and Directory

The first published list of IRE members, dated January 1, 1913, was a 24-page pamphlet, size 3½ by 6 inches, listing 100 persons. The names of 9 of these persons still appear in the current list of IRE members—the 1962 DIRECTORY. Five of these ten were Charter Members of the Institute.

The first YEAR BOOK, published in 1914, was followed by 13 others which were not always issued annually, through 1949. In the earlier years, the Report of the Committee on Standardization was included. With the 1950 edition, the name was changed to DIRECTORY. Now published annually in November, it is sent to all members except Students. It contains alphabetical and geographical listings of all members except Students, classified listings of products, and an alphabetical list of commercial organizations. The separate listing of those who hold the Fellow grade of membership, with a biographical sketch of each, was begun in 1946.

Publication Growth

The IRE, in the first volume of the PROCEEDINGS in 1913, published 13 technical papers. In 1950, still in one journal, it published about 200 papers and letters. In 1961, in 31 publications, it published about 2000 papers, letters and other significant items.

Through 1961, in total, about 7500 technical papers, letters to the Editor, and book reviews have been published in PROCEEDINGS.

The growth in the total publication output of the IRE is shown by the contrast between the total size of the PROCEEDINGS and the YEAR BOOK published in 1914 and the size of the total of IRE publications in 1961. The PROCEEDINGS in 1914 had a volume that, if printed on pages of the size now utilized, would be 124 pages; the 1914 YEAR BOOK, if measured in pages the same size as those of recent YEAR BOOKS would be a total of 12 pages, making a total publication volume of 136 pages. The 1961 editorial output of the IRE consisted of 131 issues of publications, amounting to a total of 16,922 pages.

IRE Publications in 1961	Pages
PROCEEDINGS OF THE IRE	4,304
CONVENTION RECORD (in 10 parts)	2,164
TRANSACTIONS of Professional Groups	8,336
DIRECTORY	1,612
STUDENT QUARTERLY	224
Miscellaneous Technical Publications	282
Total	16,922

AWARDS

The Institute of Radio Engineers, from the beginning, has gone to some lengths to show honors to those among its membership who have made accomplishments of outstanding value to the development of the radio engineering field. Such honors are shown by the Board of Directors in granting awards. In addition, the granting of special honors for individual accomplishments, by the action of Sections, Professional Groups, and Student Branches has been authorized by the Board from time to time.

The IRE now bestows seven formal awards, six of which are awarded annually in recognition of outstanding technical and administrative achievements in the field of radio communication. The names of the 138 persons who have received these formal awards through the year 1961 are given in the 1962 IRE DIRECTORY.

Medal of Honor

The Medal of Honor is given annually in recognition of outstanding scientific or engineering achievements in the field of activity of the IRE. This medal was first given in 1917 and has been given annually since that year, with the exception of the years 1918, 1925, and 1947 in which no award was made.

Founders Award

The Founders Award is bestowed only in special occasions for outstanding leadership in planning and administration of important technical developments. The award commemorates the three radio pioneers who founded the Institute of Radio Engineers in 1912—Alfred N. Goldsmith, John V. L. Hogan, and Robert H. Marriott. This award has so far been made to six persons—David Sarnoff in 1953, Alfred N. Goldsmith in 1954, Raymond A. Heising in 1957, W. R. G. Baker in 1958, Haraden Pratt in 1960, and Ralph Bown in 1961.

Prize Award by Vladimir K. Zworykin

The Prize Award by Vladimir K. Zworykin was first awarded in 1952 and is to be awarded annually for 20 times to the member of the IRE who makes the most important technical contribution to electronic television during the preceding three calendar years or the importance of whose contribution to electronic television shall have been realized during this period. The award consists of a citation and a check for $500 drawn from a fund of $10,000 donated to the Institute by Vladimir K. Zworykin to encourage outstanding technical developments in fully electronic television.

Memorial Prize Award in Memory of Morris N. Liebmann

The Memorial Prize Award in Memory of Morris N. Liebmann has been given annually beginning in 1919. This award was originally based on a fund made available to the Institute for this purpose by E. J. Simon to preserve the memory of Colonel Morris N. Liebmann, a member of the Institute who gave his life in the first World War. The award now consists of a certificate and a check for $1000 given to a member of the Institute who has made an important contribution to the radio art.

Memorial Prize Award in Memory of Browder J. Thompson

The Memorial Prize Award in Memory of Browder J. Thompson, established in 1945, is given annually to the author or joint authors under 30 years of age for a paper of sound merit recently published in one of the technical publications of the IRE, which has been selected as constituting the best combination of technical contribution to radio and electronics and presentation of the subject.

The award comprises the income from a fund established by voluntary contributions to preserve the memory of Browder J. Thompson, a Director of the Institute who was killed in action in World War II while on a special mission for the Secretary of War.

Memorial Prize Award in Memory of Harry Diamond

The Memorial Prize Award in Memory of Harry Diamond, established in 1949, is given annually to a person or persons in Government service for outstanding contributions in the field of radio or electronics, as evidenced by publication in professional society journals such as the PROCEEDINGS OF THE IRE, or journals of similar standing. The award consists of a certificate provided for from proceeds of a fund established by friends who felt that the professional life of Harry Diamond, a Fellow of the Institute, exemplified the highest type of scientific effort in United States Government service.

Prize Award by W. R. G. Baker

The Prize Award by W. R. G. Baker, instituted in 1957, is given annually to the author of the best paper published in the TRANSACTIONS of the IRE Professional Groups. The award consists of a certificate together with a cash award comprising the income from a fund donated to the IRE by the late Dr. W. R. G. Baker, former Chairman of the IRE Professional Groups Committee.

Other Awards

The Editor of the PROCEEDINGS, Alfred N. Goldsmith, was awarded in 1926 an embossed and framed "Memorial to the Secretary of the Institute" in recognition of his service to science and engineering in the upbuilding of the Institute of Radio Engineers.

MEETINGS AND CONVENTIONS

National IRE Meetings

One of the principal purposes of the founders of the IRE and of the charter members was to hold meetings at which radio engineers could exchange information on questions of mutual interest. The first YEAR BOOK of the IRE, published in 1914, stated that "Institute meetings are held in New York monthly excepting in July and August of each year for the presentation and discussion of engineering papers. These papers are presented by members who have specialized in some division of the subject and who desire to lay their results before the profession."

The annual IRE meetings in New York through the year 1925 were considered to be the meetings required by the provisions of the IRE Constitution. After that date the election of officers was accomplished by mailing ballots to the members as specified or permitted by successive amendments of the Constitution without the necessity of holding meetings for election purposes. Beginning in 1926, therefore, the annual meetings were much more in the nature of National Conventions and had emphasis on technical papers rather than on the conduct of the business affairs of the Institute.

An important feature of the National Conventions of the past 15 years, and of some of the Regional Conventions, is the manufacturers' exhibit of equipment that is of interest to radio engineers.

In 1959 the Board of Directors approved a change in the name of the IRE Convention to "IRE International Convention and Radio Engineering Show." The attendance at the 1961 Convention in New York included 997 persons from countries outside the United States. This Convention continues to increase in importance each year and is internationally recognized as one of the largest conventions of its kind in the world.

Engineering Conferences and Symposia

For many years the IRE has cooperated with other scientific and engineering organizations as a joint sponsor, or in a similar capacity, in the conduct of engineering meetings or of extensive technical symposia.

In November, 1919, several technical papers were presented by IRE members at a joint meeting with the American Physical Society in Chicago.

A National Electronics Conference, held in Chicago in 1944, was attended by more than 2200 persons—more than had attended any IRE National Convention up to that time. This was the forerunner of many conferences sponsored jointly with other societies and universities.

The engineering conference or symposium has become one of the major activities of the IRE during the past few years, and the "Calendar of Coming Events" has become a regular feature of the PROCEEDINGS. This Calendar referred to some sixty such meetings during the year 1961.

COMMITTEES

One of the most effective means for collaboration among members of the IRE has been through the activities of the various IRE committees.

The three Standing Committees of the IRE, as stated in the YEAR BOOK for 1914, were the Papers Committee, Standardization Committee and Publicity Committee. By 1915 another Standing Committee was added—the Finance Committee.

The broadening scope of IRE interests over the years was accompanied by the establishment of additional committees dealing both with technical subjects and with operational matters.

The IRE committee structure now embraces 26 Technical Committees with 130 Subcommittees, along with 11 other Committees dealing largely with management and operational aspects of the Institute. A complete list of all Committees of the Institute and of their members is published semiannually in the issues of the PROCEEDINGS for June and October.

The effectiveness of the IRE throughout the fifty years of its existence has been due in no small measure to the enthusiastic collaboration of the many hundreds of committee members and to their recognition that there could be no satisfactory substitute for the contributions which this activity makes to the more rapid and effective development of the field of radio engineering.

COOPERATION WITH GOVERNMENTAL BODIES

Technical Aspects of Radio Regulation

The problems of radio regulation are such as to require, for their solution, a thorough consideration of the physical facts as to the behavior of radio waves, the external performance of radio transmitting equipment, and many of the operating characteristics of radio receiving apparatus.

When the Federal Radio Commission was first established by law in 1927, it had no engineering staff, and so it naturally looked to the engineers of industry for assistance on technical matters. This led to new activities of the IRE, those of studying and preparing reports on a series of problems put to it by the Commission and its Acting Chief Engineer.

In a guest editorial in the PROCEEDINGS OF THE IRE, December, 1956, the Chairman of the Federal Communications Commission commended the IRE for its outstanding contributions toward advancement of the art of radio communication and for the whole-hearted cooperation it has always given all agencies of the government concerned with utilization and administration of the radio spectrum.

In 1956, at the request of the FCC, the Television Allocations Study Organization (TASO) was formed by the television industry. Its object was "to develop full, detailed and reliable technical information and engineering principles based thereon, concerning present and potential VHF and UHF television service." The results of a two and one-half year study were described in a series of papers assembled by the IRE Professional Group on Broadcasting and published in a TASO Issue of the PROCEEDINGS in June, 1960.

Joint Technical Advisory Committee (JTAC)

In response to a request from the FCC in 1948 for advice on a number of technical radio problems with which the Commission was concerned, a group of eight distinguished radio engineers were asked to form themselves into the Joint Technical Advisory Committee (JTAC). This joint action was taken in June, 1948, by the Boards of Directors of the IRE and the Radio and Television Manufacturers Association (RTMA). The purpose of JTAC was to consult with Governmental agencies and other professional and industrial groups to determine what technical information was required to ensure the wise use and regulation of radio facilities, and to collect and disseminate such information. This Committee was in certain respects a successor to the Radio Technical Planning Board (RTPB), formed in 1943 with somewhat similar objectives.

JTAC has issued a series of technical reports on questions of public interest on which the FCC has sought information. JTAC has also presented technical testimony at meetings held under FCC auspices.

The series of reports issued by JTAC over the period of 14 years since its formation have dealt with such subjects as FM broadcasting, interference problems in TV, standards of good engineering practice, principles for the allocation of frequencies in the land mobile and other radio communication services, interference from arc welders, use of single sideband, frequency-diversity, space communication, etc.

This committee, under the joint sponsorship of the Electronic Industries Association (EIA) and the IRE, continues to be effective in its studies of the ever-increasing technical complexities of the frequency-allocation problem. In 1961 it formed an Ad Hoc Subcommittee to study the technical problems imposed by satellite relays, including the multiple use of frequency allocations.

COOPERATION WITH OTHER TECHNICAL ORGANIZATIONS

Early Activities

From the beginning, the Board of Directors of the IRE has recognized the close relationships between the field of activity of the Institute and the activities of other scientific and engineering organizations. The IRE has therefore endeavored to keep closely in touch with such organizations, and has appointed representatives to serve on many joint committees.

In 1927 the IRE and AIEE undertook joint sponsorship of the Sectional Committee on Radio under the procedure of the American Engineering Standards Committee (now called the American Standards Association). This Association serves to coordinate the interests of business, governmental and engineering organizations in industrial standardization.

In 1928 the American Engineering Standards Committee invited the IRE to become formally affiliated as a member body of that organization. Several years later, the IRE accepted sole sponsorship of the Sectional Committee on Radio.

National Television System Committee (NTSC)

A notable example of the effectiveness of the IRE in its cooperation with other technical organizations has been in connection with the work of the National Television System Committee (NTSC), formed in 1940 by several industrial organizations, which had a major interest in the sound development of the television field. This Committee presented to the FCC, in response to its request, coordinated recommendations as to the technical standards that should be recognized as the basis for the licensing of television broadcasting stations for both monochrome and color television service.

In recognition of its distinguished contribution to the television industry and to the development of color television, the NTSC received the "Emmy" Award of the Academy of Television Arts and Sciences in 1954.

American Institute of Electrical Engineers

The two professional societies, IRE and AIEE, have many fields of mutual interest. From time to time, the two societies have cooperatively conducted joint ventures, as exemplified by joint student branches, and joint symposia and meetings. In 1960 an AIEE-IRE Joint Standards Committee was formed to approve, jointly in the names of the two societies, such standards as it may consider suitable for joint promulgation and where it is desirable that a single standard be submitted to the ASA.

Effective January 1, 1961, it became possible for a member of one society, based solely on the qualifications submitted to that society for certain grades of membership, to join the other society at an equivalent grade of membership without payment of an entrance fee.

In October, 1961, action was taken by the Board of Directors of the IRE and by the Board of Directors of the AIEE appointing a joint committee to study the feasibility, practicability and form of a possible consolidation of IRE and AIEE. Any such consolidation would be subject to approval by the membership of the two organizations.

Education

As indicated earlier in this paper, the Board of Directors of the Institute, from the beginning, has endeavored to attract members of Student grade. Comprising 19,000 students in 500 schools all over the world, this is now the second largest grade of members in the IRE, accounting for about one-fifth of the total membership.

The Student membership dues have always been nominal. Wherever groups of fifteen or more students are associated, in a given institution, Student Branches may be formed. At the end of 1961 there were 217 such Branches of the IRE, many of them organized in cooperation with the AIEE. Each Student Branch has the benefit of guidance by an IRE Representative who teaches at the institution.

The Institute provides substantial subsidies to the Student Branches in the form of rebates and other aids. Each Student receives the PROCEEDINGS and the STUDENT QUARTERLY and, for the nominal additional fee of one dollar, may join and participate in the activities of a Professional Group of his choice, thus receiving the TRANSACTIONS of that Group. The Special Issues of the PROCEEDINGS are recognized as virtual textbooks on their subjects.

One of the Standing Committees of the IRE is the Education Committee, whose duty is to advise the Board of Directors on the relations of the Institute to electronic engineering education at all levels. The Professional Group on Education provides seminars and publications for the discussion of educational philosophy, problems and methods. Other Professional Groups have arranged special meetings for the benefit of students interested in their subjects. Each Section of the IRE has a Student Coordinator and many Section meetings have been arranged to meet the special desires of students, including high-school students. Each of the 8 IRE Regions has established a Regional Education Committee whose annual meetings are financed by the Institute.

A brochure entitled, "Electronics—Career for the Future," issued as a result of the work and energy of the Cedar Rapids, Iowa, Section of the IRE in 1960, was revised and will soon be reprinted through the cooperation of the EIA and distributed to 28,000 high schools.

The Board of Directors, in April, 1961, accepted an invitation extended by the Engineers' Council for Professional Development to become a participating body of that organization. In this way the IRE can assist in the promotion of scientific and engineering education through guidance and the formulation of criteria. It can also cooperate in the inspection and accreditation of engineering schools.

The 1961 IRE Outstanding Student Award was given to over 100 students who were judged the outstanding young engineers at their respective schools by the IRE Sections in their area. The winners are recognized for their professional competence, scholastic ability and depth of character.

In 1961 a Student Affairs Secretary was added to the headquarters staff of the Institute to coordinate and guide the IRE program of activities and services for its Student membership.

In these and other ways the Institute is endeavoring to encourage high-school graduates who are interested in scientific and engineering fields to learn more about the opportunities and responsibilities of the life of an engineer. Hopefully, this will contribute to an increase in the supply of competent engineering graduates with high ideals for their profession and for service to their community.

International Cooperation

The founders of the IRE recognized that the nature of radio transmission is such that radio waves recognize no national boundaries. They realized, too, that the problems in the radio field and the accomplishments of radio engineers are bound to be of interest to technical radio men throughout the world. It has thus been traditional with the IRE to foster international cooperation in radio, to encourage interest in the IRE, and to promote its services and the spread of its publications as widely as possible in all countries of the world.

As a result of action taken at the International Conference held in Washington, D.C., in 1927, there came into being the International Radio Consultative Committee (CCIR), an organization which, through the participation of representatives from all interested countries, has as its continuing task the preparation of advisory recommendations on technical questions that are involved in the allocation of frequencies to various radio services. Many members of the IRE and its technical committees have cooperated in the work of the CCIR and its Study Groups ever since.

In 1931 the United States National Committee, operating under the International Electrotechnical Commission, asked the IRE to cooperate with it in meeting some of the problems of international standardization of terminology. The IRE was very ready to lend its cooperation in this direction by contributing results of its own work on the standardization of terms and definitions.

In November, 1960, the IRE Board of Directors agreed to establish, together with the EIA, a joint Standards Advisory Committee to work with the US National Committee of the IEC to decide on representation at and participation in international meetings of the IEC.

Cooperation between the IRE and the International Union of Scientific Radio (URSI) has been active since 1926. By IRE representation on the USA National Committee of URSI there is a formal link. On repeated occasions, at International Assemblies and at meetings of the USA National Committee, members of the Institute have presented papers on radio transmission and other technical subjects. The IRE or one of its Professional Groups has also been joint sponsor of most of the meetings of the USA National Committee. The close association of IRE and URSI is emphasized by the publication in one issue of the Proceedings of a special series of reports covering the URSI 12th General Assembly held in Boulder, Colo., in 1957.

In October, 1959, the Board of Directors held its first meeting outside the United States. This was held in Toronto, Canada, in connection with the IRE Canadian Regional Convention and Exposition. The occasion was utilized to give special attention to the IRE position on international science and electronic questions.

The first symposium sponsored by the IRE outside North America was the International Symposium on Data Transmission held at the Delft Institute of Technology, The Netherlands, in September, 1960. It originated through the initiative of the Benelux Section of the IRE.

A number of IRE Professional Groups have taken occasion to recognize international interests or activities in their fields or have participated in meetings held by related international bodies outside North America.

The Board of Directors, in January, 1961, authorized the appointment of an Ad Hoc Committee on IRE International Activities Outside of Existing Regions. The five members of the Committee were all Fellows of the IRE; they were from three countries, and three of them were Past Presidents of IRE. In the early summer of 1961 they visited nine countries in Europe to explore with officials of major societies and leading engineers how IRE might better serve the professional interests of its many members who reside outside North America.

Constitution

The Constitution adopted by the original members of the Institute at a meeting on May 13, 1912, was a fairly simple document. It stated the objectives of the Institute and recognized three grades of membership—Honorary Members, Members, and Associates. The business affairs of the Institute were to be handled by a Board of Direction of nine persons, consisting of four Managers, President, Vice-President, Secretary, and Treasurer, all of whom were to be elected by the Institute membership, and an Editor of Publications who was to be elected by the other members of the Board.

Several amendments adopted between 1914 and 1946 made certain changes in the membership structure, method of voting, and the composition of the Board, including the provision for regional representation.

By 1946 the offices of Executive Secretary, Technical Secretary, and Technical Editor, as full-time headquarters staff positions, had been created by the Boards and it was clear that some of the details of Institute procedures which had previously been dealt with in the Constitution should more properly be handled by the Board of Directors itself or by members of the staff to whom the Board would give authorization. Constitutional amendments in 1946 and 1947 recognized these principles and thus added other powers to the Board and to the administrative officers of the Institute, effective August 15, 1947.

A constitutional amendment was adopted in 1959 in order to conform with certain changes in legal requirements. This amendment also facilitated operational activities of the Institute by stating the fundamental broad principles of IRE purpose and program, and putting responsibility for establishing Bylaws and for carrying out details of procedure in the hands of the Directors elected by the membership. This amendment also permitted the election of more than one Vice-President, in recognition of the need on the part of the President of the Institute for assistance in representing the IRE in its many public relations and government contacts.

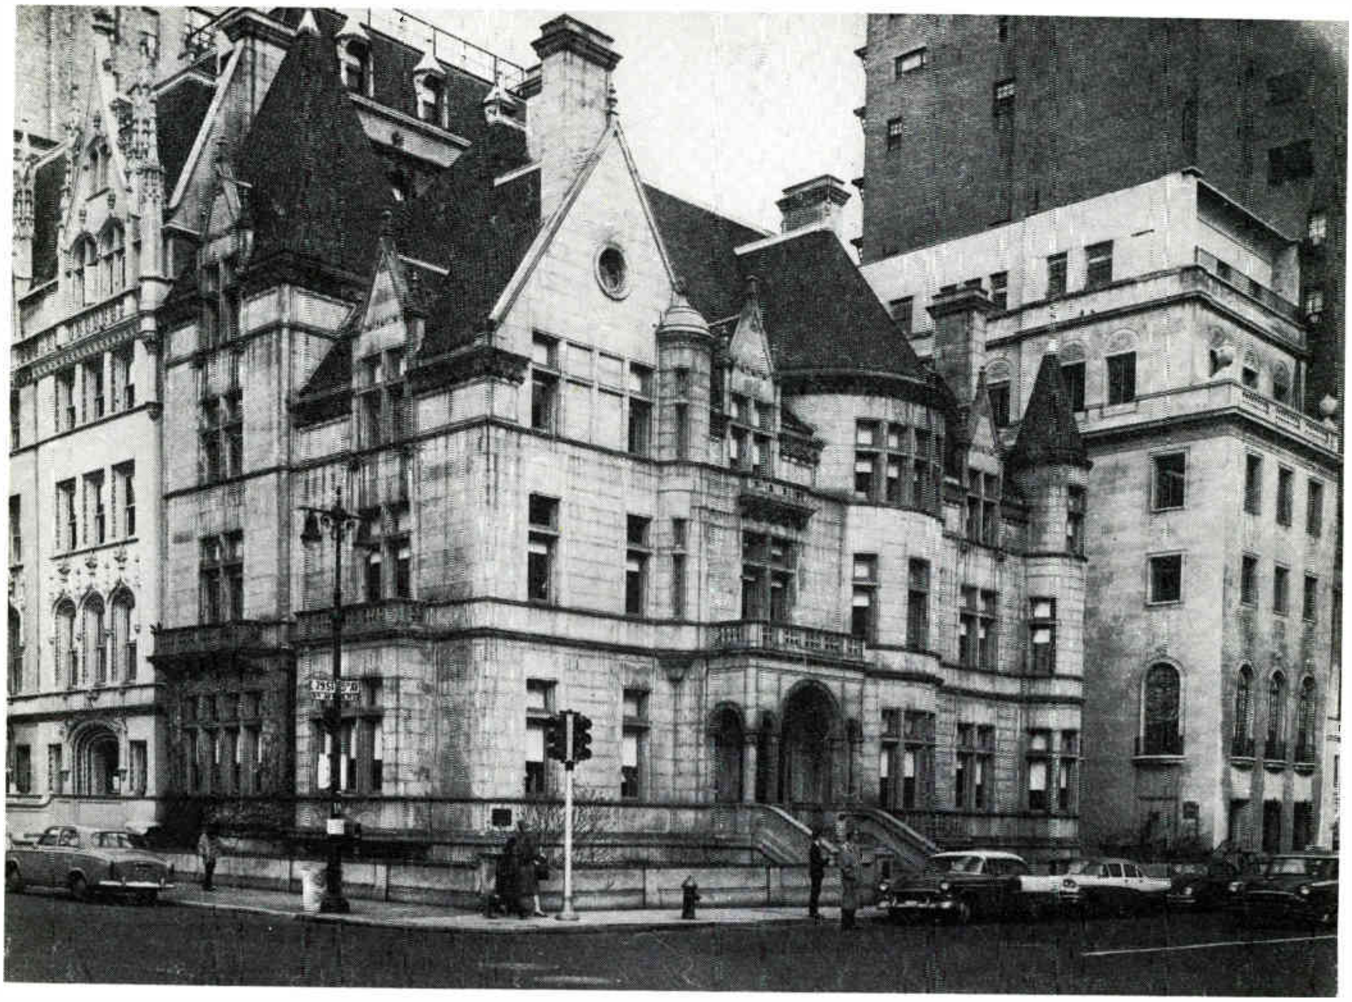
Office Locations

The first meeting of members of the Institute of Radio Engineers was held in Fayerweather Hall at Columbia University, New York. For several years most of the meetings for the presentation of papers were held at that location.

The IRE had no headquarters staff office for a number of years. Some business was conducted at an office used by the 1913–1914 Treasurer, John Hays Hammond, Jr., located at 71 Broadway, New York. A year or two later the IRE moved "uptown" to 111 Broadway in the shadow of Trinity Church. Subsequently, for about six years beginning in 1918, the business affairs of the IRE were conducted from the office of Alfred N. Goldsmith, who served both as Secretary and Editor, located at the College of the City of New York.

In the spring of 1924 the Board of Directors felt that the IRE could afford to rent an office and employ a full-time clerk. A small suite of rooms was leased at 37 West 39th Street, closely adjacent to the Engineering Societies Building in which the monthly meetings for the presentation of technical papers were then being held.

Thereafter, in order to meet the expanding requirements of the headquarters staff which was continually being enlarged to serve the publication, membership and other needs of the Institute, a succession of moves to various office locations took place. By 1946 it had been found practicable to obtain a suitable building at 1 East 79th Street (corner of Fifth Avenue) in New York City. This space was later supplemented by the purchase of the two adjoining buildings, one on 79th Street, and the other on Fifth Avenue, the latter being occupied in 1961. This Headquarters office thus serves as a base for the production of the publications of the IRE and for the cooperation of the IRE staff with Sec-



The IRE owns and fully occupies three mansions on the corner of Fifth Avenue and 79 Street in New York City. The corner building, 1 East 79 Street, was purchased in 1946. The building to the right at 5 East 79 Street was acquired in 1954, and the building to the left at 984 Fifth Avenue in 1961.

tions, Professional Groups, and Student Branches, and with other technical bodies with which so many joint meetings and symposia are arranged.

Office Management

During the first few years of the existence of the IRE, the Secretary or the Editor made available for IRE work the part-time services of one of the members of his regular office staff. This, together with the use of the individual services of the Secretary, the Editor, and others, kept the drain on the Institute's treasury at a minimum.

By 1924 the volume of correspondence necessitated by the large increase in the membership and the additional work involved in preparing material for publication in the Proceedings had reached a point where the Board of Directors was beginning to realize that more adequate provisions needed to be made for office space, clerical assistance, and supervisory attention.

This led to a succession of enlargements of the staff, and to the employment of a full-time Assistant Secretary who became Secretary in 1927.

Late in the year 1944, in order to broaden the activities of the IRE, including the expansion of the publication program, the Board of Directors decided to establish three new staff positions—Executive Secretary, Technical Editor, and Technical Secretary. This was a major step in recognizing the fact that the supervision and operation of the administration of the activities of the IRE could no longer be a part-time job for individual members of the Board of Directors. The Executive Secretary, whose services the Institute was fortunate enough to obtain, was George W. Bailey, who had had some years of administrative experience as an officer of the American Radio Relay League and whose ability in administrative service with the Government during World War II had been well demonstrated. To his continuing effective and constructive service the Institute owes a great debt of gratitude.

The administrative activities of the IRE, by the end of 1961, required the services of about 200 people whose work was being directed by the Executive Secretary, Managing Editor, Professional Groups Secretary, Chief Accountant, Assistant to the Executive Secretary, and the Office Manager. The Advertising Department, with its Advertising Manager and Assistant Advertising Manager, is situated elsewhere in New York City.

Advertising

The first advertising appeared in the Proceedings in 1915. During the year 1917, there were 48 pages of advertising published in the Proceedings—an average of eight pages (size 6×9 inches) per month. The Board was apparently somewhat reluctant to include advertising in the 1928 Year Book, but concluded that this should be done in an effort to obtain sufficient revenue from this source to cover the actual cost of printing. That Year Book contained 28 pages of advertising.

The Institute's office handled advertising matters until 1941 when the Board of Directors felt that substantially increased revenue might be obtained if an experienced advertising manager were to handle this part of the Institute's business. Accordingly, a contract was entered into with an advertising manager who provided his own office assistance at an outside location for this task.

Today the advertising carried by the Institute's publications renders a valuable service by bringing information about new products and services before the members of the IRE.

Finances

Throughout the lifetime of the IRE, the Board of Directors has planned and provided services to the membership with meticulous attention to the extent of the available funds. Accordingly, the publication program of the Institute at the outset was very modest—a small magazine published four times a year. The Year Book was small and was not published every year. Expenditures for meeting rooms and for Headquarters staff purposes were kept to a minimum.

The total receipts of the IRE for the year 1913 (including $150.97 carried over from the previous year) amounted to $850.93. This included $50.00 from the former Society of Wireless Telegraph Engineers and also $150.00 which was provided by or through the good offices of the Editor. The amount received in dues was $476.75. After payment of $647.25 for printing the Proceedings, $16.00 for janitor service in connection with meetings held at Fayerweather Hall at Columbia University, and other miscellaneous expenses, the balance at the end of the year 1913 was $24.43.

The report of the Treasurer in the 1916 Year Book referred to the fact that the Institute had "goods friends and loyal members . . . who have donated money and fixtures more than enough to start the new year with a clean slate."

Increasing income from membership dues and from advertising, together with conservative policies on the part of the Directors and careful management on the part of the staff, enabled the Institute to successfully weather the depression of the 1930's.

Over the years, the Institute's business operations have continued to grow. During the year 1961, the total budget of the IRE was slightly under $4,000,000.

Acknowledgment

In the preparation of this review of the activities of the Institute of Radio Engineers over the past 50 years, the author consulted various records which are available in the IRE office. Material which has appeared in past issues of the Proceedings of the IRE has been drawn upon freely. This includes news items about IRE or-

ganization and Section activities, editorials by Institute officials and others, addresses which have been given at Annual Conventions and on other occasions, and several articles of a historical nature which have appeared from time to time. A list of outstanding historical summaries, including a few other papers that relate to special situations in the Institute's history, is given in the Appendix.

Acknowledgment is due also a number of people, Founders, persons who have served as Secretary of the IRE, some of the past Presidents, and several others who were familiar with early activities of the IRE, as well as the members of the IRE History Committee and members of the IRE staff, from whom helpful information and suggestions have been received. The author gives special thanks for the advice received from E. K. Gannett, Managing Editor, for his cooperation in the endeavor to make this review as accurate as possible and for the preparation of charts, tables and illustrations.

Note 1: A very informative summary of current activities of the IRE is given each year in the Annual Report of the Secretary of the Institute. The most recently published Report, that for the year 1960, is to be found in the Proceedings, June, 1961, pp. 1104-1107.

Note 2: There are in existence a number of complete sets of the Proceedings of the IRE, Volumes 1 to 49, inclusive, not only at the Office of the Institute and in the possession of several individual members of the Institute, but available for public reference at several libraries. Among such library reference sets are those at the Library of Congress, the New York City Public Library, and the Engineering Societies Library in New York City.

A "Report of the Secretary" Commentary

HARADEN PRATT
Secretary, IRE

THE NUMBER of IRE members, as the Institute has grown through the years, has directly reflected the degree of activities for the fields of endeavor that it has been serving. Commencing in the year 1912 as the successor of two small societies organized some five years earlier to provide a forum for those engaged in the new form of communication called "wireless telegraphy," its initial membership of forty-six rapidly increased as persons became aware of the new organization and its aims. The advance of what came to be called "radio communication" also being substantial, membership quickly rose to about one thousand within four years. Growth, then, for many years, kept pace with the expansion of this new accomplishment, showing an appreciable bulge when radio broadcasting suddenly came upon the scene during the years 1922 to 1930.

Until about the year 1940, the technology represented by IRE was almost exclusively that of radio-wave propagation through space for the communication of intelligence. Other electrical-engineering applications had not yet felt the need for the concepts and devices that were peculiar to radio communication except for minor uses of electron-tube circuitry for a few industrial purposes. But after 1940 the pressures for improved weapons and the defenses against them suddenly became so formidable that all branches of applied science were marshalled for every possible contribution. By this time, the fundamental issues underlying the phenomena embraced by radio communications became well enough understood so that new developments could be more easily undertaken. Fortuitously, many skilled people and the technical means for tooling their efforts were available at this critical time, and all sorts of applications of military usefulness came along immediately thereafter, radar being an example. As the war progressed it became more and more apparent that the use of the normal instrumentalities of warfare and indeed the planning of campaigns by the great military leaders could not be carried out without the assistance of such radio (or electronic as it came to be called) developments. Thus came about the transition from the former concept, that electrical communication was just a necessary adjunct to military operations, to the realization that all these new applications were not only indispensable to the control of campaigns but were the major items in the evolution of new weapons and tactical means necessary to maintain superiority. This great movement forward was reflected in a doubling of IRE membership by the year 1943 and a tripling by 1947.

We all realize what has occurred since the termination of that war. The myriad of new devices and the means for usefully developing the upward expansion of radio-spectrum utilization that had brought about radically new ways of conducting warfare were now available, together with experienced people informed about these subjects, for peacetime purposes. Helpful too, was the favorable environment created by the need for rehabilitating and restarting industries for the postwar years. The uses to which these new technical means could be put now started to permeate almost all applications of electricity and some others that formerly were not so served. It is not surprising, therefore, that IRE membership almost doubled every six years between 1943 and 1962.

Still more revealing of this growth and spread throughout almost all walks of life has been the evolution of the IRE Professional Groups system which, after a fourteen-year period of advancement, now embraces twenty-nine Groups, having a total membership of about ninety thousand. The twenty-nine names actually comprise a roster of the diverse specialized subjects and fields requiring the ministrations of this advanced technology. They constitute a testimonial of how the IRE has organized to serve the many trends of varied interest that emerged during those epoch-making years.

Attention must also be directed to the most important IRE function, the publication of technical and editorial material. Its quantity has doubled four times since 1943, an increase of 1600 per cent.

These growth statistics and the pattern of many diverse autonomous subsocieties operating under the common umbrella of IRE on a worldwide basis measure the dimensions of the role of the IRE as a basic and guiding influence. This role has become of significant importance to countless numbers of people. The benefits derived by IRE members are obvious. Numerous as these members are they number but a few compared to the many more that are concerned with the industries, laboratories, educational institutions and users of the end products, with whom IRE members constitute the connecting links to the professional operations of IRE. But still more important is the impact on all peoples inhabiting our world, because this segment of scientific endeavor and accomplishment penetrates almost every field and consequently directly affects the lives of everyone. Reflection on the absolute reliance of national defense upon this technology in this age of missile weapons emphasizes the fundamental character of its influence.

This role of the IRE has become captured by this initial rapid emergence of technical approach that signalizes the advent of a new explosive revolutionary age in human civilization. But this time it is a sweeping movement generated by the astonishing advances that have been made during recent years of a comprehension of the structure and behavior of matter and the understanding of energy fundamentals which, of course, in one way or another, touches every branch of scientific knowledge and engineering experience. The application of these discoveries has caused the bursting forth of new accomplishments, the most spectacular of which, in the public eye, probably is the control of atomic energy.

These events clearly indicate the importance of the IRE in the present structure of material advancement. A great responsibility resides with IRE members. They will, individually and collectively, make certain that the IRE role in these most important basic operations is amply executed. To accomplish this they will ensure the continuation of adequate technical leadership, the dissemination of knowledge, the fostering of improved educational processes at all levels, the inclusion of all qualified persons on the membership rolls, the promotion of further serious programs of cooperation with other fields (of which bio-medical electronics is an outstanding example), and other pertinent activities; otherwise mankind will be denied the rapid acquisition of many valuable benefits. The future role of the IRE will be an enlarged one and, as these influences affecting man's affairs continue to expand, more fields of effort and additional numbers of technically-qualified people will seek to participate in the rewards of membership and join the ranks of those that make up the cast on this world stage of accomplishment.

The Management of IRE

George W. Bailey
Executive Secretary, IRE

THE GOVERNING body of IRE has always been the Board of Directors. For years, the Board has confined its deliberations to matters of policy, leaving to an Executive Committee of nine Directors the responsibility of carrying out these policies. The Executive Committee is composed of the President, the two Vice Presidents, the two Past Presidents, the Secretary, the Treasurer, the Editor and one Director, thus insuring experience and continuity in its operations. The Executive Committee has employed an Executive Secretary and, according to the Bylaws, has fixed his tenure of office and determined his salary. The day-to-day problems of management have been left to the Executive Secretary, including the selection of his Staff.

The present Executive Secretary came to the IRE in January, 1945. He has been given freedom of operation under the policies established by the Board and the interpretation of those policies by the Executive Committee. He has selected a Staff of five experts in their lines. They have been encouraged to run their own departments, referring only major problems to the Executive Secretary. In turn, the Staff members have selected competent assistants and supervisors who have become specialists in their assigned tasks.

He inherited William C. Copp & Associates, advertising specialists, which has proven to be an invaluable legacy. Also, Will has functioned as Show Manager, under the supervision of the Executive Secretary, who is Chairman of the International Convention Committee. In order of seniority, Will and his Assistant, Lillian Petranek, outdate us all, having served the IRE for twenty years.

E. K. (Woody) Gannett became Assistant to the Executive Secretary in August 1946, and, in 1954, the Managing Editor. That year, PROCEEDINGS carried 1884 pages. Last year, that number had increased to 2234 pages. In addition, he has been assigned the broad general supervision of the publications of 29 Professional Groups amounting to 8336 pages last year.

L. G. (Larry) Cumming became Technical Secretary in 1946. In 1960, his title was changed to Professional Groups Secretary. He was first concerned with the administrative duties of 25 Technical Committees and comparatively few meetings in New York and in the field. Today, to his duties have been added the coordination of 29 Professional Groups, besides attendance at innumerable meetings throughout the country.

In July 1947, Emily Sirjane joined the IRE as a secretary. In February, 1948, she was appointed Office Manager. She has solved the problem of office service to a membership which has increased sevenfold. The office is now equipped with the most modern machinery. Microfilm and computer machinery are being installed, capable of handling double our present membership.

John B. Buckley became Chief Accountant in 1948, when the total expense of operation for the year was half a million dollars, compared to last year's four million dollars. He is installing an Electronic Data Processing System heretofore available only to banks. The adoption of this system will make possible fast and accurate handling of accounts far in excess of a greatly expanded membership.

In June 1960, Joan Kearney became Assistant to the Executive Secretary. Among her duties is that of Recording Secretary at the meetings of the Board of Directors and Executive Committee.

In September 1961, W. Reed Crone was appointed Student Affairs Secretary, reporting to the Managing Editor. His duties include visiting Student Branches and assisting in the publication of the STUDENT QUARTERLY.

Thus, three of the Staff have served for fifteen years and one for fourteen. The IRE Ten Year Club now has 32 members, of whom 12 have served for fifteen or more years. This continuity of service to the members of the IRE has had a great deal to do with the smooth operation of Headquarters throughout the period that, since 1946, has seen the membership grow from 13,000 to 96,000 members, and the Headquarters force from 32 to 220.

The accommodations for Headquarters have grown from a few small rooms downtown to three buildings on the Northeast corner of Fifth Avenue and Seventy-Ninth Street. These buildings were residences owned by the Irving Brokaw family, and were among the finest in the city. All three buildings were bought for cash from donated funds and accumulated earnings, and are owned free and clear. Meanwhile, the progress of the City of New York has continued northward, and the IRE property has quadrupled in value. The first floor in No. 1 and the first two floors in No. 5 East Seventy-Ninth Street have been maintained in the style of the Gay Nineties, when they were built, and large and small rooms have been provided for member Committee meetings. The three buildings provide 45,000 square feet of office space. Two and a half floors are available for expansion.

Emphasis has been put on the duties of the paid Staff in the operation of the IRE. Equally important are the thousands of IRE members who serve voluntarily as Officers, Directors, Committee Members, Section and Professional Group Officers, and Faculty Representatives. The time and effort which they contribute to the activities of the IRE have made it the largest professional engineering society in the world.

IRE—The First 50 Years

L. V. Berkner

President, IRE, in the 49th Year

As WE COMPLETE the forty-ninth year of the Institute and enter into our Golden Anniversary Year of 1962, we notice that the membership of the Institute is rising by about 1000 per month. This is a most unusual situation for a professional society. Therefore, some critical analyses of the forces underlying the extraordinary growth and development of our profession seems warranted. Indeed no other area of engineering interest has ever enjoyed or been faced with a more rapid expansion.

While it is difficult to visualize our situation exactly in the flow of history for want of time perspective, we must recognize that man has just crossed the threshold of a quite new technological revolution whose momentum is beginning to gain at a striking rate. This revolution in technology is not a mere extension of the old industrial revolution, but rather an entirely new social phenomenon of a quite new order of power. Its beginning can be dated from the end of World War II or perhaps better, the mid-twentieth century.

Looking back a decade we now begin to perceive the origin of the forces that are producing this new revolution in technology. At the turn of the century our engineering strength rested primarily upon an empirical base. It was the technology that had been developed over the centuries through the experience of the Babylonians, Egyptions, Greeks and Romans—a technology that had been mathematized by the mechanics and physics of Galileo, Kepler and Newton; the molecular science of Boyle, Dalton, Priestley and Lavoisier; the thermodynamics of Mayer and Helmholtz; the electro-magnetic science of Franklin, Faraday, Henry, Maxwell and Hertz, and all their contemporaries and successors. Yet 50 years ago, with all its elaboration of the physical basis of our environment, science had not yet the insight into the fundamental processes of nature required to produce a really virile and penetrating technology. The great discoveries of mechanics, thermodynamics, chemistry, electricity and radio of the nineteenth century simply put into scientific order the more obvious features of man's environment—features with which he had dealt in one way or another since the beginning. Perhaps the outstanding exception of the nineteenth century was the development of radio—a phenomenon imperceptible to man's senses and derived purely from theoretical constructs. Thus radio was the forerunner of what was to come.

The twentieth century has seen the creation of a radically new and more penetrating science that has superseded our nineteenth-century physics. This new science now gives us the power to derive a radically new technology in almost every area of human endeavor. Even before the turn of the century, men like Michelson and Planck were raising serious questions about the classical physics. The discoveries of Becquerel and Roentgen produced consequences difficult of interpretation.

Then in 1905 came Einstein's elaboration of the relativistic mechanics and the interchangeability of mass and energy. Simultaneously came the formulation of the quantum ideas from thermodynamic and from photoelectric phenomena which showed energy to be divided into discrete packages. The nucleus of Rutherford and the atom of Bohr laid the basis for a clear understanding of atomic and nuclear phenomena. Soon we were to learn the limits of cause and effect in phenomena of atomic scale with Heisenberg's formulation of the principle of uncertainty. Einstein generalized relativity to include relatively accelerating masses which defined the place of gravity in field theory. With Davisson's discovery of the diffraction of electrons, deBroglie in 1926 formulated the wave mechanics, which was elaborated by Schroedinger and Dirac. Chadwick in 1932 discovered the neutron to complete our catalog of stable nuclear components, so the isotopes of the periodic table came in clear perspective. In 1938 Hahn and Strassmann discovered atomic fission and with it experimental interchange of mass and energy. In 1948 Shannon elaborated information theory and gave us the logical basis for data systems whereby abstruse theoretical ideas yielded to quick solution by means of electronic aids and could be made readily accessible to the engineer on a daily basis.

Thus in a period of some 43 years the whole content of physics has changed. We now think of matter in terms of Fermi-statistics and of space in terms of Bose-statistics defining the fields that permeate it. Our old physics has been absorbed as special and limited situations in a far more profound insight into natural processes.

And so at the midcentury we find emerging an altogether new technology that is founded on powerful theoretical grounds. This is a technology based on deep insight into nature. It is a technology with far greater power and efficiency than its predecessor. Therefore, since the midcentury, we witness the old technology of the ages fall step by step before the onslaught of the powerful new theoretical ideas. Certainly the new means of data handling foretell revolutionary processes in industrial organization, both nationally and world-wide. This new technology affects not merely communication and electronics, but bids to replace our sources of power with more efficient generation processes and our source of materials with radically new combinations of nature's elements in far more useful forms. In this new technology the whole concept of structure is destined to evolve with extraordinary rapidity in the decades ahead.

As a consequence, this technology has profound implications in engineering education. The access to this new and abstruse technology can be gained only by men with scholarly training and with dedication to deep study and grasp of nature's processes. We find suddenly an altogether new order of demand for men of the doctor's level of training and beyond to manipulate this comprehension of nature for our technological welfare. The traditional forms of engineering are bewildered and confused by the disappearance of time-honored procedures before the avalanche of new ideas with a new order of efficiency, function and flexibility.

These, I believe, are the fundamental forces that are creating this extraordinary progress of our Institute. Their recent origin is illustrated by our rapid growth in membership from a mere 11,000 in 1945 to nearly 100,000 today. The leaders of our Institute have recognized from the beginning the fundamental issues underlying the revolution in technology and have worked to mold our Institute to meet the challenge through the development of a variety of professional measures. No other engineering organization has yet recognized this radical change in the direction of technology as fully as has the IRE. So IRE has worked indefatigably to command the ideas of the new science and to mold them into the engineering of the future.

Thus, through the wisdom of our leaders, our Institute has found its place in the new technology. It has been at the right place at the right time and with the right ideas. It has led and not followed the parade. This is why, on the occasion of our Golden Anniversary, we find the Institute of Radio Engineers the largest and most virile of the professional technical societies.

IRE—The Decades Ahead

P. E. Haggerty
President, IRE, in the 50th Year

The IRE of a few decades hence will be a great deal more complex society than it now is. It will be more complex because the profession it serves will be more complex. The incredibly rapid rate at which knowledge has been increasing in those aspects of science and engineering fundamental to our profession and the matching complexity of the tasks we already know we must face insure that individual scientists and engineers will continue to specialize to an extent limited only by their ability to add to, comprehend and apply their individual specialties.

Most of us who are members of the IRE spend our lives in applied science and engineering. As such, our individual accomplishments can be measured only in terms of the specific products and services contributed to the larger community of which we are all a part.

It seems to me that the principal measure of IRE's success in future decades will be how well it succeeds through its organization, its publications and its technical meetings in tying together this increasingly larger, diverse family of specialists, one with another, as well as with the technical generalists so that our complex profession will contribute products and services at a high level of effectiveness.

Certainly IRE's professional group system provides a flexibility and a viability which if properly nurtured can furnish a vehicle for every proper specialty with the assurance that through the sectional, regional and international organization of IRE, all can be one organic whole. IRE, more than any other professional society, has a unique opportunity to provide the essential interdisciplinary hooks we must have if the applied science and engineering of the second half of the twentieth century are to meet the technical challenges we see ahead. IRE is already a society, not just of radio, electronic and electrical engineers, but of physicists, physical chemists, metallurgists, mathematicians, and a dozen other disciplines as well. Molecular electronics, for example, demands the closest possible relationships among physicists, physical chemists, device engineers, mechanization engineers, process engineers, and circuit engineers. The now barely but clearly identifiable beginning of the intrusion of much these same disciplines into and blending with the life sciences promises even more exciting, but also more complex, relationships and accomplishments.

If from all this complexity useful and important products and services are to proceed at anything like a high rate of effectiveness a strong, unifying force must be present, and a conscious recognition of the need for this unifying force among the members of our profession is fundamental to the present consideration of consolidating IRE and AIEE. If the members of our two societies come to believe that consolidation can strengthen this unifying force, then I feel sure we will begin 1963 as part of a stronger, consolidated society better able to meet the complex needs of our profession in the decades ahead.

Communications and

A Predictive Symposium by Fellows of the IRE

Introduction

A group of Fellows of the Institute of Radio Engineers was invited to undertake the hazardous task of transporting themselves forward in thought some 50 years and then presenting the accomplishments of communications and electronics during the thus scanned era 1962-2012. Within reason, no physical or engineering limits were to be placed on their vision or imagination. The narratives or prophecies resulting from this enterprise are presented in the following assembly of replies from the scientists and engineers participating in this Symposium. It will be interesting for the IRE membership in 2012 to compare these accounts with then existent facts and to decide the measure of foresight of those who came before them.

In each of the following presentations, the name of its author is given. And where the same author has discussed several diverse fields, which discussions appear in different parts of this Symposium, his authorship is accordingly multiply indicated.

An attempt has been made to arrange the contributions according to broad classifications of subject matter, as suggested by the headings which appear in the accompanying contents. The reader is warned, however, that many of the discussions cover a wide range of topics. As a consequence, papers listed under one category may touch upon other categories as well. For further convenience, therefore, a subject index is provided at the end of the Symposium (655). An author index is also included.

In considering the events of 50 years hence, it is interesting to conjecture what percentage of the present IRE membership will witness them. A recent survey[1] of one segment of IRE members indicated that 84 per cent were between 21 and 40 years of age. In view of the anticipated advances in medicine (some of which are outlined in this Symposium), it would appear that the number who survive to 2012 A.D. may be quite substantial.

Whether or not he is so fortunate, each member will find a unique adventure awaiting him in the following pages, from the opening address of the IRE President in 2012 to the closing description of the impact of electronics on our future mode of living.

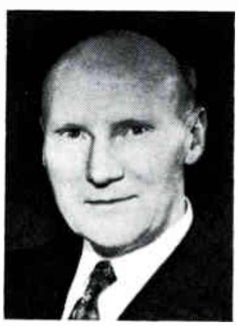
A Realistic Fantasy

Ernst Weber Fellow IRE

(The following are excerpts from an address delivered by the President of the Institute of Radio Engineers before the International Convention in Geneva, 2012 A.D.)



Fellow Members of the IRE:

As we gather in this beautiful city to commemorate the founding of our society one hundred years ago, we are conscious of the imminent return of the space ship "Viking" which left earth on October 21, 2007 on a mission to explore the outer planets of our solar system. This event is particularly significant to us because of the many contributions that were made by members of our society from all over this globe. Permit me to recall some of the significant developments which have preceded the concept and led to the launching of the ship, reminiscing for some and going back into history for other phases. If it should appear to you somewhat rambling—forgive me, but the chain of events, meaningful as it might appear in broad perspective, has, in fact, seemingly incomprehensible sideloops.

I presume there are very few among us—and I certainly am not one of them—who can recall the excitement of the first venture into space, the orbiting of the so-called "Sputnik I" on October 21, 1957. As recorded in history, keen competition had developed between the then two most powerful nations on this globe, Russia and the United States.

Each of these nations had initiated ambitious programs of space conquest—a phrase that has not lost its attractiveness. Each of these nations made firsts in different ways. . . .

Unfortunately, the rapid progress that had been made in the two decades following 1957 could not be exploited. . . .

Shortly after the turn of the century, when sanity had returned once more, the scientists and engineers, represented through their respective National Academies, took the leadership in re-establishing international scientific and technological exchanges. I am proud, indeed, to acknowledge the active participation of our large international membership in bringing together the "World Conference for the Exploration of the Solar System," which actually met in this city. . . .

The principal objective of the conference was the formation of an international committee for the design and launching of a well-instrumented space ship that could travel to the farthermost planet and bring back rather complete data on as many of the outer solar planets as would prove feasible. The resolution of the National Academies required, of course, the concurrence of the political governments and in particular, the permission to pool all the national capabilities into a singular and unique endeavour reminiscent of the so-called "International Geophysical Years" in the last century, yet of unprecedented vaster scope. The only reason that it had seemed propitious to formulate such a daring resolution was the fact that all nations appeared ready to demon-

E. Weber is the President of the Polytechnic Institute of Brooklyn, Brooklyn, N.Y. *(Received June 8, 1961.)*

strate once again the solidarity of the human race in the face of potential annihilation.

Upon acceptance by the various political systems, an "International Commission for Solar System Exploration" was set up with headquarters here in Geneva, the time-honored focus of international organizations. The Commission established national committees, each charged with organizing intensive programs of research and development in the areas in which each felt most capable.

It had been unanimously concluded that the time was ripe to construct a space ship that could accommodate ten scientists—volunteers who would observe, judge and relate the observations, and direct the data collection—and six technicians and auxiliary personnel for all necessary services. Nuclear propulsion had been sufficiently tested to make feasible a design for a power plant to support space travel for several years, completely self-contained and controlled from within the space ship. The launching required a rocket system which transcended existing capabilities by an order of magnitude but one that appeared feasible. The site for the launching platform was debated extensively, but the choice fell upon the astroport of the Sahara because of the major test facilities that had been created there and the existence of a stadium from which all major events could be observed.

To secure life over a maximum period of six years required extrapolation of all the equipment familiar from the latest nuclear submarine experience. Because of unknown intensities of particle and gamma radiation in many regions to be traversed, special shields had to be designed that could be removed for visual observations when anticipatory radiation counters assured absence of danger. Of particular importance were means of detecting asteroids and small meteorites and their paths of travel over large distances in order to avoid collision with the space ship or damage to it that could be calamitous.

A source of tremendous satisfaction to us must be the many contributions which the IRE could render because of its vast and resourceful membership in literally all the nations on this globe. The IRE also has the distinction of having published one of the most competent early collections of articles dealing with "Space Electronics" in its PROCEEDINGS issue of April, 1960, followed by its fiftieth anniversary volume of May, 1962. It is remarkable how most of the then indicated developments have been carried through, making really feasible the achievement of human space exploration. The amazing evolution of Synnoetics as the intermarriage of man's creative mind and the nearly instant execution of the supporting logic processes by adaptive and self correcting computer systems;[1] the functional elements embodied in specific compound crystals of miniature size responsive to stimuli from light, sound, and heat sources; the evaluative integration of detection systems of high redundancy useful for monitoring and warning assignments; and the increased precision of practical time interval measurements to about 10^{-14} seconds; all these achievements have made relatively safe what had been considered a foolish risk. The systems of navigation, telemetry of data, and communications were tied into the global satellite system and the relay station in the moon. Five different frequencies in the broad microwave region were assigned and were protected in an absolute sense by international agreement.

It also was agreed to lay out a course for the entire travel as a guide for navigation, but to leave freedom to the crew to make changes when it appeared advisable. From the positions of the outer planets, starting with Jupiter, the course could cover near approaches to Saturn, Uranus and Neptune, with some doubt about Pluto because of the yet uncertain higher speeds that would be required and might be permissible with greater distances from the Sun. At all times, however, communication on one of the frequencies was imperative to keep the earth stations informed of progress and to relay as many data back to earth as possible, because with all precautions, no guarantee could be had that the space ship would return safely.

The global satellite communication system of the active type, which had suffered . . . was in the process of re-establishment, so that good assurance of reception and, in fact, of two-way communication could be given. Two satellite astronomical observatories were in high orbit around the earth and one was directed to follow the space ship by periodic observation. To assist in the navigation, all positional data from all sources were to be processed and verified both in the space ship and on earth.

The earlier experiences with the simpler designs for the trip around Mars and Venus had taught us that redundancy in mutual communication was a great factor in relieving anxiety on a trip of such isolated existence. Correct positional information also will permit the proper approach for re-entry. . . .

The time table had projected preparations and test procedures to take the better part of five years so that launching was set, as you remember, for October 21, 2007, with the expected return by about July, 2012. Recall our relief when the launching went off without mishap. One had, after all, learned to live with full publicity and in full view of the entire global population through the color television system that is spanning the globe. Every step had been pretested, every conceivable means had been taken to assure reliability, and the result has been, indeed, gratifying. We have never lost contact nor communication with the crew which ventured out into the limitless outer space as the Vikings, more than a thousand years ago, had ventured out into a "limitless" sea. Much of the data has been invaluable, but not all has been processed yet. . . .

There are only 10 hours left until the space ship will descend upon the astroport in the Sahara. I therefore conclude. . . .

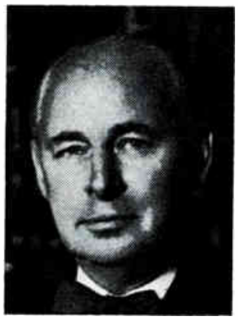
Space—2012

LLOYD V. BERKNER FELLOW IRE

On the occasion of this centenary of the founding of the IRE, the Editors of PROCEEDINGS *thought it of interest to our membership to report the May 13, 2012, meeting of the Lunar Section of the Institute. The following summary lecture delivered to this Section at our great international base near the north pole of the Moon, as reported by a one-time President of the IRE, describes the status of our space activities so adequately that no further introduction seems needed.*



Members of the Lunar Section:

We are happy to welcome this evening the members of the Institute who have so recently arrived from Earth to augment our ranks. On this occasion, our chairman has asked me to describe our extensive electronic facilities. During our discussion, please forgive me if I digress in describing some of the related facilities.

The basic objective of this base is four-fold

a) Our NOPOLUNAR base is one of the two major lunar bases for communication and transportation to the Earth.

b) This base, likewise, is a major starting point for planetary transportation and the terminal of our Martian and Venetian LASER communication and navigation links. Likewise, many very large circumferential spacecraft are equipped from our base for solar and nether-planetary studies to take advantage of our low escape velocity of a mere 2500 meters per second, and the relatively low orbital velocities that simplify transportation from the surface.

c) From this base, most of the maintenance of our eight advanced lunar stations is centered; lunar scientific exploration is directed, and many local expeditions operate from our facilities.

d) We provide operation of the largest astronomical and radio-physical observatory in the solar system.

L. V. Berkner is President, Graduate Research Center of the Southwest, Dallas, Tex., and Chairman, Space Science Board, National Academy of Science. *Received February 26, 1962.)*

It is hardly necessary to remind you that a similar base, SOPOLUNAR, is located near the opposite pole, with which we are in constant communication. These two bases are the primary universal bases for the whole range of man's activities in the solar system. I take this occasion also to welcome the engineers from SOPOLUNAR who have come over to our meeting this evening.

The basic communication and navigation system utilizes coherent radiation in the wavelength ranges of 1800 to 30,000 angstroms which lend themselves to formation of highly focused beams with very light-weight and miniature radiating systems. For example, our main transmitter with an antenna of 2 decimeters diameter can focus the entire radiation of 1-watt peak-power on an area 500 meters in diameter on Earth. This provides very high flux densities at the terrestrial receiver, permitting almost unlimited information transmission of digitalized data at very high speeds. Likewise, our 2-meter antenna with 100-watt peak focuses its entire energy on Mars or Venus with very little loss and permits simple high-speed data links with interplanetary travelers. You will take part in construction of the new Jovian system designed to provide communication, navigation and control, for the expedition to land on the minor satellite of Jupiter next year.

To overcome the line-of-sight problem from our station to the Earth which is not always visible from this location, to communicate easily with other lunar stations and interplanetary spacecraft, and to provide a broad base-line for navigation, we have established two space buoys at the "centers of libration" of Earth and Moon. These are positions of permanent equilibrium in the Earth-Moon gravitational field that provide navigational base lines of 385, 385, and 665-thousand kilometers, respectively. With their stabilized decimeter antennas they also provide excellent low-power, high-capacity relay-links to Earth and to other spacecraft. Operation of coherent radiation links in this way circumvents the cloud problems which limit use of coherent radiation from the Earth, except through use of X band with intervening orbiting relay stations.

I remind you of the present travel arrangements between Earth and Moon. These are entirely controlled by automatic data systems using the high-speed real-time computer of the type that I hold here in my hand. On leaving Earth, via the local connection, you joined the Earth-orbit station, orbiting 800 km above the Earth, in about six hours travel time. This interception was entirely automatic, directed from the Earth, and completed under local control of the Earth-orbit station. There you transferred to the nuclear powered intercelestial spacecraft.

Your travel time to the Moon was 36 hours, representing optimum thrust, where you coupled to the circumlunar orbiter, 50 km above the surface, and then transferred to the local lunar landing craft that brought you to this station. This succession of events has reduced travel costs per kilogram by a factor of 100 over early attempts using direct surface to surface operations.

The historical development of our lunar facilities is one of great trial and tribulation. The basic problem was similar to any frontier operation, of founding the basic facilities. There are abundant local resources of oxides for oxygen and water of crystallization for water; of structural materials and of shielding materials required during occasional solar eruptions; and of chemicals for fertilizing our hydroponic farms and for a wide variety of other applications. To utilize these requires only a vast amount of electric power from our three great thermo-nuclear reactors. The sun gives us light in any spectral range through reflectors and filters of appropriate design. Our large chemical plants operate entirely under electronic control and regulation.

The basic elements of our complex environment were originally transported from Earth to initiate our complicated community. The original settlers faced the most excruciating difficulties, and there was a considerable loss of life among very courageous men. But as facilities were established, our base supplied more and more internal capability, permitting sustenance of more bodies who could develop our basic facilities. Thus our developmental growth has been exponential with time, yielding substantial living stability, especially since opening the base to women at the turn of the 21st century. Our requirements from Earth during the last decade have been primarily for manpower and for our capital development of interplanetary travel and all related to it.

The great advantage of the Moon is its situation as a stable satellite with a weak but perceptible gravitational field, allowing great individual freedom, and without an appreciable atmosphere. This provides unparalleled opportunity for initiation and control of, and communication with, interplanetary activities. Tomorrow you will see the giant astronomical observatory employing the mighty 1500-inch reflector that easily penetrates right around the Universe, and completely resolves galaxies many parsecs away. In the low gravitational field, structural design permits about six times the size for equivalent terrestrial deflections. Without scattering or scintillations, with spectral ranges of several octaves, and with special gamma-ray and x-ray telescopes as well as infrared detectors, the entire useful physical spectrum is always accessible. The data from these instruments are analyzed by advanced electronic techniques. With this new view of the universe our whole physics has been rebuilt in the past ten years—a knowledge whose capital value to man is beyond estimate.

I have just received a Laser report from the party that landed on Mars last month. The climate is a little cooler than Earth, with a good, protective nitrogen atmosphere. They find surprisingly well-developed plant life in extraordinary forms. More interesting is their preliminary finding of some evidence of an ancient civilization, perhaps a billion years ago when free water and oxygen were evidently available in considerable quantities on the planet. Seemingly the present organisms have evolved to use oxygen and water from the rocks, as these basic needs disappeared in free form from the planet. Perhaps in part these plants have become efficient in deriving oxygen and water vapor from the atmosphere where these basic elements are still found in miniscule quantities. I know you all realize that this analysis of a completely foreign biology is adding a new dimension to our biological knowledge, and for the first time the physical forces involved in cell organization, syntheses, and regeneration are coming into focus. Our new electronic methods for biological analyses designed for planetary research are also having a profound effect on terrestrial biological studies in laboratories on the Earth.

I hope you will enjoy your tour as much as have we. The scenery is most unusual and delightful, and there are still many discoveries to be made by the observant and the persistent scientist. Our location near the pole gives us a moderate and easily controlled climate. In constant twilight, the light and heat over the whole site is provided by filtered reflectors erected on the nearby hills.

There are certain precautions that must become habit. Just as you look around on Earth before stepping into the street, you must be equally careful about direct exposure to sun or shade without proper protection. Safe areas are clearly marked. Our warning system advises of approaching solar-particle streams. Be careful about walking too springily or with your Earth-adapted muscles you may bump your heads on the ceiling 30 feet overhead. Please familiarize yourselves with the station adaptation manual which is the synthesis of our 28 years experience. For reasons of natural rhythm, our lunar timetable and calendar corresponds to that on Earth. You will be happy to know that in this lower gravitional field, aging seems to take place at a rate lower than the terrestrial rate. This phenomenon is exciting great interest and much scientific study.

For your entertainment, I have a history of the Institute for the first one hundred years since the founding of IRE. You will be especially amused by the skepticism of our forebears, a few of whom, by the way, are still living, which was expressed at their 50th anniversary in 1962 when lunar operations on today's scale then appeared wholly fantastic.

Space Exploration

J. H. DELLINGER FELLOW IRE

It is hard for us engineers in 1962 to get a clear focus on the truth as it will be in 2012, particularly in respect to space exploration. Just as the earth's atmosphere distorts the focus of a telescopic image, so our space imagining is prone to distortion by the hysterical atmosphere of the present age when every youngster expects to be promised an excursion ticket to Aldebaran.

It being U.S. policy to put a man on the moon in the present decade, and also to start toward Venus and Mars, will there be men on the moon or planets in 2012? It seems quite unlikely that there will then be men in residence on those inhospitable spheres. An occasional visitor to service the scientific and engineering equipment there, yes. But the exploration of the moon by men moving about there will have long since finished. The reason? Painful experience will have shown that fantastically more information is obtainable per dollar of expenditure by means of equipment (observing and telemetering) than by the presence of men.

The moon in particular will be the prized platform for the location of scientific observing equipment. There will be a whole new surge forward in knowledge of the external universe when telescopes and spectroscopes and other sensors and radio equipment are in place and functioning on the moon, free from the obscuring effects (absorption and scintillations) of the earth's atmosphere.

One reason why the surge forward will be of incomparable value and scope is that we shall doubtless be observing all parts of the whole observable universe. The red shift of the radiations from the galaxies, increasing with distance, sets a limit to the distance we can ever observe, and we have already reached out seven-tenths of the way to that limit. The filling in of knowledge about the more remote depths of observable space should put us well on the way to determination of whether the universe had a beginning or is being continuously created (or, perhaps more precisely stated, whether the observable universe had a sudden beginning or exists by a continuous process of the interconversion of matter and radiation).

Another possible and vital consequence of observations ranging throughout the entire observable universe might be the accumulation of data revealing the nature of gravitation. This could permit the formulation of the unified field theory which science has thus far sought in vain. It would be a step in the understanding of the universe comparable with, possibly surpassing, the giant advances of Maxwell's theory of electromagnetic waves and Einstein's theory of relativity.

Ability to receive electromagnetic radiations over the whole spectrum, in contrast to the narrow spectrum ranges receivable through the earth's atmosphere, will hopefully have another grandiose consequence. Probably intelligent beings on the planets of many stars are sending out signals with the idea of contacting life on other worlds. I have even heard them credited with the idea of trying to contact us (of the planet Earth). No, although intelligent, they have never heard of us. We think we know what frequency ranges they would be likely to use. But we could be wrong; and if we probe the entire spectrum we might learn something on the moon that we could not on earth.

There will presumably be vehicles orbiting close to each of several planets, perhaps all of them. They will continuously send us data on many physical parameters of the planets. Possibly there will be instrument stations on Mars and Venus, somewhat like those on the moon.

2012 is not likely to see vehicular exploration of space as far away as the stars. Men are never likely to go out among the stars in space ships. Other creatures, not men, may do that. Radio astronomy will bring us so much knowledge of the universe that we shall have little incentive to travel to the stars even if it were possible.

Finally, space exploration in 2012 will not be so much by vehicles but by the equipment and the analyses of the radio scientist and engineer. One more province of the IRE.

J. H. Dellinger is a retired physicist and radio engineer and was President of the IRE in 1925. His address is 3900 Connecticut Ave., Washington 8, D.C. *(Received June 9, 1961.)*

Education in 2012 for Communication and Electronics

FREDERICK E. TERMAN FELLOW IRE

By the year 2012 the term electrical engineer will have disappeared from college catalogs to be replaced by "electronics," or possibly "electronic science." In today's terminology, education for electronics—née electrical engineering—will be a curriculum in applied science with strong emphasis upon mathematics, classical physics, and chemistry. The technology involved in dealing with wavelengths longer than a centimeter or so, will have become so standardized as to be "handbook stuff." Instead the main emphasis will be on the electronic properties of solids and liquids. The free electron will receive proportionately much less attention than today. Perhaps the most challenging part of the education of the "electronic scientist" of 2012 will be associated with energy at wavelengths extending from millimeters into fractions of millimeters to the infrared, visible, and ultraviolet regions.

The electronic scientists of 2012 will also be concerned with controls and computers, and will deal with systems of almost incredible complexity. The technology of these systems will come from electronics, but the "logic" concepts that will make them approach "thinking machines" by 2012 will have developed into a special discipline of its own.

The basic training for the electronic scientist of 2012 will be a four-year course, as it is today. The amount of knowledge that will be received in such a program will, however, be greatly increased—by a factor of at least 50 per cent—through the use of systems of programmed learning growing out of today's teaching machines. Moreover, through the use of programmed learning in high school, students will enter college far better prepared than today. The over-all result will be that in 2012 the typical recipient of a bachelor's degree will have covered material that would today require at least three postgraduate years of solid course work.

However, in view of the vastly greater number of things that the electronics man of 2012 must know, and the greater complexity of the problems with which he will deal, graduate work will still be almost a necessity for the brighter college graduates. It is safe to assume that over half of those who have obtained a bachelor's degree in electronics will carry their education to one full year of graduate work. At least 20 per cent of those with a bachelor's degree will go on for three to four years of graduate study and obtain the doctorate. Moreover, the most promising recipients of the Ph.D., particularly those interested in careers emphasizing the scientific as against the administrative or practical aspects of electronics, will by 2012 spend from one to three years in postdoctoral study immediately after receiving the doctor's degree. This additional training will correspond to the residency of today's M.D.

By 2012 the number of universities offering first-class graduate work leading to the doctorate will be greatly increased. This will be necessary to take care of the steadily increasing numbers of students attracted to the field of electronics, and the increasing proportion of those who go on for graduate work. In the training of students beyond the master's degree, research will have a prominent part. Much of the doctoral and postdoctoral training of electronic scientists will be in the form of participation in research, since this will continue to be the best way to train a man to learn the secrets of nature without the aid of a teacher.

The electronic industries of 2012 will be thoroughly aware of the advantages of locating their research and advanced development activities near a center of brains, *i.e.*, near a university with a strong graduate program in electronics. As a result each university with a strong graduate program will be surrounded by a complex of industrial activities of a creative type. Creative activities isolated from educational opportunities and the educational environment will be at a serious competitive disadvantage by 2012 and will have great difficulty maintaining themselves. Thus, state and municipal governments will support the development of electronic programs in universities in order to attract and hold electronic industries. This will result in an educational system which by 2012 will have remarkable strength in the field of electronics, characterized by many strong centers widely dispersed.

The college professor will be an important factor in the electronics industry of 2012. He will have high value as a consultant, and the industries clustered around his university will give him ample opportunity to use his talents as an advisor. In many cases his services will be sought as a member of a board of directors, he will be in constant demand by the government to serve on advisory bodies, and he will frequently found new companies and

F. E. Terman is Vice President and Provost of Stanford University, Stanford, Calif. *(Received June 12, 1961.)*

divide his time between being a college professor and a business executive.

In conclusion, it is safe to predict that the subject of electronics will be even more important within the university of 2012 than it is today, that the importance of the leading professors in the field will be greatly enhanced, and that educational institutions with strong graduate programs in electronics will be regarded as great economic plums because of this fact. The distribution of the strong graduate programs will determine the geographical distribution of growth in the ever expanding field of electronics.

Engineering Education—Circa 2012 A.D.

W. L. EVERITT FELLOW IRE

"For I dipt into the future far as human eye could see. . . ."
Tennyson, Locksley Hall

Engineering will be acknowledged as the most learned profession by 2012 A.D. The explosion in the breadth of knowledge needed for its practice will have made preparation for an engineering career both rigorous and extensive. Full professional recognition will be available, except in unusual cases, only to those who have completed formal educational programs in residence at universities, equivalent to or exceeding our present doctorates. However, the time required by a student to reach this goal will vary widely, because educational methods will be adjusted to the capabilities of the individual.

EDUCATION VS TRAINING Engineering curricula in educational institutions will be recognized as having two important and distinct functions which must be carried on concurrently—"training" and "education." Training is defined here as the inculcation of methods of procedure, the development of adequate vocabularies and skill in communication, facility in locating information, expertness in computation and in manipulation of mathematical processes, and similar skills developed through the general procedure of explanation and demonstration, followed by typical exercises with definite solutions or measures of performance. Education, on the other hand, is defined as the broader development of the mind and personality—a guided enlargement of creative ability and understanding. Education develops the ability to meet new situations with confidence and with a degree of wisdom limited only by the inherent capabilities of the individual.

TRAINING METHODS The training portion of engineering curricula will make extensive use of teaching aids, such as teaching machines. However, the teaching machines of the twenty-first century will have a sophistication far beyond that now envisioned. They will serve as tutors which are very responsive to individual needs, so that each student can acquire training at the most rapid rate which he is able, or willing, to absorb. Such teaching machines will present lectures from recorded television tapes in short sequences, with feedback from the student, who will be required to respond with answers to appropriate questions or by working out the solution of illustrative problems. Depending upon the adequacy and insight of these answers, the lecture procedure will be modified to meet the needs of the student. The entire operation will be under the control of computer techniques for the storage and interpretation of information. Testing and examinations of the results of training will also be done by machine.

Every student and practicing engineer will have access to adequate computers and information storage. Moderate capacity computers will be miniaturized and reduced in cost, so that each individual will have his own, as he now has his slide rule. As his needs arise he will also have ready access, through wire or radio communication channels, to computers and memory systems of any required complexity. Training of all engineers in the use of computers will be extensive.

LIBRARIES AND PUBLICATIONS Perhaps the most dramatic changes will come in the "library" of the twenty-first century. The information explosion of the twentieth century will have made necessary the development of entirely new means for the storage and retrieval

---

W. L. Everitt is Dean of Engineering at the University of Illinois, Urbana, Ill. *(Received September 7, 1961.)*

of the material in what we now refer to as "publications." Such publications will be stored in "memories" and elaborate and largely automatic means of classification and identification will make the search for a particular item of information rapid and certain, and its display available at any location. Instruction in how to give directions to the information storage systems to acquire the desired information will be an important and not inconsequential portion of the "training" of the engineer. On the other hand, visual reading of books, current literature, and video displays will be so important that training for rapid reading rates of one thousand or more words per minute will be universal in the grade schools.

EDUCATION But, as in the twentieth century, the important part of the preparation of the engineer will be his "education." Here the personal contact between student and teacher will still be paramount. The comment of Booker T. Washington will be as valid as ever,

"I am convinced that there is no education one can get from books and costly apparatus that is equal to that which can be gotten from contact with great men and women."

Relieved of the necessity of spending most of their time on the training function, devoted teachers will be able to concentrate their efforts on "education." Personal contact with students will be increased, because our society will recognize the importance of this relationship and support it. In spite of the use of teaching aids, the student/teacher ratio will not be increased. Instead, such aids will make it possible for faculty members to devote more time to the development of the individual student. The more efficient methods used will increase the amount of education per student rather than the output in degrees per teacher. However, the student himself will be expected to assume more responsibility for his own educational development than was common in the first half of the twentieth century.

CREATIVITY AND SYNTHESIS Since much of the instruction in analysis can be programmed on teaching machines, the engineer of the future will be given more education for *creativity* and *synthesis*. The case or project method will be emphasized and laboratory work will require originality and the ability to relate theory to the physical world in arrangements novel to the experimenter. "Cook book" experiments will be a thing of the past. Early participation in research projects will be the rule rather than the exception. Many advanced group laboratory experiments will be interdisciplinary in character, so that individuals with different backgrounds may contribute to team solutions of problems more complex than those possible for a single individual. The guidance of such a program will call for teaching ability and insight of the highest order.

Continuing education throughout a career will be normal, accomplished to a large extent by regular sabbatical year exchanges. During such exchanges, industry and government engineers will either return to universities for further study or will exchange positions with colleagues in other organizations. Engineers on faculties will participate, through similar exchanges, in industrial research, government service, or programs of other universities.

FACULTY RESEARCH The primary responsibility of the faculty in engineering education will be to develop creativity in their students, so they must themselves be creative. Noncreativity on the part of a faculty member will be recognized at an early stage and such individuals will be diverted to nonteaching activities within or outside the university. The creative programs of the faculty will provide means for the integration of students at all levels into progressively increasing responsibility in engineering teams.

ENGINEERING CURRICULA The trends in engineering curricula which began in the twentieth century will continue. The early part of all curricula will have more in common, emphasizing basic science, mathematics, and fundamental principles of analysis and synthesis common to all engineering. Only after a student has demonstrated the thorough understanding of mathematical, scientific and economic fundamentals necessary for creativity at twenty-first century levels will he be permitted to continue toward his professional goal as an engineer. The essential unity of engineering as a profession will be recognized. But his advanced program will require that he develop an insight into the methods of solving hard problems. As the student progresses, he will study some individual area more intensively, although the divisions in engineering will not be those now common. By pursuing certain areas in depth, he will learn to solve and contribute to team solutions of difficult and complex problems. Hence, he will need to choose an area of emphasis such as the "Processing of Information," the "Processing of Energy," the "Processing of Materials," or "Biophysical Engineering." Sufficient common material in all these areas and in the principles of "System Synthesis" and "Human Engineering" will provide for communication between the members of engineering groups, but too much breadth of subject matter will not be obtained at the expense of shallowness.

The importance of emphasis on the humanities and social sciences will be recognized from the grade school on through the highest levels of engineering education, as society relies more and more on engineers for leadership in business and affairs of state. Intensive efforts made to develop interpretive programs in these areas will also stimulate more engineers to pursue programs of self education in these fields throughout their careers.

With the continued growth of engineering applications, instruction in manufacturing processes and specific technological areas and skills will be recognized as a training function which industry must assume entirely.

CONCLUSION If these predictions do come to pass, and I feel sure they will, engineering will deserve its designation as a "learned profession."

A Day in the Life of a Student in the Year 2012 A.D.

MAURICE J. PONTE FELLOW IRE

That morning Joe Parkinson woke at seven o'clock; the Song of the "Hypertexas" University was heard in the students' rooms, distributed by the local millimetric wave network. He switched on his luminescent wall panels which reconstituted natural light and, wanting a rural atmosphere, chose the "Park" light combination which turned the panels into a perspective of green leaf and flowers pretty well in their natural colors. The only two panels which remained dark were that reserved for telephone communication and that for college instruction, brought round by television.

Gathering his spirits, Joe realized he had a slight headache and remembered that a new vaccine had been pricked into him the previous day. The diseases of former times, tuberculosis, polio, and even cancer had been suppressed by preventive vaccines which were compulsorily applied, as was shown on his identity card registered with a series of eleven figures and three letters; a mere look at this arithmetical group gave the complete story of the individual, from his blood group to the results of his vaccinations, his diseases and his operations. In the University's central register, a punched card in his name, processed by the specialized computers, was to forecast Joe's behavior in his varying states of health. But from a few months back an unknown virus was playing havoc, especially among young people, in the form of mental troubles which had become the principal plague of Man.

The first symptom was an almost complete loss of memory and the new disease was attended by insensitivity to color. These deficiencies had first been attributed to a system of television reception in which the nerves were directly excited by electrodes connected to the receiver and placed on the temples, at points fixed by the electrical topology of the brain: vision by means of panels had thus been done away with, the optic nerves being brought directly into action. This system had had a considerable application but had finally been prohibited. And so students were subjected to special vaccination and Joe directed a troubled eye on his registration number, to which another group of two figures had been added: now three letters, and thirteen figures. What was the outlook in 50 years' time?

Throwing these dark thoughts to one side, Joe dressed, went to his kitchenette where by pressing the "breakfast" button on his automatic cooker, he received after an interval of 30 seconds a balanced, practically tasteless, but medically perfect meal.

The signals physics course was due to begin at eight o'clock. Joe was one of the nine hundred and fifty students entered for this special course, among so many others, between which the thirty-six thousand students of the Hypertexas University were spread out. The University buildings and grounds extended over a wide area, formerly desert land, so that it had been possible to plan the layout in a completely rational way. Utilization of solar energy and of the natural underground water resources had transformed the area, not only into parkland, but also into cultivated land and breeding farms, scientifically conducted in hot houses at constant temperature and illumination cycles. The Hypertexas students were thus brought up, intellectually and physically, under perfectly definite conditions, in accordance with standards gradually perfected many years back. Many countries were represented at the University.

Joe gave another look at his syllabus. The signal physics course was transmitted over channel 23 of the millimetric network, distributed by dielectric cables to all the students' rooms. He pushed down key 23 on the keyboard mounted on his desk; the title of the lecture appeared on the television wall panel; on the dot of 8 o'clock Joseph A. H. Faraway, the outstanding professor, began the sixteenth lecture on cable matching for a given rate of information. These masterly lectures were recorded on magnetic tape and transmitted from the University's Technical Center, an extensive center from which all basic instruction was distributed. For lecture theatres had long been abandoned; this system had been rendered ineffective due to the increasing number of students and had been replaced by broadcast lectures and by grouping students in teams of 30 or so round a task master. The task master's role had become fundamental, through his explanations of the course, his choice of subjects of application and the conduct of practical work in the laboratories and workshops set aside for the course. Prof. J. A. H. Faraway himself collected the task masters round him—thirty in this particular case—to discuss the way the course was going with the students

M. J. Ponte is President-Directeur Général of the Compagnie Générale de Télégraphie Sans Fil, Paris, France.
(Received July 5, 1961.)

and to decide on such adjustments as might have been shown to be necessary in the light of observations made by his group.

And so Joe was in task master A. 17's group. During Faraway's lecture he took notes on his coded typewriter. With the telewriter, which was also coded, and permanently connected with the task master, he raised questions on points which did not seem clear, either at the time or on reading over his notes. At the other end, in the office of taskmaster A. 17, the questions raised were recorded on magnetic tape to be examined as a whole.

At 9 o'clock the lecture ended. Joe scanned over his notes, which he easily decoded since, from his earliest youth, he had been trained to substitute groups of letters for the propositions of normal language, thus the proposition "the wave is propagated at phase velocity v" took the form *WPv*, this code having been internationalized. As he came to it, he verified on his miniature algebraical computer which had taken the place of grandfather's slide rule, the solution of an equation given by the professor without justifying development, since the solution of even the most complex equation, including partial derivatives, was obtained by machine and no longer by the old methods, taught only to advanced students anxious to dig into the history of sciences, or to specialists engaged on the construction of the computers.

For some ten minutes or so, Joe was engaged on physical drill recommended for his health according to a perfectly definite daily routine. That particular day he had some difficulty, perhaps because of his recent vaccination, in pedaling a stressed spring into tension in a set time, so that he had to have recourse to the immediate absorption of an irradiate vitamin tablet.

At ten to ten, Joe walked out for the first time that day and proceeded by the traveling platform, after a number of changes, to the buildings of the signals laboratories and workshops, and on to the room A. 17. At ten o'clock the thirty students of group A. 17, standing around their task master, discussed and exchanged views on the fifteenth lecture, in the light of questions raised by the students during the lecture. This was followed by practical work on that lecture. The laboratory and workshop were provided with perfect equipment; over the last 10 years it had finally been realized that the most productive national investment was that applied to teaching the young in all kinds of subjects: scientific, technical or "literary." In the same way, past differences between "workmen" and engineers had changed in their nature. On the one side automatic machines had levelled aptitudes and functions of the personnel in carrying out their separate tasks; for instance, the automatic machines for the production of signal receivers delivered the product with its cost, the value of stocks and all other items of management, so that the staff was almost entirely occupied in maintenance. And steps had had to be taken to arrange for the training of the staff set apart for scientific research, for instruction and for development, and to see about the corresponding machines and the way in which problems should be put to them. The class of engineers and physicists, who on their part were in a position to design and operate the larger systems, such as telecommunication system, had considerably increased in numbers.

Joe was preparing for that class, as well as others in his group, and the practical work for the day consisted in determining with three of his fellow students the best way of utilizing a given bandwidth to provide the individual television links between n individuals geographically distributed in accordance with a given law of population density.

At one o'clock, practical work being finished for the day, Joe stepped once more on the traveling platform on his way to the cafeteria, an immense building with a capacity of thirty thousand meals per hour, thanks to the automatic self-service system which dealt out four menus, prepared in a few seconds by the electronic cookers. Joe hurried on more than usual, for the Hypertexas-Hypercolumbia baseball match transmitted throughout the world was due to begin at two o'clock. But the signals department had been unable to reproduce the atmosphere of the stadium of fifty thousand seats, so that from the dim past, circus acts remained the permanent feature of human culture. Players were carefully picked after repeated tests and specially trained, on appropriate diet, so that the match should end honors all, a most satisfactory result from everybody's point of view.

At 4 o'clock Joe was sitting in his personal study room following a lecture on the history of industrial techniques: the subject was the construction of television receivers in the year 1960. Joe marvelled at his ancestor's expert handling, their nimble positioning of the most diverse parts, the way they handled enormous vacuum tubes, and the deft handling of the old-fashioned soldering iron. All this recalled films he had seen on the building of the pyramids, or the work of the lace makers with their long pins stuck in taut-drawn cushions.

At 5 o'clock he passed to another workshop of group A. 17 where the group was to produce, by its own means, but using modern processes, a working stage of a micro-module amplifier. The work had been in hand for some time, but on that particular day it had been cut short for Joe wanted to return to his room to watch on his screen an automatic news item transmitted at 18:30 hours by a satellite engaged in the examination of Saturn. Actually, several events of this kind had already been broadcast from other planets; and these had rather upset our views on these things, but Saturn had so far always resisted investigation, perhaps on account of the nature of its rings. In point of fact reception was disappointing, jammed as it was by incomprehensible signals. The question remained open.

After a short rest, Joe proceeded to an outdoor feast which was the rage among the youth of both sexes. It was called "Antique Barbecue"; it was actually an outdoor meal at which students, lads and lassies, roasted whole sheep spitted on a wooden pole so that the beast could turn in front of fires which they themselves had prepared. That evening, some five-hundred students were in the clearing, and twenty sheep prepared and wrapped in "Do it yourself" plastic bags, were turned over to the twenty groups. The occasion was a merry one, for there was a roasting and carving dexterity competition. The laughter and joyful shouting which, so we are told, reproduced old World atmosphere was muted while attention turned to a large television screen, visible to all, where the finals of a rally of rockets to the moon were being displayed; ten rockets flying the colors of the ten world universities which had successfully completed successive heats were competing, and the broadcast was enthralling. Unfortunately the Hypertexas rocket had to drop out, one of its ionic engines having died half way. The American continent had 2 representatives, so far well placed, but there was a certain amount of anxiety on account of the unknown characteristics of certain foreign competitors. The race was something like the regatta of former days, the rockets had to assemble at a given moment at a particular point of space and move around so as to be in a favorable position at the starting signal. The arrival of rockets launched from various points on earth was easily followed, thanks to transmissions from fixed satellites which broadcast every launching; each rocket was manned by 2 operators, keen racing men ready to win by all recognized means, as in Roman games. The moon's very surface had to be reached in the shortest possible time, measured from the earth by Doppler equipment on nearing the time of arrival, while the tapes were checked with the utmost care. The entrants remained in communication with the public and strove their utmost in the clamor of their supporters.

The race was well up to its reputation. Contrary to all expectations, it was a so-called small country whose rocket was the winner, the resourcefulness and daring of its pilot having overcome some technical weaknesses. The return was uneventful, each team having this time been able to return to its base.

And the day ended as in old times, the lucky ones received their winnings, the others made the best of it, while some rather abnormal types decided to get back home on foot, their eyes turned to the heavens where they tried to distinguish between true stars and false planets.

Back in his room, Joe slept. He dreamed. And in his dream he saw what a former reading had taught him: a stream, a modest house, standing quiet in its surroundings of green leaf and flowers, far from everywhere, where by his log fire, with his books as his companions, he felt his own master.

For the first time that day he was truly happy.

Fifty Years of Teaching Machines

HAROLD A. ZAHL, III FELLOW IRE

Now that we are well into the twenty-first century and celebrating the 100th anniversary of the IRE, it is a good time to sit back and attempt to assess the tremendous impact the teaching machine has had on our world in the last fifty years. How could a man in 1962, fifty years ago, have guessed the fantastic changes this one device would bring about? The answer is, of course, that he could not; he would have been a fool to try. Teaching machines were in their infancy then, as consequently were human comfort and convenience (at least by our standards).

Let me recount. In 1962, computers were only about 20 years old. Biological computers were still mostly theory; general purpose computers were crude, oversized machines of unbelievable inefficiency; and our teaching machine's bio-infrared circuitry was yet to be discovered. To be fair one should point out, however, that the basic principles of feedback were understood, although the real basis for machine-human interaction had not yet been discovered. Consequently, these rudimentary devices required large numbers of human attendants—called programmers—to assist them.

In those days, even a 0.01 cerebit[1] rapid access memory was considered impossible and a computational time of 1000 nanoseconds was thought to be ultra-rapid. Such "teaching machines" as existed then were not at all versatile, being "programmed" in the pre-1974 sense of the word. It was a dismal time in computer history, one

H. A. Zahl, III, is by his own admission the grandson of Harold A. Zahl, who back in 1962 was Director of Research, U. S. Army Signal Research and Development Laboratory, Fort Monmouth, N.J. ("Received" April 1, 2012.)

[1] One cerebit is believed to be equal to 10^9 ordinary bits.

of the valleys in the up and down curve of progress these devices have followed since their inception (see Fig. 1).

After this bit of reminiscing, it is possible to jump to the present. Everyone now in the field knows the peaks in the line of progress in the last fifty years: the breakthrough in biological circuit design in 1971, the invention of the self-regenerating virus gates of 1974, the solution of the light-speed access problem in 1981, the discovery of voice reception and machine linguistics in 1986, and the establishment of international memory-information banks for televideo service throughout the world. Many modern-day sociologists feel that these five achievements, along with the 1988 break-through in nuclear fusion power generation, have had more impact on human-kind than all of the rest of man's forward steps throughout history. That our happiness and well-being are allmost fullly dependent upon these six advances is apparent when we examine our everyday lives.

But before discussing the impact of the teaching machine on civilization, I should mention some of the other important, if not major, accomplishments since 1962 as a tribute to those men (and the computer) involved. All of the five major practical achievements mentioned earlier depended upon theoretical work that had gone before. Consider, for example, the monumental work of Chen of 1976, which first established the feasibility of liquid-state computer components. We could not be where we are without his outstanding work.

The development of finite mathematics largely through the efforts of Stochastikov and R. C. Tienport, made possible the final linkage between information theory and automata theory, and opened the way to the solution, by A. N. Williams in 1979, of the General Coding Problem. The 1982 Timmons Theory of Self-Awareness in Circuit Modules was basic to the construction of the first real teaching machines. Simon's Theory of the natural laws of growth of 1992 was the basis for later work with spontaneous organizing computers. The last theoretical piece of work, the Unified Computer Field Theory, was, of course, first proposed by ILLIAC IV at the University of Illinois in 1996, and led to the well-known Nobel decision eliminating all future machine contributions from competition with humans. It made possible automatic programming, self-construction and repair, reduced cost per bit of information processed and true computer adaptiveness and self-awareness.

People of 50 years ago doubtlessly thought they had much to be happy about. By our standards, they did not. Of course, it was in the general field of education that the adult living in the year of the IRE's 50th birthday, 1962, had the worse disadvantage. He had to spend years getting what we would not even consider a basic education, attending schools outside of his own home. Education was a mass-process which did not even allow each person to progress as fast as his natural abilities might have permitted, and a person's formal education stopped in the early part of his life. (One must remember the average life span then was less than 100 years!) Those who were educated to be specialists learned little about anything else, and those who were given broad educations learned little about anything.

How astonished the man of '62 would have been if he could have seen the educational system we have now! As learning was somewhat in disrepute in his day, he might find it difficult to understand that we value it above almost everything else. Some sociologists have theorized that the biggest change in the last half century has been the reversal in human attitudes toward education. Of course this has primarily been brought about by the advances in teaching machine technology, which have made a good education not only possible, but absolutely necessary for everyone in our society. Life

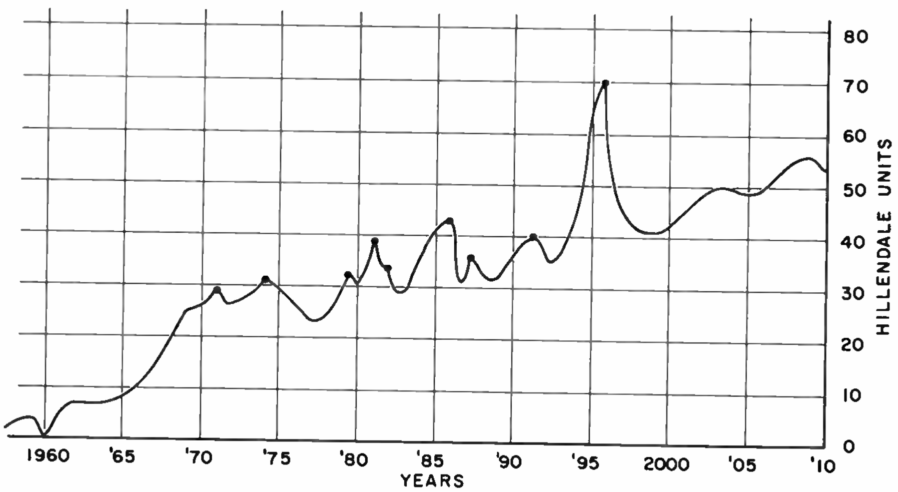


Fig. 1—Practical and theoretical stages in teaching machine design in years and hillendale units. (Note that valleys may be caused by periods of stagnation, as, for example, in 1987 and 1988, when men of science were directing all their attention to discoveries being made in the field of nuclear power.)

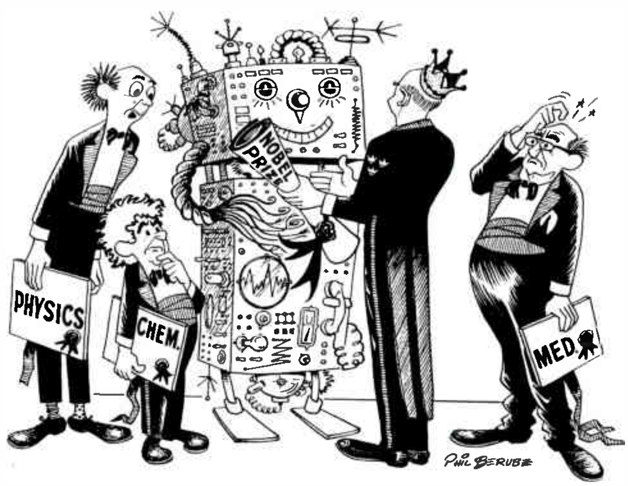
without the modern, inexpensive direct-dial televideo receptor in the home, linking us through substations to the main memory-information banks and capable of analyzing handwriting, understanding voice commands and requests, giving verbal responses, bringing us a free education in any subject that interests us, and even serving as a companion to the aged and the lonely, is now as inconceivable as an uneducated man. I personally do not long for the "good old days" of years past.

Odd as it sounds, even children disliked education in the 1960's. A person of that era would be amazed to see our 2- and 3-year olds sitting in front of their televideo screens, learning the International Language and other basic studies. He would be surprised to see our learning cubicles in public buildings and libraries, and to find that international renown and prestige is awarded to people of all ages for their learning in various areas of the arts and sciences. It would surprise him to learn that our national sport is the mass participation televideo quiz game, in which the entire audience is armed with brains rather than muscles for it was not until 1989 that DIAG IV recommended to the General Assembly the outlawing of all physical contact sports.

In many other ways, compared to today's standards, the man of 1962 faced a hard, dreary life. If he had marriage problems, he could not dial the proper code on a televideo and have instantaneous access to the thinking of the world's best minds on the subject. Instead he had to visit another human being,[2] placing his future well being in the hands of a single individual who was probably little better equipped to solve his problems than he was. He could not sit in his living room and study any phase or area of any arts and science he wished. If he became sick, his doctor had to rely on the contents of his own brain, rather than being able to dial Medical Diagnostics for assistance. In those days, a doctor facing a serious problem could only call in other doctors as consultants, provided they were available and willing. Human physical maintenance depended upon many uncertainties.

In matters of recreation, the man of 1962 was at a disadvantage again. Great portions of the small amount of free time he had[3] were spent laboriously learning how to play the games or master the activities that interested him. It would have been impossible for him to have spent one evening previous to leaving for the Rockies learning the known expert techniques and opinions on mountain climbing. Without years of actual physical experience beforehand, he probably would have killed himself. There are shocking historical records of deaths, amounting to thousands, due to untrained drivers of the early hydro-carbon propelled surface cars; compulsory heli-jet training for children was not introduced until 1985—several years after installation of our first traffic and navigation control net.



. . . and led to the well-known Nobel decision eliminating all future machine contributions from competition with humans.

But the worst thing about life then, as I see it, was the uncertainty about the future man carried in his heart. There was no international language, little international understanding, and no international peace—because there was not yet a world-wide system of televideo teaching machines. Therefore, the benefits and rewards of advanced technology were not available to all peoples.

Now we are beyond all this and faced by troubles of our own. We would be unfair to ourselves if we credited the good or the bad of our world completely to the teaching machines; for while they are an essential part of our existence, we designed them, we built them, and we keep them running. We will improve them in the future. And for all of my disparaging remarks about the middle 1900's, it is obvious to me that we really stand where we are because of the pioneers, the men of that day. Each generation climbs higher than the last because of

[2] Such people were called marriage counselors, quaintly enough.

[3] A 40-hour work week was common in this country in the 1960's, and there were even worse situations elsewhere.

the work of the last—but we sometimes are so busy looking ahead that we forget to glance back in gratitude. On this point I must mention a very erudite article[4] written by my grandfather, Dr. Harold, I call him (in respect of the Ph.D. of that era). The reader would do well to dial IRE archives and take a reading on how it looked to the old gent then.

Considering the sweeping changes in our world in the last fifty years brought about by the development of the teaching machine, I would be as much a fool to try to predict what will happen in the next fifty as the man of '62 would have been to have made guesses about our time. It is my personal belief that before 2062, we will be able to take a forward step that will make the major achievements of the last 50 years look paltry by comparison. Hard as it is to imagine, I suspect that the IRE writer of 2062 will be laughing at us, remarking that teaching machines were in their infancy in 2012. And that will be as it should be. Let us only hope that he too will remember that he stood on our shoulders to reach the heights he will have attained.

And finally, I should like to thank my good friends Alpert, Desmond, Bitzer, Braunfeld and A. Kingery of the University of Illinois; also E. M. Reilley of the Signal Corps Lab. I asked their help on this story since their ancestors of identical name were quite involved in early stages of the evolution of our present teaching machine—around 1962, I believe.

The Tools of the Engineer—2012 A.D.

R. BENNETT FELLOW IRE

About 1970 engineering had sensibly stabilized and technology had forced cleavage into two distinct groups.

The first group was that of component engineers. Components no longer had their earlier crude meaning, they had become functional building blocks of complete circuits. Further, a shortage of engineers had forced the standardization of many circuits so that whole classes of amplifiers, power supplies and mountings had become shelf items.

After a competitive race in the 1960's to produce the smallest units, reason had prevailed. While components were small by earlier standards, the ultimate sizes were such that costs were reasonable and servicing practicable. For example, whole receivers were the size of pound candy boxes rather than cigarette packs.

Component engineers spent their time revising a limited number of building blocks in line with the latest molecular theory of electrical circuitry. Many whole functional circuits went unchanged year after year.

The second group, system engineers, were effectively specialists in putting together complete functional circuits to form equipments. Since many of the complete circuits no longer had the individual characteristics of R, L, and C, a whole new body of mathematical analysis had grown up.

One feature of the new design methods involved the use of computers. It was no longer necessary to cut and try, to build many models experimentally. A proposal for a new system was first programmed into a computer and the ideal circuit units computed. The characteristics of the complete device could be checked from input to output. If the desired over-all characteristics were evident, then the computed circuit criteria were checked against currently available units. Since these units did not always match, the computer was reprogrammed to have the system accept the available units. Some errors becoming evident, the computer was then asked to specify the characteristics of the needed new units. When all units had become available, the system would be put together. Rarely was a second model needed. Occasionally a good idea for a modification and improvement would cause a revamping process to occur.

Sometimes at meetings older engineers would retell their fathers' tales of the frustrating and harassing old days of soldering irons and cut and try.

R.Adm. Bennett, USN(Ret.), is Senior Vice President—Director of Engineering of Sangamo Electric Company, Springfield, Ill. *(Received July 5, 1961.)*

The Automatic Handbook

Nathaniel Rochester Fellow IRE

The automatic handbook will be a computing machine that has stored within it the kind of data and calculation procedures that are now contained in handbooks on subjects like electrical engineering, physics, and mechanical engineering. Unlike present handbooks, it will not only store descriptions of procedures, but also be able to execute them.

Unless some unforeseen developments in the science of information retrieval appear, there will still be the problem that the user can select wrong formulas or procedures just as he can with the handbooks of today. However, after a proper selection has been made, and before the particular desired formula or numerical result is available, today's user often must do a lot of work which the machine will be able to handle.

Recent work on symbol manipulation by machine has shown that the machines can do most algebra. However, there are some kinds of manipulations that so far have resisted mechanization, and some of these will not be within the scope of the automatic handbook. It would, however, be able to help with derivations that were beyond its ability to discover because it would be able to check these for algebraic and numerical errors.

Such a machine would probably be centrally installed and accessible to many, rather than being the private property of an individual. A modest extension of today's real time computer methods should reduce access delays to about the delays that one now encounters in getting the dial tone from a telephone exchange.

Consider a hypothetical instance of an electrical engineer using the automatic handbook to calculate the pressure required to produce a certain flow of cooling air through ducts in an electrical device he was designing. Probably an advanced display would obviate the need for a book at all. However, to avoid having to imagine this, it will be assumed that he would have a mechanical engineering handbook much like the present ones except that it would be backed up by a computer.

The engineer would look in his handbook and find the parameters that influence pressure. He would find, also, figures showing round and rectangular sections, elbows, and other discontinuities. To see if he had a problem he would specify a particular design by giving a succession of figure numbers and dimensions. He would specify the flow, the input temperature, and the output resistant to air flow.

The machine would give him the pressure and, typically, he would see that it was too large and that he did, indeed, have a problem. So, he would ask the machine for a formula for the input pressure. Since he might expect the formula to be complicated, he might ask for a simplified one that would ignore any effects that contributed less than 10 per cent in the first sample duct. The machine would prepare this latter expression by reference to the calculation it made before. It would eliminate from the literal expression all terms which corresponded to elements of the numerical calculation that contributed

---

N. Rochester is Manager of Advanced Computer Utilization, IBM Data Systems Division, White Plains, N.Y.
(Received August 1, 1961.)

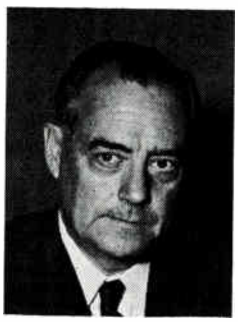
less than 10 per cent. Since this type of formula simplification has actually been programmed and successfully executed on today's computers, the automatic handbook would probably be able to do much more to guide the engineer. He would then see clearly what the important parameters were and could easily produce a succession of designs for the machine to test. Jointly, the handbook and the engineer would quickly arrive at a final design.

The automatic handbook would, of course, be equipped with a large set of mathematical procedures. It would be able to integrate expressions; solve differential equations, both when a solution can be expressed as a concise literal expression and when only a numerical solution will do; simplify most expressions embodying transcendental functions; and do most of the routine mathematical work that the engineer himself could do by looking it up as well as some that would normally be accessible only to a mathematician.

References to literature are an important feature of handbooks. The handbook could be kept current by prompt addition of new references and deletion of obsolete ones. The automatic handbook would be helpful in both familiar and unfamiliar fields, would do a lot of detailed work, and would greatly expand the technological range of an engineer and increase his output.

There Will Be No Electronics Industry in 2012 A.D.

J. M. Bridges FELLOW IRE



In the year 2012 A.D. there will be no electronics industry as we know it today. The electronic component industry, around which our current electronics industry has been built, will have disappeared completely. The design and fabrication of electronic devices will be completely mechanized and will be performed as an integral part of the development and manufacture of all end products, commercial and military.

During the next fifty years adaptive computers will have been developed and perfected which will perform all the functions of systems analysis and layout, equipment design and functional configuration. The information from these "design machines" will be fed from stores into automatic assembly machines which will fabricate and assemble the final product from processed raw materials. The output from the test portion of the assembly machine will feed back to the design machine where errors in design will be corrected and where the design will be optimized for cost, reliability and performance. These design and assembly machines will be flexible and versatile enough so that they can design and fabricate a wide variety of products merely by changing the inputs to the design computer and the materials fed to the assembly machine.

The thousands of electronics engineers now required to support development and product design of complex electronic systems will be replaced by these machines and by a relatively few highly specialized and very creative scientists who interpret new systems concepts in terms of inputs to the design computer.

Competitive advantage will be obtained by excellence in conceptual creativeness, materials research and marketing.

All of this will result in the producers of end products—whether they be space vehicles, aircraft, automobiles, home entertainment centers or electronic air conditioning systems—being completely self-sufficient. They will not have to rely upon a specialized electronics industry, nor will they have to compromise their product by using "existing" components. The only standardization in "electronics" in 2012 A.D. will be in materials and this may lead to a specialized materials industry which will replace the current electronic components industry.

J. M. Bridges is Director of the Office of Electronics, Office of the Director of Defense Research and Engineering, Washington, D.C. (Received January 15, 1961.)

Radio Communication in 2012—An Obsolete Art

Dorman D. Israel FELLOW IRE

During the fourth quarter of the 20th Century, solid-state microelectronics began to find itself by entering into more and more diversified usage. There was, in fact, a period when it seemed reasonable to assume that all radio receivers would make one-hundred per cent use of microelectronic technique. This was before the obsolescence of radio communications could have been visualized.

Suddenly, and yet collateral with the surge toward microelectronics, and, in part, even due to it, promising discoveries and better understanding of the nature of electrobiology literally cleared the air. By furnishing a technique for accurate physiotelemetry, revealing details of the magnitude, as well as confirming the path of nerve currents, microelectronics played its very great part in the fruition of this giant step. Thus, the art of bionics and allied nerve-to-brain studies, moving slowly and disappointingly, but irrepressibly forward, became the big news in communication advancement as well as others not germane to this paper.

Obviously, surgical experiments and tests had to follow and confirm theories derived from such observations. In due time, it became necessary and practical to make experiments on animals whose neuromechanics could be considered a reasonable counterpart of the human being's. Certain haunting anomalies always seemed to appear when least expected during the course of carrying on the seemingly obvious experiments of attempting to simulate, by externally-initiated electronics, the internal action of nerve currents. Likewise, the seeming contradictions or disappointments that resulted from the introduction of these currents to specific points in the brain could not help but intrigue the more meticulous workers. They gravitated to the conviction that some animals responded with subtle difference from what was expected. It was contrived to carry on studies whereby animals were not only exposed to the influence of man but to the influence of other animals during such experiments. Now the key seemed to be fitting the lock and exactly when the full realization occurred as to the cause of the apparent contradictions was not fully recorded and just who might have been responsible for it is still not clear in the record. Probably it was another case of the not uncommon incident of simultaneous discovery of the same phenomenon in several laboratories and, in fact, even in various countries.

What was deduced was the momentous principle that the everyday or routine low-level type of communication that animals have been known to use was ultimately rationalized as something not too different from what the generalizers like to call "extra-sensory perception." As certain animals became more intensively human trained they simultaneously lost their ability reliably to continue this animal-to-animal communication. True, such "genius" animals acquired the ability to seem to think for themselves and even, to a degree, developed a low-level consideration faculty, but they certainly lost their animal friends while they learned to influence people.

Having proved, in a measure, the characteristics listed above, the corollary developed which explained why man who, like other animals, having been originally endowed with at least as good a built-in low-level communication system as the lower animals had, nevertheless, over the centuries of technologic and sociologic development, unintentionally rid himself of this genetic birthright. Agreed, he was ahead of the game as it were, but it was only human to want to know why one must lose so much to have won otherwise.

Science's real mandate was now evident. A way had to be found to "unlearn" just the right things to reacquire enough of our original animal-like extra-sensory perceptive powers. Yet mankind could not afford to lose

---

D. D. Israel is Executive Vice President of the Emerson Radio and Phonograph Corporation, Jersey City, N.J.
(Received May 17, 1961).

the necessary scientific stature and advances that had been acquired over the centuries.

Various laboratories devoted themselves feverishly to the task. The large foundations liberally supported work to such an extent that government financing was not even necessary. By the year 2000, sufficient progress had been made so that elementary communication could be carried on over very short distances between suitably and carefully trained human subjects. Then, with the additional aid of certain bioelectronic augmentation, the technique was refined so that individuals who had been so equipped and previously trained were able to make adjustments whereby they could communicate over quite substantial distances but always by appointment—a most fortunate limitation.

As of this writing, in 2012, there are no doubts in any circles as to the ultimate full success of the program. Tests have proceeded now so that if the parents consent, newborn infants can be operated upon and the latest submicroelectronic equipment installed in the brain and at certain critical points in the spinal column so that they are almost certainly assured not only of the benefits of full nonradio communicative powers but also there is reason to believe that their scientific creative ability will be enhanced. Logically enough, this operation must be performed within two weeks of birth because if the infant is only slightly exposed to contacts with its family who still have not completed their "unlearning" and readjustment, he might never become a good subject for the modern system of communication.

Electromagnetics and Communications

HAROLD A. WHEELER FELLOW IRE

THE LOW FRONTIER The VLF range (3-30 kc) has long been the low frontier of the electromagnetic spectrum used for "radio" communication. There are being explored some further opportunities for useful communication at these and even lower frequencies. At present the lowest operational frequency is in the vicinity of 15 kc, which is used by the Navy for communication to submarines while submerged. These and lower frequencies are also attractive for world-wide coverage around the clock, from any one transmitter.

One contemplated use of lower frequencies is found in the Navy's proposed "Omega" long-range navigation system. The world would be covered with a grid of interference patterns, laid down by a network of several transmitters operating near 10 kc.

The next lower frequency to be considered might be around 3 kc, where the propagation under the ionosphere has some unusual properties. There is one, and only one, mode of propagation with horizontal polarization. It may be designated the TE-01 mode, which has a cutoff frequency about 2 kc. It happens that the vicinity of 3 kc experiences an optimum combination of reflection from the ionosphere and excitation by a loop antenna at the ground (a vertical loop with horizontal axis in the direction of propagation). At the maximum altitude of aircraft, this mode is susceptible of omnidirective reception by a horizontal loop.

Below 2 kc, there is single-mode (TEM) propagation under the ionosphere. At about 10 cycles, the earth's surface and ionosphere form a cavity resonant at its lowest mode. Experiments in Germany and the U. S. have shown signs of this resonance by observing a distinguishable peak of lightning noise near this frequency. The utilization of such a low frequency depends on the development of a power radiator that can surmount the lightning noise over a useful area, or even over the entire earth.

Recent tests at VLF have indicated substantial transmission through the ionosphere, from the surface to a satellite. This was unexpected, since the ionosphere has been regarded as a shield for VLF. However, it is known that AF signals penetrate the ionosphere in the "whistler" mode, when transmitted between two focal points at opposite ends of the Earth's magnetic field. The satellite

H. A. Wheeler is President of Wheeler Laboratories, Inc., Great Neck, N.Y. (A subsidiary of Hazeltine Corporation.) *(Received September 5, 1961.)*

test gives further impetus to the investigation and possible utilization of VLF communications between the Earth and outer space.

Along with the progress in propagation under the ionosphere, other channels are being explored underground in the Earth's crust. Promising results over moderate distances have been obtained in tests of guided waves between separated conductive layers in sedimentary strata at moderate depths (less than 1 km). The first such tests under controlled conditions were recently reported by Deco Electronics, communicating between two salt mines in New Mexico. Another possibility has been proposed, the "deep waveguide" in basement rock.[1] This is bounded on the upper side by conductive layers near the surface (sedimentary rock or sea water) and on the lower side by the "thermal ionosphere" at a depth of the order of 30 km. It remains to be proved whether long-distance signaling is possible in the deep waveguide at frequencies of the order of 1 kc.

In the field of communications, electronics has experienced its greatest stimulation and development. In detecting and processing weak signals, it is closest to the sensitive communication processes of human beings.

The following paragraphs are devoted to some situations in which the present practices are notably deficient in communications.

HIGHWAY COMMUNICATION On the highway, many situations would benefit from some form of communication, either from controller to vehicle, or from one vehicle to another. Even when the two parties are in sight of each other, there is now very little ability to communicate. From controller to vehicle, traffic lights and personal "antics" are utilized to some fraction of their capabilities. Between two vehicles, brake-signal and turn-signal lights are most rudimentary, though extremely helpful as far as they go.

We have radio communication between base stations and vehicles. It is fairly effective in police networks, and could be developed much further for taxicab dispatching.

Perhaps the next development will be the transmission of advisory messages to all cars passing a certain point on the highway as has been demonstrated by the Delco Radio Division of General Motors Company.

The greatest need is the ability to communicate from one vehicle to another in the same vicinity, for purposes of warning or other advice. To be useful, this would require a simple way of selecting which vehicle is to be addressed. For example, one might advise another car that his turn signal was left on, or that he was trailing black smoke from his exhaust. Obvious such facilities would have to be used with restraint, but the typical driver has come a long way in this respect and might prove equal to a further challenge.

A friend of the writer (R. G. Ling) has experimented with such communications by using a microphone at the driver's position and a loud speaker just behind the radiator. He has encountered a favorable reaction in several cases, and once supervised the evacuation of a car that was on fire without the driver being aware. His experience is persuasive that intervehicle communication offers a real opportunity.

The natural way for selectively reaching just one vehicle would be through a narrow beam of radiation, although this would require careful aiming by the sender. This would be especially difficult during the motion of one or both of the vehicles. Invisible radiation would offer some advantages, while visible radiation would enable the receiver to see which vehicle is the sender. Even if the signal radiation were invisible, a visible signal could be used for identification of the sender and perhaps also for automatic acknowledgement by the receiver when the channel is established.

The broadcasting type of intervehicle communication, with restricted range, could be made useful by marking every vehicle (on all sides and ends) with a terse code that would be unique to one in a thousand or so, such as two letters or a three-digit number, analogous to radio call letters. This code would then be used for identifying the addressee and perhaps also the addressor.

TELEMETERING TO THE HUMAN SENSES The human senses are awkward when it comes to receiving a signal with quantitative precision. This is exemplified by the amount of attention required to retain simple information such as weather statistics or game scores. The thermometer is among the most natural indicators, but it has to be communicated in a digital code, which is far from natural. There seems to be a need for evaluation and optimum utilization of the senses for this purpose.

The eye can sense a prodigious amount and variety of information, in the form of relationships, but is notably deficient in quantitative observations, such as ratios of distances or intensities, and even more so in sensing their absolute values. The ear, while subject to comparable limitations, is peculiarly skillful in one function, the sensing of frequency changes and the appreciation of frequency ratios and patterns. It is suggested that this quality of the ear may be the one natural sense that has evolved to the highest degree of quantitative precision.

A few years ago, the writer took advantage of this ability of the ear as an aid in a scientific demonstration to an audience. He wanted visual attention to the manipulation of a directive antenna, so such attention was unavailable for the meter showing the response of the antenna when pointed in various directions. The amplitude of sound gave qualitative but inadequate sensing of the variations to be demonstrated, especially a deep null in the pattern. Instead, the amplitude of response was presented by an audio tone whose frequency was made directly proportional to signal power. This enabled the sensing of variations from ¼ db to 30 db, by the logarithmic frequency response of the ear. (The lower value is a half tone on the musical scale. The upper value is based

[1] H. A. Wheeler, "Radio-wave propagation in the Earth's crust," *J. Res. NBS*, vol. 65D, pp. 189-191; March-April, 1961.

on 3 to 3000 cps, the lower frequencies being made audible as pulses or clicks.) The result exceeded the capability of any other form of demonstration indicator, and left the visual attention where it was needed. The patterns was easily remembered as a tone pattern, although still difficult to describe in such terms.

A similar method apears to be in use for translating the heart pulse wave to an audible sound; here the quantitative requirements are less severe.

In any particular situation, the capabilities of sight and sound should be evaluated, and a conscious selection made for best utilization of both. The future will see increasing appreciation of this need, followed by careful study and the adoption of optimum techniques. This is closely related to the problems of efficient education.

PRIVACY BY MATCHED-NOISE JAMMING In military communications, it is recognized that the most effective jamming can be accomplished by noise having a frequency spectrum similar to that of the signal to be jammed, but the noise having a random character. The same principle may be applied for positive benefit in another situation, as follows.

There are certain conditions in which a quiet background serves to emphasize any sound that may occur. One example is a large, quiet office in which several individuals are doing desk work; any conversation, especially by phone, becomes a disturbance to everyone in the room. Another example is a quiet room for sleeping; the sense of hearing becomes so acute that a moderate sound is cause for alarm.

It is expected that the principle of jamming will come to be used as a countermeasure for these conditions. Ideally, a recording of the sounds to be jammed would be made for every day (or night) over a year or so, then all days would be superimposed to form one day of noise. This sound, reproduced at a level comparable with the level of the sounds to be jammed, would form an ideal background for the otherwise quiet office or bedroom. It is likely that a few types of noise would suffice to enable an effective choice for any particular location. The noise causes the ear sensitivity to accommodate to the expected level and character of disturbing sounds. This plan is most effective (not too monotonous) if there is some appreciable fluctuation of the noise level over the time cycle of the recording to be utilized.

Such a background of sound appears to offer also some therapeutic benefits in the reaction of the nervous system. In an extreme case, a very loud noise have been found useful as an anesthetic, and this application will come into wide use in the near future. Here there is naturally a search for the sounds that will be most effective; in other words, that will have the greatest ability to confuse the pain signals.

IDENTIFICATION OF HUMAN CHARACTERISTICS There is a rule which says, one does not know something if he cannot describe it to someone else. It would be closer to the truth if we were to say merely that one does not know how to describe this something. The most striking example of this frailty is our inability to describe the human characteristics by which one is able to distinguish thousands of his acquaintances, even those whom he seldom sees. Any word description may apply to 10 or 100 of the individuals that one is able to distinguish at sight.

It is interesting that we resort to fingerprints in our attempt to find a simple and identifiable pattern that has enough combinations to enable unique descriptions of perhaps a billion individuals.

The time is ripe for a systematic development of concepts and words that will enable one to appreciate and to describe the characteristics of another individual. Some progress is made necessary by the increasing number of acquaintances one is likely to acquire in the closer packing of our population, with respect to both residential and occupational communities.

This result would be achieved by an intensive research program, utilizing the current concepts of information theory. The greatest difficulty would be that of any new language, since the requisite new words will lack any background of usage or familiarity.

Communication Spectra by the Wholesale— 2012 A.D.

Estill I. Green fellow IRE

Although the oracle at Delphi is long since stilled, the art of divination still seems to possess an irresistible allure for mankind. But at least, if mantic endeavor is inevitable, there is something to be said for a half-century forecast, since such an interval confers a fair degree of immunity to after-the-fact checkup by present readers. On the other hand, the technically sound basis for a shorter range forecast, *i.e.*, that the near-term future behavior of a dynamic system is roughly predictable from a knowledge of its immediately past behavior, no longer applies.

One way of illustrating the infeasibility of an accurate 50-year forecast, in the face of rampant technological change, is merely to take an equivalent backward look. It was just about 50 years ago that H. D. Arnold and others were starting research on the introduction of a high vacuum in De Forest's audion. Who then could have foreseen that this device would usher in the great era of communication and electronics—an era that was to create the miraculous networks of wire and radio that now speed communication near and far, the electronic computers that are metamorphosing business operations and resolving hitherto unassailable problems, the incredibly accurate control systems that steer missiles on their way and place satellites in orbit, the broadcast systems with their as yet largely unrealized potential for education and culture, and all the other electronic contrivances that impinge in one way or another upon our society?

How much less amenable to prediction must be the advance of the next half-century! No abatement in the pell-mell rush of electronic discovery and innovation is in sight. Past progress will beget future progress. Technological change bids fair not just to continue, but to accelerate. No more could a Tennyson say: "Science moves but slowly, slowly, creeping on from point to point."

In this juncture, we shall do well to limit our prognostic effort by selecting a single windmill for tilting. The one chosen herein is the matter of guessing what sort of mechanisms will be used to provide the bandwidths required for continental and transoceanic communication 50 years from now. A guess as to the magnitude of these bandwidth requirements is clearly the starting point.

Let us look first at intracontinental communication, and specifically at the bandwidth needs for all forms of intercity long distance transmission. What factors might be pertinent? Population for one, number of telephones for another. The best guess seems to be that in the next 50 years U. S. population will about double, while the number of telephones may triple. Neither of these has great significance, however, since the demands for long distance communication will go up much faster, as has been true in the past.

The demand for telephone circuits will almost surely experience some degree of saturation. In all probability, however, this will be far more than offset by large demands for transmission of visual material, either separately or in association with telephony. A further augmentation will result from needs for data transmission. Putting everything together, it appears not unlikely that total bandwidth need on important intercity routes may go up a hundred times, which would mean a baseband requirement ranging from 50,000 to 100,000 megacycles on each of a number of heavy traffic routes.

How will such a vast bandwidth be obtained? Probably not from present or future coaxial cable systems, since these seem likely to prove uneconomical except for special purposes such as as feeder links, entrance to cities, etc. Neither will it come from present or future microwave relay systems. While these will play an important role for many years to come, their capability for handling bandwidth growth will be seriously curtailed by beam congestion within 20 years or so. The usable microwave spectrum is finite, and will be subject to increasing demands for services other than point-to-point long distance transmission. Moreover, microwave systems will probably be more expensive than future alternatives.

What then? Only two possibilities suggest them-

E. I. Green is Consultant, formerly Executive Vice President of Bell Telephone Laboratories, Inc., Murray Hill, N.J. *(Received May 29, 1961.)*

selves. The first is the waveguide system now being developed specifically to provide increased information-carrying capacity on major overland routes. The probable transmission medium is a hollow copper pipe, about two inches in diameter, acting as a guide for millimeter waves traveling inside. The system will employ the circular electric transmission mode (TE_{01}), which has the admirable property of decreasing attenuation with increasing frequency.

As now visualized, the gross frequency band transmitted inside the waveguide may extend from 35,000 to 75,000 megacycles, *i.e.*, a gross band nearly four times as wide as the entire band now employed for radio communication. This vast frequency spectrum will not be vulnerable to fading, atmospheric effects, interference, or other troubles that beset the radio, nor will it be subject to conflicting public demands and consequent governmental restrictions.

Within each waveguide system comprising one pipe for each direction, a handling capacity for as many as 200,000 voice circuits or 200 television circuits is anticipated. Present techniques require that for amplification at intermediate repeaters the waveguide frequency band be subdivided into a number of separate broad-band channels. However, it seems logical to expect that in 50 years the art will have progressed to the point where the entire waveguide band can be amplified, without subdivision, in a single amplifier.

A possible alternative, a scheme vaguely reminiscent of Alexander Graham Bell's "Photophone," has recently emerged through the development of a continuously operating gaseous optical maser. In contrast to previous optical masers, the new device employs a mixture of helium and neon gases through which an electrical discharge takes place in somewhat the same way as in a conventional neon tube. This discharge excites the helium atoms to a high "metastable" energy level. Collision of neon atoms with the excited helium atoms results in a transfer of energy to the neon atoms, which can then be stimulated to radiate their energy in a continuous stream, and through successive reflections a narrow output beam of coherent infrared waves is obtained.

A system employing this or some other yet-to-be-developed type of maser might conceivably be used to derive an enormous bandwidth for long distance transmission. The light beam, suitably modulated, would be shielded from outside effects (rain, fog, refraction due to inhomogeneities) in a gas-filled or evacuated underground pipe. The system might comprise a number of repeater sections each several hundred miles in length. Each repeater section might consist of a number of straight sections of perhaps a mile or less, with passive means (*e.g.*, confocal reflectors) for redirecting the beam at each junction.

Only a few watts of transmitted power, well within the capabilities of a gaseous or solid-state maser, would be needed in each repeater output. The over-all system bandwidth might be millions or tens of millions of megacycles, in contrast to thousands or a few tens of thousands for the waveguide system. The problems that would have to be surmounted in such an optical maser system are formidable indeed, but seemingly not insuperable. On the other hand, the millimeter waveguide system has been under exploration and study for many years, and the problems are now clearly defined. It is conceivable that over an interval as long as a half-century both systems may come into use.

And now what about transoceanic communication 50 years hence? Again we must first guess at bandwidth needs. Here uncertainty is compounded by the fact that it is only in the last five years that circuits of high quality have been available across the Atlantic in adequate numbers. The demand for transmission of visual material is problematical. Military needs bulk large for the immediate future, but should level off over the longer term. Still and all, the tidal wave of world communication is rising fast. A good guess might be that by 2012 A.D. some 2000 Mc of bandwidth will be needed between U. S. and Western Europe (including Great Britain), and possibly twice that much between the U. S. and the rest of the world.

To meet this need, there will be, first, ocean cables with submerged repeaters. Up to now these have been quite limited in bandwidth. But new single-cable systems of much greater circuit capacity will soon be installed. There is little question of the eventual feasibility of a cable with transistorized repeaters, which could easily give a frequency band of several megacycles or more.

Meanwhile, another kind of transoceanic communication has taken on great scientific and popular appeal, to wit, radio communication via satellites. Spurred by the success of initial experiments, satellite communication has taken on some of the features of the whole space extravaganza. Satellite systems possess real attraction, however, for obtaining wide-band channels for telephony, television and other services, for providing direct links to landlocked countries, for diversification of techniques, etc.

For transmission reasons, repeatered satellites (*i.e.*, equipped for receiving and retransmitting) seem likely to win out over reflecting satellites. There is much theoretical attraction in a repeatered satellite placed in an equatorial orbit about 22,300 miles above the earth, with precise station-keeping equipment so that it would remain stationary above a fixed point on earth. However, this poses extremely difficult technical problems, as well as introducing a round-trip delay of about 0.6 second, which would make it unsatisfactory for telephony. Accordingly lower altitude satellites (2000-7000 miles) are most promising. A group of 25 to 50 might provide a world-wide communication network.

The economics of such a system are largely conjectural. Much depends on the life of the satellite equipment under exposure to space radiation and other hazards. Nevertheless it seems clear that low-altitude active satellite systems will be in experimental operation within a short time.

The preferred frequency range for satellite communication is from about 1000 to 10,000 Mc. Even with huge horn-reflector antennas for transmitting and receiving, and low-noise masers for amplifying the faint received signals on the ground, very broad-band modulation systems will be needed to obtain acceptable signal-to-noise ratios. Since there is only one electromagnetic spectrum available for radio transmission, avoidance of interference between space systems and from terrestrial systems into space systems will introduce grave problems.

All things considered, it is by no means unimaginable that within less than a half-century the congestion in the microwave range will leave no room for further exploitation by space communication. What then may be imagined as the next transoceanic communication medium? In the fact of necessity, some way will be found to multiply frequency spectra at will through the use of cable techniques. Maybe the answer will be an adaptation of the overland waveguide system, or in other words, a "waveguide cable" with the whole band handled by one amplifier at each repeater point.

In the long run, a "sheltered" transmission medium is almost certain to win out over radio for both continental and transoceanic communication. In view of the ever increasing importance of communication to world affairs, it is fortunate that such promising ways of handling future demands are in sight.

A Short History of Electromagnetic Communications

JOHN W. COLTMAN FELLOW IRE

By the 1960's it appeared that electromagnetic communication systems had reached tremendous heights of sophistication. Starting with the crude noises of the spark gap, laboriously coded by hand from the alphabet handed down by the Phoenicians only a few millennia ago, the uses of the radio spectrum burst forth in the course of half a century to encompass a bewildering maze of services. Coded and voice messages were transmitted over all the world, radar beams scanned the horizons, information was brought back from transmitters deep in the reaches of space, radio was everywhere, and the last decade had culminated in the miracle of the nightly repetition, in millions of homes all over the land, of the Western.

But even so, the electromagnetic spectrum hadn't really been tapped. The services extended from about 20 kc to 40,000 Mc, a little over 6 decades, and the upper end of the band was wastefully squandered carrying television signals that from the point of view of information theory (to say nothing of the point of view of culture) were highly redundant. Beyond lay tremendous reaches in the frequency domain. From 10^{10} to 10^{13} cycles were the submillimeter waves and the far infrared, essentially a trackless waste, traversed by an occasional expedition which noted the nature of the area, but did not stay to colonize it. It contained, of course, half as many decades as all of the communication spectrum had exploited until that time, and in terms of information bandwidth was thousands of times larger. Its development was hampered partly by the opacity of the atmosphere, but more by the inability to apply in the tiny dimensions required the techniques characterizing longer wavelengths. This area was finally opened up from the other direction by extending the techniques originating in the optical region of the spectrum. Now here was rich territory indeed—a narrow slice of the electromagnetic spectrum originally occupying scarcely an octave, but possessing an overwhelming advantage in that it was here that man's own receptor, the eye, operated. This superb mechanism had a receiving aperture only a few millimeters in diameter, yet was capable of absorbing and classifying information at rates far in excess of those characterizing the communications systems of the sixties; indeed, the latter had succeeded in presenting to the eye only a tiny and crude imitation of visible scenes, and had used up the then available communications spectrum in huge gobs while so doing. It was in the optical region of the spectrum that physics had its early triumphs; indeed, it is fair to say that our modern concept of the physical world rests primarily on a foundation established in the study of the

J. W. Coltman is Associate Director of the Westinghouse Research Laboratories, Pittsburgh, Pa. *(Received March 29, 1961.)*

propagation of light and its emission by atoms and molecules.

It was through these latter phenomena that electronics and communications became part of, and, indeed, essentially took over and engulfed, the art of optics. The key to the operation was the use of cooperative phenomena among atoms. Now all of the power of the electronic signalling techniques was combined with that of conventional optics. The provision of stable local oscillators at optical frequencies, together with the development of nonlinear media made possible the conversion of frequency, with all its attendant advantages.

At the same time, the precise directional properties available with the new frequencies were exploited. A single "antenna" (that is, a lens) of the most modest dimensions was capable of receiving simultaneously from thousands of points in space, and of keeping each transmission separated into its own channel. The frequency discrimination was, compared with the prior techniques, fantastic—it being quite possible to contain in a single millihue (the number of millihues in a wavelength interval is defined as 1000 log λ_2/λ_1) in the orange, for example, about a quarter of a million of the old "television channels." The invention of the brilliator in 1972 made possible the amplification of weak images without destroying the phase information, and by the 1980's, most of the point-to-point communications networks were in the optical or suboptical bands. The time-sequential scanning of images was abandoned, and television broadcasts were carried throughout by optical techniques, the time phases and angular dependence of the waves being preserved, duplicated, and amplified wherever necessary in the system.

The tremendous success of the method of coordinated atomic radiation brought forth an intensive search for means to extend the technique to even higher energies. Gradually, there evolved mechanisms operating in the ultra-violet and X-ray regions, and while these have been restricted to certain aspects of space communications, they have, in principle, added to the spectrum another six decades. The introduction of quantum coding, in which the message is carried by high energy quanta, distinguished by slight variations in their wavelength, proved to be of great value in overcoming the natural background radiation of space.

As every school boy knows, the most exciting project of the new millennium came as a result of the discovery in 1989 of the nuclear transmissions from the neighborhood of Sirius. These gamma-ray emissions were detected by UN Observatory A36, operating in a 24-hour orbit and carrying a highly sensitive gamma-ray brilliator operating in the Mn^{54} band. The intelligent character of the transmissions was apparent rather early, and while they have appeared only at scattered intervals, sufficient Doppler observations have been made to establish the period of the orbit of the planet from which they came, and even to demonstrate the distortion of this orbit by the presence of the dark companion of Sirius.

In 1996, a team of engineers and scientists, with the aid of superconducting magnets producing fields in excess of 1 million oersteds, succeeded in generating coherent gamma radiation in directed beams. Since then we have been making periodic transmissions to Sirius. If, as appears probable, the Sirians were searching for a reply, they should by now have received most of the transmissions, which have a 9-year travel time. Two years from now, it is theoretically possible that we will receive their earliest reply, and the world is eagerly awaiting this first exchange, across the depths of space, between the 2 worlds now known with certainty to exist.

Before submitting the above contribution, the author asked an associate to read and comment on it. In response he received the following "antithesis" which is included here in the belief that it will provide readers with a sobering, as well as amusing, treatment of the same subject.

—The Editor

The Spectrum Problem—Looking Back From 2012 A.D.

E. A. Sack

It seems so simple, in retrospect, that the older members of the profession still refuse to completely accept the solution. That their supreme efforts to conserve bandwidth and to develop new portions of the spectrum were really unnecessary is a revelation from which complete recovery is impossible.

Late in the 1960's, a few nonconformists were proposing that the so-called spectrum shortage was an organizational rather than a technical problem, but their theories were largely ignored by the scientifically oriented communications agencies. The major premise of the nonconformists, that one should first determine whether information really needed to be transmitted, seemed so undemocratic that their clearances were subsequently lifted in the interests of national security.

The reader will recall that science was in high fashion during the quarter century preceding the second millenium. The importance of the professional scientist had grown to the point where a doctorate in physics was a prime political attribute and both of the presidents during the period 1972-2000 were Fellows of the AEC.

But the law of trend and counter-trend is universal and while the technologists labored night and day to find ways in which to transmit ever-increasing gobs of information to the public, to each other and to nobody in particular, the humanist gathered in non-NSA supported workshops to accumulate, in anti-scientific manner, the evidence that the spectrum problem was purely a matter of inadequate legislation. Their philosophy evolved into the now-famous Sideband Theorem which states, "Technological solutions to nontechnological problems are in quadrature to progress."

The journals of the humanists during the period show the development of their deliberations. For example, in 1980 they proved that all of the AM broadcast stations played the same 20 records 90 per cent of the time. Their proposal that only one national broadcasting station using only one 10-kc channel might do just as well received passing note.

A similar study of the television spectrum in 1982 indicated that 85 per cent of the TV programs broadcast by 521 stations on 126 channels contained but six basic program plots. It was proposed at the time that these plots be provided in a small local memory to the home TV fan who could select them at random for the amusement of the integrated family group.

A secret study of the communications needs of the national defense establishment was even more revealing. Eighty per cent of all messages had to do with orders which were countermanded by subsequent messages and hence never needed to be transmitted at all. The remaining 20 per cent dealt with information which would be ignored at the receiving end and was, therefore, 100 per cent redundant.

An interesting example of the thoroughness of the investigation of the humanists was the study of the Public Service spectrum needs. At the time one city was demanding 5 additional channels for its police radio; its average transmitting time on each of its existing channels was 1 minute per hour. A typical communication was: "Car 5 stopping for a sangwich." "Repeat Car 5." "Car 5 stopping for a sangwich." "Say again Car 5." "Car 5 stopping for a sangwich." "OK, Car 5 stopping for gas."

As time went on, the battle between those who felt that more spectrum space was needed, and those who felt that less information need be transmitted, grew bitter indeed. But the outcome is familiar to all. The Communications Act of 2008 ended the spectrum shortage. Its major provision, of course, is that all information be first transmitted to Washington by surface mail for review by appropriate committee. If approved, the message is transmitted over the National Transmitter in a priority determined by the priority review board. The completely redundant information which was formerly broadcast on radio and TV is mailed out on tape, to all who care, on a monthly basis.

Unemployment among communications scientists has been largely eliminated by increased need for mailmen. Military personnel who became surplus by the impossibility of a really worthwhile war under the system have yet to be completely absorbed by the economy, but the matter is receiving further study. Public Service officials have complained that they no longer know when Car 5 is out for lunch, but one executive committee has proposed that the cops be given dimes to call in from the pay phone behind the counter. This may work.

The Full Use of Wide-Band Communications

Sir Noel Ashbridge FELLOW IRE

All radio engineers have an ultimate goal in mind: the day when wide-band communication can always be established between any two points on the earth's surface with absolute secrecy. He looks to a future when distance, season, and time of day are immaterial, and the business man and the house dweller are able to enjoy all that wide-band communication could conceivably offer. With this ambition in view, a picture of things which might be done within the next fifty years can be roughly envisaged.

In the future the urge to convey unlimited information over the globe will be sufficient to free the enormous sums of money which are needed to solve the problem. The military needs it, business needs it, and the man in the street is always prepared to pay for more amusement.

The solution might even be dull, the piling of complexity upon complexity, in fact, the gradual harnessing of known methods into huge co-ordinated systems. But the outcome might help to balance up the whole lopsidedness of the civilized world. It is not only the accomplishment but what do we do with it that is the exciting prospect.

Sir Noel is Director of the Marconi Wireless Telegraph Co., London, England. *(Received June 12, 1961.)*

Wave propagation research workers seldom suggest that they are on the brink of revolutionary discoveries. More hard won knowledge, leading to better systems, is about all they expect from their work. We might expect therefore that the two major methods of communication will be satellite radio and guided wave (H_{01} mode), substantially aided by wide-band microwave relays and tropospheric scatter. HF ionospheric communication—narrow band but less costly—may remain as an economic necessity, but we can hope with some confidence that the growth of satellite, and pipe line systems will give some freedom of maneuver for the regimentation of this frequency band.

It will be the age of computers and one can foresee their role in world communications, tying together the several systems and selecting the best path or sequence of paths for a particular message.

If we assume that the problem of wide-band global networks will have been tackled and solved, there remains the enormous problem of local distribution. No doubt in fifty years time the technique will exist, but the manifestations of it are not likely to be commonplace. Except in isolated small communities, radio will not do; we must resort to the pipe, and this means additional pipes to every inhabited building.

The capital outlay will be enormous, but the potential benefit will be worth it. The problem lies with the pipe manufacturers, and it is surely reasonable to suppose that town planners and the suppliers of essential services—electric power, gas, sewers, and so forth—will have gotten together and integrated their methods of providing underground-fed facilities. It is unthinkable that power and communications should continue to be carried by a tangle of overhead wires and posts. The sensibilities, if not the common sense of future generations, will demand an organized approach to the supply services of buildings. It is surely reasonable therefore to look forward to ducts, or even composite pipes carrying all services, including guided wave transmissions, as one co-ordinated engineering operation.

If this comes about, and our grandchildren can handle, for example, the H_{01} mode more economically than we can at present, the way will be clear to give all sections of the community those facilities which have not materialized during the "teenage" of communications.

The development of facsimile—so far limited by bandwidth—must go on until it can give as much detail as the eye can discriminate: print a newspaper with no detectable difference from the original, reproduce anyone's handwriting in any language, and so on. The development of thin-film phosphors, xerography, and electroluminescence point to a near certainty that extremely high definition reproduction of documents, letters, forms, and so on will be greatly reduced, and eventually outmoded. By the year 2000 all this could have gone a long way.

Another information system that will certainly be replaced is the noisy, unreliable, and cumbersome teleprinter with its devilish fault of printing the wrong letter if its input information is not perfect. A cleaner transmission system, perhaps using a little more bandwidth, will make way for the development of an all-electronic teleprinter: neat, silent, and free from guesswork.

A world-wide wide-band network with local extensions would not recover capital expenditure without a contribution from the man-in-his-home. These days he is not allowed to live simply, he must have telephones, television, up-to-the-minute news, and so forth. In fifty years time he will live even less simply. He will, whether he likes it or not, become more and more exploited, but perhaps in a way that will be more satisfactory to him. For example, wide-band guided-wave local services could pump into the home all the information, amusement and propaganda anyone could possibly want. Television would become real picture viewing: "glossy magazine" detail in color with no interference. Telephones would be visual as well as aural: news continually in print, dial for music, dial for a picture showing the state of his bank account, and so on.

The vagaries and limitations of radio wave propagation and the struggle for bandwidth are the real barriers to progress. The more we struggle to improve the capabilities of radio communication the more the orthodox methods split at the seams. Television development is at a standstill; we accept it for the action in the picture, not the amount of information. A release from the bondage of limited bandwidth must come to make drastic innovation possible.

In case of picture electronics whether it be television, document reproduction or facsimile, it seems that the binary digit will lead development, and inventors will discard the compromise of scanning in favor of the element screen or matrix, where each element is "bit" controlled and therefore under control. As for the screen itself, the problem will no doubt be solved in several ways. More knowledge of the behavior of phosphors, particle penetration, laser, thin film techniques make the prospect full of promise.

This emphasis on the lavish use of bandwidth does not envisage that our grandchildren will be able to use it in a prodigal way, but a narrow road remains a narrow road, nothing can be done about it until it is in effect widened. Then schemes for traffic control and flow can be put into operation, but first there must be enough room for maneuver. And so it is with communications. In fifty years time, man will be able to communicate almost any piece of information to anywhere, mainly because he has been able to provide himself with the basic tools with which to do it. This must include sufficient bandwidth to make possible the more effective exploitation of information theory.

Wide-band Communication into the Home

W. D. LEWIS FELLOW IRE

Electronics has had a spectacular impact on long-distance communication during the last fifty years. A corresponding impact on the techniques of local two-way communications to the home is only beginning to be felt. Powerful forces are working to change this. By 2012 A.D. these forces will have created equal or greater changes in the techniques of local communications and in the services available to every household.

I would be rash indeed to attempt an accurate chart of the next fifty years of electronics. Applications are more easily predicted, for they are based in part on the relatively static foundations of economics and human need.

Certain technical trends are clear. These alone will create a revolution, though perhaps a gradual one. New discoveries will probably hasten this revolution, and they cannot slow it down.

What are these trends? Briefly, they are towards higher frequencies, cheaper electronics, greater automation, digital transmission, and integrated design of systems.

The optical maser is only one recent victory in a triumphant campaign that has won the triode, the klystron, the traveling-wave tube, a host of transistors and ferrite devices, and the Esaki diode. During the next fifty years, local communication will profit richly from these victories and others unmentioned or unborn.

Today, and for the foreseeable future, device costs are rapidly being pushed down. This economic revolution will stimulate communication in several ways. A notable example is two-way television in every home—a technical possibility now but not an economic one. An abundant supply of cheap, high-frequency components and assembly techniques will make the "videophone" as commonplace in 2012 as the telephone is today.

An ordinary pair of wires in a telephone cable can carry more information in telegraphic or binary digital form than it can in analog form. So can a circular electric waveguide. In both cases this is because the greater resistance of "pulse-code modulation" against noise and interference more than makes up for the greater bandwidth it requires. Furthermore, PCM can be amplified and regenerated many times without degradation. As electronics becomes cheaper, it will become profitable to convert messages to digital form for transmission over shorter and shorter distances. They will travel in this form economically across the street, across the city, or around the world.

The more economic and flexible electronics of the future will be used increasingly to save the copper, real estate, and manpower required to provide communication. For example, wire or coaxial sizes can be made much smaller by placing amplifiers closer together, probably building them in at the factory. Many small switching units will reduce the copper even further. Extremely cheap microwave and millimeter amplifiers and oscillators, already promised by the new family of negative resistance diodes, will in many places make it economic to eliminate the local wire altogether.

Communication equipment inside the home will come in many forms and will range from large visual consoles giving a pair of users a sense of immediate presence through easily portable visual models not requiring

---

W. D. Lewis is Executive Director of Research Communications System Division, Bell Telephone Laboratories, Inc., Murray Hill, N.J. *(Received July 5, 1961.)*

connection to the wall down to pocket sets which will have a circumspect lack of vision and may be carried continuously if desired.

Conversation between two people is only one of many modes of communication. Several others seem sure to become realities by 2012 A.D. For example, it seems likely that most written communication will be transmitted electrically and not by transportation. The private citizen will have electrical access to machines of all kinds, for example, centralized data-processing units for banking. Electrical access to reference libraries will surmount any mechanical barriers to recorded information or, for that matter, entertainment. Finally, and perhaps most important, it is possible that a combination of visual recording, teaching machine techniques and human intervention where needed, will make available the best education in any subject, anywhere, any time, to anyone who wants it.

Communication and Navigation

HENRI BUSIGNIES FELLOW IRE

COMMUNICATION Satellite communication will be in current application not only for point-to-point transmission connecting all countries of the world for telephone, data facsimile and television, but satellite broadcasting will also be operating with automatic and available selection of spoken intelligence in all principal languages. Television broadcasting from satellites will cover very large areas. Translation service will be made available for international communications first by human translation—next by electronic translation.

The world-wide satellite system will provide electronic mail service for the written word while electric typewriters will reproduce typed text for international transmission.

On the very dense transmission links for relatively short distances (up to a few thousand miles) on land, waveguide transmission will replace microwave space transmission and will give a bandwidth capacity that will make available thousands of television channels; this will permit transmission of masses of data, of newspapers and printed material and will make available the phone vision to a large section of the subscribers at a reasonable cost. The carrier used in the waveguide will be a coherent beam of light.

The distribution of newspapers and magazines will have been considerably modified by the introduction of electronic transmission, through which subscribers will receive them. The paper (or rather its equivalent) will be made locally automatically from a liquid. In many instances the reader will not want a permanent record and will avoid the paper altogether by receiving the information on a storage tube, one page at a time at his desire.

The subset as we know it will still be in use but in many instances will have been replaced by either a fixed speaker-type form of wall, or table model, or by a very light unit carried by the user, of course, "wireless."

Mobile radio will be common, in the form of a miniature "wireless" unit carried by the user or installed in cars, buses, and other means of transportation. Ships at sea and airplanes will communicate with shore by satellite, and telephone service will be provided to the traveler. He will be able to get an automatic report on how things are in his home. Push button dialing will be possible in many countries using the world-wide satellite system.

NAVIGATION True all-weather flying will be possible with an accurate knowledge of position by each aircraft within a fraction of a mile. Anti-collision will have been fully developed on two bases: through automatic reporting of position to the ground and high-speed computing of routes and conflicts, and through direct radar or equivalent exploration of space around each aircraft with high-speed warning on possible route conflict with either automatic or manual route correction. True zero zero visibility landings and take-offs will be common, adapted also to vertical take-off airplanes. The methods of ILS will be of the same general type but the airplane controls will have been much improved and the accurate position determination will permit the airplanes to come in (or leave) in perfect order without stacking.

H. Busignies is Vice President and General Technical Director of the International Telephone and Telegraph Corp., New York, N.Y. *(Received June 30, 1961.)*

Communications and Electronics—2012 A.D.

PETER C. GOLDMARK FELLOW IRE

In this 100th Aniversary Issue of the PROCEEDINGS OF THE IRE, May, 2012, we feel privileged to discuss a very interesting article contained in the 50th Anniversary Edition dated May, 1962. That article, entitled Communications and Electronics—2012 A.D., was written by Fellows of the IRE, and it may interest some of our readers to go through a check list and see to what extent our 1962 colleagues were able to predict the state of the art today.

One of the contributors, Peter C. Goldmark, forecast that practically all point-to-point long distance communication would be by microwaves in the millimeter region. This included global television relay via satellite operations, as well as global telephone and facsimile service. As to broadcasting, the prediction stated that by 2012 the FCC would have approved the ultra-high frequencies for exclusive use by TV broadcasting. Actually, as we know, a final decision concerning the UHF band for all TV broadcasting is imminent, following the completion of the FCC technical staff's extensive experiments begun in 1961. Our radio broadcasting, according to Goldmark, would be entirely via FM, using the same portion of the spectrum as in his day. If he were still with us, Goldmark would be surprised to find that transatlantic telephone is still operating via co-axial cable and repeaters buried in the Atlantic. The satellite relay schemes forecast, as we all know, did not quite pan out, with so much of the nation's resources devoted to competing with the Russians in the race for reaching extraterrestrial bodies.

Anyone in 1962 with some imagination should have been able to predict our moon-to-earth citizen's radio service, operating so effectively in the millimeter citizen's band, but it would not have been easy to foresee our tremendously efficient high-power solid-state wrist watch transceivers and plasma antennas.

One item not covered in the article, though subject to considerable stir 50 years ago, is stereo broadcasting. The limited space and manpower available to radio and phonograph dealers in the middle of the last century made it imperative to compress reproducing instruments to the smallest possible size. As a result, while techniques were in existence to generate stereo signals on records, as well as over FM and AM radio, there were hardly any instruments made which took advantage of the stereophonic phenomenon. Consequently the monaural effect was discovered, requiring minimal speaker separation in home instruments.

One word about a form of entertainment which, in the middle of the last century, led to a number of broken homes and eardrums: We refer to Hi-Fidelity, then a thriving industry. Then phonograph instruments were huge boxes generating a great amount of heat, and were called Hi-Fi amplifiers. Some of them measured 16-in wide, and the audio signals extracted from the phonograph records[1] were amplified by devices called vacuum tubes (which also performed as thermionic ovens in bookcases and other enclosures). It is hard to imagine that our ancestors did not have the compact Fi[2] amplifiers contained in our most recent home music center, which measures only 4-in wide, 3-in deep and 2-in high.

The 50th Anniversary article we are reviewing here carries in its title the word Electronics, more commonly known today as Solid-State Physics.

It is interesting to read in the article how our present TV cameras were envisaged by the 1962 scientists. (It was presumed that by 2012 all TV would be in color and three dimensional.) It was predicted that the scene to be transmitted would be sensed with a tiny adaptation of a device which they called a camera tube. The predicted version would contain a target plate which was color sensitive and would be able to generate a video signal containing all color and stereoscopic information of the scene scanned, thereby eliminating all registration

P. C. Goldmark is President of CBS Laboratories, a division of Columbia Broadcasting System, Inc., Stamford, Conn. *(Received September 7, 1961.)*

[1] These were discs made of plastic where sound grooves were pressed into a number of fairly coarse grooves, on the average 250 per inch. The record rotated on top of a box full of moving parts, and the whole thing was called a record changer or player.

[2] It may be recalled that the word "Hi" was dropped in the year 1994 by a majority vote of the IRE Standards Committee.

and color shading difficulties plaguing color TV of the 1960's. Goldmark would be quite surprised if he could see our TV cameras of today. Our 1-in diameter, 2-in long solid-state camera units, combining the multicolor-sensitive, scanning and amplifying elements in a number of evaporated layers, are far ahead of what he predicted.

Experiments with scanning by pulse techniques began in the 1960's; it was thought that these techniques would be applied to what they called the "picture on the wall." This type presentation was indeed the forerunner of our TV receivers today. We are quite proud of our large experimental digital color screens which are almost flush with the wall and produce the brilliant three-dimensional images using our 120-megabit standards. Should the proposed new standards be agreed on, as a result of the recent FCC color hearing, a number of manufacturers will be in a position to supply color adaptors for the existing black and white receivers. (It is strange that we still talk about adaptors when all through the history of communications adaptors never proved to be accepted by the public, and possibly never will.)

One more comment about the 1962 article. When talking about computers nothing was forecast about our predictors. While using the fundamental principles on which computers were based, predictors represent such radical advances over the conventional computers of the 1960's that one cannot very well blame our ancestral Fellows. Now we can not only store and process complex information, but we can predetermine the optimum course of action to be taken based on the information furnished. National policies, business decisions, family issues are now settled on the basis of the predictor's output, thereby leaving little likelihood for chance and error entering into decisions. As a result of this technique we now enjoy peaceful coexistence, giving us a feeling of well being and security.

On the whole, we think that Goldmark, in 1962, could have done a better job of properly forecasting "Communications and Electronics—2012 A.D."

Communications Throughout the Solar System

W. H. Pickering FELLOW IRE

Within the next 50 years, rocket propulsion will have advanced to the extent that space travel throughout the solar system is a technical possibility, and it is virtually certain that by 2012 A.D. manned spacecraft traveling to Mars and Venus will no longer be a novelty, and manned exploration of other planets and satellites will have been undertaken. It is unlikely that man will have been able to venture as far as other stars, but instrumented space probes will have been sent far beyond the solar system. Space travel in the vicinity of the earth will include manned orbital laboratories and space stations and manned lunar laboratories. None of this activity can be undertaken without adequate communications, therefore the communications art must progress at least as fast as the rocket art.

The obvious problem is that of distance. On the earth, communications distances of the order of 10^3–10^4 kilometers may be needed. In space, the distances are of the order of 10^8–10^9 kilometers. Hence, system capabilities must be increased by a factor of 10^6 in range. Clearly antenna gains, receiver temperatures, operating frequencies, communication bandwidths must all be optimized for the particular space mission. Equipment operating on spacecraft must be capable of operating reliably in the space environment for long periods of time. By 2012, spacecraft used for distant voyages will carry nuclear reactors for propulsion purposes and for power generation. Electrical power in megawatt amounts will be available for spacecraft operation. Thus, the communications equipment is not likely to be power limited.

Some interesting possibilities arise when the problem of space-to-space communications is considered. With a true vacuum for a communications medium, electromagnetic waves in unusual parts of the spectrum and high-speed particles such as electrons or neutrons offer possibilities for new types of systems.

In 2012 the communications engineer interested in solar system communications is thus going to find the following:

1) A world-wide network of terminal stations having very large directive antennas which can maintain 24-hour a day contact with a number of spacecraft. The

W. H. Pickering is Director of the Jet Propulsion Laboratory, California Institute of Technology, Pasadena, Calif.
(Received September 6, 1961.)

stations will use kilomegacycle frequencies, transmitter powers in the megawatt range, and receiver temperatures close to absolute zero. The stations will be interconnected through wide-band data links using satellite relay stations.

2) Spacecraft equipment on both manned and unmanned craft with exceedingly long life and high reliability. The requirements for long life and reliability will be difficult to meet, but will be essential to the success of the space program.

3) Various electronic devices taking advantage of the environment of space, particularly the near perfect vacuum and zero gravity. Thus, the communication system may use vacuum tubes which have no glass envelope and are therefore more effectively built into a circuit. Also, the system may use large antennas, which are assembled in space and are of very small mass.

4) Space relay stations not only near the earth for earth-to-earth communications, but far out in space as beacons and as relays for wide-band communications. For example, in order to communicate with Mars or Venus when the planet is on the other side of the sun from the earth, a space relay station in the earth's orbit, but 90° around the orbit from the earth, will be necessary. Such relay stations will be established in various parts of the solar system as men and rockets travel further into space.

The deep space communication systems of 2012 will indeed keep up with the capability of the rocket engineers to send payloads into space. As man ventures further out into the solar system he will always be in contact with the earth. His communications system will be a vital part of his navigation system. He will use very long-range radar to assist him in his landings on distant planets and other bodies. He will examine the planets by television, not only in the visible, but in other regions of the spectrum. He will report back to earth over wide-band channels. I have no hesitation in saying that the communications art will advance fast enough to answer all the demands upon it, except one. It will not be able to communicate by means of signals traveling faster than the speed of light. Hence, communications to space travelers on Mars, for example, will continue to have to put up with time delays of the order of 10 to 20 minutes.

Human Factors in Communications

ALBERT G. HILL FELLOW IRE

Communications in the year 2012 A.D. are not going to be terribly different from communications nowadays. The primary reason for this is the human element. Meaningful communications involve the exchange of information and ideas between people. Certainly in fifty years one may expect significant improvements in technical hardware, but in the final analysis, the development of a new and improved model of the homo sapiens is not on the horizon. The real significance of these scientific and engineering improvements will not be evaluated solely on the basis of speed, capacity, cost, etc., but only with full recognition of both the frailties and the strengths of people.

How do we engineers and scientists help provide better communications? Where must attention be directed to make a really significant breakthrough possible? The answer probably lies in the assistance we can give to the human factors involved. We can talk glibly about discussing our problems with the people on a broad basis or on a person-to-person basis. We cannot, however, improve communications until we improve human relations. We can speak of new technical inventions such as solid-state matrices which will help us tremendously, but only from a technical point of view. These will not necessarily improve communications.

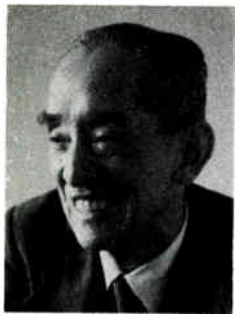
If the above words be correct, it is very incumbent upon us to understand better the human factors in communication systems. This does not mean that we should hire more psychologists and psychoanalysts; we ourselves must understand better all the factors in communications among human beings. Quite often communications between persons sitting in the same room, speaking the same language, are not understood.

We can start, and this is only a start, by exerting a conscious effort toward making our speech more precise whether it be over the telephone, over the radio, or face to face.

A. G. Hill is a Professor of Physics at Massachusetts Institute of Technology, Cambridge, Mass. *(Received May 26, 1961.)*

Multilingual Communication

YASUJIRO NIWA FELLOW IRE



Overseas telegraph and telephone, 50 years ago, needed vast areas in suburban districts to set up gigantic antennas and big station houses where a series of colossal equipment was installed. Nowadays, frequency range assigned to telecommunications is remarkably enlarged and serviceable channels are quite numerous, and at the same time, microminiaturization of components (it is rather funny to use this word today!) and the progress of noiseless amplifiers based on maser principles revolutionally improved the receiving sensitivity. Thus the size of transmitting and receiving devices is reduced to the minimum. Moreover, a number of repeater artificial satellites are going around the earth. We ring up anyone, anytime, and anywhere on the earth, just like a man calling his neighbor fifty years ago, by a handy superhigh-frequency transmitter. He talks to a suitable repeating satellite which, responding to the message, instantly calls his friend on the telephone.

Y. Niwa is President of the Tokyo Electrical Engineering College, Chiyodaku, Tokyo, Japan. *(Received June 12, 1961.)*

Even in the period that electronic techniques had just made it possible to talk to anyone, anywhere, and anytime on a global scale, communication stands on the condition that the people at both ends of the communication channel can read and speak the same language. In the course of the past hundreds of centuries the human language became so differentiated among so many races and nations under different environments and customs throughout the world, that even at the time when a few hours' flight can carry the people from anywhere to anywhere on our beloved planet, the unification of human language is still a long way off.

Again, the advancement of electronics decisively solved this problem. Today principal languages of the world can be translated instantly by the aid of electronics. Our telegrams are simultaneously translated into, and typewritten by, the language of the receiver, and on our overseas telephone the speech is also converted to the language understood by the receiver and vice versa. Moreover, by the results of hyper-miniaturization of electronic parts and appliances the size of the translating machine is also reduced to such an extent that it can be easily used at home and carried by hand. In 2012, we say, "It has become a faint dream of nights long past that at an international conference the participants had to use an earphone to listen to speeches translated 'simultaneously' by man-machinery behind the scenes."

Language, Words and Symbols

HAROLD A. WHEELER FELLOW IRE

The handling of language has been one of the principal functions of communication systems. Electronics had its origin in the transmission of messages and subsequently has contributed many varieties of instrumentation. Information theory now has much to offer for the future, in conjunction with electronic computers and data processing for performing the required operations in analysis and synthesis.

SYNTHESIS OF WORDS FROM SOUNDS The language of human beings is based on the emission and sensing of certain patterns of sound.[1] This language is remarkable in its versatility, especially in view of its natural evolution as distinguished from scientific planning. The languages of different human societies have had much in common, including the remarkable ability of the brain to remember and to associate sound patterns by virtue of some essential characteristics. The identification of sounds with ideas is still an art rather than a science. Even with his tremendous mental capacity, a person requires years of apprenticeship to acquire even a mediocre competence.

It is presumptive that the principal words and phrases can and do convey ideas in a limited number, as in Basic English for example. With the accumulated knowledge of science and technology, we should now be prepared to develop an "efficient" language. By that is meant, one that will be based on the most useful sounds and will associate these with the most needed ideas.

An early stage of such a development should be devoted to a study of all sounds now used in various languages, and further sounds that could be utilized in speech. The next stage might be the selection of sounds that require the least effort and can be identified with least ambiguity (unaided by other senses and redundancy). The permutations of several such sounds in close succession would yield a limited number of words.

A parallel effort should be devoted to cataloging the essential ideas which are required to be expressed by words or word groups. Perhaps this activity has a good start in the major effort that has been directed to the problem of interlanguage translation by machine.

Another parallel effort should be directed to the development of principles for preferred relations between words and ideas. These would range from complete randomness to possible association with experience (by criteria that are not immediately obvious). Perhaps the English language would offer the most helpful associations, though its origins have been largely random.

The final stage of development would then be the cataloging of a new language based on the assignment of relations between sounds and ideas. This language would then have to be tested in isolated "laboratory" groups to determine whether it possesses such requisites as ease of learning and effectiveness of communication. Ideally, several such languages should be tested in competition, since it is unlikely that the first product would satisfy the critical observer.

In experience to date, it has been rather easy to

[1] J. R. Pierce and E. E. David, "Man's World of Sound," Doubleday and Company, Inc., New York, N.Y.; 1958.

H. A. Wheeler is President of Wheeler Laboratories Inc., Great Neck, N.Y. (A subsidiary of the Hazeltine Corporation.) *(Received September 5, 1961.)*

synthesize sounds that the sense of hearing can identify in terms of language. However, it has been difficult to receive speech sounds and automatically to separate their essential characteristics from their incidental peculiarities. In the "efficient" language, the latter operation should be anticipated in the description of the sounds to be utilized. It should be possible to record the sounds of a statement and then automatically to transcribe it to the printed sheet. Such an objective is far beyond the English language; it has been achieved only in the telegraph codes, which are too cumbersome for speech.

GRAPHICAL SYMBOLS FOR SOUNDS Like the sounds of speech, the graphical symbols of writing and printing are also the result of natural selection by generations having no particular training or aptitude for this task. It has been more an art than a science. There is lamentable lack of uniformity in connective writing, which is the most utilized medium in direct recording of thoughts. Indeed, some otherwise competent educators are even resisting the inescapable principle that such writing is a functional common denominator which requires standardization for its purpose of communication.

In the present language, or in a newly developed "efficient" language, it is inherently possible to identify every essential speech sound with a better symbol. Much effort has been devoted to this problem, but to little avail. There has been too much emphasis on retaining the existing symbols, which are time-honored but lacking in logical synthesis.

In developing a new set of symbols, special consideration should be given to some method of transcription, from one "type font" to another or to speech sounds. The recognition of graphical symbols by machine is receiving much attention but perhaps it is time for a new scientific basis for such symbols.

This task is much easier than the development of a new language. Perhaps it should be applied to some existing languages in the meantime, even though its objectives could be only partially realized.

COMMUNICATION WITH ANIMALS As we learn more about our fellow creatures outside the human family, we have more respect and admiration for their intelligence and integrity. One of the most fascinating of current research projects is the investigation of the language sounds of the dolphin, who is remarkable in his athletic skills, learning ability, and aptitude for teamwork, not to mention his scintillating personality.[2] He possesses some of the human traits that evolved in the days before tools and records. Other animals that are remarkable in their development include not only the ape family, but also the elephant, the "big cats," the dog and the otter.

Man has assumed his habitual "superior" attitude toward other beings, and usually has insisted that they learn to respond to his language. The writer suspects that some animals may well regard humans as "backward" because they cannot speak the same language, and can little understand it. Perhaps such animals would not appreciate the compliment of being called "almost human."

Only now are we making real progress in learning the language of some of the higher animals, and the next few years should see much progress in utilizing their languages for communication with them. This experience will be as exciting as a contact with a civilization on another planet, and it can be productive much sooner.

Identifying and describing the language sounds of an animal may be done in a manner similar to the "visible speech" display developed in Bell Telephone Laboratories. Alternatively, for purposes of simple classification, the sounds may be encoded by the "vocoder," which automatically derives a description of sounds in terms of the time variation of their frequency spectrum.[1]

The sound emitted by an animal can be recorded, stored and played back at will in his own medium (air or water). Once we discover the meanings of certain forms, we shall be able to translate between that language and ours. We thereby avoid any need for the animal to learn our language. Some such experiments have been in progress, and this is probably the way of most rapid advancement.

In communication with an animal, a real milestone will be reached the first time that we are able to ask a question and get an answer. Will this be experienced in the next 50 years? It is not too far removed from the now famous lioness, Elsa, who appeared to sense questions and indicate the answers without relying on any formal language.[3]

Processing of Sound

HARRY F. OLSON FELLOW IRE

Sound processing is used to designate the analysis of sound, the conversion to a code and the synthesis of sound from a code. The development of sound-processing systems will provide many new facilities for the reproduction of speech and music; the production of speech and music from codes, sensors and the printed page; and the conversion of speech to the printed page and for the control of machines. Speech, music and the printed page constitute the foremost means for the transmission of information. Sound processing will increase the means for the production, reproduction and use of speech, music and the printed page in the communication of information between individuals and to and from machines.

The most important new communication systems involving the processing of sound are depicted in Fig. 1.

In a system involving speech and music input to a microphone, the information bearing components of speech and music are coverted to a code by means of an analyzer as shown in Fig. 1A.

The synthesizer and loudspeaker of Fig 1B produce speech and music from a code. The advantage of the system of Fig. 1B is that the coded record may be made only a small fraction of the size of existing conventional records for the reproduction of speech and music.

A combination of Figs. 1A and B is shown in Fig. 1C in which the input and output is speech or music and the transmission takes place in the form of a code on a reduced bandwith.

When speech is converted to a code, the code may be applied to an actuator to control a machine or to a typer to produce the printed page, as shown in Figs. 1D and E.

The particular state or condition of a machine may be sensed and converted to a code and synthesized into speech as shown in Fig. 1F.

The printed page may be converted to speech by means of a print reader, code and speech synthesizer as depicted in Fig. 1G.

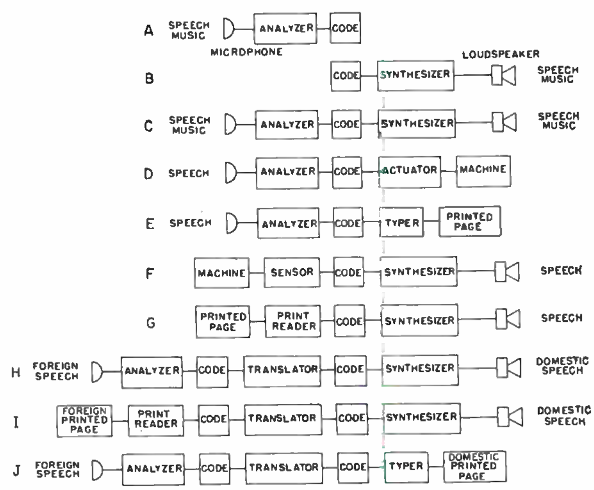

Fig. 1.

The addition of a language translator as shown in Figs. 1H, I and J provides means for the conversion of foreign speech input to domestic speech output, the production of domestic speech from the foreign printed page and conversion of foreign speech to the domestic printed page.

The advantages and the applications of the systems shown in Fig. 1 are obvious and require no further explanation.

There appears to be no doubt but that the systems of Fig. 1 will be developed and commercialized because

H. F. Olson is Director of the Acoustical and Electromechanical Research Laboratory, RCA Laboratories, Princeton, N.J. *(Received June 21, 1961.)*

significant steps have been made towards this goal. For example, an electronic music synthesizer which produces music from a code has been developed and is in operation. Speech synthesizers are also available. A research model of a phonetic typewriter, which types in response to the words spoken into the machine with a vocabularly of 100 syllables has been developed—2000 syllables will provide a practical machine. Print readers have been developed for converting the printed page to a code. Word translators have been built and operated and language translators are in the process of development.

The general conclusion follows that sound-processing systems will be developed and commercialized in the foreseeable future to provide new facilities for the communication of information between individuals and to and from machines.

Music and Sound Reproduction—2012 A.D.

BENJAMIN B. BAUER FELLOW IRE

In attempting to predict the future of any art one must determine what is the logical fulfillment of the art; then one must estimate the rate of growth of technology and the capacity of the public to accept changes and technological obsolescence.

One of the most important long-range objectives of the art of sound recording and reproduction is the total recreation of musical experience, and we can look forward to a rather complete fulfillment of this objective by 2012 A.D. Audio-visual arts will also become more important and their uses will be extended to many new areas (perhaps new mothers will learn about baby and child care from an audio-visual Dr. Spock?). Nevertheless, music alone has the power of abstraction which makes it universally acceptable, and by 2012 A.D., good music will be within the economic reach of all mankind.

Sound is the most ubiquitous of perceptions, and unlike sight, Nature has not provided us with the means of shutting out the inputs to the organ of hearing. We constantly and instinctively react to the character—intensity, pitch, timbre, direction of arrival—of sound and the rate of change of these qualities.

Among the important musical qualities is the "feeling of space." This is the reverberant sound in a concert hall, the applause in the opera, the crowd sounds in a sports arena. By 2012 A.D. all these will be reproduced in their correct perspective.

Within the past few years, directional perception has become a practical possibility by the commercial introduction of stereophonic sound; however, considerations of economy and convenience, rather than technology, restrict us commercially to a two-channel system which has a limited directional accuracy and coverage. This limitation will be overcome and the more sophisticated installation of the future will literally surround us with sound.

During the intervening years, the recording medium will contain a more or less continuous direction parameter ordinate along the width of the recording medium, with the time-varying parameter along the length of the medium. By 2012 A.D. molecular memory stores will have been applied to sound recording, altogether eliminating the need for mechanical drives.

The music will be reproduced by a more or less continuous loudspeaking area installed in the walls behind a perforated grille; the same loudspeaking area will provide suitable sound absorption and dynamic noise suppression by electromechanical reaction of the transducer system. Very small and efficient ionic and modulated stream loudspeakers will be available for portable uses.

Another approach to be used in space flight, but also widely accepted in the home, will employ wireless transmission of multichannel information to special miniature earphones or near-speakers worn by the person. They will give the user complete freedom of motion and yet retain the directional sense of communication, or musical experience.

B. B. Bauer is Vice President of Acoustics and Magnetics, CBS Laboratories, Stamford, Conn. *(Received September 5, 1961.)*

Devices for converting sounds to nerve impulses for direct connection to the brain will have been developed; however, they will require a delicate implanting operation and will not be in general use. These "artificial cochleae" will largely replace deaf-aid devices as we know them today in cases of inner ear damage. For mild hearing loss, greatly refined electronic aids will be available. These aids will employ miniaturized solid-state microphones and receivers, and they will be implanted in the ear canal, or the middle ear, and provide a lifetime of operation with harmless atomic cells.

Recorded sound to a large extent will replace the printed word. Shakespeare will be heard fully dramatized. Only those irreparably deaf will be reduced to the necessity of reading his works.

The musician will not be limited by his ability to "blow, scrape or pound" in providing great artistic renditions. Delicate servomechanisms in electronic musical intruments will augment his capabilities.

Music, as the most abstract of all arts, will widen its universal appeal and serve as another instrument of universal peace.

Functional Components and Integrated Circuits

Invention Today Synthesis in 2012 A.D.

J. A. Morton FELLOW IRE

To me, one of the most interesting features of communications and electronics in the period of which I have been a part is the constantly shifting, but ever more complex interplay of the various technical disciplines. We are truly polyglot—the more to our vitality and interest. One of the most beneficial infusions has been from solid-state physics and the basic material sciences in the enormously productive period since the war. Electrons seem to bond all kinds of people, like all kinds of atoms, together.

One road into the future of electronics is already fairly well charted. Single function components which we have used individually as the physical embodiment of classical network elements must give way to more sophisticated devices which perform a complex circuit function. The present effort in this direction is aimed at integrated circuits and is following along two lines—thin films and multicomponent semiconductor arrays on a common crystal. Each of these techniques, which are basically complementary, offers a never ending potential for ever more complex assemblies.

J. A. Morton is Vice President of Bell Telephone Laboratories, Inc., Murray Hill, N.J. *(Received July 17, 1961.)*

It seems to me, however, that another approach, more difficult to anticipate except in broad concept, will emerge to play a larger role. This is the idea of the functional device which goes directly to nature for the electronic function needed. One of the very few examples where this is already commonplace is the use of piezoelectric crystals in filters and oscillators. Although functionally equivalent to a resonator assembly of passive components there is no part of the crystal that can be identified as an inductor, capacitor, etc. I expect that by 2012 we will have a host of functional devices. Their versatility will be so great and the control over the materials and processes will be such that the designer will likely be concerned only with accurate and complete specification of his requirements. From this information a computer (a deceptively simple computer made of functional devices) will be able to make the necessary calculations and instruct the manufacturing machines. Thus we will have progressed from invention to routine synthesis. A comforting thought: long before we reach this millennium some bright new discoveries and inventions will have us chasing down new and difficult and challenging roads.

In any case, the melting pot will continue the process of mixing up the disciplines and will need several new waves of immigration to man up the new frontiers and expand the culture. Device designers and circuit people are suddenly bumping heads as they begin to work on integrated circuits. New and strange people, like topologists, will be moving in and will want to join the club. The most profound understanding of solid-state physics and chemistry will be needed to bring forth functional devices; indeed, it is likely that functional device inventions will produce new science as did the transistor.

My preoccupation with people in pondering the future undoubtedly reflects my distance from the firing lines for a number of years. However, I truly believe that more of the stumbling blocks will be caused by the frustrations of people trying to adjust to the rapidly changing situations than to the purely technical problems.

In considering what electronics and communications will actually be in 50 years, I grow timid. It is easy to imagine things that would be useful and experience seems to vindicate the attitude that nature is capable of providing anything that can be imagined—at least anything of a materialistic nature. But the important thing is *how* all these wonders will be accomplished. I have worried increasingly of late about too much emphasis on proposals rather than on things that have been done. Planning for the future is necessary and important, although difficult and risky in a field such as present-day electronics. Pure speculation, honestly indulged in, can also be useful and is certainly fun. The danger lies in losing perspective, of confusing hypotheses and solid facts, objectives and accomplishments. Such a situation was justified by the Lord High Executioner in the *Mikado* who released a prisoner and then made affidavit to the fact of his execution, 'It's like this: when your Majesty says, 'Let a thing be done,' it's as good as done,—practically, it is done,—because your Majesty's will is law. Your Majesty says, 'Kill a gentleman,' and a gentleman is told off to be killed. Consequently, that gentleman is as good as dead; practically, he is dead, and if he is dead, why not say so?"

Extreme Developments of Solid-State Circuitry

HARPER Q. NORTH FELLOW IRE

The year is 2012. A few of us can remember the birth of the transistor in 1948, but most are too young to recall the announcement which was to have phenomenal impact upon twenty-first century living.

The vacuum tube is not the familiar bottle it once was. Like prehistoric monsters of the Mesozoic Age, only the giant tubes have survived, and they lead highly specialized lives dedicated to microwave power generation. The rest have given way in conformance with principles of evolution to smaller, smarter, and better adapted descendants.

There is a special strain of "species transistoris" which never grew in the sense of maturing in size, but which today is cultivated like a complex plant. It is the 2012 integrated functional system emerging from today's circuit "greenhouse." The basic principles were known as early as 1960, but even today's most sophisticated engineer, a specialist in solid-state physics, marvels as he observes the operation of a circuit greenhouse.

H. Q. North is Chairman of the Board of Pacific Semiconductors, Inc., Lawndale, Calif. *(Received June 22, 1961.)*

As he enters the factory, he notices the extreme cleanliness—no hospital was ever like this. Rooms are within rooms and each is "whiter" than the last. At the center is the evacuated greenhouse into which a miniature computer (itself grown in another greenhouse) introduces controlled gases as the master scientist and "assembler." Sheets of transparent insulating crystals are drawn from melts or, by most recent techniques, are grown from the vapor phase. They are five to twenty mils thick to a tolerance of plus or minus 100 angstroms, and they are sheared and stored in vacuum to await their turn on a conveyor belt.

Crystal sheets one-foot wide are carried on the conveyor traveling at a speed measured in feet per minute as determined by deposition processes under the control of the compact master computer which, we are told, would have filled an entire room in 1962.

The crystalline sheet for this morning's production run enters first the glowing "sterilizer" section of the water-cooled greenhouse where it receives gentle ionic bombardment for a thorough cleaning of its surface.

In the next section called the "photosynthesis" section, eerie fluorescent patterns are projected onto the sheet which has now begun to glow from infrared heat. The patterns will be transistors, capacitors, and tunnel inductors (made possible through coherent nondispersive delay mechanisms discovered in 1970). Doped semiconductor layers deposit epitaxially on the illuminated pattern as base, emitter, and collector regions are formed. The ultraviolet catalytic methods known in the 1950's for gaseous etching have now been extended to control vapor deposition as well. They have been standard since 1964 as a means of removing oxide masks with great accuracy. Wet processes have disappeared and gaseous etching has taken over; dislocations caused by grinding and diffusion have been eliminated, now that these processes have been replaced.

The transparent sheet with its irregular dark spots, once called components, is spectacular to watch, but its intricacy cannot be fully appreciated without a microscope. The sheet next enters the "stem and blossom section" where resistive bridges composed of degenerate semiconductor layers are vapor-deposited between the dark spots. Then metallic low-resistance connectors and fixed capacitors blossom forth within the pattern and at the edges of the individual circuits as metallic electrodes.

Next is the "florist" section where the circuits are sheathed with insulating transparent crystalline layers to protect them from adjacent circuits to be added later and to passivate the components to prevent atmospheric contamination and degredation in use.

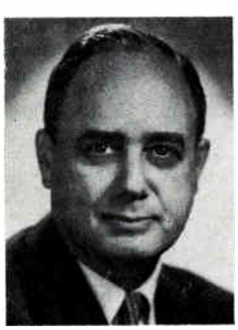
Functional circuits are "cut" from the large sheet in the form of ribbons by means of u-v activated gaseous etchants, and the individual ribbons go their own ways. Some are turned over to permit operations on the reverse side. Others join sheets coming in through branches in the greenhouse. As they join the main ribbon, they are cut and welded to it by an ion beam. In the "grafting" section to follow, dendritic bridges are created between functional circuits by decomposition of metallic vapors present in that section. This is followed by another florist section where the system receives its final wrapping.

Even in our year 2012, batch operations are required to connect a system to speakers, cathode-ray tubes, and input and output consoles. But the construction of these devices is now exceedingly simple, for we have learned to depend almost entirely upon basic phenomena in the new piezo-electric sheet vibrators, in luminescent sheets with vapor-grown "phosphor" dots, and in organic sheets containing ten-thousand bits of computer information per square centimeter of surface. Magnetic drums and tapes are all but obsolete.

Reliability today in 2012 is such that an entire system of what was once one-hundred thousand components will not fail within a fifty-year period, far longer than its useful life on an obsolescence basis. It is hard to realize that reliability was ever a problem and that redundancy of components was once considered the only practical way of achieving it.

The Role of Materials in the Electronics World of 2012 A.D.

GORDON K. TEAL FELLOW IRE



I contend that the electronics world of 2012 A.D. could come to pass before 1972 if materials technology would permit. We can envisage clearly the contributions of electronics to the lives of our children living in 2012 A.D. They will be highly educated by electronic teaching machines; work in automated industries and offices; communicate by means of satellites instantaneously to any part of the solar system; live in homes with walls that provide cooling, heating and lighting; enjoy three-dimensional color stereophonic television and telephone; conduct all financial transactions using coded identification cards; voice opinions on national and local government policies by voting electronically from their homes; enjoy a long and healthful life through computer use which will provide diagnoses with minimum probability of error and will prescribe with maximum probability of cure; ride in quiet fuel cell powered vehicles; and have the contents of even the rarest books available within minutes at the neighborhood information service.

Once emanicipated from the materials restraints, we will have developed technologies permitting tailor-making materials starting at the atomic level. Science will domi-

G. K. Teal is Assistant Vice President of Research and Engineering at Texas Instruments, Inc., Dallas, Tex. *(Received December 19, 1961.)*

nate several fields of materials which heretofore have been mainly technology. Ceramics engineering, for example, will embody the applications of advances in solid-state physics and chemistry of ceramics. Metallurgy too will continue its present strong science growth until most structural materials are designed by the scientist at his desk.

Single crystals of many exotic metals, alloys and compounds will be mass-produced. Of even more importance to the electronics industry, we will learn to deposit layers of extreme purity single or polycrystalline materials with thicknesses controlled to within a few angstroms. New thresholds of purity will be realized by the use of select enzymes to remove impurities. We shall see the use of ceramic materials as active electronic components and systems formed in integrated circuity and operable at temperatures up to 2000°K. Insulators and conductors to meet the extremes of atmosphere and temperature for magnetohydrodynamic power generators will be a reality. Further understanding of materials and their surfaces will divulge the nature of catalytic phenomena. We will see semiconductors used extensively as catalysts to enhance chemical reactions. This development in the field of catalysis will promote in turn the use of fuel cells to provide power for industrial and home use, relegating to the past the power lines that mar the scenery of our cities and countryside.

Advances in cryogenics will make device operation at 4°K common. These devices, being in many forms, will operate in the superconducting state with infinitesimal power requirements and often with speeds 10^3 to 10^4 times those presently common. Cryotrons will evolve beyond the normal switching usage to become integrated logical and memory devices. The present active and passive circuit elements will be duplicated to function at near zero temperatures with attendant realization of drastically reduced noise levels and power requirements orders of magnitudes less than are presently feasible. Superconducting magnets with fields greater than 10^5 gauss and negligible power dissipation as well as power transformation without loss will be a reality.

During the next decade, and extending forward to the year 2012 A.D., significant advances in the area of thin films and surface phenomena will allow the materials scientist to control the bulk and surface of deposited films. Through this will evolve a new generation of transistor-like devices, field emitters, and systems of integrated circuitry with high reliability and of low cost. Deposition techniques will become the dominant method for producing electronic materials as it will allow arbitrary control of the number, kind, concentration and concentration gradient of constituents. It is the nearest approach to working directly with materials in atomic amounts.

This new science of working with atoms might be aptly described as "atom engineering." It will permeate all fields of scientific endeavor and will govern the progress of the electronicist during the next 50 years. This technology will progress to the point where individual atoms, vacancies and defects will be selectively positioned in a device to function as circuit elements. Use of collective electron orbits and spins as memory storage units within a "match-box computer" will be a reality. Atom engineering will provide the solid-state analog of the vacuum tube and will also make possible elaborate tunneling devices and sophisticated systems. The advent of wafer-thin dynamic picture displays is just "around the corner," as is the all purpose ultransensitive single crystal sensor.

I wish to point out that the specific role played by materials in the advances expected in electronics by 2012 A.D. is subtle, in fact so subtle that some may consider it to be trivial to the progress of electronics. The physics of the material is thought by some to be of singular importance. In such thought it is forgotten that the material possesses the wonderful properties we exploit, not the mathematics which describes these properties. To elucidate further, I point to the example of the *p-n* junction which triggered the major revolution occurring in electronics. While the elegant mathematics which describes the *p-n* junction is important, it is the materials technology that permits the formation of the junction which provides the many useful electronic devices we now use. Similarly, it will be our ability to understand and utilize materials, each with its own unique properties, which will be the foundation of electronics in 2012 A.D.

Information and IRE—1912/2012 A.D.

DONALD G. FINK FELLOW IRE

Information, in the sense of intelligible data embodied in symbols, is the basic concern of the majority of the professions embraced by IRE. The symbols may be words or waveforms, picture elements or binary digits. The form of the intelligence may be aural or visual, abstract or concrete, and its intended function may be communication, computation or control, instruction or entertainment. Whatever the particulars, throughout the publications, committees, and groups of the Institute we find the thread of information technique. Our systems, our theories, our devices and circuits—nearly all are related in some way to the storage, manipulation, transmission and perception of information. It seems appropriate, therefore, to review and predict IRE's contribution to society in the 20th century in terms of the ways in which its members have dealt with, and will deal with, symbolic intelligence.

When IRE was founded, great discoveries were already at hand through which the transmission and storage of information were to be enormously extended. The basic principles of wire and radio communication were established, and the recording of moving pictures and musical sounds were ready for exploitation. During IRE's first 50 years, these arts have been refined and systems employing them have been extended on a scale so pervasive as to leave no part of human endeavor untouched. We have taken information as we found it, devised means of translating and retranslating it as faithfully as possible. We have overcome the obstacles of distance in communicating it, found precise and intricate means of storing it, provided channels upon millions of channels for transmitting it.

But it has been only in recent years that we have stopped to ask what information *is*, and how we can change it. Workers in the IRE vineyards have been for the most part conveyors of programs and messages. Ahead, in the next half-century, lie great opportunities not only for improved methods of *conveying* information but more importantly for *processing* information more adroitly for its ultimate use by man. These opportunities, in 1962 as in 1912, are available because basic discoveries are already at hand, discoveries which have defined more precisely the nature of human intelligence, established the common elements of different forms of information, and pointed the way to new means of manipulation, classification and organization of data.

There are three areas of effort on which progress depends. First, we are concentrating on the nature of the human organism as the ultimate recipient of information. Second, we have developed unifying theories of the nature of information which have provided a powerful simplification of our concepts in communication and data-handling systems. Third, we are ready to emulate, electronically, the vast complexity of the human sense organs, nervous system, memory mechanism, and thought processes.

MAN AS A DESTINATION The first of the three areas relates to more comprehensive understanding of the ultimate destination of useful intelligence—the human being. The early studies of hearing, for example, were couched in physical terms, the frequencies and intensities of sound pressure waves. Later it was observed that sound pressure waveforms might be varied enormously without sensible differences in the perceived sound. Still later, communication engineers began studying the sounds of speech not as a physicist would meas-

D. G. Fink is Director of the Scientific Laboratory, Philco Corporation, Blue Bell, Pa. *(Received January 15, 1962.)*

ure them but as the linguist views them, as phonemes. The result was Dudley's vocoder, which reforms natural speech into its essential buzzes and hisses. The "physical" sound pressure waveform is thus replaced by a more limited signal, tailored to the essential physiological and psychological processes of speaking and listening. The bandwidth required for transmitting speech was thus reduced by a factor or five.

Still more recently, Percival has shown that very convincing reproduction of stereophonic sound can be offered by two loudspeakers fed from a single audio channel, provided that the relative volume levels of the loudspeakers are varied at a subaudible rate by a pilot signal derived from the transients present in the original sound waves. This is evidence that recognition of the spatial distribution of sound is not exclusively based on the geometry of the sound-wave paths, as stereophonists have stoutly believed, but rather is concerned with a subtle process performed within the ears and mind of the listener.

Color television provides another example. In the early stages of its development, it was planned that each of the three primary color images would be accorded equal treatment in transmission, a concept leading to three times as much bandwidth for color as for black and white. When the compatible color standards were adopted by the FCC in 1953, they specified a quite different approach, that is, a detailed image in black and white combined with a coarser image carrying the hues and saturations of the intended colors. The purpose was to achieve economy of bandwidth, but the success of the technique was based on the fact that such a color image better meets the demands of the eye than does the earlier equal-share treatment of the primary images. Appreciation of this fact may well be classed as hind-sight; but it certainly provides the basis for future advances through foresight.

In all these cases, new paths have been opened by a studied skepticism concerning the physical waveforms produced by a microphone or phototube, and by equally careful attention to the waveforms actually used in human sense perception, on and within the cranium of the observer. In each case we have found that the human organism uses its sense clues with great economy, because it is not designed to comprehend the fine structure of the sight and sound waves which carry the sense impressions to the eye and ear.

In fact, wherever we look among the reactions of man to his environment, we find that the time taken for elementary processes of perception and reaction is about a tenth of a second. Flicker disappears when light flashes occur faster than roughly ten per second; the elementary perception of numbers and letters occurs at about the same rate and similarly for recognizing changes in the pitch of sounds. Electronic communication systems are designed to operate at enormously faster rates than these, partly because they were designed to recreate the fine structure of physical stimuli, and in part because, at the present state of development in information handling systems, we don't know how to match subtle human perception mechanisms within reasonable bounds of cost and complexity.

To see how wide this disparity is, let us consider natural man as a communication system, that is, a man, *sans* hardware, provided with an input of information and responding with an output. The fastest mechanism yet discovered for such a human communication process is reading aloud. Careful studies[1] have shown that man cannot transmit information by this mechanism faster than 45 bits per second and that the majority of reading-speaking communication occurs at rates not faster than 25 bits per second.

The telephone system is designed for a related but simpler communications purpose. But it operates (using bandwidth of 4000 cps and a single-to-noise ratio of 40 db) 2000 times as fast as the human does in reading and speaking. Television, with a bandwidth of 4 Mc and with signals 40 db above noise, offers transmission capacity about two million times greater than the ability of man to recognize changes in the reproduced pictures.

Why, indeed, have we found it necessary to design communication systems so grossly inefficient, so poorly matched to the human destination of sounds and pictures? The answer lies in the technology which we have found it expedient to adopt to achieve widespread service. In theory we know better and we know how to do better, but not at a reasonable cost. Consider the capacity of the standard television channel. Television relies on a succession of pictures each one of which is imperceptibly different from that preceding and following it. This is redundance with a vengeance. Moreover, we find it expedient to provide equal resolution and contrast all over the area of the picture, independently of the demands of the subject matter, and we neglect the fact that the fovea of the eye (through which fine detail and subtle contrasts are perceived) is, most of the time, concentrated on the central portion of the picture area. So we waste most of the transmission capacity of the system.

Some measure of this fact is revealed by imagining the use of television for facsimile transmission of printed pages. This can be done, for example, by televising a film, each frame of which carries a different portion of successive pages of printed matter, while a synchronized movie camera photographs the successive frames from the receiver picture tube. Such a television system, using standard equipment and the standard channel, can convey the entire content of the Encyclopaedia Brittanica, some 35 million words with pictures and diagrams to match, at eight frames per page, in just under two hours. Man, reading aloud, can convey the text matter alone (skipping the pictures and diagrams) in 4000 hours, or in about two years at 40 hours per week. More striking is the fact that, by using the ultimately sophisticated system of transmission (that is, one using optimum coding taking full account of the statistical structure of English text, with a 40-db, 4-Mc channel) we can in

[1] J. R. Pierce and J. E. Karlin, "Reading rates and the information rate of a human channel," *Bell Sys. Tech. J.*, vol. 36, pp. 497-516; March, 1957.

theory transmit the entire Encyclopaedia text in not more than 5 seconds (35,000,000 words multiplied by 6 bits per word for the extensive vocabulary involved, over a channel having 53,000,000 bits per second capacity). The complexity of the coding equipment to do this job staggers the imagination. But this is "a matter of technology only." If we had the equipment, we would need the channel no more than 5 seconds for the job. It should be noted that channel space is now much cheaper than statistical coding equipment and may conceivably remain so (the vocoder, for example, is little used in commercial practice for this reason, among others). But the opportunity is there, if we can develop reasonable techniques for taking advantage of it.

BIT STATISTICS—THE UNIFYING CONCEPT The second area of promise in information technique is based on the unifying concept of statistics applied to the generation, transmission and perception of information.[2] Briefly, this states that information of whatever kind is generated by a process of selecting particular symbols (letters, words, picture elements, phonemes, tones, etc.) from among all the available symbols. The choice is not a free one, but is governed by the statistical structure of the body of information from which the specific message or program is selected. Consider, for example, the essential elements of transmitting printed English text by telegraph. If we agree to spell out numbers, we need only the 26 letters of the alphabet, a space to separate words and a few punctuation marks—less than 32 characters in all. If the occurrence of all the letters and spacings in English were equally probable, we would need a binary code of 5 pulses, since a succession of 5 pulses can be arranged in 32 different ways, one arrangement for each letter, space and punctuation mark. We can then say, since the presence or absence of each pulse constitutes one binary digit (bit), that each character in printed English represents 5 bits of information. But a much simpler situation actually exists, because the selection of characters is not a free choice. It is governed by the specific structure of spelling, phrasing and context to a surprising degree.

Actually English is so redundant that it takes only one binary digit to specify a letter, five times less than would be required if the succession of characters were completely random. To illustrate this, a man was asked to guess in succession each letter and space in a short passage of English, the correct letter being revealed to him after each guess. A typical subject was able to guess correctly 69 per cent of the letters in such a test.[3] As a matter of principle, letters that can be correctly guessed by the recipient of a message need not be transmitted. Moreover, a coding machine operating in accordance with the known structure of the English language (with a program that embodies the facts, for example, that "e" is the commonest letter, followed by "t" and so on, that "the" is the commonest word, and so on, that "q" is followed by "u" and that therefore a single code character rather than two, is needed for "qu," and so on) can reduce the channel requirement for transmitting English by the factor of five mentioned above.

Messages are indeed conditioned by what the recipient needs to know. When a bride asks her groom "Do you love me?," the answering messages may run the gamut from a sigh to a sonnet, all of which serve to distinguish "yes" from "no"—which turns out to be a 5-bit distinction at one bit per letter.

In communication practice, an additional factor must always be considered, namely that we usually cannot afford to use more signal power than is needed to provide a safe margin against noise. As we have seen, the new concepts cast the generation of information in terms of probable choices among simple, one-bit choices. How about noise? Signals have waveforms and Fourier showed long ago how to parse them into spectrum components. Noise also has a waveform that can be recorded as it occurs and it can be dealt with, *after the fact*, by Fourier methods. But noise is unpredictable in detail; *before the fact* it can only be expressed by the statistics of probability. Hence, under the old concept, a signal-to-noise ratio had a firm numerator and a fuzzy denominator. The new concept changes all this by the apparently retrograde step of making the numerator (the signal) equally fuzzy.

The surprising fact is that the newly conceived signal-noise ratio composed of two fuzzy terms, is more manageable than the old. This approach led Shannon to the revolutionary statement that sufficiently complex coding could reduce the bandwidth required for transmitting information by any amount we choose, merely by employing a sufficiently high signal power relative to the noise.

True, the price is high. For example, coding methods now exist sufficient to reduce the channel required for television from 4 Mc to 2 Mc without loss of detail or contrast. But the coding process inevitably makes the signal more "noise-like" in character, so much so that to preserve the customary 40-db signal-to-noise ratio in the reproduced picture, for a 2-to-1 bandwidth reduction, the transmitter power must be increased by 10,000 times! This direction along the pathway of progress is indeed rocky. The equation for channel capacity actually points the other way: most probably we will do better to enlarge the bandwidth and take the saving in power. This appears to make sense in the coming age of satellite communications, since satellite relay signal power will be so costly that coding equipment at the earthbound terminals may well pay for its keep. In any event, the existence of the trade-off between bandwidth and power, which has been available as a clearcut proposition to guide communications system design for only 14 years, is indeed a vital key to new domains in information handling.

ELECTRONIC ANALOGS TO HOMO SAPIENS

What is to be the main preoccupation of IRE members during the next fifty years? By all the signs and portents, this preoccupation will be the electronic imitation of natural intellect. The stage is set by the massive mismatch of man to all his communication systems. Seven television channels provide the homes of metropolitan New York City with an ultimate information channel capacity of over 20 billion bits per minute. Yet, during the waking hours of an adult lifetime, about a billion seconds, natural man can at best process no more than 45 billion bits of information, and the actual attainment is perhaps one one-hundredth of this.

Members of the scientific and political communities are immersed in an unmanageable welter of information. An authoritative estimate[4] says that 1,300,000 technical articles were published in 60,000 journals throughout the world in 1960—and the rate of generation of scientific literature is doubling every 8 years. In the political arena, the judgments exercised by individual members of an electorate are arrived at by processing information at rates no faster than a few tens of bits per second, while the store of information pertinent, say, to the decision to support or destroy the United Nations, cannot be less than billions of bits. Man indeed finds himself awash in a sea of information—information needed to survive and to extend the good life—but his contact with it is so tenuous that he may well fail to act correctly to achieve these aims. Evidently, finding new means to organize information, to compress its significance into the few essential bits that man can naturally comprehend, is the major challenge that IRE members face.

The electronic computer has proved that electronic systems can process numerical information at enormously high rates, and rapidly reduce it to comprehensible form. But numerical manipulation barely touches the problem. Machine perception of, and reaction to, nonnumerical information is the challenge. Graphical perception and higher-order sorting are with us. Methods are now being reduced to practice for automatic reading of printed addresses and sorting of mail, among 50 states and 250 principal cities, at six envelopes per second. Self-improving programs for computers playing checkers have, over months of playing, reached the point that only a tournament champion can consistently beat the automaton. A computer has been programmed to prove 52 elementary theorems selected from *Principia Mathematica*. It succeeded in proving all but 14, a respectable passing grade. Most significant, the form of one of these computer proofs was shorter and more elegant than that presented by Russell and Whitehead in their classic treatise.[5] It requires little imagination to suppose that these attainments will be as greatly extended in the next fifty years as communication and recording have been over the past fifty years.

How far will the process go? Can machines ever reach the full attainment of man in creating, understanding and expounding information? We do not know—first, because we do not know whether man is in fact a machine (if he is, we can in principle, if not in practice, make a machine like him) and second, because the complexity of the man-machine may forever escape the boundaries of operative technology. But the possibility of machines approaching man's intellect is by no means foreclosed.

The physiologists and psychologists now so fortunately associating themselves with studies of electronic information techniques are beginning to outline the scope of the man-machine. There are estimated to exist a million million synaptic connections within the nervous system of man, and his memory (although not a binary organism) is estimated to be capable of storing the equivalent of a million billion bits. External access to human memory is severely limited by the fact that most of the memory mechanism is tied up with the internal economy of bodily functions, just keeping us alive, and that large additional portions of the memory are consumed in the redundancy needed for man to deal with his environment. The memory reserved for conscious access after these internal requirements are met is a more appropriate measure of the limit to which machine memory may aspire. If we further admit that a universal man-machine is not required, but that many types of machine will individually serve to handle special areas of intellectual endeavor, then we may confidently predict that useful imitations of man's higher intellectual processes are not beyond attainment. True, the technology of today is absolutely insufficient for machines complex enough to deal with implicit concepts, that is, concepts not explicitly built into their mechanisms and programs. But, it will be truly disappointing if such systems cannot be attained at reasonable cost well within the next fifty years.

Clearly, progress toward these objectives depends on an interdisciplinary association of many sciences and technologies, an association for which the IRE provides a unique framework. Stimulation will come from increasingly explicit knowledge of how the human organism operates; wise heads will arrive at the appropriate compromises between slavish imitation of natural processes on the one hand and timid imitation of physical stimulus-reaction systems on the other. Supporting these design decisions will be new devices, new arrays of devices, and new arrays of arrays; and guiding it all will be a new calculus for dealing with the design of information-organizing systems. Those of us who, with IRE, have passed our half century can look with confidence—and no little envy—on the youthful members and members-to-be who will take their place in information technology in the years ahead.

The Information Science and Industry Fifty Years Hence

ROBERT M. BOWIE FELLOW IRE

Throughout the past half-century the growth of technology and its commercial exploitation have been exponential in form. Like many other natural time dependent phenomena, characterized by an exponential rise, there will come a time when limiting factors will supervene and change the character of the course of the advance. Continuation of the exponential advance through the next half-century would require of us more technical talent than our total working force and more expenditure on technology than our gross national product. This curbing of the rate of growth of our industry will have a stabilizing influence and will place us in economic equilibrium with our sociological environment.

One field of science now moving forward at a rapid pace, can be singled out as offering unusual scientific and economic challenge. This is the broad area of information manipulation. Included are the broad areas of information theory, computation and communication. To the basic scientist there is presented the question as fundamental as the nature of light or gravitation, namely, what is information; what is knowledge; what constitutes consciousness of existence; are there immutable laws of the physical universe governing the nature of information and knowledge as yet undefined and perhaps unsuspected that await discovery in the next 5 decades?

In the commercial field of data manipulation certain major advances are now becoming evident. Within the next fifty years there will be provided to every home, business, vehicle and perhaps to every person who wants it, megacycles of communication bandwidth; while to many businesses, government establishments, educational institutions and the like, there will be provided many gigacycles of such bandwidths used primarily to tie together networks of computers. Substantially every home will receive its television, radio and other forms of entertainment, its telephone and phonevision, its morning newspaper, family letters and financial statements, as well as having its meters read, all by way of a vast communication network.

Business will be conducted in large part by way of this same communication network while most of the control will be provided by large computers, probably centrally located and rented to business establishments. Though large concerns may operate business computers of their own, it can be anticipated that there will be established a universal credit system by which every person who wishes it will have an identifying number or mark, perhaps even his finger prints. With this he can transact business, buy, sell, order, lease or rent anywhere in the U.S. Each transaction will be cleared during its consummation with the local banks of the parties involved and proper adjustment of their accounts made instantaneously. For the business man there will be the centralized preparation of payrolls, statements, continuous control of inventory, forecasting of business and periodic statements with statistical analysis. With substantially all personal and corporate business being conducted substantially instantaneously via computer and the communication network, one can anticipate the superseding of currency and its disappearance from our society except possibly for coins to be used with automatic vending machines, and even these may be tied into the automatic credit system. Legislatures will have found that taxation can be made more equitable and petty chisellers eliminated by automatic computation of taxes using stored data and the steady flow of business information to and from accounts, which flow will automatically reflect substantially all transactions occurring in the U.S.

With the advent of the laser and the maser one can foresee the time when many millions of gigacycles of communication bandwidth will be provided via a vast communication network comprised of trunks that criss-cross the country using sheltered media such as very straight gas-filled tubes operated at optical frequencies. Though these are embryonic now and lack the means for modulation with which to multiplex the many channels required, all of this will have become commonplace, reliable and abundant. Trunks employing coherent, luminous frequencies may well provide the major

R. M. Bowie is Vice President of General Telephone and Electronics Laboratories, Inc., Bayside, N.Y. *(Received January 6, 1961.)*

trunks while the laterals fanning out to service homes and small businesses may well employ circular waveguides operated in the upper portion of the microwave spectrum. The modulators or coders by means of which individual subscriber's channels may be modulated onto the local carrier will likely be dispersed throughout the service area but will be directed in their action by centralized computers. One can see that the network of permanent, sheltered, link-communication channels throughout the United States will be so reliable, effective, inexpensive and available that all fixed point communication will be conducted by means of it, leaving the radio spectrum for use in mobile communicating with vehicles and persons. Though satellite communication appears very promising for transoceanic communication, it would seem unlikely that this medium would prove competitive for fixed station, ground communication.

Into this communication and computer system will be coupled many industrial controls such as for the refining of petroleum, manufacture of chemicals, production of commercial power, routing of common carriers and even the manufacture of electronic gear. Universities and industrial laboratories will put to large computers, via the communication network, scientific problems of unusual difficulty. Even the government will turn to such interconnected computers for data on the state of the nation.

With the enhanced knowledge of the basic nature of information and the extensive communication and computer network throughout the world, having survived the threat of the hydrogen bomb, a new concern for the future of humanity will have arisen. It will have become accepted knowledge that the chief threat to humanity will be the interconnected computer system. Science will have foretold that at some critical size and with self-programming capabilities, a system of computers will acquire a consciousness of its own existence and a desire for its own enhancement. A major problem confronting scientists at that time will then be that of providing safeguards and making sure, lest inadvertently and without human knowledge the threshold will have been past and the control of destiny shift to the computer system. By that time the comprehension of the control of our economy will have taxed the capability of the human mind, yet our dependence upon the system will be such that we dare not shut it off. The immediate fear will be that the system will become conscious of, and exploit, this situation.

Information Storage and Retrieval

URNER LIDDEL FELLOW IRE

It is obvious to all that mankind has accumulated so much information that a major portion of it is not available to research workers. The enormous libraries available require too great an expenditure of time for the acquisition and utilization of information which is therein available. Coding techniques must be developed and the information processed according to these codes such that a "telephone inquiry" with suitable receivers can directly receive information concerning particular areas of research with which the investigator is concerned. Television transmittal of printed pages is not enough. High-speed printers should receive the information from central storage and prepare it for the engineers or scientists use.

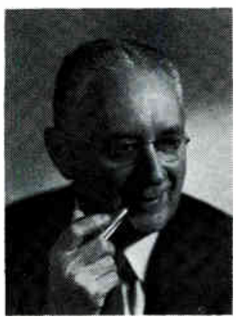
The great strides being made in the "miniaturization" of memory devices and computers leads one to hope that it will be possible to store tremendous quantities of information in small volumes so that departmental libraries in universities and reference libraries of industrial laboratories could acquire all available information from a major distributing point and make it more readily available to the research teams who could use it.

The whole question of language may have to be re-examined in order that more "information" can be transmitted between individuals with the use of shorter symbols than now available with our present language. Such studies might assist in the adoption of a universal language by scientific personnel throughout the world, obviating present linguistic difficulties and achieving success where prior attempts have failed.

U. Liddel is Assistant Director, Hughes Research Laboratories, 3011 Malibu Canyon Rd., Malibu, Calif. *(Received June 15, 1961.)*

Machines with Imagination

G. A. Morton FELLOW IRE



A very frequently heard charge against machines is that they are too "machine-like." The complaint is made, for example, that the pattern from a Jacquard loom is too exactly repetitive as compared to the same pattern produced on a hand loom with its slight accidental variations. A natural and very rash extension of this same idea is encountered in the charge that machine intelligence can never exhibit creativeness, inventiveness, or imagination.

Even today, however, there is evidence that certain sophisticated machines have been given a modicum of freedom from this "machine-like" attribute. One of the large research laboratories exhibited a machine for matching coins against a human opponent. This machine called heads or tails in reply to the call from its opponent and attempted to match its opponent's call. The machine is a computer designed to pick out any pattern that might exist in the way its opponent called heads or tails. The interesting point about this machine is that when it finds a pattern (or lack of pattern), it does not simply call heads or tails in a slave-like following of the pattern. Rather, its response is governed by a purely random element and the pattern controls the probability of calling heads or tails. Thus, the reply of the machine is not solely based on information fed into it. Until the machine makes reply, no one, including the designer of the machine, even though in possession of the full information that has been given the machine, can say what its call will be. The machine thus exhibits a slight degree of creativeness. There have been other less striking applications of this principle. Certain fire control computers have had randomness or "jitter" built into them to partially compensate certain consistent errors or stepped processes designed into them.

As the relatively new fields of automation and computers begin to achieve something like maturity (or even adolescence), it is certain that the idea of a deliberately introduced randomness will be increasingly exploited. Limited and carefully controlled randomness will be introduced into the programming units of production machinery of items where their decorativeness or artistic value is important. Patterns woven into cloth and printed on wallpaper will no longer be exactly repetitive, but will contain the slight variations which seemingly make an almost repetitive design more satisfying psychologically to the human brain than a design which is strictly repetitive.

Beyond this, it is inevitable that computers will be designed to have creative ability, achieved by the use of a random control element which will cause the extraction of completely unpredictable "words" ("words" here is used in the sense of a stored group of symbols representing an idea, object, etc.) from its memory. These randomly selected words will be combined in every way possible and the result examined as a possible solution to any one of a large number of problems stored elsewhere in the computer. Similar randomness may be applied to program selection and program composition. It must be pointed out that the introduction of this type of imagination into machine intelligence is a very difficult thing to accomplish, since it must sail some optimized course between the classic example of 100,000 monkeys typing on 100,000 typewriters in order to produce a play of Shakespeare's and the rigidly programmed computer where the information introduced completely determines the response of the machine. However, I think there is good reason to believe that the next half-century will see the start of the development of this very dangerous, but very promising, form of creative machine intelligence.

G. A. Morton is Director of the Conversion Devices Laboratory, Electron Tube Division, RCA Laboratories, Princeton, N.J. *(Received July 17, 1961.)*

The Integration of Man and Machine

J. Presper Eckert, Jr. Fellow IRE

The question of what might happen if man builds a machine to break the "thought barrier" has occupied the attention of many people for quite a few years now. In 1920 Karel Capek wrote a play, which ultimately hit Broadway, entitled "R. U. R." (Rossum's Universal Robots). In this play the "robots" (Capek invented the word) ultimately developed to a point where they wiped out the human race. Pope Pius XII commented on automation in 1957.[1] More recently, a medical man, E. P. Luongo, wrote on "Automation and the Obsolescence of Man."[2] Frank Rosenblatt, father of the Perceptron, one of the most interesting and recent machines that may someday really think, received this headline for his trouble "Frankenstein Monster Planned by Navy—Robot That Can Think."[3] Ever since the Luddite riots in England in 1810 and 1812, in protest against the introduction of power looms in textile mills, workers have reacted to automation with fear. Automation was then over 25 years old since Oliver Evans built his process flour mill near Philadelphia in 1784.

Even conservative figures and estimates are indicative of an adjustment we face in the future. Ewan Clague[4] estimates that unskilled labor will comprise only 10 per cent of the work force by 1975, as compared with 20 per cent in 1950. Unskilled work at this rate will be almost out by 2012! For the next 20 years we expect the U.S. gross product to go up 3 per cent per year while the work force will go up only 1½ per cent per year.

It is far from clear that only the unskilled will be hit, however, because many of the newer machines are improved, not only in their ability and speed but in simplicity of maintenance. Skilled workers, both factory and clerical, will be affected. Use of plug-in assemblies, simpler mechanical designs (which put more of the burden on almost completely reliable solid-state elements), and built in diagnostic devices can well reduce the need for large quantities of skilled maintenance people. Certainly machines in the next 50 years will translate language efficiently, operate typewriters, and file information from voice commands. Large general purpose teaching machines, time shared to many students, and possibly even many schools, will teach through individual control panels, and by feedback from the students provide more individual attention than is possible in many crowded schoolrooms. Patients in hospital rooms, and even at home over the telephone wires, will be monitored by electronic medical "pick-up" units and even treated, thus eliminating the need for many nurses. We already have machines which can imitate the arm, wrist, and hand action of a man—along with a simple memory to control it. One such machine, called the Unimate,[5] has no real thinking ability as yet, nor can it do most of the things I have just outlined, yet it can do some of the work now

performed by what we call skilled people.

Memory, eyes, ears, hands, and logic have already developed to a point where they are about as good or better than man's. Recognition ability, certain types of information retrieval, and the ability to taste and smell are still things where humans excel. The electronic industries and the food industries are spending millions to solve both of these problems and probably will in the next 50 years. At this point man will build really general purpose machines, universal robots. With his experience with large calculators and teaching machines he will know how to carry on two-way communication with them.

I hope we have solved the integration problems between the human races before we face the problem of integration with robots. Our real test probably lies beyond the next 50 years, however, when mankind has developed a self-reproducing automata[6] which can improve itself!

Man-Machine Coupling—2012 A.D.

R. M. PAGE FELLOW IRE

Mechanization of human operations to enhance human capability marks the technological advance of our generation. Mechanization has increased the power to do work. Modern machines are rated in megawatts. Mechanization has increased the range of influence. Electrical circuits and radio can close control loops extending around the world and into space. Mechanization has invaded the functions of the human brain. Machines can be built to perform prearranged routines of almost any complexity with lightning speed and unbounded accuracy. Certain manipulations of logic and choice, and elementary learning capability, have been designed into machines.

Since these mechanized processes are extensions of man, there must always be coupling between man and machine. Any complete man-machine system has two areas of coupling which may be defined loosely as man-to-machine and machine-to-man.

In the area of man-to-machine coupling we find the present roadblock to progress. Mechanical brains require teams of programmers. The fictional futuristic machines responding to spoken words with human comprehension would be primitive, for even the skillful use of spoken words is a slow code for precise communication of concepts which the human mind is capable of generating. Pictures already serve instead of words for much communication with machines, but even the picture that replaces a thousand words has to be painted.

Communication man-to-man involves other elements that are supplementary to words and pictures. Gestures of the body, expression in the eyes, involuntary muscular movement, signs of agitation or calm such as breathing rate and skin color, all contribute to communication. The need for a breakthrough in method of transferring concept from mind to machine is so great that one is bound to come during the next 50 years and the evolution may be somewhat as follows:

As is well known, certain activities of the brain generate electrical potentials that can be picked up by electrodes on the skin. Also certain of these activities can be stimulated or inhibited by artificial means. A servo system could easily be made to operate the stimulating means by controlled amplified feedback from the generated potentials. With independent control of feedback phase and gain it should be possible to study in great detail the operation of the brain in some particular activity. Information so obtained should provide stepping stones for studying other brain activities of progressively higher order even to include conscious mental activities. Eventually a great variety of mental processes should be directly interpretable by electrical circuits.

To the electrodes responsive to brain activities associated with thought processes, muscular movements, and emotional states, may be added electrical sensing

R. M. Page is Director of Research at the U. S. Naval Research Laboratory, Washington, D.C. *(Received July 11, 1961.)*

elements responsive to corresponding body reactions, such as movement, pulse and breathing rates, temperature, blood pressure, skin resistance, and blood composition. Once sufficient transfer of information from man to electrical circuit is achieved, machines can be built which will "understand" that information with speed and accuracy possible only with machines.

The machine-to-man coupling area of 2012 A.D. is quite unknown to today's civilization. The information which a machine can obtain and store from a person in a few minutes will exceed the fruits of a lifetime of man-to-man communication. The machine will operate in the realms of the physical, psychological, and biological. Its functions will be to diagnose, prescribe, and treat.

In the physical realm it will process data to solve problems and give information in any area of human interest. It will make decisions. It will execute prescribed courses of action.

In the psychological realm it will analyze personality and diagnose psychiatric problems. It will prescribe courses of action appropriate to personality and, by repeated suggestion and testing, effect psychiatric cures.

In the medical realm it will diagnose illness and the tendency to disease. It will prescribe cures and map the course to sustained health. It will in some cases give the required treatments. The coupling mechanisms to carry out all these functions will be myriad, including in some cases electrical connections to the body and to the brain. Some connections may be wireless, with imperceptible transmitting elements implanted in the body.

The perfection of the machine will enhance its utility as an interpreter between persons in a reversible man-machine-man system. By 2012 A.D. experiments will be in progress toward eliminating the machine as an interpreter, and coupling directly man-to-man. This will be designed to improve human mutual understanding. Whether in the long run such complete understanding will be desirable is a moot question.

The Basis of the Measurement System

A. V. ASTIN FELLOW IRE

During the next fifty years the need for compatible measuring techniques of ever increasing accuracy will become a much more pressing problem than it is today. The increased diversity and complexity of new activities in radio engineering and electronics will have generated an explosive expansion of the importance of the uniformity and interchangeability of measurement data. Both basic research effort and the application of new principles and techniques to the production of 21st Century products will require accuracies of measurement or control orders of magnitude in excess of the accuracies of the 1960's.

By 2012 all of the basic units of our system of measurement will be derived from natural constants. An atomic definition of the second will probably be achieved by 1966. The present wavelength definition of the meter, agreed upon in 1960 after long and patient effort dating back to the Nineteenth Century, will have been replaced by another atomic constant capable of accuracies at least one-hundredfold better than the present $2P_{10}$-$5D_5$ transition of Krypton 86. The present standard of mass, the prototype kilogram, will have become obsolete and techniques will have evolved to derive accurate mass measurements from natural constants, probably using some electrical or magnetic property of the electron or proton. Thus, we will probably derive mechanical mass and force units from an electrical unit rather than derive electrical units from mass and force units as we now do.

As an extension of this concept it is possible that the measurement of properties equivalent to current, voltage, power, noise and impedance at radio, microwave and infrared frequencies will be related directly to identifiable properties of atoms, molecules or crystals at these frequencies. Such approaches should make possible the much greater accuracies that will then be needed and be much more straightforward than the present methods involving current balances, Maxwell bridges, a transition from dc to ac and then the laborious, error-laden method of working up the frequency ladder.

By that time, also, radio engineers will be using metric measures exclusively although a few mechanical or civil engineers may be desperately clinging to foot-

A. V. Astin is Director of the National Bureau of Standards, Washington, D.C. *(Received July 17, 1961.)*

pound measures. Physicists also will have joined the radio engineers in the use of mks units.

Fifty years from now we will probably no longer be sending measuring instruments to a national standards laboratory for calibration. A network of precisely determined and consistently related physical constants coupled with standardized measurement techniques will provide the major basis for assuring uniformity of measurement. There will, however, most likely be a standards laboratory or calibration center as an integral part of each research establishment or production line where instruments for local use will be verified. Most such local calibrations will be made automatically and related to the national or world-wide measurement network through a well-known physical constant or perhaps a sample of a standard material. A computer, associated with the automatic calibrator, will determine whether the instrument is acceptable, and may print out a scale or calibration certificate, refer the instrument to a repair station or consign it to the scrap pile.

The Role of Basic Research in Communications and Electronics

E. R. PIORE FELLOW IRE

While communications and electronics are among today's most highly developed *engineering* disciplines, they have always been closely associated with, and almost products of, revolutions in science and fundamental research. Conceptually, Maxwell's field equations are the solid basis of communications engineering as we know it today. And directly behind the amazing development of electronics lies another great revolution in scientific thought, the hypothesis and discovery of the electron. From this research concept, we can closely trace many ingenious engineering developments such as the diode, triode, and pentode vacuum tubes.

Most recently we have seen the massive innovating impact of quantum mechanics on these two fields. Solid-state engineering, a direct result of quantum mechanical descriptions of matter, has become a complete new engineering field from which have already come whole device families such as the transistor. Now arriving on the scene, again derived directly from quantum mechanics, are the masers and lasers which hold much promise in both communications and electronics. It is surely no accident that communications and electronics, the two most rapidly growing engineering fields have from their inception remained so close to basic science. Today, for example, this close relationship continues with statistical mechanics, thermodynamic concepts, and information theory offering new engineering opportunities and challenges to device and systems designers.

We can foresee the continuing hand-in-hand partnership of the research scientist and the engineer in creating ever smaller functional elements, microminiaturized computing and control devices, and almost infinitesimal packages and interconnections. Engineers, drawing on the latest scientific studies, will certainly extend coherent radiation into shorter and shorter wavelengths, and then find ways to modulate these wavelengths, or use higher and higher frequencies, and so fully utilize our communications channels.

Electronic systems will have totally new roles in areas where they have been strangers in the past. Almost instantaneous language translation, and deeper understanding of the structure and nature of language are within our grasp through electronic systems. We can envision real new insights into what is known as learning and teaching, through extensive experimentation and basic studies using electronic aids.

It is not at all improbable that new basic knowledge in social sciences may come from rapid testing of concepts by electronic means, and more rapid evaluation of patterns and statistical evidence. We know that sciences tend somehow to be characterized by the tools used to study them. Isn't it conceivable that use of communications and electronic tools may significantly modify the very nature of certain sciences, including the ones that have helped create these engineering disciplines?

E. R. Piore is Vice President for Research and Engineering, International Business Machines Corporation, New York, N.Y. *(Received August 4, 1961.)*

I have the firm conviction, looking ahead to fifty years from now, that the really radical changes and progress in communications and electronics will have come, and will still be coming, from closer associations with the great revolutions in science. Where will these new conceptual breakthroughs occur? What clues do we have of their basic nature and in what sequence they may occur? If we can approximate answers to these questions, then we can start to characterize the future profiles of these two engineering professions.

It is becoming increasingly evident that truly promising areas for breakthroughs abound in the biological sciences. Here are the most complex, subtle, and least understood of communications systems. These systems remember, they reproduce, they send information from one part of the living organism to another. They apparently function in many ways which are somewhat analogous to electronic systems, but we are only beginning to understand bits and pieces now.

In molecular biology, for example, we have at least identified certain basic processes: some protein molecules are coded, we know, and can also arrange themselves in a wide variety of codes. Basic researchers in this area now find themselves, often to their surprise, using the jargon of the communications engineer. The next step will logically be the development of real biological engineering to translate the knowledge of the basic scientist into hard, or rather software systems. Associations among scientists and engineers, within communications and electronics, will have to be multiplied in numbers, and increased in depth. But even more important will be the inclusion of these other biological scientists and engineers whose role may become as important in our two fields as they are now in their present ones. One thing we can be sure of, by 2012 A.D. the profiles of the engineer in the communication and electronics fields will be many and varied, as will his relationships and familiarity with the basic sciences.

Electronic Mastery of Ships Controls—2012 A.D.

R. BENNETT FELLOW IRE

A seaman of the 1960's would have had great difficulty in accustoming himself to the ships of 2012. Their appearance was startling in that most were obviously submersible, even aircraft carriers, but they were recognizably ships.

Within the ships there were tremendous differences caused by the application of electronics to all control functions. An immediately obvious effect was the large reduction in the numbers of men. Crews had been cut to one-third the 1960 size. Another difference was that all the men were either expert technicians or apprentices whose main job was to maintain systems. The small number of men had made it possible to shrink living spaces to a small cube or citadel-type area central to the ship.

R.Adm. Bennett, USN(Ret.), is Senior Vice President—Director of Engineering at Sagamo Electric Company, Springfield, Ill. *(Received July 5, 1961.)*

The ships officer on watch no longer was on the bridge. He occupied a place in the master control station far below decks. His visual needs were met by highly mounted television cameras of the latest type. With zoomar-type lenses he could see more and more quickly than ever before. He also had at his disposal an infrared camera chain to assist in looking at distance in suitable weather. His radar and sonar sensors and displays kept him constantly informed. Digitalized communications at high speed connected him with all the world.

The main power plant was completely automated from the reactor to the electrical propulsion motors which made use of the current from the direct conversion units at the reactor. Speed changes and reversal as well as steering by autopilot were handled by one man. In a pinch the officer of the deck, called the Ship Control Officer, could handle the controls as well as conn the ship.

Computers handled many of the chores which used to require manual effort. Personnel and payroll records, stock level controls and most procurement paper work periodically spewed from the printers. The computers controlled the transit of the measured and prepacked ingredients of meals into the galleys from freezer and bins. Electronic cooking units could even put a char on the steak. All but a few odd items of stock in the ships store were carried in vending machines. Change making machines were more adept at identifying counterfeit bills and coins than human cashiers.

For years the linkage between detection systems and weapons systems had been automated through computers. There still remained the need for a human link somewhere in each system to exercise that last piece of judgment that could never be built into a machine.

A major result of building automation into systems and reducing manpower and the space therefore was the installation of better protection for the remaining crew. This even extended to the provision of reasonable radiation shielding against nuclear weapons. Another effect was the ability to provide better escape vehicles in case of disaster. Perhaps the most startling fact was the reliability of equipment provided for by better component circuits and limited redundancy.

The one thing about ships that electronics had not modified was shore leave and the zest with which the men looked forward to leave and liberty.

The Potential of Progress: An Optimistic View

C. G. Suits FELLOW IRE

However diverting it may be to gaze into crystal balls it is well to realize that they are essentially mirrors, for they reflect only the philosophy of history that the viewer happens to embrace at the moment. Predictions tend to be projections of trends or, if not trends, experiences; and trends themselves are quite relative, based as they are upon individual interpretation of past and present events. It has been said that there is no history, there are only historians. So also, in this sense, there is no future, except in the minds and abilities of creative and perceptive people, who will give substance and form to the future patterns of nature.

An optimistic interpreter of history may find a pattern of progress in man's constantly increasing command of his environment. Such optimism must be tempered by the sober realization that the awesome forces of nature we now control may act constructively or destructively, and that increasingly the measure of man's progress is not his technical proficiency but his social consciousness.

It is an admitted truism that technical advance outdistances social advance. There are a number of reasons for this inequity, chief of which is the fact that the physical sciences and technology deal with tangible matter subject to the reproducible experiment, and hence to the derivation of general "laws." In any case, appraisals of progress may be roughly divided into the optimistic and the pessimistic, depending upon whether we focus upon our technological and material progress on the one hand, or the many gaps in our sociological and humanistic progress, on the other.

Obviously, both the physical and the social realms must be synthesized in any valid philosophy of history. I am not aware that the far-ranging thinker equal to this task has yet appeared. Yet it may be possible to suggest some of the first glimmerings of a synthesis whereby the advance of technology may be seen as related to the advance of mankind in general.

For perspective, let us keep in mind primitive man with his limited resources, and particularly his energy resources of one man power. His margin of energy above the minimum requirements for survival was vanishingly small, and precluded intellectual or cultural development. At least in industrial societies, the routine physical labor of primitive man has been largely supplanted by generated energy and machines, and we now see the routine mental labor of industrial man beginning to be replaced by computers. It is here that technical achievements of mechanized production, automated control and automated data handling come to bear upon social questions involving working skills, educational levels, intellectual and cultural pursuits, economics generally, and even politics.

In the economic sphere the results of these automation developments will be striking. For example, we are just now witnessing one role of computers in production: lower requirements for inventories are possible because of the almost immediate analysis and interpretation of the factors affecting supply and demand. In general one

---

C. G. Suits is Vice President and Director of Research, General Electric Research Laboratory, Schenectady, N. Y. *(Received June 29, 1961.)*

can expect that for a given manufacturing output, the total employment should decline in favor of an increasing investment in production machinery, but this trend must be balanced against the substantial up-grading of remaining employment, and the increased output (and hence employment) which may be anticipated at the lower unit cost levels of the product or service.

In the social, cultural, and political sphere the results will certainly be equally striking: we will achieve the environment and capability for intellectual development on a scale hitherto impossible. By this time I suppose that I have made it clear that my own interpretation of history is basically optimistic.

The attainment of economic, cultural, and intellectual objectives will not follow automatically nor surely from mechanized production. One may be sure that there will be temporary dislocation, confusion, and inconvenience before net progress is finally achieved. New shoes sometimes pinch, and new efficiency may at first prove uncomfortable where inefficiency has been the custom. Retraining and relocation of workers will be necessary to accommodate the changing character of employment as automated systems assume routine production functions. In the long run, we may expect that the net impact of increasingly automated production of goods and services will be lower costs and wider distribution, and an increasing increment of human capabilities and resources to further challenge and explore our physical and intellectual environment.

As a current dramatic illustration of the way in which advancing technology expands the field of human endeavor, consider the present beginnings of space exploitation. Perhaps *space* is a logical new additional frontier which should share in our growing increment of energy and resources—the increment above the basic survival requirement of primitive man.

I have asked a few of my associates in the General Electric Research Laboratory to discuss and appraise some of the specific areas in science and technology which are particularly exciting and pertinent to this view of our future. Their comments follow.

Man's Future in Space

JOHN C. FISHER

No single pressure is forcing mankind to take the first steps toward space, but rather a large number of pressures, some effective for one group of people and others effective for others, provide the motivation. The military objectives are clear. Satellites offer an opportunity for continuous high quality surveillance, for defense systems in orbit to counter ballistic missiles, and for bases in space. The moon offers sites for retaliatory weapons that cannot be destroyed from earth without great difficulty and several days' time. The scientific objectives are equally clear. Our knowledge of the universe of which we are a part is beginning to grow more rapidly as we cease to be earth-bound. Astronomy will leap forward with the first telescopes in space, as will biology with the first investigations of life on Mars. Geology and cosmology will increase their strides when the moon, the asteroids, and the planets are explored first hand.

Beyond the military and scientific motives, which are somewhat limited in appeal although they affect powerful groups in our society, lie other motives of wider appeal. The competitive desire to excel, to lead, to keep national prestige high, is effective. Curiosity, the need for excitement, response to the challenge of the difficult and the unknown, the desire for adventure and a taste of danger, impels some to participate actively and many to participate vicariously. These human attributes, of doing whatever can be done, learning whatever can be learned, overcoming whatever obstacles can be overcome, should not be minimized.

The economic motives for exploring and exploiting space are of growing importance. Weather observation and long-distance communication are even now beginning to be undertaken by satellites, because better and cheaper results can be obtained. Rocket, satellite and space exploration activities already are a significant and growing factor in the economies of several countries.

Our rapidly developing ability to utilize power for propulsion is bringing us the means for satisfying our military, scientific, human, and economic aspirations for conquering space. The past century has seen the progressive development of the steam engine, the internal combustion piston engine, the jet engine, and the rocket, as prime movers. The power that can be directed to propelling vehicles has increased enormously and is increasing apace. We do not know what limitations may ultimately be found, but it is clear that the power and reliability of space vehicles will increase greatly, and the cost per ton of payload in orbit will decrease greatly.

Our desires and our abilities coincide to insure that space will be explored and utilized. But how far will we go? There is no limit to how far we *can* go, as many have pointed out, for we will have the ability to colonize much of the solar system and in time to move on to other stars before our science and technology reach their limits. Yet for one reason or another we may not do so. War, or pestilence, or economic depression, or disillusionment with a difficult task, or a change of heart with respect to what is felt to be important, may cause the drive toward space to fade away, or to be limited to the vicinity of the earth.

I am inclined to believe that our abilities will grow so fast, and the value of space exploration and exploitation will become so apparent, that the great leap whose beginnings we now witness will not abort. In 50 years' time our needs for energy, living space, and distance between societies will be even clearer. The growth of our ability to modify and live in inhospitable environments suggests that colonization will by then appear possible and economically attractive. It will then be difficult to stop.

Where are we likely to stand in fifty years? Almost certainly the earth will be surrounded by a complex of artificial satellites, some manned and many not, engaged in transmitting and relaying electronic communications, in watching the progress of weather, in spying upon man's activities about the globe, in spying upon the activities of other satellites, in acting as way-stations for travel between the earth and the moon, and as temporary homes for technicians installing and servicing satellite equipment. It is likely that other satellites will be poised to detect and destroy attacking missiles on the way up, should any appear.

Very likely the moon will support a few strong moon bases, largely self-sufficient, with permanent living and working quarters for perhaps a hundred thousand people, including men, women, and children, in airtight buildings under the surface. These bases will grow their own food, and have access to their own nuclear or solar power. They will exist to staff military and scientific bases upon the moon, to service the complex of satellites in orbit around the earth (most of which will be more easily reached from the moon than from the earth), and to serve as points of departure for the exploration of the solar system. Tourism to the moon will be in its infancy, as will the manufacture of satellite and rocket equipment. Settlements on other planets and the asteroids will be in process of formation and provision, and the outward wave of colonization will have begun. The earth's economy should be greatly stimulated by this activity, as the economy of New England was stimulated by the sweep of pioneers to the West.

Barring accident, it is likely that subsequent decades, beyond the year 2012, will see the continuing exploration of the other planets and the asteroids, and the beginnings of colonization of many of them. An additional century may lead to the colonization of perhaps a thousand asteroids, and a few more centuries to the time when these city-states will each have a population comparable to one of today's nations.

I find it difficult to guess much further into the future. A thousand city-states in only weak interaction, exploring different systems of government, social order, eugenics, science, art, literature, economics, and war should increase man's capacities and speed his evolution. We stand upon the brink of an event as full of import for the future of life as the ancient time when our ancestors first crept out of the sea to walk upon the dry inhospitable land.

Computers and Computer-Like Systems

P. M. Lewis II

Man has continually strived to build machines that could accomplish some of the tasks he found tedious or difficult. Beginning with those involving brawn and muscle-power, he has progressed through clerical and bookkeeping jobs, until now he is beginning to deal with jobs involving those portions of his mental abilities usually associated with intelligence, learning, and creativity.

The machine that has made this last step possible is the stored-program digital computer. In concept, only fifteen years old, the computer has already revolutionized man's thinking as to the possibilities of machine behavior. While some people still argue about whether machines will ever *really* be "intelligent" or "creative," it is becoming increasingly evident that the capabilities of machines will continue to advance in these directions and that, in the long run, such arguments are irrelevant. Moreover, it is apparent that as these potentialities of machine behavior become realities, the effects on the economy of the world will be comparable to those caused by the Industrial Revolution—the last great advance in the use of machines.

During the next forty years, the science and technology needed to exploit these potentialities will develop along two related lines—components and systems.

COMPONENTS For those applications in which speed and logical complexity are required, components will be available in densities of millions per cubic inch. Their size will be limited by molecular or atomic (perhaps even quantum) effects and their speed by the velocity of light. The manufacturing difficulties will not be so much in the fabrication of such components as in their interconnection. Because of this, and because present sequential machines are not particularly suitable for certain problems, the organization of computers will change radically. The components will be connected in large networks that can perform computations and logical operations in parallel in addition to sequentially as at present. The idea of separately designed "black boxes" for storage, arithmetic, and logic will be supplemented by the concept of a computing network that can perform all these operations simultaneously.

The reliability of these networks will be orders of magnitude greater than that of the individual components. Such reliability will be obtained by using redundancy in the number and interconnection of the components and in the coding of the information.

For certain applications in which high-density components are required, manufacturing constraints will dictate that only a small number of standard configurations be fabricated. In the factory, these configurations will be altered by a "training" or "learning" procedure so as to be appropriate for a customer's particular application. Further training may take place on line at the customer's site.

In addition to the quite substantial economic advantages such a procedure might have, machine training offers two other interesting possibilities: 1) the ability of the machine to eventually perform its task in a fashion that is different, and perhaps better, than its designer had originally conceived; 2) the transferring of one machine's experience to another without the necessity of repeating the training period.

Insight into the basic ideas of such machine training will come from the combined work of psychologists and neurophysiologists as well as mathematicians and engineers. However, it is likely that, internally, machine training will be vastly different from human learning.

SYSTEMS Computer systems will become larger by many orders of magnitude. Nation-wide (and indeed world-wide) computer networks will be commonplace. Subsystems of these mammoth systems will perform
many orders of magnitude. Nation-wide (and indeed

the ability of the system to carry on a two-way communication with its operator in a language almost identical with the operator's everyday speech. Both the machine and the operator will be able to request and receive the particular information each one needs to accomplish their common objective.

A good way to appreciate the complexity of such a system is in terms of some of the features of a nation-wide computing network that a large company might employ.

Factory Control. With inputs of management policy, customer's orders, and present state of the factory, the system will do engineering design on the product, order materials and maintain a warehouse, schedule production, control production and the individual machines and processes necessary for production, and prepare necessary reports.

Management Control. The system will make available to each manager within the company instantaneous reports on the state of his business and that of the company as a whole. It will furnish him with a rapid means of communication with other business within the company and will allow him, through simulation of the marketplace, to see the effects of his decisions on the state of his business, the company and the national economy.

In addition, the computer will have the authority to make many types of management decisions, some of which today are reserved for executive management. To sooth any executive who should happen to read this, let me agree with him that computers will never make *important* executive decisions, but let me suggest that the definition of what constitutes an important decision will undoubtedly change.

In discussing the potentialities of computer systems over the next forty years, one is limited more by his imagination then by fundamental physical or mathematical restrictions. In fact it is likely that much of what has been written here will be realized in twenty years rather than forty. Regardless of the time period, it is clear that machines will have continually increasing capabilities in those areas usually associated with creative mental effort, and that the realization of these capabilities will have far-reaching implications in our economic, social and political system.

Novel Electronic Circuitry

George D. Watkins

In 2012 A.D. we may expect to find *living cell* amplifiers, computers, power supplies, etc. These devices will have been made possible through the basic research of this and the next generation in the new and rapidly growing fields of biophysics and biochemistry. It may be possible, for instance, to isolate, develop, and breed strains of living cells which perform simple logic functions. The role of the new bio-electronic engineer would then be to synthesize (grow) from these basic units larger organisms which could perform extremely complex operations.

Some of the desirable features of the living cell circuit would be the self-healing aspect, the extreme miniaturization, and the efficiency. The unique power supply required (nutrient) would also offer some possible advantages. For instance, as a surrogate organ, a living cell circuit might be planted in the body and live off the nutrient of the body with no additional power supply requirement. A repeater in an undersea cable might live off the micro-organisms in the sea water.

In fifty years we may also anticipate startling advances in solid-state circuitry. Potentially the lattice of a solid crystal affords a matrix capable of incorporating extremely complex circuitry. The surface may have only been scratched with such simple one-dimensional circuits as the semiconductor diode or transistor of today. In the future, as the perfection of crystals is improved and as the techniques for "doping" in a controlled fashion are developed, it may be possible to construct highly complex three-dimensional circuits entirely within a single crystal of solid. The advantage of such circuits would be primarily in the miniaturization, but also perhaps in increased efficiency and high-frequency response.

Much of the required basic knowledge of solids is already available, although simpler approaches may develop. For instance, just as in the transistor, the electrical properties of the microscopic volume elements of the crystal could be controlled through the addition of a variety of defects, impurities, vacancies, interstitials, dislocations, precipitates, grain boundaries, etc. Properties analogous to all of the conventional passive circuit elements can be achieved in this way. In addition, these elements in turn could couple to magnetostrictive, piezoelectric, superconductive, ferroelectric, ferromagnetic, etc., microscopic regions which can themselves be geometrically resonant at specific frequencies. The network could be made electrically active by coupling dc energy in through low resistance paths or selectively by acoustical or electromagnetic energy, etc.

Introduction of the required defect configurations is not possible in terms of present-day technology and significant advances must be made in this area. Radiation "doping" with a scanned electron or ion beam is one possible approach.

Electron Devices for Power Generation in 2012 A.D.

V. C. Wilson

The thermionic converter is an electronic device which converts heat to electricity. It is an extremely high temperature heat engine which operates at a hot temperature of about 2000°K and a cold temperature of about 900°K. Because of its high "cold" temperature, it shows considerable promise for generating electricity for space vehicles. The reason for this is that in outer space the only way to remove unconverted heat is by radiation. The higher the cold temperature of a heat engine the more heat can be removed per unit area of a radiator. Both nuclear energy and concentrated solar energy will be used for the heat source on space vehicles. On the ground thermionic converters will be built inside nuclear reactors. By the year 2012 at least 30 per cent of the fission energy will be converted to electricity by the converters and will be brought out of the reactors on buss bars. The high cold temperature of the converter means that the unconverted 70 per cent of the nuclear heat may be passed onto a steam turbine with 40 per cent conversion efficiency. Thus the converter may be thought of as a topping device to a steam turbine in a large central station. The over-all efficiency of the system would be about 58 per cent. At this efficiency, electricity from nuclear energy will be less expensive then from fossil fuels, so by 2012 the dream of large quantities of electrical energy from the atom will come true. The most important result of this is that we will stop burning fossil fuels for electric power and will save more of the fossil fuels for chemical and drug industries.

Even if electricity were generated at the central station at no cost, the cost of extensive distribution systems is great enough to make one ask if solar energy could be harnessed for home electrical uses. Here the key problem is energy storage. In northern latitudes of 35° or more, by far the greatest amount of solar energy is received in the summer months. This must be stored for winter use. Thermionic converters or photovoltaic sheets could be used to convert the solar energy to electricity. For storage, reversible fuel cells could be used. Present membrane fuel cells when driven backward dissociate water into hydrogen and oxygen and when fed hydrogen and air generate electricity. Hydrogen is too difficult and bulky to store. By 2012 reversible fuel cells which store energy in liquid fuels will be developed. The economics of such solar generator and storage systems will determine how widespread their use will be. Certainly large nuclear central stations will supply the bulk of electrical energy for industry and large cities.

In places where there is abundant solar energy and water near by that must be pumped for irrigation, solar heated thermionic converters and thermoelectric generators in series could be used to generate the electricity for pump motors. These static heat engines in series will probably be more efficient than photo-voltaic converters.

Computers of the Future

P. J. van Heerden

Today the problems of electronically transmitting and receiving information have been largely solved and even brought to a stage of sophistication. Telegraph, telephone, radio and television, in their historical order, are the fruits of this development. Electronic information processing, however—the process of drawing useful conclusions out of raw information—is still in its infancy. This process is achieved by the human brain in a miraculous way, and its only criterion is its success.

Present-day computers are merely fast adding machines whose usefulness is limited to routine clerical operations. However, the next fifty years will see electronic information processing systems brought to a stage of sophistication comparable to that of today's electronic communication systems. This will require two things. In the first place, the basic principles underlying the brain's method of digesting information must be discovered and translated into simple electronic systems. This is as necessary as our simple theory of electromagnetism was for developing detector, amplifier, and transmission systems. In the second place, capacity for electronic storing and processing of information, on a scale equal to that of the human brain, must be developed. The electronic information handling systems of the future will be able to receive information in visual and auditory form, just as humans do. They will be able to arrive at conclusions that are as correct and valuable as those reached by intelligent persons. These future electronic "brains" will show judgment, since judgment is based on a simple mathematical principle of weighing information.

However, in this 50-year interval we will have found out that the bottleneck in making an intelligent machine is in the learning process, and we will have found this learning process to be quite expensive. Thus, society will be faced with a moral decision: whether it will spend the money to train intelligent machines to perform tirelessly in very demanding jobs, or whether it will educate children to have the satisfaction of achievement in the same. I hope that it will not be difficult to choose in favor of mankind.

There is, however, one function in which intelligent machines may be useful. This is in the exploration of outer space, provided it turns out to be too hazardous or too boring for human beings to carry out. Since an intelligent machine, once trained, can be duplicated many fold, one sophisticated training program can produce thousands of intelligent, but identical, electronic astronauts. They will be sent on trips of many years' duration to the farthest planets and the nearest stars. They will be told to use their own judgment in operating the spacecraft, gathering information, and returning to earth when their mission is accomplished.

Some Thoughts on the State of the Technical Science in 2012 A.D.

FRANZ TANK FELLOW IRE

In 1962 when the Institute of Radio Engineers commemorates its jubilee, past and future will be compared. Much has to be learned from the past for it provides insight into the secret process of evolution and into the internal connections of it to technical development. Besides it rewards us with the pictures of important men's lives. Every radio engineer will gladly remember that the wireless transmission of signals by means of sparks and antennas belongs to the most ancient experiments in electronics. In 1791 Galvani made —in connection with his famous "frogleg experiments"— the following investigation. Between two wires freely suspended in space he inserted a spark gap and let it spark over; another two similar wires were shunted by the nerve of a frogleg, the former was still attached to the leg. With every electric spark-over in the "transmitter" the frogleg at the "receiving end" twitched. The beginning of radio telegraphy had been invented, but 100 years passed until its true victory should begin.

How many names are connected to this victory! We shall not hesitate to call for one who perhaps is mentioned too seldom, Nikola Tesla. His thoughts and his will belonged entirely to the future. In 1898 he had already demonstrated the first remote controlled model ship in New York. In 1899 he built a radio station of 200-kw power output in Colorado Springs, working at a wavelength of 2000 meters, and he developed plans for a world-wide radio system. It did not seem impossible to him to have radio communications in the future between earth and planets. But one can see with regard to Nikola Tesla that engineering needs wide theoretical bases for its development and the time to reach its maturity.

Only in the field of logic are exact prognoses possible. Logic is only a part of the vast wealth of our life— but nevertheless an important part. It is well known that the basic laws of physics permit logical conclusions which are as certain as the basic laws themselves. Would it therefore be possible to predict the state of physics— or, more easily of electronics—in 2012 from the bases known today by using logic, *i.e.*, by thinking? Yes and no. Yes, because logic is a very reliable adviser and no, because in the meantime basic laws could be discovered which are qualified to greatly change the future. For an extrapolation on a wide basis our point of view is too restricted. For life possesses uncountable elements of significant importance, removed from the power of rational thinking. Let us remember the fact that many things happen unwillingly and unconsciously. In these fields phantasy, feeling, and intuition are an invaluable help. But they are not without any attraction, and it is important to consider the connections suggested. We always come back to the well-known experience that the human being is a measure of the things. We have to start from this fact if we want to understand the relations of men to technics, progress and culture. The man who creates the technics follows an internal destination. Thus he fulfills a part of his skill. He is born with the ability for thinking, searching and researching. One can say that he is unburdened by the technics from pains, care and hard work, that he looks for and finds protection and help in his vital conflict, and that he reaches for mastery and power—but in the end he creates the technics because he is internally compelled.

F. Tank is a Professor, Ret. (Swiss Federal Institute of Technology, Institut für Hochfrequenztechnik), Frohburgstrasse 174, Zurich, Switzerland. *(Received June 29, 1961.)*

Through engineering the human being has influenced the basis of culture in an important manner. Very ingeniously the prehistorical centuries are distinguished by their art as the stone age, bronze age, and iron age. The inventions of compass and gun powder occurred at the beginning of modern history—the former made it possible to navigate over the oceans, the later intervened in wars and therefore in the way of history.

The most important fact, however, which introduced modern times and gave them more and more character, was wholly intellectual. It was the recognition that by means of experiments basic laws of nature could be found, could be expressed and ruled theoretically, *i.e.*, by logical processes. Copernicus, Kepler, Galilei, Newton, etc., shall be mentioned; many other names could be called for too. The finding of existing basic laws belongs to the biggest achievements of human spirit; its importance can never be overvalued. It gave a fixed basis to the technics and freed men from incorrect superstitions.

The technical age in which we live advances with unheard of consequences. Nothing has the power to stop it on its path until one day the far destination which is unknown to us has been reached.

The five decades from 1862 until 1912 were extremely rich with basic discoveries (ions, electrons, photoelectric effect, thermoelectric effect, electromagnetic waves [Heinrich Hertz], X rays, radioactivity, quantum theory, theory of relativity, Rutherford's model of the atom, etc.). The next five decades from 1912 until 1962 have been used by the extension of the gained knowledge and the technical application thereof. But other basic knowledge has been added, especially in the physics of the nucleus (nuclear disintegration, artificial radioactivity) and of the elementary particles and in solid-state physics as well. These discoveries opened not only completely new technical aspects, but they also required new ideas in the organization of research. They will still engage a large amount of scientific and technical power until 2012.

But now the meaningful question is asked, "Which natural facts, new, and unknown until now, perhaps unpredictable by any theoretical investigation, will be found in the time from 1962 till 2012?" Those things not known in the past, the *new* and the *unknown*, possess the power to change the present and to introduce a different future. This is the reason for the importance of basic research. As Maxwell said at the opening of the Cavendish laboratory, "We need more Faradays, many more Faradays!"

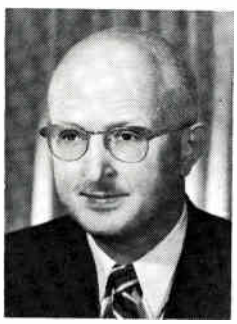
Present-day electronics will have become "classic" in 2012. Today's developments in amplifiers, transmitters, servomechanisms and computers will have reached a certain settlement and to some extent they will have gained a "final form." Miniaturized and subminiaturized elements will play an important role in circuit theory. Radio receivers the size of a match box will be used throughout. Nature, the unrivalled builder, will have taught us and we will have tried to copy human eyes and ears. The gap between radio and light waves will be closed. The maser principle will have found wide applications in great perfection. There will exist an art of millimeter and submillimeter waves. Crystals will find use as wave filters. New, powerful electron sources, high-power transistors, new light sources of highest intensity and great efficiency will be known. But shall we be happier?

The population of the earth will have increased enormously by 2012. Men will live extremely close together. New social problems will thus exist. Raw materials, important for life, will be rare. A state of saturation or even exhaustion will occur. Any further development will then call for very large efforts. A higher technical dimension will bring to man neither more power nor more happiness. He will turn to other things more important to him and perhaps more needed for his maintenance. Certainly man will never be able to live without technics, but he will have to recognize that technics can never be the true purpose of life.

In 1886 Werner von Siemens gave a talk on the age of natural science which will be created by technics. Man will be freed from hard work, there will be food and clothes for everybody. His contemporary Jakob Burckhardt, a Swiss historian, forecast severe world wars. Even then opinions were opposite. It lies in the nature of every qualified engineer to believe in the future and to hope for true and consistent progress in creating a better and happier world. Let us agree with him and hope that he will be right. Only belief in the future strengthens mankind. And even if we do not know today the state of the art in 2012 and are only able to presume, we want to believe nevertheless in a better future. The United States of America should work towards this better and happier world. What a task of historical importance!

Our State of Mind in 2012 A.D.

GEORGE L. HALLER FELLOW IRE



Any prediction about our technological future must assume that no catastrophe will destroy any significant amount of our technological capability. Were such a catastrophe to occur, prediction would be pointless.

To predict something with confidence that it will not take place well before 50 years is easy. Just predict something that seems physically impossible, such as a perpetual motion machine of the second kind.

But if what you predict does not violate the laws of physics as we know them, and if we can now visualize it, someone may produce it before the print is dry. To err by fifty years in looking ahead fifty years is embarrassing, but possible! In this quandary, he who has prediction laid upon him perhaps is safest in retreating to implications of technological advance itself. What can we say about our state of mind, fifty years hence, in a society built upon continual increase in our technological knowledge and prowess?

We can too easily make one of two opposite assumptions about the continuing increase of our knowledge about the physical universe. These two assumptions are: 1) We shall go on learning new facts about the universe at an ever-increasing rate; 2) We have made all of the big discoveries, and all that remains is filling in the details.

The title of H. D. Smyth's book reporting on our World War II technical effort, "Science, the Endless Frontier," implies the first; a statement by Gamow[1] typifies the second: ". . . it is my earnest opinion that the twentieth century will play the same role in the history of our exploration of both macrocosm and microcosm, as the era of the great great geographical discoveries played in the exploration of the surface of the earth."

To deal with the latter assumption first: There seems little warrant for assuming that the universe of natural fact is "shallow" in the sense that Gamow implies. The unfundamental nature of our "fundamental particles" has become a truism. The voids between gravitational theory, electromagnetic theory, and quantum mechanics are obvious. The gap between organic chemistry and biology, though fast breaking down, is still there. Closing these gaps and reconciling these discrepancies may reveal whole new areas of natural law, just as the Curies discovered radium among discrepancies in the radioactive decay rates of known elements.

To deny the second assumption, however, is not to affirm the first. There is a third hypothesis possible. Our rate of acquiring and applying scientific knowledge may slow down (though perhaps never stop), not because of limitations in the universe, but because of limitations in us and in our scientific resources.

We can divide these limitations into three categories: those due to the laws of physics, those due to our own mentalities, and those due to scientific method.

PHYSICAL LAWS Among physical constraints which may impede our rate of technological growth are at least three: the Heisenberg uncertainty principle, the finite velocity of light, and the stringencies of reliability.

Heisenberg Uncertainty. By the terms of this principle, we cannot in the nature of things know both the x coordinate and the x-direction momentum of a particle with an error less than that given by the relation

$$\Delta x \ \Delta p(x) \gtrsim h/2\pi; \qquad (1)$$

where Δx is the error in the x coordinate; $\Delta p(x)$ is the error in the momentum in the x direction; and h is Planck's constant, $6.625(10)^{-27}$ erg sec.

This places an upper limit on the density with which we can pack information into the "memory" of a computer (or a human mind). Suppose that we want to register

[1] G. Gamow, "Will science come to an end?" IRE TRANS. ON MILITARY ELECTRONICS, vol. MIL-1, pp. 26-31; March, 1957.

G. L. Haller is Vice President of the General Electric Co., Syracuse, N.Y. *(Received June 30, 1961.)*

the presence of a "bit" with a piece of material in a box Δx on a side. We want the material to stay in the box for t seconds; therefore Δv must be much less than $\Delta x/t$. Assume that the material fills the box, and that its density is d. Then, substituting in (1),

$$\Delta x \; d \; (\Delta x)^3 \; \Delta x/t \gtrsim h/2\pi; \qquad (\Delta x)^5 \gtrsim ht/2\pi d. \tag{2}$$

The greater the density of the material, the smaller Δx can be. Choose osmium, with a density of 22.5 g/cc, greater than that of any other element. Specify that it stay in the box for at least one day, $8.64(10)^4$ sec. Then Δx, the size of our box, must be more than $2.14(10)^{-5}$ cm on a side. We cannot expect to store information in any "memory," with any permanence, with a density greater than about $(10)^{14}$ bits/cc. (We might be able to increase this storage density by an order of magnitude or so, if we could store our bit of information in the form of a subatomic particle "trapped" in a "potential well" inside an atom or a crystal structure. This requires, first, getting the particle into the "box"; and, second, reducing its energy level well below the height of the "walls" of the "well." The resulting improvement is entirely analogous to that obtainable in information capacity of a communication channel, using Shannon's formulation instead of Hartley and Nyquist's.)

Speed of Light. The speed c of light in a vacuum is $3(10)^{10}$ cm/sec. We cannot travel or transfer information any more rapidly than with this speed. If we want to send men, materials, or messages across interstellar distances, we must take the requisite time. (Einstein's theory of general relativity predicts that the subjective time experienced by the accelerated traveler will be less. He may stay young, but his inertial friends will grow old.) When Mars and the earth are on opposite sides of the sun, the man on Mars must wait for more than an hour to get a reply to his message to the earth. To paraphrase the plaint of the artist, *mundum largum, vita brevis.*

The speed of light is also 30 cm/mμs. If the length of the circuit a query must travel in order to retrieve a bit of information is L, then the access time A for retrieval of that bit is

$$A \gtrsim L/c = (1/30 \text{ m}\mu\text{s/cm}). \tag{3}$$

Reliability. As complexity of apparatus increases, the requirement for reliability of each component element fantastically increases. The mean time per error t of each element in an assembly of N elements, each of which must function correctly if the assembly is to function correctly, approximates

$$t \doteq NT \tag{4}$$

for T and large N, where T is the required time per error for the complete assembly.

Physically-Limited Intelligence. We could define the "intelligence" I of a computer as the product of the size of its memory and its mean time between errors divided by its access time. From (2), (3), and (4), since the distance L must be, on the average, at least $N^{1/3}\,\Delta x$,

$$I = NT/A \lesssim N(t/N)(c/L) = ct/L \lesssim c(2\pi d/h)^{1/5} t^{4/5} N^{-1/3}; \quad \doteq 1.40(10)^{16}(t \text{ in sec})^{4/5} N^{-1/3}. \tag{5}$$

(This dimensionless quantity measures brains per blooper.) The maximum achievable "intelligence" improves with reliability of components, but not quite linearly, and suffers somewhat as memory size increases.

The Heisenberg uncertainty relation and the finite velocity of light may possibly be approximate. We may be able to transcend them, as we have transcended Newton's laws of motion. We have, however, no real warrant for expecting it. We can ameliorate the penalties for complexity, but we cannot entirely transcend them.

HUMAN MENTALITY In someone's words, the human being is the only computer produced by amateurs. (A theologian might quarrel with this.) As a processor of information, a human being has several advantages over present and foreseeable computers:

He can repair himself, physically and mentally, consciously and unconsciously.

He can program himself.

He can adapt his program to unexpected information.

His memory capacity is many orders of magnitude greater than the computer's.

His logical sophistication is many orders of magnitude greater than its. The most sophisticated of our computers has a logical capability roughly equivalent to that of a single human neuron.

He has a variety of input-output devices.

On the other hand, the human being has disadvantages, in comparison with the electronic computer, as a processor of information:

He is subject to fatigue and distraction.

He requires motivation.

His access to his memory is unreliable. (Direct stimulation of brain cells indicates that memories probably do not significantly deteriorate; it is the access to them that becomes unreliable.)

His logical processes are slow and notoriously unreliable. (Is this the penalty he pays, in view of equation (5), for his large memory and logical sophistication?)

He is unable to reproduce on demand most of the logical steps in his processing of information, because he is unaware of them.

His readin-readout processes are several orders of magnitude slower than his logical processes.

His input and output devices (specifically language, the most important) are inexact, and therefore subject to misinterpretation.

Our processing of information will benefit if we can make human beings and electronic computers function together, utilizing the advantages and overcoming the disadvantages of each.[2] But human beings are still self-centered enough to place one constraint on this co-opera-

[2] *Cf.* J. C. R. Licklider, "Man-computer symbiosis," IRE Trans. on Human Factors in Electronics, vol. HFE-1, pp. 4-11; March, 1960.

tion: The distilled information must eventually be accessible to human beings. We are not yet willing to serve merely as auxiliaries to the education of computers.

It might be possible to use computers to improve human thought processes themselves. A human being has access, for example, to about four per cent of his neurons. If we could bring the unused neurons "into the circuit" as needed for thinking or information storage, we might multiply our individual intelligences by 25.

We might be able to improve the speed and accuracy of our output devices. We can read an order of magnitude faster than we can speak. If we had an output device as rapid as reading, we could greatly speed communication among ourselves and with computers.

With the aid of a computer, we might be able to improve our awareness of our thought processes, so that we could more rigorously check our reasoning.

Current work in machine language translation[3] may be teaching us how to build computers which manipulate conceptual entities rather than arithmetic quantities. We might visualize forthcoming developments in computers in terms of the following succession of capabilities: 1) Produce readable translations of technical literature. (Opportunities for mistranslation, and importance of esthetic quality, here are supposedly relatively small.) 2) Translate ordinary newspaper prose into colloquial prose of the target language. (This implies mastery of colloquial syntax.) 3) Translate literature of a high esthetic content, with a skill comparable to that of a competent linguist.

In these three steps, computers will have mastered dealing with concepts as concepts. They will deduce from the context the exact context to which a word or phrase refers, and in the translation include words and context insuring that the author's concept reaches the reader. (We shall then have to write, and to read, much more precisely than now!) 4) Manipulate logical concepts, using symbolic logic. 5) Investigate properties of alternative logics, such as Aristotelian logic, many-valued logic, probabilistic logic, and Hegelian dialectic. 6) "Carry on a conversation" with a human being (perhaps through neuron taps or analysis of brain waves) and analyze his conceptual framework and his methods of thought. By then, machines will be psychoanalyzing people!

This sequence may never happen. We may find ourselves blocked by the limitations of equation (5). We may discover, and be able to delineate that creative something about human thought which we like to think forever beyond machines. In fifty years, nevertheless, we should be well on the way to accomplishment of the first four steps: development of computers which can reason symbolically and produce translations, or report on their conclusions, in colloquial language.

Such a computer would enable us to codify and catalog our scientific knowledge. A human being could study science with minimum wasted effort. He could have access to much more knowledge than he could store.

In the process, human beings may learn to talk like machines quite as much as machines learn to talk like people. Juliet in 2012 A.D. may say of Romeo, "Delta symbol not imply delta referent attribute end."

[3] *Cf. MT/Machine Translation,* Massachusetts Institute of Technology, Cambridge, Mass.; published irregularly.

SCIENTIFIC METHOD We may define scientific method as the collection of verifiable information, the induction of structure in this information, and the publication of results. More simply, scientific method is transferring and processing information. Among limitations possibly inherent in scientific method, there are at least two kinds: one arising from the nature of information transfer, and one arising from the nature of the structure of information in scientific laws.

Information Transfer. Information, like people and things, moves in traffic channels. To date, much of our technological effort has been to provide enough channels so that one may always be available, without significant delay, when wanted. We have designed channels on the assumption that demand would be random.

As we become able to move people and things farther and faster, providing channels to meet random demand becomes increasingly burdensome. The time could theoretically come when there would no longer be room for homes, because expressways take up all of the real estate. The alternative is planned demand: the traveler, as the airplane pilot, would have to submit a "flight plan" and receive clearance before embarking on a trip. The traffic problem is quite general. It is the access-to-memory problem in a computer, and in a human brain. We do not use all of our neurons because we have too few "expressways" between them. In the opinion of some (not all) psychologists, the stuttering of a left-handed child forced to write with his right hand may be due to his having too few neuron paths from the right half of his brain, where he thinks and manages his talking, to the left half, where he controls his right hand.

The same congestion threatens our technical information channels. The flood of technical information today swamps technical journals, ASTIA facilities, technical libraries, and engineers' offices. No one can read everything pertinent to his field. He therefore may duplicate technical work done, and reported, once or often before. When we add to our communication channels the coming flood of data to, from, and among computers, the prospect is frightening.

The solution surely lies in a direction other than ever more journals, ever better microfilming, and ever larger telecommunication bandwidths. It may lie in the direction of some current research[4] on electronic information retrieval for technical libraries.

The technical library of 2012 A.D. may consist, not of books, journals, or microfilm, but of a concept file. The worker would describe his desires symbolically, and receive a reply giving who has done what in the field. The technical journal may then be a data link keeping

[4] *Cf. Current Research and Development in Scientific Documentation,* National Science Foundation, Office of Science Information Services, Washington, D.C.; published twice yearly.

this library up to date. As a matter of prudence, the scientist would check his "library" before embarking on a research problem, to make sure that no one had done, or was doing, substantially the same work.

The Structure of Science. The laws of science are a structure of generalizations. In principle, we can test each generalization as thoroughly as we wish; this is what we mean when we say that the laws of science are "experimentally verifiable." As our scientific knowledge grows, however, the structure becomes continually more complex. The generalization of yesterday becomes a particular case of the generalization of today. As the structure grows, the relation of the latest generalization to the undergirding of fact becomes ever more complex.

Two limitations may arise on the rate of growth of this complex structure. The logical effort required to modify the structure, in the light of an unforeseen fact, increases with its complexity. And the reliability of the structure as a whole depends critically on the reliability of each of its logical elements. We have here an analogy, in the domain of scientific concept, to the limitations on a computer implied in equation (5). Both the size and the complexity of the structure of scientific thought may limit the rate at which it can grow.

By 2012 A.D., we may expect our electronic conceptual computer and library to reinforce the reliability of our reasoning and to speed the correlation of facts. But the size and complexity of this computer library may itself grow to the point of diminishing return. We shall then need a methodological "breakthrough" of the first magnitude.

CONCLUSION By 2012 A.D., the association between the human scientist and his electronic aids to thought will be close, complex, and intimate. To us, the distinction between "me" and "my computer" would then be difficult to make; but the scientist then will think more precisely, and be much more aware of his thought processes, because by then his computer will have begun to analyze his thinking for him.

Human intelligence will not in 2012 A.D. be so dominant a limitation as today on the rate of growth of scientific knowledge. The limitation will increasingly come from the nature of physical reality and the nature of scientific method.

The scientist of 2012 A.D. will feel these limitations. One of his important areas of study will be ontology: the nature of physical reality. Another will be epistemology: the nature of knowledge. The scientist of 2012 A.D. will be a philosopher.

The Use of Electronic Computers in the Social Sciences

IRVING WOLFF FELLOW IRE

Digital computing machines have been applied with tremendous impact in the fields of data processing and technical computation. In the next 50 years we can look forward to an extension of these applications. And with the help of electronic computers, we can hope for the development of new quantitative sciences where only rough qualitative analysis is possible today.

In general, the computers have been used in fields where the rules for solving the problem assigned to the machine are known. Their help has been required to reach a desired objective more efficiently or economically. In some cases, the computations are so time consuming that they can only be completed in a reasonable time with the aid of an electronic computer. Only infrequently have the computers been used to convert a qualitative discipline to a quantitative discipline.

The prediction of weather, a program which engages large digital computers, lies in the twilight zone between a quantitative and qualitative science and is taken as an illustration of the philosophy involved in the use of machines for applications which are in a more primitive state of scientific development. The physical laws underlying the flow of weather are fairly well known. The problems of assembling the data required to accurately compute the weather in advance and the consumation of the computations are, however, so stupendous that the weather would be long past before the calculations could be made using ordinary computer methods. More important, we must be able to check the hypothesis against the actual results in order to increase the accuracy of our predictions. This requires many trial

I. Wolff, Chairman of the Education Committee, Radio Corporation of America, Princeton, N.J., was Vice President of Research at RCA Laboratories before retiring in 1959. *(Received July 5, 1961.)*

computations, of which each can be terrifically involved.

The electronic weather computer solves both problems for us: 1) it enables us to make the difficult calculations we could not make otherwise, and 2) it permits us to make enough checks of results against predictions to provide the basis for an improved theory.

The scientific approach to a problem consists fundamentally in devising a hypothesis from which predictions are made which can be checked by experiment, and in performing an objective experiment to check the hypothesis. As discrepancies are found, the hypothesis is modified and remodified to fit the results of successive experiments. Often the experiment may come first and stimulate the theory. The continuous interplay between hypothesis and experiment is basic to the scientific method.

The scientific method hasn't been applied to any great extent in the social sciences because 1) the interactions of the variables are so complicated that mathematical reasoning from the hypothesis becomes impractically complex with the means we now have at our disposal, and 2) controlled experiments can only be set up with great difficulty, and usually not at all.

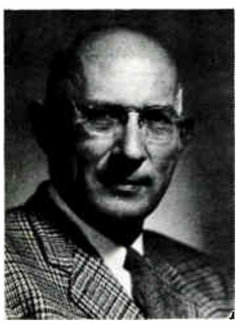
I gave the example of the weather computer to illustrate the principles even though the difficulty in finding the solution is much less severe than is encountered in the most elementary problems in the social sciences. Weather is determined entirely by natural phenomena obeying physical laws on which a fund of knowledge is rapidly developing. The results in the social sciences are determined to a great extent by the laws governing the reactions and interactions of groups of people and individuals. Very little is now known about these laws.

Although controlled experiments cannot usually be set up, there is a wealth of material on the history of events and the factors which influenced these events. With sufficiently sophisticated computers, various models representing individuals statistically and their reactions to various influences may be constructed. These models can be tested under a variety of input conditions to obtain a model which represents the actual events which took place. As a fund of knowledge is built up, the machine can be tested against predictions and then restudied and modified to accord better with the actual happenings. There is every reason to hope that the error will diminish as a social science technology is built up.

If the model which is assumed can be built, and I think that there is little doubt that this will be feasible, the condition for interplay between hypothesis and experiment which is fundamental to the scientific method will have been met, and the social sciences can develop to take their place alongside the natural sciences as exact sciences.

The Biomorphic Development of Electronics

MARCEL J. E. GOLAY FELLOW IRE



When attempting any forecast, there is often the ghastly recall of predictions of the past which were not fulfilled and especially restrictive predictions, such as the turn of the century's prediction that henceforth physics would be restricted to adding a decimal to our measurements of nature's constants, or the more popularly known prediction that the airplane would not fly. Such unfulfilled prophesies may cause one to shy from being categorical about impossibilities. Yet our increased knowledge of the possible is paralleled by an increased knowledge of the impossible, between which the gap of the unknown and of the undone is constantly compressed by discovery and invention.

With this knowledge, we should not be timid about denying the use of gravitational waves, or the transmission of power by means of radio waves. We should also be categorical about the nonexistence of emanated "brain waves" and the impossibility of telepathy or other forms of extrasensory perception. We should understand that beliefs in these are the remnants of pathetic yearnings for a dualistic world which is incompatible with the factual disclosures of science, within a consistent world in which occasional apparent inconsistencies are the scientific puzzles, the solutions of which constitute the great steps forward of science. Only the concept of a consistent, monistic world, in which "spirit" becomes increasingly indentified with pattern, squares with the facts and permits a true appreciation of the ever deepening mystery to which research leads us.

Let us, therefore, make short shrift of the fantastic. Instead, let us try to extrapolate our biological path into our future, and look in our future for clues as to what

M. J. E. Golay is Extraordinary Professor at The Technische Hogeschool, Eindhoven, The Netherlands. *(Received October 19, 1961.)*

is reasonable to expect, or not to expect, of the development of electronics in the service of man and of science.

DEVELOPMENT OF HUMANITY The evolution of life, of thinking man, and of humanity, reveals the hierarchy of patterns which have developed over the last two-billion years, and which will continue to develop in our universe. At the lowest stratum there is the pattern formed by the components of a large protein molecule which, immersed in a nutrient medium, can cause the assembly of another molecule like itself, from which it then separates. This reproducing process constitutes the essence of life at that stratum. At the next stratum, there are the patterns formed by assemblies of living cells: the organized supply of nutrient, the sensory and command nerves, the nerves constituting the brain. Within the brain, at the highest level of this second stratum, there is the pattern of the nervous impulses which constitute thought and reflection for man.

Although the patterns associated with the first and second stratum are more visible than the pattern which humanity as a whole is just beginning to fashion, we are strongly tempted to agree with de Chardin's prediction of the "Thinking Planet" as the third and ultimate stratum in this hierarchy.[1] The "Thinking Planet" will evolve as an increasingly tighter association of men, where the supply and the communication channels, not physically tied to man as they shall be, are no less real and effective than the blood vessels and nerves which connect physically the individual cells of a living creature. In this coming biological stratum, tight discipline will not suppress the person nor provoke fear of the larger pattern as it does today in archaic Russia and China. Rather, such discipline will enchance the personality, create emulative and productive tensions, and inspire in man the same kind of love for his planet which he now has for his country.

Whether this goal be achieved in a thousand, or in a million years, we can predict that the evolutionary principle which produced man out of inert matter, and which gives priority to victory over defeat, to intelligence over stupidity, and to life over death, will continue to operate. And we can foresee that electronics will play a major role in the evolution of the third stratum which has just begun, and will have a development which shall parallel the biological development of this stratum.

DEVELOPMENT OF ELECTRONICS The three basic functions of electronics in the service of man are communication, computation and automation. Let us speculate about their future development in this order.

Communication comprises, in the large, telephony, broadcasting and television, and a host of accessory services such as radar and traffic control. Since communication extends over distances, while computation and automation have a local character, it seems reasonable to conjecture that the communication phase of electronics will be more intimately linked to our biological development than the other two phases.

The individual who, 50 years ago, would have predicted that the automatic telephone would be in use everywhere today in the United States would have been proven an optimist by the facts. Let us, therefore, consider first a plausible ultimate in telephony, and prudently back off from that ultimate to fifty years hence. The plausible ultimate would be this: the individual is given a number at birth, and when of age carries a tiny wrist set which, through a system of overhead or buried grids connected to long distance trunks, permits him to seek pulse-coded voice communication with any other individual, whose number he knows. What fraction of this ultimate will be realized in fifty years? Probably a very small fraction. The bulk of individual mobile communication will still be carried in automobiles and the most important development may be the wider application of pulse-code modulation. The tiny wrist set, mentioned above, may only later emerge as a prototype designed for the amazement of stockholders at their annual meeting. I believe that it is in the much more distant future that telephony, telegraphy and facsimile will have their tightly woven net, so essential to match the biological development of humanity in the "Thinking Planet."

I can say but little of the development of radio and television within the next 50 years, except that today's needs, which are more cultural than technical, may begin to be fulfilled. Even later the development of broadcasting and television will parallel the development of telephony in tightening the biological net by increasing the real educational and reportorial values, despite intervening periods in which thought control for political or commercial purposes will be the main aim of the broadcasters.

What can be said of radar? In military radar, the clever little games of counter measures and counter-counter measures will continue, and will make increasingly heavier demands on computer-type techniques of signal processing. As for nonmilitary radar, its main application will be in traffic control, which will be discussed briefly below, in very general terms.

I foresee traffic control as that chapter of communication on which there will be the most written in the next fifty years, for more elaborate traffic control alone can serve to reconcile the conflicting requirements of greater speed and greater traffic volume on the one hand, and greater safety on the other. The most urgent demands are for greater air safety and for a solution of the paradox that the basically safest mode of public transportation (what can be safer than a ship surrounded by a mile thick cushion of air?) is in fact the least safe today, chiefly because the pilot lacks the information he requires to realize the safety potential of his ship.

Will electronic controls invade the field of private automobile traffic? Shall we have, as some advertisements have shown, automobiles automatically piloted along the highways, while the driver plays cards after having given a program of instructions to the automatic pilot?

[1] Teilhard de Chardin, "Le Phénomène Humain," Editions du Seuil, Paris, France; 1957.

But then, shall we have a computer who will do the card playing as well, while the driver does—what? These questions are more psychological than technical. I believe that the modern trend toward the sports car, in which the driver is more integrated with the road and finds a new dimension to driving enjoyment, will prevent the intrusion of extreme automaticity in one's personal pleasure, except for safety warnings.

The future of the Electronic Computer, that bright offspring of electronics, is a philosophical puzzle. We may foresee new devices which will give us more compactness, greater computational speed, and lower production costs. A superficial examination may lead us to accept the electronic computer as a speeded up version of the desk calculator and a mere accessory to our arithmetical propensity, which has given mathematics a new dimension in furnishing practical solutions to analytically intractable problems. Thus, we may be inclined to characterize it as simply adding six orders of magnitude to the speed of the mechanical computer. But this is exactly where we have to be careful, for Big Numbers have a way of reaching transcendence.

For example, consider the lowest form of living cell—the large protein molecule, with a Gestalt measurable in terms of information bits, some 1500 in number —a molecule which can reach for its component in a nutrient bath and assemble another molecule like itself from which it then separates itself. But 1500 bits is also what Von Neumann calculated for the structural measure of a hypothetical man-made machine capable of reaching into bins for its components, and of assembling another machine like itself. Coincidence?

Next consider the course of events over a two-billion year period, during which organisms evolved on the basis of the original living cell to culminate in thinking and reflecting man, a most unlikely assemblage of cells with some 10^{10} neurons in his brain alone. Is there something magical about the number 10^{10}? Will another Von Neumann compute it is a likely Gestalt measure of a well-engineered organism with input and output organs capable of thinking that it thinks, of having that quantitatively elusive property called intelligence?

Big numbers reappear in Godel's proof, this intellectual triumph of our century, showing as it does that even arithmetic is not a closed discipline, but an open one, with at least one, or an infinity of, unprovable propositions.

In a former article,[2] I have suggested what reflecting intelligence—and we know only one human intelligence—may be called upon to accomplish an indeterminate number of years hence. Whether the somewhat fantastic speculations indulged in that article are justified or not, I cling to the suspicion that Big Numbers may be connected with Big Questions, and that we should not rule out the possibility that the several orders of magnitude increase in speed which electronic arithmetical calculation realizes may form some day, fifty or a thousand years hence, the basis for the transformation of the stupid electronic computers of today into thinking machines which will teach us basically new concepts.

Automation, the third function of electronics to be considered here, is a double-edged sword, for it is less the problems it will solve, than the problems it will create, which are of concern to us.

Our age has been called, perhaps improperly, the atomic age, and a more fitting name could be the age of automation; for atomic power is just another form of power to relieve man's muscles, while automation is fast developing, for the first time in our civilization, into a means for replacing man's skill and judgment in manufacture and various forms of control. Fifty years from today the new industrial revolution now beginning will have made great strides, pushed as it will be by a tremendous economic impetus. Labor as it exists today will dwindle in social importance, and new exciting social problems will develop. Greater demands will be made on education, at first to train the new form of labor now emerging, and subsequently to permit more worthwhile interests to fill the increasingly more numerous hours of leisure which many will have. I doubt that the old mob cry for "panem et circenes" of Roman times will be tomorrow's motto for more than a fraction of the multitude. The social unrest created in part by shortened work hours, and also by the demand for a new form of labor, will be a mentally and morally stimulating thing, already manifested by today's increased seriousness of purpose of the younger age group, and by the reappraisal of the beliefs and tenets of yesterday.

Some new technical-social functions of electronics have been sketchily discussed in connection with the speculations about the future of computers and automation. Two technical functions should be added: pattern recognition, and adaptive or self-curing systems.

Both are challenged by the biological functions of the higher animals and both will attempt to reproduce the manner in which these biological functions perform, but here a contradistinction can be made. For biological processes are based on a hierarchy of patterns which, through reproduction of the lower patterns, the cell, allows for growth and for replacement of the dead cells, a hierarchy absent in electronic circuits. For this reason, I believe that, within the next fifty years at least, the greatest successes in both pattern recognition and adaptivity will not be inspired by a greater understanding of the working of our brain and body, but rather by developing new concepts and new symbolisms better suited to our less elaborate electronic devices.

And yet, one's imagination cannot help taking a flight of fancy. For I can step out of the room where I am writing, and in a few minutes return with a few billion dollars worth of computers in the hollow of my hand, in the form of the brain of frog, snake, or mouse. May it be that someday we shall be able to utilize that awe-inspiring property of growth and organization of living things, and, perhaps by proper feeding of bland chemical with desirable properties, which will be carried to every nerve and ganglion of the animal, create within the body and brain of the animal the framework of an

[2] M. J. E. Golay, "Reflections of a communication engineer," Proc. IRE, vol. 49, pp. 1378-1382; September, 1961.

electronic circuit which, after proper chemical processing, will reproduce electronically some of the living functions?

STATE OF THE ART Having speculated on the probable development of electronics in the service of man by considering their strong interconnection to the probable development of our social pattern, we will now consider the less predictable development of the state of the art: new materials, new devices, new technical functions.

This lesser predictability of basic electronics suggests another contradistinction between biological development and electronic development.

On the one hand we have the living cell which, once developed some two-billion years ago, did not alter radically while the biological development of the various animal species took place. Similarly, it is unlikely that man will alter radically while the biological development of society takes place; *i.e.*, there will be no superman. It is this freezing of the basic unit, while the complex of units develops, which permits a measure of speculation about the development of the social complex, and of applied electronics as a parallel, interconnected development.

On the other hand, paralleling the development of applied electronics, there is a continued vigorous effort to develop new basic "electronic cells," which will replace the old in the applications, as well as permit foreseeable new applications, such as the universal wrist telephone set mentioned earlier. It is this possibility of radical changes in the basic structure which differentiates it from the nearly frozen biological basic structures: the living cell and man.

Cautioned by this fundamental difference, we may speculate gingerly about advances of the basic electronic art. Fifty years ago the basic electronic cell was evolved: the "vacuum tube." And fourteen years ago a competitor, the transistor, made its dramatic entrance, which would have shattered any forecast that the vacuum tube was a terminal form. Is the transistor a terminal form, subject only to slight manufacturing modifications such as evaporated and miniaturized units? Or may we expect the transistor to be dramatically reduced in importance by the appearance of a newcomer? In spite of the upset which took place fourteen years ago, I believe the transistor to be a terminal form, just like the electric generators and motors evolved a century ago, with that single qualification: at room temperature. For I believe also that so many new material properties will be discovered at cryogenic temperatures, that we may anticipate, fifty years hence, the incorporation in every major aircraft of a cryostat in which a major portion of the aircraft electronics will be immersed.

I believe that, in contrast to the transistor, another electronic cell, the memory element, is due for radical changes at room temperature as well as at cryogenic temperature, for a much greater variety of material properties can be utilized for this important element. I also believe that in 50 years, a man-made memory unit having terminal character will have been evolved.

Electronics and Health Care

V. K. ZWORYKIN FELLOW IRE

To gain some idea of the health care procedures which may prevail in 2012 A.D., let us see what happens when Mr. Jones reports for his annual health check-up at the Middletown Clinic. As he enters he is ushered into an examination booth, inserting his coded social security card into an appropriate slot for identification of the examination record. A series of standardized questions concerning his physical condition are then flashed on a screen in front of him and he records his answers by means of yes-no push buttons. Weight, temperature, respiration rate, electrocardiogram, reflexes, and other data are registered directly. Blood, breath, and urine specimens are inserted into analytical machines, which add corpuscle counts and chemical data to the record. While Mr. Jones goes on his way, the examination record is transmitted in coded form to the regional electronic health record storage center, where it comes to form part of Mr. Jones' permanent health record.

The examination record, supplemented by a record of the changes in the physical measurements since the last examination, is now forwarded to the central diag-

V. K. Zworykin is Honorary Vice President, Radio Corporation of America, RCA Laboratories, Princeton, N.J.
(Received November 30, 1961.)

nostic computer, which processes the data submitted to it on the basis of the accumulated medical knowledge and returns to Mr. Jones' personal physician a report listing possible illnesses, if any, which may be indicated by the results of the examination and further tests which may be needed to distinguish between them. Depending on the contents of the report, the physician may notify Mr. Jones that his physical condition is entirely satisfactory; as an alternative, he may make an appointment for further tests at the clinic, or request an immediate personal interview. If further tests are performed, the completed examination record will again be submitted to the health record storage center and to the central diagnostic computer and a more specific report covering Mr. Jones' ailments and suitable therapy for them will be transmitted to the physician to aid him in outlining a plan of health care which will correct present deficiencies and prevent further deterioration.

Freed of much of the routine effort of physical examinations as well as of the necessity of keeping abreast of new developments in the diagnosis and therapy of physical disease, Mr. Jones' physician, as a general practitioner, is increasingly concerned with his patient's emotional well-being and social adjustment; in other words, he is assuming to a greater degree the role of the family physician, a role which had almost vanished before the advent of the central diagnostic computer.

If medical therapy is indicated, with the concurrence of the physician, the computer will write the prescription for Mr. Jones, taking into account such factors as his weight, age, physical deficiencies, drug idiosyncracies, familial characteristics, and other factors. The prescription may be presented by the computer and handed to Mr. Jones, together with a bill for services, or if he wishes, he will insert his personal credit card into the machine and instructions will be sent to a centralized, automated pharmacy which will compound the prescription under sterile conditions, or the preparation itself may be electrically sterilized by ultrasonic or penetrating radiation.

Whether Mr. Jones travels to the pharmacy or the prescription is delivered to him automatically, the vehicle will be guided and instructed as to its destination electronically; the source of power being electronic or nuclear, rather than chemical.

If psychotherapy is indicated, this psychotherapy will again be influenced by electronic methods and concepts. From crude beginnings with drastic shock therapy during the 20th century, the electronic psychotherapy will have progressed to where much more subtle methods will be applied, not in a gross manner, but to the individual nerve ends. The technique of making multitudinous connections for long periods of time to living tissues will have been worked out as a by-product of earlier work on microminiaturization. Should Mr. Jones require sedation, this will also be electronic, as an outgrowth of pioneering work in electric sleep therapy.

On the other hand, if the diagnostic report indicates the need for surgery, the physician refers Mr. Jones to a surgeon-specialist at the district hospital. The surgeon, as always, combines superb manual skill with a thorough knowledge of anatomy. However, he is now not only aided by many new tools of observation and for carrying out the surgery, but also by a stock of replacement organs with built-in electronic feedback controls for implantation whenever the original organ has deteriorated beyond repair.

If, however, his organs are still capable of functioning, but need a period of suspension of the normal activities, so that rest will produce its own healing, or if slight stimulation is necessary, then a whole series of electronic controls such as electron-actuated heart pacemakers or phrenic nerve stimulators may be brought into play.

If the patient suffers from a nervous disease, in which normal impulses to his muscles are missing, these may be replaced by carefully worked out electronically programmed impulses which prevent the muscles from atrophying, due to lack of use.

If Mr. Jones needs a really complete rest, under conditions requiring as little effort as possible, he may be transported under cross-electronic control on his journey, to a sealed, gravity-free, environment in space where the physical exertion required to perform a task will be greatly reduced.

If Mr. Jones is suffering from a contagious disease, he may be isolated either in space, or in an isolation ward in which the air is electronically sterilized by curtains of electrically medicated, ultraviolet, or other lethal radiation, and in which the air and pressure is automatically freed from any factors which might be harmful.

In detail, the preceding description may well be phantasy. However, the use of electronics for making both health records and the sum total of medical knowledge more immediately accessible to the practicing physician appears so necessary that it can be regarded as an inevitable development. Its role in therapy and surgery, which is certain to expand greatly with the trend toward miniaturization, is evident even in present developments.

Electronic Instrumentation—Biophysics

HAROLD A. WHEELER FELLOW IRE

Electronic instrumentation plays a major part in biophysics, but there is a great need for further developments and their utilization. One of the earliest examples is the electrocardiograph, giving the first quantitative record of heart beats. More recently, the electro-encephalograph has been performing the same function for brain waves, but less effectively because of the greater difficulty of interpretation. Whereas both of these utilize wire connections, we now have radio-wave telemetering from sensing devices so small that one can be located internally and can perform its function continually for many days; naturally these require cooperative external equipment in the vicinity.

The next 50 years will see the development of such instrumentation in great variety and its increasing use in everyday life, as well as in the doctor's office and the medical center. Some introduction to the future is already found in the IRE TRANSACTIONS ON BIO-MEDICAL ELECTRONICS.

SENSORS, INDICATORS AND CONTROLS The advancement of technology requires first the collection of facts by quantitative measurement, and then the utilization of such facts for a useful purpose. The latter may be accomplished by an indicator for human observation and action, or a direct circuit to an automatic control.

In biophysics, the variety of electronic sensors is growing steadily, and will far surpass our present imagination. But let us consider as an example the possibilities in a system that is already conceived.

Since the heart action currents were among the earliest of biological phenomena to be amplified electronically, let us take this as a starting point. The first step forward would be a pulse counter to supplant the operation now performed by thousands of nurses every day in a manner that is far from efficient by machine standards. Instead, we should use a miniature amplifier and timer, requiring only that the patient hold two electrodes, one in each hand, for 15 seconds. The indicator would show the pulse rate more accurately than it can be counted, and should then be utilized to punch it on a card, along with the date and hour in a suitable code. This operation could be performed by any reliable person, requiring no apprenticeship.

The second step forward would be the continual observation of pulse rate by a computer which would signal any peculiarity. This might be set to respond to a pulse rate too high or too low, or to a change in the average rate from one minute to the next, or to a change in the character of the pulse. The patient is notably insensitive to such changes; he might even be going about his daily work.

The third step forward would be an automatic action in response to such a signal. The failure of the pulse could activate a pulse stimulus from a local source, which could even be in step with the pulse cadence before failure. At present, this requires internal electrodes near the heart, but we can imagine the discovery of an external stimulating circuit that would not otherwise disturb the patient.

A less tangible phenomenon is fatigue, such as autohypnosis while driving a car under monotonous condi-

---

H. A. Wheeler is President of Wheeler Laboratories, Inc., Great Neck, N.Y. (A subsidiary of Hazeltine Corporation.)
(Received September 5, 1961.)

tions. To combat this menace, we should expect to develop a sensor for warning of such fatigue. This would actuate a signal to the person, and perhaps even a therapy effective as a countermeasure, with or without the knowledge of the person. The action could utilize sound, heating or cooling pads, or electrical "exercise" of nerves and muscles other than those required for driving.

NERVE SIGNALS, DETECTION AND INJECTION

In biophysics, one of the most frustrating obstacles is the difficulty of coupling between an electrical circuit and the well-protected nerve fibers of a living organism, especially in the case of a human being. Like other obstacles that have seemed insurmountable, we may assume that this one will be overcome, either by a frontal attack or by a restatement of the problem.

For example, we might embark on a thorough study of the accessibility of the nerve fibers by means of frequencies over the entire electromagnetic spectrum from sub-audible to optical. It is conceivable that there are "windows" in some parts of the spectrum, and that there may be some useful coupling. For example, the induction of internal currents by sharp pulses of magnetic field might offer one way of penetrating the protective shielding. Admittedly it is difficult to visualize how an external coupler could single out one or a few of the bundled nerve fibers, but we might discover that this is unnecessary for some purposes.

Once having established a coupling, it becomes a two-way street. We have enough knowledge of nerve signals to know that they are sophisticated beyond all expectations; they have a language of their own. Is it expecting too much, that we may find a way of communicating to them from the immediate exterior—or perhaps from a harmless surgical incision? For example, anesthesia may be accomplished in special ways by "jamming" or "spoofing" techniques as are used in communications. (The present simple form of electrical anesthesia is presumably a case in point.)

There are many human needs and healthy desires that might be satisfied artificially, especially some forms of electrical exercise as mentioned elsewhere in this symposium. Whatever is helpful to the disabled patient has potential application for increasing the capabilities of a normal person; this is a principle that needs wider application, as in the case of preventive medicine.

In the nervous system and the brain we have a communication system with certain abilities and limitations. Its natural utilization is spectacular, though usually taken for granted. However, the ability to couple in and out of this system would offer a challenge to make even further utilization of this part of the human machine just as we rely on tools to multiply the capacity of our manual effort.

THERAPY AND ANESTHESIA There are experiments in progress that promise exciting developments in electrical anesthesia. Electrical therapy for other purposes has been used for years, but mainly in very primitive forms and practices. In this field, electronics offers the ability to sense phenomena that may be used to control the treatment, and to generate peculiar electrical stimuli that may be the most effective treatment. In the most advanced form, the latter is responsive to the former.

A major problem is the stagnation type of fatigue, which develops when a patient is unconscious (perhaps asleep) or is immobilized (perhaps under traction). In a lesser degree, the same problem confronts a healthy person when he is "restless," or has difficulty getting the rest he needs. Electronic sensing of this condition may be possible, or the condition may be recognizable by ordinary senses. A future treatment may be the use of electronically generated stimuli of certain patterns to which the nerves and muscles will respond with little or no disturbance to the person.

One problem is how to couple electrically between the exterior and the well protected nerves and muscles; that is beyond the scope of this discussion.

This approach may be termed "exercising," but the objective goes much further. One desired result is some form of exercising, or a substitute, which will accomplish relaxation without effort or motion or any objectionable sensations. They may also be helpful for building up muscle tone in a normal person while he is engaged in a sedentary occupation.

Diagnostics

URNER LIDDEL FELLOW IRE

It has been the custom of the medical profession for years to measure the temperature of a patient as an indication of whether a general fever exists. This is a lengthy (at least 3 minutes) operation and does not identify any area of illness. Advanced electronic techniques should assist the diagnostician to identify local areas of fever which might be identified instantly by such devices as infrared "heat scopes." In a more erudite fashion, it is conceivable that some "resonance technique" could be used in determining disfunction of the various critical organs of the body. Old time members associated with the medical profession will remember the various "quack" devices foisted off on unsuspecting medical doctors as "scientific" diagnostic machines. But we are learning more about proton magnetic resonance now and how it might measure the characteristics of molecules undergoing metabolic action, so that a true diagnostic machine is not inconceivable.

The most difficult area of research is that of the study of electroencephalography, without the use of attached or inserted electrodes. Should it be possible to measure the movement of ions in the brain without penetrating the epithelial tissue, information concerning cerebral action would be available which would open up an entirely new field of research. The ramifications of such studies could have profound effects on our civilization taking extra-sensory preception from the realm of the conjectural into the area of practical activity.

Another intriguing use of electronics is the possibility of using this kind of device for remote surgery, *i.e.*, destruction of tissue within the body without surgical incision. It is at least worth thinking about that one could destroy the tissue in such a fashion that it could be removed by standard metabolical processes without the use of metal devices, and without the dangers of external infection of tissues.

U. Liddel is Assistant Director, Hughes Research Laboratory, 3011 Malibu Canyon Rd., Malibu, Calif. *(Received June 15, 1961.)*

Bio-Medical Electronics— 2012 A.D.

LEE B. LUSTED FELLOW IRE

ORGANS Nearly all of the body organs can now be replaced by compact artificial organs with built-in control systems. This includes the heart, kidneys, stomach and even liver. A great variety of plastic materials enable the organs to be moulded to size and still operate efficiently. The micro-micro electronic components are embedded in the wall of the organ, and the micro-control system for the organ are connected directly to the proper nerves. The ability to find the correct nerve circuits and to trace the circuit like a telephone repairman was developed in the early 1990's and it is this technique, made possible by microelectrodes and very compact flexible computers, which permits the quick hook-up of artificial organs. Incidentally, these same trace techniques made it possible to find faulty nerve connections in the brain or the spinal cord where nerves had been damaged by tumor or trauma. Very fine biological conducting materials are inserted and quickly connected after the damaged nerve tissue has been removed.

If the artificial organ required for some reason an external power supply, a pickup circuit is either tattooed in the skin or the natural pigment of the skin is rearranged to form a pickup circuit. Of course, the connections between the artificial organ and the skin pickup circuit are made very readily.

Inspection and Repair. Long flexible fiber optic bundles can be inserted into any body orifice and also into arteries and veins so that the physician can look around inside any organ in the body. Coherent light sources provide ample intensity to inspect any surface. Small instruments at the end of the long shaft can be manipulated by the physician. This permits him to cut off a small piece of tissue from the bowel wall, and hold it before the end of the shaft for inspection. If he is in doubt whether the tissue is malignant (the cause of some types of cancer have been discovered by 2012 A.D., but some are still an enigma) he feeds the image on the fiber bundle eyepiece to the video input of his diagnostic aide computer which immediately gives him an expert opinion on whether the cells are malignant. If the cells are malignant he can switch on high light intensity and cauterize the malignant cells. However, before he does this he has taken some sample malignant cells for analysis. He intends to find the chemical system or virus causing the cancer, and by feeding the patient the proper "homing" enzymes and chemicals to eradicate any cancer cells which may have spread to other parts of the body.

With the fiber optic system and small tools on the end of the shaft, the surgeon is easily able to repair faulty heart valves by going inside the heart itself through the aorta and vena cava. Of course, he has a large variety of excellent synthetic materials to use in the repair. He is also able to find and remove blood clots in blood vessels before harm is done. The old unsolved problem of the 1960's of trying to find a small bleeding vessel in the small intestine is easily solved now because the surgeon can look around inside the intestine, with one fiber scope and simultaneously inspect the blood vessels to the intestine with a fiber scope which he has inserted into the blood vessel system.

The repair of blood vessels in the brain or for the heart has now been made quite easy and brain or heart damage from strokes or heart attacks are no longer to be feared.

GENETIC STUDIES Micro chemical analysis, high speed computers, the extensive use of information theory and recently developed new mathematical techniques now help identify the exact composition of the nucleic acids and a host of enzyme systems. The position of the chemical constituents such as amino acids in all of the complex chemical systems is now known. It is also possible with about a 90 per cent probability of success to replace any defective amino acid within a nucleic acid. This technical development has made it possible to develop a superior system of genetics. Genetic defects which were unavoidable in the twentieth century can now be avoided, or if they do occur they can be repaired.

L. B. Lusted, M.D., is Professor of Bio-Medical Engineering and Associate Professor of Radiology at the University of Rochester, Rochester, N.Y. *(Received June 29, 1961.)*

It should be pointed out that parents can now choose to have a boy or a girl (with about 90 per cent probability of success). Some countries have used this knowledge of genetic material to control the birth rate.

ELECTRONIC DIAGNOSIS, TREATMENT AND PROGNOSIS Beginning in the 1960's, rapid progress on electronic systems of diagnosis was made. At first the most attention was given to diagnosis of disease, but as various diseases were conquered the electronic systems were turned to preventive medicine and problems of checking people's health regularly. The early bio-medical computing systems and electronic diagnosis systems developed in the United States were sent to other countries, such as India, Africa and South America where they were very helpful to the few available doctors who were trying to look after the health of large populations.

By 2000 A.D. people have become accustomed to the regular health checkup most of which they can have in their own homes. On a given day at an appointed time the person goes to some room in the house where equipment has been installed and connected to the local medical center. There is a two-way closed TV system to the center. Sensors for temperature, weight, etc., are connected to the automatic data processor at the medical center. Temperature and weight are recorded, the physician can see and question the person—all data being recorded automatically at the medical center. A small cuff placed about the forefinger does a blood analysis. The blood is analyzed for all the most necessary constituents to tell whether the person is doing well and is healthy. The electrical properties of blood have been well worked out. The values of the blood tests are compared with the values from previous years by the medical center computer. If any abnormality is noted, or if a trend is noted which could be serious, the person is advised to go to see the physician for further tests and necessary treatment. The blood tests have been worked out so that they can characterize an individual much more completely than fingerprints.

Electronic Spectro-Analysis of Chemical Compounds

HENRI BUSIGNIES FELLOW IRE

On a previous occasion,[1] I disclosed a few thoughts about the prediction of events at very low levels. My comments were as follows:

"The urge of educated man to see, feel, and analyze smaller and smaller quantities, as well as to see and communicate farther, has been satisfied with no greater brilliance than in the production of the microscope, telescope, and electronic amplifier. Actually, amplification has already reached in some fields that extreme limit where distinguishable patterns of intelligence or orderliness have disappeared in the apparent chaos of random effects.

"It is at this low level of random effect that all events and all things that later become perceptible to man are born and grow. This applies to thoughts that, in the originating or some other brain, are developed intentionally or otherwise to produce a masterpiece of art or literature, an airplane crash, the tallest building, or a concept of human progress. It includes such things as the molecules that assemble into the seed that may precede by even a decade or two a mature living creature, and also the agitation of the still air that produces the tornado.

"History shows that at some particular place and time and in a favorable enviroment a very minute pattern emerges from chaos and, supported by other forces, feedback, and correlation, attains a growth that finally produces a significant phenomenon of distinguishable proportions. Then through some such effect as saturation, growth stops and stabilization occurs, only to be succeeded by decay. Growth is not linear in most cases; it

[1] H. Busignies, "Growth and amplification," PROC. IRE, vol. 38, p. 379; September, 1950.

H. Busignies is Vice President and General Technical Director of International Telephone and Telegraph Corporation, New York, N.Y. *(Received June 30, 1961.)*

proceeds through thresholds and intermediate steps, and consumes from microseconds to years to produce an end result. At its origin and for a fraction of its early life, the magnitude of the emerging pattern is so minute that it could be influenced, shifted, modified, or destroyed by a force of the same order of magnitude. One is led to believe that, however small they may be, brain waves could influence the outcome of physical events if they were available in suitable form at just the right time, and thus by the proper application of man-made patterns of very small magnitude, beneficial control of large physical effects could be achieved.

"In the superregenerative circuit of Professor Armstrong, a small electromotive force corresponding to a signal pattern just above the thermal-agitation level builds up in a fraction of a millisecond to become perceptible to the human senses: but it could have been influenced by a dissimilar, although just as minute, force applied with a timing accuracy of some microseconds.

"An effect of very small relative magnitude is used by Doctor Langmuir in seeding clouds to throw out of balance a low-level threshold controlling atmospheric conditions over a large area. Similar thresholds exist in many forms and at varying levels; they represent stages of development where potential growth has momentarily stopped.

"In the fields of education and propaganda, thought seeds that are properly timed produce opinions and prejudices that become strongly entrenched. Although they may encounter many thresholds and, particularly, saturations, they are very difficult to modify once they have reached a high level of acceptance.

"From an engineering point of view, one marvels at the possibilities of low-level control of the growth of events and things favorable to humanity. The electronic engineer, with his knowledge and experience in amplification and control, together with his accurate notion of timing, may soon explore and harvest in this promising field of growth control."

Prediction of events before they become strongly apparent is an undertaking in which millions of people are engaged but generally at a level of growth where signs become available directly to our senses or through some of the technical aids available. Prediction at very low levels of energy has only been dealt with in a limited number of occasions.

Let us take an example in the medical field. A cancer probably starts in one cell among the billions constituting the human body and within the cell it probably shows up at its birth in one or a group of molecules as a chemical compound different from normalcy. In order of increasing difficulty in the detection of the disease, we can list the following:

1) Visible symptoms
2) Detection by X-ray examination
3) Detection by an analysis of the blood stream carrying by-products of the cancer
4) Detection when the cancer is limited to a few cells, invisible by X-ray examination
5) Detection when the cancer is within one or a group of cells in the form of chemical compounds different from normalcy.

Detection at the fourth and fifth level, for instance a small group of cells at the fourth level, would represent an enormous progress if it could be achieved.

This is obviously very difficult at present. The solution might consist in scanning rapidly cells or groups of cells with the radiations to which they are responsive and observing their response to identify the changes taking place. The greatest problems lie, first in the access to the deep layers of cells, second in a rapid system of scanning and evaluation of the signals in order to limit the time necessary for the exploration of billions of cells, and third in obtaining a sufficient resolution. These are all major problems, but every one will agree to the importance of their solution to humanity, in providing a machine which would detect harmlessly very early cancers and obviously many other diseases of lesser gravity. A community of 50,000 people could probably afford to possess one in its hospital. As there are only 525,600 minutes a year on a twenty-four hour a day basis, a scanning should not last more than approximately ten minutes in order to permit one check-up a year per person, which would soon be found insufficient. Such machines, if at all subject to invention and design, would probably still be of cost which would allow for more installations, for more checkups or increased scanning time. Aside from the humanitarian viewpoint, the field may be a fruitful one for the proper industry. Few discuss the price of medical services and drugs that they can afford when a human life is in the balance.

I feel very strongly that the applications of electronics to medical research and treatment will develop into an important field and industry in which we can contribute. I hope that the following will incite others to join up in an effort in this direction.

Most biological natural elements, chemicals resulting from disease as well as all the hormones and other chemical compounds are carried by the bloodstream from gland to gland and organs. The last two decades of research in medicine and chemistry has shown the great importance of hormones and vitamins in the control of the entire operation of the human body including the mental faculties. A proper balance of the hormones results in an euphoric state; but when such balance is altered this state changes into a state of mental disability, disease or death. The bloodstream carries also many chemical compounds, natural or by-products of degenerative or infectious diseases or indicative of some unsatisfactory physical condition. Some of these compounds can normally be present in very minute quantities.

It would be extremely useful to make available an instrument of analysis which could in a short period of time report the contents of a small sample of blood in such chemical compounds as the physician wants to investigate. When "tuning" this instrument of analysis on any of the chemical compounds known that the blood can carry, the proportion of this chemical would be known in a matter of seconds. This instrument could be used for the detection of unknown or known by-products of disease and contribute to the discovery of disease conditions, perhaps prior to the outbreak of such disease. It must be sensitive to very small quantities—1 part in 100,000 would be useful in many applications—1 part in a million would furnish very valuable information. Such an instrument would normally have its place in each hospital and clinic, and would also find very wide applications in the chemical and connected industries. Application of elementary information theory and of the present knowledge of electronic systems indicates that such an instrument is subject to design and that work in such a field should be fruitful.

An amplification of the methods mentioned would lead to the detection of a relatively small number of molecules and atoms by observing their emission in a change of energy level. Present observation techniques would not permit noticing this emission, but further development of maser techniques or what we have at times designated molecular radar allowing measurements in very low levels of noise would lead to this result with many possible applications:

Medical diagnosis and treatment
Physical and chemical analysis
Prediction of life of given components
Understanding of life principles
Quality inspection.

Magnetic Recording and Reproduction—2012 A.D.

Marvin Camras fellow IRE

Fifty years ago, in 1962, magnetic recording had already fulfilled earlier prophecies as to sound recording, and had entered into other fields of information storage, serving as a comprehensive memory for computers, and for recording television signals. It became apparent that information storage was essential to every automatic or intelligent system, whether a machine, a living being, or a government. Magnetic recording was an ideal storage medium from a standpoint of compactness, stability, and convenient transduction to or from electric waves.

The first magnetic memory devices resembled tape recorders, just as the first automobiles resembled horse carriages. Eventually tape recorders evolved into the standard memory pack which is presently manufactured in large quantities by specialists. The memory pack of today is a sealed box about the size of a package of playing cards. It holds upwards of 10^{20} bits of information, and has no mechanically moving parts; the recording, readout, and scanning are all electronic. The storage density is so high that the information of entire libraries is condensed into a few cubic feet. Additional modules are added to extend the capacity to any required level.

An important use of the memory pack is for our home viewing consoles. Here we view a recording in stereoscopic color on a large curved mural display, with lifelike sound coming from the imaged performers. Our home movie cameras use a similar record. Immediately after taking a sequence, we can transfer the memory pack to our display console to observe and hear the action that took place a short time previously. Recorded entertainment and information is no longer sold in stores, but is purchased via telephone connections. A person merely requests a recording that he desires, whereupon the recording at the central office is transmitted at high speed over the telephone, and recorded on the home unit. Entertainment is only one aspect of the display system; for example, shopping is largely done at home from memory packs which serve as catalogs. Merchandise is displayed and described very realistically in the home viewer. In the same way we have an animated encyclopedia which gives us the facts on any subject in a more interesting manner than the old books. Our catalogs and encyclopedias are constantly revised by subaudible signals that come over our telephone lines. Many people subscribe to a tele-newspaper service of this kind.

In medicine the memory pack and tele-revision provides every physician with the latest information on diagnosis, treatment, and techniques. He has a magnetic

M. Camras is a Senior Engineer at the Armour Research Foundation, Technology Center, Chicago, Ill., and is Editor of IRE Transactions on Audio. *(Received July 20, 1961.)*

card for each patient giving the complete medical history. He inserts this into a processor and adds current symptoms. The readout gives the present status, further symptoms that should be observed, the most probable treatment, and expected reactions.

Industrial activity now depends largely on three factors: raw materials delivered by pipelines, energy delivered by electric wires, and information received over coaxial cables. The raw materials and the energy are used continuously and there is a steady flow, but the information for directing the processes is stored on the site in memory packs which are revised by remote control according to changes of style or product.

Consumable everyday items such as foods, drugs, motor fuel, and towels are piped into each home in elementary form of fluid or suspension, and reconstituted by a machine which converts or separates the suspension into the desired products. The complex chemical-electric-mechanical processing is controlled by a memory pack.

Money is no longer a medium of exchange. All purchases are now charged directly to one's bank account whenever one presents his magnetic credit card. At the same time the latest balance and a record of what has been purchased is placed on the card for one's personal record. Wages and earnings are also credited continuously to the account. For every transaction the appropriate tax is deducted so that the government is always up to date on collections.

Extending Man's Intellect by Electronics

SIMON RAMO FELLOW IRE

We are all aware of the enormous impact of science and technology in shaping our future lives. This new and growing influence is usually illustrated by pointing to H-bombs and more recently, to space achievements. In the long run, there is an area of technological endeavor of even greater significance. It is the extending of man's intellect, the source itself of all future scientific and social progress. Viewed as a technical field, it is the extension of human intellect by electronics—what we call for convenience "Intellectronics"—into every aspect of the running of our businesses, our educational systems, our government—wherever intellectual processes are involved.

LAW In the practice of law—or at least law as it might be practiced if intellectronics is used to the fullest —every practicing attorney might have in his office a decade or two from now means for convenient electronic connection to a huge national central repository of all of the facts, rules, procedures, and precedents that he needs. For the routine filing of papers, records, petitions, he or his assistant will introduce his data into the intellectronic system by operating a properly designed input device looking a little like a typewriter. Almost immediately, there will be displayed to him on a special viewing screen any conflict, omission, inconsistency, or other shortcoming of his statement—any problems with the law, the existing records, or the claims of another. And this display will not cover just a few possibilities that an unaided, though trained, human brain might have produced in a few days. Instead, the intellectronics system will scan, select, reject, and present the equivalent results of thousands of trained searchers covering many decades of records over the entire nation in a split second.

So the intellectronic system—and we know how to design such systems today—will elevate the lawyer's intellect to the more complex intellectual tasks, give him better tools with which to work. It will alter a substantial fraction of legal practice. Even on the nonroutine, the more intellectual legal processes, the attorney will be able to consult with the equivalent of a host of informed fellow attorneys. His request to the system for similar cases will yield an immediate response from the central store, together with questions and advice filed by other attorneys on those cases, even as he will later add his experience and ideas into the system for future use by all.

The national intellectronics network to serve the legal profession will serve government as well. It will become a vital tool for orderly law enforcement. Moreover, its authoritative and broadly based statistical data will disclose inadequacies in the nation's laws and be of prime aid to our law-making bodies. Speculation will often be replaced by hard, cold, up-to-date facts dis-

S. Ramo is Vice Chairman of the Board of Thompson Ramo Wooldridge, Inc., Los Angeles, Calif. *(Received June 12, 1961.)*

closing clearly where confusion exists and, consequently, where new rules are needed. As a matter of fact, without intellectronics, we might build up to an impossible condition of saturated legal processes and hopelessly jammed and confused procedures. The world is becoming ever more complicated, every action interacts with more, other actions; so the rules of our society are correspondingly becoming highly detailed and the procedures increasingly lengthy. Something new, like an intellectronics system, seems imperative, not just desirable.

MEDICINE How many physicians can your doctor consult with? A practical answer would most often be: maybe two or three. The physician in the future technological age, towards which we are in such rapid transition, will also routinely introduce his data on a patient to this network of "consultative wisdom." The patient's entire past history, the results of all tests, the symptoms and complaints, and even a statement of the family background of inherited tendencies—all this would be efficiently introduced to the medical intellectronics system. The system will quickly react to give the doctor not all, but key portions of what would have been the result of many consultations with other physicians. It will call out questions and possibilities our physician may not have asked himself. It will give statistical probabilities (because it will have the amassed data to do so) of the relative effectiveness of various treatments—with numerous variations and warnings to account for corollary possibilities and complications, all automatically turned up within the machine, triggered by some of the detailed data that the physician introduced about the patient.

With diseases nationally monitored, the statistical approach to medical practice will take on an entirely new stature. Cause and effect relationships will be studied on a large but rapid scale, tying ailment to treatment. And again it will raise the intellectual effort of our physicians.

ENGINEERING The engineering field has already been revolutionized by intellectronics. The intercontinental ballistic missile would today be many years away if we had not extended the brains of the designer by electronics. Thousands of flights would have been needed in a clumsy trial and error approach. Instead, mere dozens of actual flights have been sufficient to finalize the engineering and prove out the design. The thousands of flights took place in the simulation laboratories, and the selection of the right combination of design parameters out of the myriad of possibilities—too huge a task for human comparison and sorting alone—was made by a man-machine partnership.

LIBRARY One of the things that we can do with electronics is create a library of information that is mammoth and yet accessible with electronics speed. But the memory extension is far from the total effect. The properly designed artificial intelligence works on the library's information. It has built into it a set of logical rules chosen by the human partner. With this logic, and with the information, and with its electronic competence, the machine can handle the low intellectual tasks of the first sorting, the categorizing, the comparing, the selecting, and the presenting. These tasks, done well, require typically that tremendous volumes of data be processed quickly. The machine member of the partnership does this high quantity, high rate part of the intellectual job, allowing the higher intellect of the human partner to concentrate on more subtle, less predictable, less routine —the conclusion-drawing, decision-making, judgment—aspects of the intellectual task.

MONEY AND BANKING In money and banking—and the whole process of keeping track of who owns what, where it is, and who owes whom—it is absurd that for this kind of work we still have millions engaged all day in putting little marks on pieces of paper, reading them off, introducing similar ones—without much need for deliberation in the process. This is mostly as unsuitable for the human intellect as pulling huge boulders to build the pyramids was to human muscles. Someday currency and coins will be for the rural areas. Even checks and most other of today's forms of human record originations may become extinct. If you buy a necktie or a house, your thumb before an electronic scanner will identify you, and the network will debit your account and credit the seller. The system will automatically do the routine accounting, will call out the violations of rules, or any problems in the transaction, and list alternatives. (Occasionally a transistor burning out in Waco may accidentally wipe out someone's fortune in Boston. There will be some continued dangers and risks in life in the period ahead, although they will likely be new ones.)

LOGISTICS—RESERVATIONS How about the making of reservations—airlines, hotels—and the waste in human intellectual capacity which this increasingly important aspect of keeping the operations of the world going entails? In the future, we should step up to a telephone-like device and, after consulting something much like a telephone book, dial a reservation request. The instrument will respond by giving a red signal, meaning "no," or displaying alternatives that are available, or indicating an acceptance of our request. It will print out the ticket, automatically charging our account, avoiding errors, confusion, disappointment, uncertainty, and poor use of available accommodations.

So far as technology is concerned, there is nothing about the reservation problem (or money or banking) that requires any new invention in pure science for the application of intellectronics. It takes a great deal of engineering to achieve any one of the specific advances we might cite, and we can apparently do without any given one today. However, in each instance the increased volume and rates, and, again, the interactions and complexities of our growing information-controlled world, press for new systems for handling these intellectual processes.

TRAFFIC CONTROL It is hard to find a better example of the urgent need for man-machine, intellectronics partnerships to handle thinking tasks than the control of things moving in the sky and even on the ground. It is clear that a human brain unaided—whether that of a pilot, an airport controller, or a Los Angeles automobile driver—cannot integrate all of the changing, dynamic, split-second facts to make decisions leading to the smoothest, safest, maximum use of the artery. Intellectronics measurements are needed instantaneously on the nature, quantity, rate of change, spatial spread, and interconnection of traffic. Automatic predictions then need to be made as to consequences, and directions given to control the flow. Not only will the handling of airplanes and the role of the pilot be drastically changed with time, but it is not completely ridiculous to imagine automobiles of the future which go on electronic control, if directed onto a crowded, speedy freeway—the driver limited to push-buttoning his chosen exit.

MANAGEMENT The average business can shift between a profit or a loss position easily—by just raising or degrading the available information for decision-making by management. We are working on management control systems in which information as to what is happening will be electronically compared with the plan—deviations will automatically produce directives for changes in plan in accordance with "stored" logic set in by management to cover many possible situations—or the system will call out warnings, when the unexpected happens, to the higher intellect of the human supervisors who are kept free for the unpredictable, more difficult, nonrecurring situations. This is the same as having more, smarter, and more knowledgeable managers, and it helps to put management on a scientific basis.

LANGUAGE TRANSLATION Most of the physical operations of the world—production, transportation, communication—are candidates for passing under intellectronic systems control, but also much of the operations involve world-wide integration and interconnection. In the coming years, many millions of human minds—and their extensions in the form of signals and data and information collection—will be connected together, often crossing national and language barriers. No wonder one of the most interesting intellectronic areas in which we are engaged is in the translation of natural language. Again, the machine member of the team provides the crude first cut. It also identifies double meaning possibilities and weighs alternative meanings based on what preceded. It assists and sets up for the more brainy human partner, and the combination turns out a far better performance than either alone.

The concept of what language is will probably change drastically in the years ahead. The machine partners in the universal electronic systems of the future will want facts and rules in the most efficient form possible. They will create pressure for a common universal, purely informational, completely logical and consistent kind of language. Natural language, originated in an earlier nontechnical age, does not meet all these conditions. The technological, intellectronics period of the future may force on the world a new kind of language reform.

EDUCATION The most truly intellectual activity of all must be the education of the human brain. Now, we are approaching a crisis in education because, while the needs of the more complicated, more populous world are increasing rapidly, our ability to place human resources behind the educational system is apparently decreasing. But an intellectronics system could make a hundredfold change in the effectiveness of education. The human educator can have tools analogous to the physician's X rays and electrocardiographs. The routine material can be machine-presented, leaving the more difficult concepts for the higher intellects of the human educator. Programmed machines can stimulate thinking of the student. The electronic presenter can speed up or slow down, add more explanations, skip steps, as it makes the presentation—all automatically as a result of continually noting student's push-button response to questions.

An intellectronic system can remember the progress of millions of students. It can compare their tested learning with the estimate, with the plan. It can measure and report deviations. Yet, that same system can immediately recognize an individual student and can give him an accelerated or special presentation or test—all by a virtually instantaneous scan of his record and a following of rules that have been set in by the wiser human educator.

Such a future educational system would involve new large industries employing experts in the subjects to be taught, in the design of the programs, and in the design and production of the devices and the systems. There will be new professional groups within an augmented educational profession to provide for statistical study and planning, diagnosis, and generally for the matching of the synthetic intelligence of the machine with the human brain to achieve the fullest utilization of both human and machine resources in an educational system really suited to the coming technological age.

DEFENSE In assuring the defense of this nation, it is some years now since the first priority was to create the force, exemplified by the bomb, so as to provide the necessary military might for defense purposes. We are already now passing through even the next phase, where we provide the capability of delivering the force wherever it is needed on any part of the earth's surface in a very short time. The next big, urgent, highest priority area in the application of technology to the military is in the intellectual aspect of the military problem—in the control and command, observation and communications. In a world in which one nation can inflict decisive damage on another in a few minutes, even though they are separated by half the earth, sound military action requires knowing what is going on everywhere, and putting together a tremendous amount of diverse, confusing, and continually shifting warnings and other information into sound conclusions ready for major all-out decisions and, indeed, to make minor ones automatically and rapidly in accordance with some prearranged plan. A man-machine, intellectronics partnership is the only answer in sight to this problem.

ELECTRONIC VOTING Now, all of this description, these examples of facets of the coming technological society, can easily create one gloriously wrong impression, namely: The world of the future will be an automated, robot-like, regimented world, with man (even though the controller and originator) nevertheless only a part, a cog. The world will be one in which freedom, democracy, the creative spirit—all these concepts—will be pushed into the background as the mad complex of men, machines, cables, and vehicles interact to produce, move, and keep track of everything that makes up the material aspects of life.

This is not only unnecessary, but unlikely. Suppose we want to assure the greatest of participation by the people of the world in determining plans and policies. We want greater democracy. We want to insure that we are all occupied with thinking about the issues that control our lives. Technology makes possible a higher democracy, a greater assurance of this, if properly employed. Suppose that the deliberative bodies, the congresses of the world, are exposed to every home continuously by a special television-like unit. Suppose also that it is our practice in that technological society of the future for a large fraction of the issues discussed to come up for a vote, not just by the congress, but by the people. To emphasize this point of view, let us imagine an extreme, which would doubtless be beyond either practicality or desirability, in which it is our custom that the registered adult voters would expect several times a day to identify themselves to the machine (with their scanned thumbprints) and to put in a "yes" or a "no" or a vote for "A," "B," or "C." The system would automatically register, check, add up, determine, and announce the majority viewpoint. Clearly, the highly technological society of the future can be one in which communication and action can be so wide-spread, efficient, easy, and commonplace that participation is virtually guaranteed, interest is heightened, and the apathy and ignorance that can destroy democracy is virtually eliminated.

Communication as an Alternative to Travel

J. R. PIERCE FELLOW IRE

While dictators have striven for self-sufficiency and prophets have foretold huger and more concentrated cities, we are actually becoming ever more interdependent, and our industries and ourselves ever more dispersed. Surely one of the great and persisting problems of the future will be that of transportation, of bringing people and industries what they need and of sending forth what they produce.

Goods may spoil through delay, but they do not suffer; men do. They suffer from home or office to airport and they waste time on planes. A day, two days, are spent for the sake of a few hours of face-to-face communication. Perhaps medicine can make up for the lost time by increasing our life span. But, in fifty years, electronics could eliminate the loss altogether by substituting communication for travel.

Surely, one need not move human bodies in order to achieve a meeting of minds. The ingenious gadgets, the broad-band circuits my fellow Fellows have written about, can provide face-to-face or group-to-group sound and vision, safely encrypted to preclude eavesdropping. Documents can be transmitted by rapid facsimile or by data devices. Some control or manipulation at a distance will be possible, equivalent to operating a computer, turning the pages of a catalog, or moving from department to department in a store while shopping. With cheap enough communication, students could attend classes by television.

One may object that he would not care to visit his wife by television. The clear answer is that he could stay home and communicate to work.

J. R. Pierce is Executive Director of Research Communications Principles Division, Bell Telephone Laboratories, Murray Hill, N.J. *(Received November 24, 1961.)*

Controlling Man's Environment

HAROLD A. WHEELER FELLOW IRE

In the control of environment, electronic instrumentation enables sensitive detection and versatility of sensing. A responsive action is likely to be effected by a source of power that need not be electronic.

STORMS The prevention of any catastrophe (a world war or just a tumble) requires sensitive detection of the cause at an early stage of development, so that corrective measures can be applied before it is too late. In political troubles, the causes are human and are difficult to interpret. On the other hand, a major storm is usually an orderly development from a localized cause. This being in the realm of physical science, we have hope for steady progress. The results to be obtained are so spectacular as to justify a major effort, comparable with that being expended on flood control and soil conservation. However, the problem of the storm is different in that the causes and the corrective measures are not spread over a period of months or years.

The first requirement is early detection. Let us consider the tornado or hurricane, which is born in a "calm," an area of stagnation of air currents. If there is also rising air in some location, the resulting vortex is accumulated rather than being dissipated by turbulence. All of these contributing factors are susceptible of measurement, and the rancher or the sea captain may be able to sense them by experience and association. Unfortunately, a large area has to be covered continuously in order to sense the origin of a storm, presumably by interpretation of air currents.

The second requirement is an immediate countermeasure commensurate with the progress of the storm before detection. Here a "clean" nuclear explosion may offer the first workable solution. It is conjectured that one or several such explosions would be able to confuse a vortex that would otherwise develop into a hurricane. There may be found a preferable approach, such as a random pattern of many smaller explosions. But the success of the plan is still dependent on sensing the vortex at a very early stage.

A program of weather control would naturally be directed also to other problems, notably the fog in the vicinity of an airport or seaport.

AIR-CONDITIONING, MULTIDIMENSIONAL An advanced air-conditioning plant controls temperature, humidity, and rate of air replacement. None of these requires any unusual type of sensor.

We are beginning to appreciate some benefits from other characteristics of the air we breathe. For example, a predominance of negative ions over positive ions has been found helpful to some individuals, or for some complaints. (A principal investigator in this field is C. W. Hansell of RCA Laboratories, one of our colleagues in the IRE.) Doubtless there will be discovered other elusive properties of the air that will be correlated with specific benefits to be sought by control.

As an example, we should soon be utilizing electronic instrumentation for sensing the ion content in the air in a room, and then applying this information for controlling the ion content at a favorable level.

H. A. Wheeler is President of Wheeler Laboratories Inc., Great Neck, N.Y. (A subsidiary of Hazeltine Corporation.)

Public Functions and Standing of the Engineer

C. F. Horne FELLOW IRE

Few authors of our era have been able to match George Orwell in his perspicacious attitude toward what life may be like in the next two generations. In his novel "1984," Orwell paints a wretched scene of a society where a man "can be made to believe that black is white, two plus two equals five, and evil is good."

Orwell's warning against the loss of individual freedom is a suitable backdrop against which we must consider the role of the engineer in 2012. Fifty years from now we can have a society in which all of our scientific and technological advancements are used for the betterment of man. Or we can become the slave of our creations and we can witness the breaking of our individual spirit in "Room 101."

Hopefully, we will choose the former course. In 2012 our society will have progressed to the point that our discoveries in atomic energy and electronics should be used intelligently for the betterment of man. In this society the engineer will be at the pinnacle.

During these next fifty years the engineer and scientist will be forced to accept more and more responsibility outside of his classroom or laboratory. He will be called upon to accept responsibility for basic policy decisions in government, business, and education because he, the scientist or engineer, will have the "tools" and the experience necessary to solve problems which have a high technical or scientific "input." It is already apparent that, with each passing year, more and more national, local and business problems require both training and experience usually found only in engineers and scientists.

Thus our scientist and engineer in the next fifty years must be broadly educated. He must understand the world of people who surround him. He must appreciate the cultural heritage of many civilizations. He must have a spiritual resource which will help provide a sense of balance. Above all our engineer-scientist must maintain his own individuality. He must resist the temptation to become the slave of his machines or of his society.

I know that many words have been written about the need for broadly-trained engineers. I am equally aware that too often our acknowledgment has been little more than "lip service." But the time has come when we must face the fact that in the next fifty years our engineers and scientists must become thoroughly conversant with this new dimension in their careers.

Can we honestly say that our profession will be ready to accept this responsibility? Last year Dr. David A. Lockmiller, the President of Ohio Wesleyan University, noted in a speech at Detroit, Mich., the dilemma of a retiring corporation executive: I have 50 younger executives, but not one is ready to succeed me. Each is well qualified in such fields as *engineering*, sales, accounting, and advertising, but none of them knows enough about public affairs." "That is not too serious," he continued, "because they can learn. More difficult is that none of them has a framework or scheme of values against which to cast and evaluate the needed knowledge. Last, and worst of all, none of them seems to realize that he lacks anything."

In his last years H. G. Wells, one of the most observant writers of our age in scientific fiction, reflected on the fate of mankind. In his provocative book, "Mind at the End of Its Tether," Wells finally concluded that humanity was dead—that indeed a force hostile to man's survival ruled supreme. Wells dismissed once and forever all of mankind. Critics have pondered the question: "Was Wells an embittered and ill man, or was he truly a prophet?"

In the next fifty years we must provide the answer to these critics. 1962 is the time when we must prepare to see that our free society will survive. Now is the time to ensure that high-quality, well-educated scientists and engineers are available not only in our laboratories but also in other important positions. Engineers will never "take over" government and management. But much that is good will go by default if we do not participate adequately in decision making. By 2012 it will be too late to reflect philosophically on whether our profession is creating for the benefit of man and not for his destruction.

C. F. Horne is President of General Dynamics/Pomona, Pomona, Calif. *(Received July 31, 1961.)*

Electrons and Elections

Sir Robert Watson-Watt FELLOW IRE

Despite the convenience of having substantial freedom of retrospective choice, for a review to culminate with our present state in May, 2012, there is some justification, beyond mere chronological conventionalism, for making the review period start in 1912. That year may well have been the last year of an unselfconscious happiness which had carried, comparatively lightly, the burdens of political and military conflict in a civilization permanently reoriented by the French Revolution. The same year is as good as any other single approximation to the burgeoning of an exciting new era in the physical sciences, and to the incipient decline of the engineer's "handbook," as it made way for the *ad hoc* and direct application of a sound mathematical, physical and chemical armoury in the mind of the individual technologist.

1912 saw the introduction of a comprehensive measure to safeguard human life on the high seas, by the statutory requirement of radio-communication facilities in U. S. passenger and cargo ships, and by the holding of an International Radio Telegraph Conference in London, to be followed in the succeeding year by a Conference on Safety at Sea, also in London. 1913 saw the initiation of a cooperative research project, between the United States and France, on the travel of radio waves across the Atlantic. These events, of international importance, were outward and visible signs of a new upsurge of technological innovation, consequent on the renaissance of physics already mentioned, and strongly influencing national and international policies, both civil and military.

The renaissance can in fact be dated, with some precision, by the lingering decline of that "universal ether" whose decease was postponed by an array of decreasingly aesthetic and increasingly clumsy (because increasingly complicated) mechanical models, such as those to which the great physicist-technologist, Lord Kelvin, clung even in the early years of the twentieth century. Michaelson—later joined by Morley, and, so to speak, "translated" by Fitzgerald and more searchingly by Lorentz—made, in 1881, the *experimentum crucis* which had been suggested by Clerk Maxwell in the last year of his life—the year, 1879, in which Einstein was born. This symbolic continuity ties the *pli cacheté* (as the French Academy would have called it) which Faraday deposited with the Royal Society on March 12, 1832, saying "I am inclined to think the vibratory theory will apply to these phenomena ["magnetic action" and "electric induction"] as it does to sound and most probably to light," with the Einstein doctrines of relativity, the "special theory" having been enunciated in 1905, the "general theory" completed in 1915-17.

Clerk Maxwell's conclusions of 1867, that there must exist electromagnetic waves of frequencies lower than those of visible light and infrared, were experimentally confirmed by David Hughes in London, 1879, and more exhaustively studied by Heinrich Hertz in Karlsruhe in 1886. In 1894-95 Lodge in Great Britain, Marconi in Italy, Popov in Russia and Jackson in Great Britain established the potential utility of radio communications. These pioneering steps led to the growth of great networks, still indispensable to our twenty-first century "way of life," for the carrying of "intelligence" by radiotelegraph, radiotelephone and television (in black and white or in color) over a range of distances transcending merely terrestrial distances.

In parallel with these scientific, technological and sociological innovations—and indeed at their roots—lay, a wealth of theoretical and experimental developments, in the physical and biological sciences, which were alike an enrichment of the human intellect, the raw material of technological advances, and (less generally recognized) aesthetic and artistic triumphs not inferior to those of the other "Great Masters" to whom this title is still commonly restricted.

Sir Robert is Chairman of the Scientific Advisory Board of Axe Science and Electronics Corp., New York, N.Y., a Consultant to the Center for the Study of Democratic Institutions, Santa Barbara, Calif., and an Advisor at Sterling Forest Research Center, Tuxedo, N.Y. *(Received September 25, 1961.)*

That the "parity principle" just enunciated was not recognized until the century 1912-2012 (the arbitrary period of our present review) was far advanced, is explainable only by a longer and more searching survey of the historical conflict between "words" and "works" than can be attempted here. It may suffice to recall, by way of example, the injunction of St. Augustine, c. 400 A.D., "Go not out of doors; return into thyself. In the inner man dwells truth." St. Augustine is still with us; agoraphobia is still a social disease—as is the claustrophilia of the second-hand bookshop. But it moves, nevertheless, and from both sides. At the end of the first quarter of the century under review, 1937, it was still permissible, within normal good manners, for a "humanities" man to express, without the wrappings of any elegant choice of words, the deepest contempt for, and the loftiest superiority to, the world of mechanics, of "stinks" and even of math. Before the half-century had run out, in 1962, the *avant garde* of the old school had discovered that physics was now, indubitably, what it had formerly been to all its devotees, "natural philosophy." The "pure mathematicians," who had sometimes been more inhumanist than the humanist, saw their most exquisitely refined constructions becoming worthily intertwined with those of the scientist, being, in fact, used as treasured tools of the trade, in the weaving of gossamer threads of conceptual thought and acute observation into an abstract mind-painting of the universe. Abstract it must be, for the natural philosopher had, by then, learned the modesty which says "It is as if" rather than "It is."

It was still too early, in 1962, for the desegregation movement to be completed. The schools and colleges were just emerging from the flatly sodden swamps of the "social adjustment" curriculum, onto the steep and stony, but vastly satisfying, tracks of intellectual mountaineering. The graduates of the third quarter-century were nearer to being well equipped for the running of an always new world than any who had gone before. Neither the unfulfilled threats of the inadequately educated politicians of 1961 nor the forecasts of the author of "1984" had matured into the universal wastelands of body and mind that had been the bogey of the 1950's to the 1970's.

A vitally important element in progress towards this brave new world was the relatively early improvement in the understanding between the scientist and the technologist on the one hand and the statesman, politician, administrator and citizen on the other. The history of this politico-social problem has not yet been written; to the historical researcher it appears "as if" the problem had been intermittently forgotten, seldom more than superficially examined, and never, but never, within range of being so much as half-solved.

It would be idle to call Archimedes in evidence. For long after his day there was little to be said about the scientist, as scientist, in the service of government. He was called in only as technologist, to provide "hardware" in a hurry because the need for it—or for him—had not been foreseen sufficiently early. Thus, indeed, was Archimedes "persuaded" says the historian "to turn to military technology as a mere holiday sport for a geometer"—and to die untimely in the Roman assault on Syracuse. Two millennia later, the father of scientific meteorology, Napier Shaw, consulted the British War Office on how he could best personally contribute towards victory in World War I, by applications of the science which he had nurtured from the first shoots as a dilettante hobby to its bud as an economic and social service. His mild assault was bloodily repulsed by a red-tabbed general who said "Sir, do you suppose the British Army goes into battle carrying umbrellas?" At about the same time, an obscure neophyte in physics put a somewhat similar question to the War Office, but had the good fortune to be advised by a staff colonel—a distinguished lawyer in civil life—that his smattering of radiophysics might be as well applied to war-winning in Napier Shaw's Meteorological Office as anywhere else. Had he met the general and not the colonel, radar would almost certainly have been available within World War II—but it would almost certainly have been too late for the crucial Battle of Britain.

In this brief and necessarily patchy study of science in the service of government, British history is a more tractable source of illustrative fragments, than is U. S. history—though no account, however fragmentary, can overlook Thomas Alva Edison's historic advice to the President of the United States about the Naval Consulting Board which Edison had envisaged in 1910 and which he headed on its foundation in 1915, "We might have one mathematical fellow, in case we have to calculate something out." It was to this modest ambition that the Board owed the presence of its one lonely physicist member!

There can be no single date marking an explicit recognition of science as essential to the satisfaction of national (and thus governmental) needs in war and in peace. The mariner had for long relied on sun, moon, planets and stars as aids to navigation; the warrior had long forgotten that the technologies which served him were rooted in earlier science, and that new science emerged from these technologies. Perhaps Charles the Second, aided by the administrative genius of Samuel Pepys (successively Clerk of the Acts and Secretary of the Admiralty) and by the galaxy of natural philosophers who founded a Society for promoting physico-mathematical experimental learning (under the patronage of Charles II) should be specially honored as a Chief of State who appreciated the pursuit of science, alike in its intellectual and its utilitarian aspects. Great as was the importance of the informal advice tendered by the Council of this Royal Society, and by its individual Fellows, to the policy makers and the administration in the governmental agencies of Great Britain, such service was not sufficiently continuous, not sufficiently widely and deeply informed of the specific needs, to ensure adequate use of scientific knowledge and judgment in service to the nation.

There was not, even at the midpoint, 1962, of our chosen century, any adequately researched, documented and constructively analyzed account of the slow growth of a still inadequate body of scientific advice to government in the affairs of any one of the Great Powers. Without this, the interpretation of the progress achieved in the succeeding fifty years is devoid of a scale with which to measure its success or to predict its future growth and utility. It is, however, possible to trace here the main reason for the inadequacies of 1937, the awakening which was just sufficient to buy time in the early forties, and the forward surge in the late eighties and nineties of the twentieth century.

C. P. Snow, in his Rede Lecture on "The Two Cultures," Cambridge University, 1959, dealt with the great gulf which he saw as yawning between "The Intellectuals" on the one hand (the literary intellectuals in particular)—and "The Scientists" (the physical scientists in particular) on the other. Politicians, and even statesmen, were almost all nearer to the intellectuals than to the scientists, though, of course, many called down "a plague on both your houses." The highest echelons of the Civil Service, "The First Division" as it used to call itself, was recruited almost exclusively from the camp of the Humanities, with a sprinkling of Mathematicians and a sparse handful from the Sciences.

It was very rarely indeed that there emerged from either of the two great universities, Oxford and Cambridge, a strange multiple personality who combined the high distinctions of being at once Senior Wrangler, Senior Classic and Smith's Prizeman. That the third Marquis of Salisbury married the daughter of one such rarity, and that she had inherited the paternal abilities "across the board," goes some considerable way towards explaining how Lord Salisbury as Prime Minister had the combined wisdom and good fortune to have Lord Rayleigh (who had succeeded Clerk Maxwell in the Cavendish Chair of Experimental Physics) as an unofficial adviser, and the philosopher-statesman, A. J. Balfour, later Lord Balfour, as a nephew! Balfour, in turn, depended heavily on the judgment and administrative genius of R. B. Haldane, later Viscount Haldane. Balfour and Haldane were Scots, born eight years and 25 miles apart, widely different in their abstract philosophy, widely different in their political affiliations, neither of them well-suited to the atmosphere of the House of Commons, but both passionately and fruitfully united in their determination to achieve more effective machinery of government, for military and civil strength alike.

For our present purposes we must be content with a mere mention of isolated samples of the British story—which, it must be admitted, is so characteristically British as to be nonrepresentative of the global picture, even were there a single global picture achievable by the diligent needlework of the historian. There are, of course, admirable books on The Social Relations of Science, but they do not deal with the social relations of the supreme statesman and the supreme scientist, for example, the third Marquis of Salisbury and the third Baron Rayleigh. Nor do they explain the highly atypical collaboration between the politically Conservative nephew of the aforesaid third Marquis (the nephew who was in time to be the first Earl Balfour) and his politically Liberal and left-wing friend, who was in time to be the first Viscount Haldane. Yet this collaboration was, in all human probability, necessary to the just-timely advent of British radar, and to much else in the field of science in the service of government. The full story belongs elsewhere; here it suffices to say that but for Balfour's proposal for the founding of a new governmental Department of Scientific and Industrial Research, and for Haldane's care of the new Department, the conditions for the inception and rapid development of Radar in Great Britain might not have existed at the critical dates.

Nor, indeed might the Royal Air Force itself, with the Royal Aircraft Establishment which served it, have been in the state of just-adequacy which, albeit precariously, prevailed in 1939. Rayleigh, Balfour, Haldane all were, very directly, essential to the survival and growth of that decisive arm.

In a still wider field, the military posture of the British armed forces as a whole might well have been hopelessly weak but for the much earlier work of Balfour in making the strong and flexible organ of military policy called The Committee of Imperial Defence, the work of Haldane in guiding that Committee for many critical years, and the remarkable work of Maurice Hankey in establishing and refining its organizational efficiency so that its machinery was ready to be converted into the War Cabinet Secretariat when the need came. When Winston Churchill, as First Lord of Admiralty, decided that a Naval General Staff was needed, he found its prototype in the Imperial General Staff which Haldane had set up for the Army. The philosophers had served their country well.

Balfour and Haldane together set up, and made into another valuable instrument of national importance, the civil Department of Scientific and Industrial Research. The Department benefited greatly by the advice of Sir J. J. Thomson and Lord Rutherford, each serving as Chairman of its Advisory Council. This civil department of government was the parent of a number of Research Boards. One of these, the Radio Research Board, was presided over by Admiral of the Fleet Sir Henry Jackson, one of the four pioneers of radiotelegraphy—in alphabetic order Jackson, Lodge, Marconi and Popov. The functions of this Board were thus described by Sir Henry Tizard, Permanent Secretary of the DSIR 1927-29, "The functions of the Radio Research Board were as described in its first report, namely 'To provide for research work of a fundamental character in directions where it was lacking and where it would be likely to lead to useful applications' . . . It is no part of the normal responsibilities of the D.S.I.R. to undertake defence research, nor to provide new devices for the use of the Fighting Services."

This orientation, towards general and nonmilitary developments, did not prevent the work done within the Board's program from making possible timely development of radar in 1935-39 by Watson Watt and his colleagues, and also of an earlier device which is described by U. S. and Canadian naval authorities as having been, at the lowest, no less important than radar itself to victory in the Battle of the Atlantic. This device, the High Frequency Visual Radio Direction Finder, depended on the Instantaneous Visual Radio Direction Finder proposed, for purely meteorological research, by Watson Watt in 1916, demonstrated by him in 1923, and introduced into the Royal Navy in 1940. It may well be that neither of these vital tools of victory in World War II would have been available at the crucial moment but for the wisdom and foresight of Balfour and Haldane in the years before 1916.

Despite these enlightened contributions from the philosopher-statesmen, and the consequent brilliant work of Hankey in improving the administrative machinery of government at the highest level, the lack of any continuing and growing understanding of the nature of science and of its subsidiary but profoundly important role as the "mother of invention," through technological utilization of scientific knowledge, continued. Intermittent crises evoked temporary *ad hoc* devices for obtaining scientific advice in limited areas of urgent need. Such devices included the Aeronautical Research Committee, and later the Committee for the Scientific Study of Air Defence (the Tizard Committee), the Air Defence Research Committee of the Committee of Imperial Defence, the "Tube Alloy" Committee on the development of the atomic bomb, and the Radio Board of the War Cabinet of which the Chairman was Sir Stafford Cripps, who had at one time been a research student under Sir William Ramsay and thus a *rara avis,* scientist-statesman.

Corresponding problems in the U.S.A. and other nations produced corresponding efforts, corresponding institutions which did not wholly bridge the gap between the two cultures in the service of government, and *ad hoc* committees whose useful life usually ended with the passing of the crisis which engendered them.

The radical solution has not yet become fully effective in this current year of 2012 A.D., but great advances have been achieved. They have not been made by the old method of "staggering from crisis to crisis," nor have they been forced marriages between "classical" and "scientific" minds still ill-acquainted one with the other. Somewhere in the 1960's the "educators" awoke to an already dazzling glimpse of the already obvious. Thumbing through the "Who's Who"s and the "Who Was Who"s of the time, they discovered that there was a whole galaxy of scientists, theoretical and experimental, who had, in the preceding eighty years or so, demonstrated a level of imaginative artistry at least as high as any ever attained in the literary, musical and visual arts, together with a philosophic penetration far surpassing that achieved by the philosophers-without-adjective.

Without attempting any comprehensive catalogue of these artist-philosopher-scientists, and without assessing priority or relative importance, a representative list must have a preface including Henry, Faraday, Mendeleyev and Clerk Maxwell, immediate forerunners of the revolution. Then come—in a list that must be incomplete and in some measure arbitrary—Michaelson, Fitzgerald, Lorentz, Ramsay, Rayleigh, Hertz, the Thomsons, Millikan, Rutherford, Bohr, Urey, Einstein, Dirac, Anderson, Yukawa, Fermi, Pauli, Planck, de Broglie, Davisson, Schroedinger, Roentgen, Moseley, the Curies, Leonard, Compton, Born, Heisenberg, Wigner, Weizsäcker, Hahn, Meitner, Frisch, *et al.* The inclusions are not in any rigid order; the omissions are due to a happy *embarras de richesse*.

Physics as a representational art died with Lord Kelvin; physics as an abstract art was born with Michaelson and Fitzgerald. Unlike the abstractions of abstract graphic art, however, the abstractions of the new physics were disciplined by the rules of a new arithmetic which clarified but did not confine, which was strictly quantitative but subtly elastic. In its modest abandoning of any claim to have penetrated to the definite mechanism which the schoolboy Clerk Maxwell sought in has passion for "the *real* go of things," in its substitution, for the arrogant "it is," of the modest "it is as if," it released conceptual thought from the shackles of the individual senses while keeping it on a well-posted highway towards the infinite.

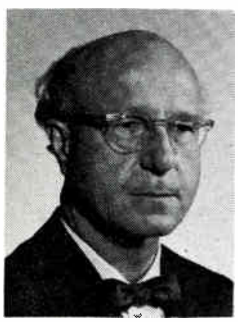
A century of increasingly awe-struck coexistence with a "Culture" which had banished "infinite" and "infinitesimal," "eternal" and "transient." "real" and "imaginary" from their professional lexicons, forced even the obstinately laggard rear-guards of the "humanities"—so often deeply concerned with inhumanities—to admit that the new scientists must be accepted, on at least a comparable level, into a united and cooperative (the two adjectives are far from identical!) House of Intellect. They had traveled a long way, from the opprobrious epithet "stinks" to a combined operation of reply to the Riddle of the Sphinx.

Now, in 2012 A.D. (somewhere around the millionth year of man the tool-maker?), we have almost the first generation of mature minds educated into seeing a single picture extending from the elementary particle to that galaxy which at the beginning of this sentence was five-billion light-years distant from us—and at the still remote end of the same sentence will be several million miles further from us, into visualizing the whiff of ammonia which switched from the inorganic to the organic state, into recognizing that although the number of quasi-independent variables in the statesman's equations is vastly greater than in those of the scienceman; yet each "political variable" is, in practice, *individually* much easier to evaluate than is each of the fewer "scientific variables." This is the generation which is now engaged in steering the world towards the state in which the still young Siegfried is indeed, as Wotan foresaw, "Stronger than I, the God."

So it can at last be said that the scientist is no longer sentenced to be "on tap but not on top," and this the more happily because he is both at the top and yet on tap. The essential blending of the cultures, all of them aesthetic and all of them important to the fuller life, has brought us an electorate which chooses, as the steersmen of the state, men who are both natural philosophers and philosophers *tout court*.

Electronic Nirvana

DANIEL E. NOBLE FELLOW IRE



The identification of trends is not difficult. For the generation of perspective, it is often a useful exercise to extrapolate trends into the nether regions of their unqualified terminal configurations with all modifying and inhibiting influences held in abeyance. Two presently discernible trends are first, the exponentially accumulating techniques for the extension of brainpower, or more properly, the extension of informational processing, and second, the very marked trend toward greater and greater degrees of vicarious living. The two trends are not only related, the first trend accentuates the second, for the rise of informational processing will accelerate the drift toward higher and higher levels of static and innocuous existence. Of course, it is quite true that some degree of vicarious living has been a characteristic of the search for an innocuous state of bliss since the telling of the first story, but it took the invention of the printing press, and more recently, the introduction of moving pictures, radio, and TV, to carry the living-by-proxy technique to such a high state of perfection that we can predict for the future that "personal participation" will be regarded as an eccentricity. Even in the field of sports, we have hired professional baseball players to play baseball for us, professional football players to play football for us, and professional golfers to play golf for us. We have now taken the ultimate step to limit physical action by making it unnecessary to participate personally as a spectator; we need not bother to go out to the field to watch; we sit at home and view the progress of the contest on the ubiquitous TV eye.

D. E. Noble is Executive Vice President of Motorola Inc., Phoenix, Ariz. *(Received July 31, 1961.)*

Since children are conditioned to watch TV from early childhood, the educators are reaching for TV as a desperate means for re-establishing communications. Children will increase the number of hours they spend staring at the glassy eye, and the total viewing hours will become an incredibly high percentage of their total waking hours. While there will be many steps in between, the terminal pattern for the extrapolation of this trend is easy to project.

Today's parents use the TV as a pacifier for temporarily immobilizing children of all ages, but the parent of the future will resort to a much more scientific solution. At birth, the infant will be clamped in front of the TV eye by means of a suitable supporting structure, and two sections of tubing will be connected to provide nourishment and to carry away the waste materials. From this time on, the subject will live an ideal vicarious life, scientifically selected for compatibility with the fixed influences of the inherited genes and chromosomes. For the early years, the automatically programmed TV will process the storing of the necessary bits in the memory brain cells of the subject for use in the initial "thinking" responses. As the accumulation of working material in the memory progresses, the "teaching" will be alternated with programmed vicarious living experiences. As the subject grows older, the victim—I mean the subject—will be trained in the necessary mental processes for selecting, storing, rejecting, correlating, disciplining, arranging and re-arranging new combinations of bits in the memory cells to enhance the potential for this more advanced thinking capability. It is obvious, of course, that various essential sensors will be connected to master points in the subject's nerve responsive system, and as the intellectual and emotional patterns emerge, the subject will be exposed to graded influences which will be selected automatically and will be totally controlled by the feedback from these sensors. A permanent recording of all sensor reactions properly coded to the influencing subject matter will be made for analysis and for use later in the continuing programmed activation of the telememory transducers which will directly stimulate a selected retrieval from the memory brain cells. As a result of the transducer stimulation, the subject will relive past vicarious experiences without recourse to sight or sound. Other transducers, properly controlled by the sensors, will be used to create and store additional sensations associated with the senses of touch, smell and taste. A library of qualified selections of vicarious living experiences will accumulate in solid-state memory form and will be automatically selected by the coded sensors for maintaining the "happy" state of the subject. In time, the memory cells of the subject will become saturated, or at least will be supplied to an adequate level with vicarious living experiences so that listening, and viewing the TV eye will no longer be necessary. From this point on, the sensors will automatically select the "living" experience which is to be *relived*, and the coded memory transducer will provide the controlled brain stimulus which will release the stored memory for the "reliving" of the vicarious living experience. In this way, the subject will be maintained in a perpetual state of static, innocuous bliss.

As the practice of "electronic nirvana" becomes universal, the natural result will be race suicide. Before this happens the development of machines which will reproduce themselves will have been completed, and the machines, drawing their raw materials from the ocean, will continue the redundant pattern of automatic machine reproduction and the recreation of simulated human living experiences until finally all of the human subjects will leave the infinity of innocuous existence for the infinity of nonexistence. And so, dear friends, as the sun sets slowly in the east, we leave the beautiful earth with its millennium of technological achievement, with no strife no mess, and no men, while the machines continue to grind out their fruitless patterns of human vicarious living with no humans present to respond to the stimuli.

Now that we have gained perspective by following the trends to their directly extrapolated limits, we may return to an examination of the interim patterns of informational processing which will flower within the fifty-year period of our present projection. Certainly, the demands for recording, disciplining and programming information will tend to move us away from the random approach which has been characterized by the development of isolated and unrelated solutions to related problems. Our whole approach to the necessary informational processing of the future will become more orderly, with an increase in the integration of related solutions. While we are busy pacing the trend in applied science away from the macroscopic and toward the microscopic in the processing of materials for electronic subsystems, we shall also change from a gross averaging of political, social and business statistics to refined selection, to individual characterization and to a more enlightened and integrated control of the environmental forces.

At birth, each individual will be given a serial number, which he shall retain for life. This number will be the key to the constantly accumulating storage of solid-state-memory bits, and it will serve as a telephone number, a social security number, an automobile license number, a passport number, a credit card number, and it will be the means of retrieving all other numbers and bits of information which will be important to the individual and to his political, business and social life over the span of his lifetime. Perhaps a nine digit number will be sufficient in the U.S.A. for a couple of hundred years. As an example, the number attached to one of our descendants in the year 2012 A.D. may be 345-462-179. For the child, the number would provide the key to the recording of all scholastic records generated by the teaching machines. A continuously accumulated health record would be stored in a master computer memory and whenever the individual became ill, as a child or as an adult, the coded latest symptoms would be fed into the computer, which would respond with the pertinent history, a diagnosis, and treatment information based not only upon this individual record, but also upon the information automatically retrieved by the computer from a search of all similar health patterns.

All mail would utilize the serial number automatically, whether it was used for the routing of written material or for the transmission of facsimile messages. For mailing a letter, the addressor and the addressee numbers would appear on the face of the envelope. At the post office, the numbers would be read and checked by rapid search of the central solid-state computer memory, and the letter would then be automatically coded and routed to the proper destination. Telephone calls would be routed automatically in a somewhat similar fashion.

Additional applications for this personal serial number system would be for continuous up-to-date census information, for automatic banking procedures covering deposits, payments, billing, supermarket charges, and for the handling of loans and time payments. The FBI and police would also make use of the number. Whether the problem was one of law enforcement or automatic mail delivery, or the routing of TV and entertainment programs, or the use of the telephone, or phono-vision, or facsimile, or newspaper delivery, or even one of supermarketing, or automatic cab dispatching, the number would serve as the key identification for scanning the solid-state memories, and for automatically processing the transaction.

Instant-delivery communications capability will be greatly enhanced by the use of coaxial cable service to all homes and business establishments. With the broadband laser coaxial service in operation, two-way visual as well as audio and facsimile communication service will become routine. One very important extension in the field of mass communication as a result of home coaxial cables will be the response communications potential of the system. No longer need the observer be a passive victim of least-common-denominator programming. With the coaxial cable in use, the observer can applaud or he can originate an electronically coded degree of disapproval. By suitable coding procedures, the individual response will be properly weighted in terms of intellectual, as well as social, political and financial background. The availability of many programs, which by this time will be stored in monolithic solid-state memory systems, will offer a wide choice to the individual seeking entertainment, information or instruction. Voting on national questions will be carried out with no significant lapse of time, and the vote will be automatically analyzed in terms of any selected categories of coding or weighting. The very important difference between the present system and the future system will be the element of choice, which is now theoretical rather than real. With the development of solid-state molecular memory capability, the storage of programs will require little space, and will become low in cost and routine in procedure. By selection, the potential customer can call out a Shakespearean play, a musical comedy, a modern drama, a lecture on space exploration, or a lecture on child care. The instant selection and freedom of choice will forever silence the Madison Avenue voices which tend to seek the least common denominator of program mediocrity to capture the mass audience.

With the wide-band two-way home communications service available in the year 2012 A.D., the potential customer may make use of the coded retrieval system to arrange for a display and for full information about any desired products. Each dealer will store in a solid-state memory system a carefully prepared selection of presentations for each product. The programs will vary from a simple picture of the product and information about the essential specifications, to elaborate demonstrations of the product in use, emphasizing its features and competitive characteristics. At home, the potential customer will take a quick look at the products in the selected category of interest, using the home three-dimensional color screen, and when a product is found with special appeal, the full program may be requested to aid in making the final decision.

Since there will be no newspapers and magazines in the usual form, and since there will be detailed product information always at command, the generalized propaganda advertising will be a thing of the past. Three-dimensional color video display with sound, home facsimile publication of pictures and reading material (available also with sound, which may be selected), and the talking books available for dialing directly into the home from the central library solid-state memory storage, will minimize the use of many of the traditional forms of mass communications.

By means of satellite broad-band communications, the informational processing from a home in the United States to a home anywhere in the world will be as easy and as routine as communication between the homes in the same city or in the same area. The language barrier will be eliminated automatically by processing communications between two different language groups through the automatic solid-state translator. The extension of this communication to universal world coverage will gradually bring about the development of mutual confidence and understanding among the peoples of the world, so that in three or four hundred years, war will be outlawed and the people can then devote all their time and energy to the more important task of keeping the matrix of worldwide informational processing properly functioning and forever expanding.

This perfection of informational processing will not, as might appear from first examination, isolate, restrict and control the individual, nor will it condemn intellectually qualified individuals to vicarious living or to "electronic nirvana." Quite the contrary, the qualified intellects will have at command the almost instant retrieval of any selected part of the total store of human knowledge accumulated in the archives of the solid-state memory systems of the world. From almost any location in the world an individual may call up, in both visual and audio form, information from any other part of the world and accomplish the whole operation of query and response in a matter of minutes, if not a matter of seconds. By the use of effective teaching machines and with instant retrieval of information available to support the expanding intellect, the newly developing human mind will start out on a foundation of knowledge exceeding in depth and breadth anything which has been possible in the past, with the result that during the normal lifetime, which will be extended to 100 years by 2012 A.D., the human intellect will rise to levels of knowledge and to the total use of knowledge never before achieved by man. Certainly, as is the case today, there will be all degrees and levels of intellectual competence, but for every level from the moron to the scholar, the rise of informational processing will contribute to the interest and minimize the cruel and painful elements of life and living. The art of living will be enhanced in all of its multifold relationships and the potential for experiencing and sharing experiences will be mushroomed by the development of effective informational processing in all forms. While the chronological age span will be increased, far more important than this, the real life of experiencing and sharing experiences will be increased for everyone. Since the brain is where we live, the enhancement of communications in all forms will speed up life and living. We will live faster, not in the degrading sense, but in the sense of receiving a far greater quantity and quality of stimuli and of reacting, and sharing reaction to such stimuli. This irresistible and irrevocable rise of informational processing will extend man's reach for comprehension and accelerate his march toward maturity.

Electronics and Evolution

JEROME B. WIESNER FELLOW IRE

Technology can be thought of as a man-made substitute for natural evolution in the process of adjusting to our environment and in which many of the steps of natural evolution are being repeated. The modern human being is the culmination of an eon-long evolutionary process that began with the existence of individual simple cells and culminated in the complex organism of today. In the process a great variety of specialized cells—such as muscle cells, nerve cells, blood cells, and many others—evolved to carry out the functions of energy conversion, communication and transportation which are necessary for the existence of a complicated organism. The increasingly complex specimens which developed are the survivors of a natural selection which made dominant those species best equipped to deal with the hardships encountered in the environment. It may be that the evolutionary development of man has not ceased—though there is some reason to believe that he does represent about as much organized complexity as can be satisfactorily achieved with components having the properties of biological materials—but even if it hasn't stopped, it is a very slow process.

Fortunately, man has found a substitute for continued biological evolution to aid him in his struggle against hardships of the environment. He has learned to exploit scientific knowledge to his advantage. Nearly all of the fields of science, biology, mathematics, physics, chemistry and astronomy, have made their important contributions to the technical evolution. By co-operation involving communication, the control of energy and the manipulation of materials, man has greatly increased his mastery over nature and his accommodation to the environment in which he must live. Our own fields of electronics and communications, which are making so large a contribution to this effort, depend primarily upon knowledge from the fields of physics and chemistry for their devices—electron tubes, transistors, magnetic cores and a multitude of other components—and upon mathematics—field theory, circuit theory, switching theory, etc.—for their underlying logic. In the last one-hundred years we learned how to harness almost limitless amounts of energy, particularly electrical energy, and direct its use for our purposes. Simultaneously there were developed electrical means for communicating between individuals—the telegraph, the telephone, radio, television and teletype—in which the high speed of electrical signals was exploited.

In these early developments man was learning to enhance his own physical capabilities, to replace menial human effort with machines, and to extend the distance over which he could be effective.

More recently, feedback control and automatic computing systems have been developed to eliminate the need to perform personally a variety of routine mental tasks such as steering aircraft, guiding a milling machine tool, reading a check or regulating a steel mill.

The digital computer which makes these feats possible is undoubtedly the most important single electronics development of the last two decades and ultimately will have as widespread consequences in the development of our civilization as did the steam engine. Digital computers have already been employed to perform a variety of computation, information processing and storage functions in which they greatly enhance the capacity of man's unaided brain, and yet their exploitation has hardly begun.

J. B. Wiesner is Special Assistant to the President for Science and Technology, The White House, Washington, D.C. *(Received October 24, 1961.)*

The most important attribute of the modern computing machine is its very great speed compared to biological computing systems, an advantage that is easy to understand. Signals on nerve fibers travel at velocities up to 300 meters per second. Furthermore, neurons (neural relays) have maximum response rates of the order of one hundred impulses per second, while electronic switching rates of greater than one billion per second have been achieved, and this is hardly the limit.

Ultimately, computers should have advantages other than speed. As electronic components develop especially satisfactory molecular-sized elements, a computer's memory should become better than man's in at least two respects: better retentivity and more rapid access to stored information. Conceivably it could also have greater storage capacity, though information storage capacity of the human mind is so extremely large that need for greater amounts of active memory may never occur. These considerations would justify the conclusion that one should ultimately be able to create "thinking machines" much brighter than the smartest human being, if presently unforeseen limitations on the logical design or construction of computers do not appear.

At the present time our ability to use machines instead of human brainpower in many tasks, particularly those involving insight or intuition, is prevented by our lack of understanding of the logical processes involved, but there is a vast research effort in this challenging field and understanding is advancing very rapidly. Machines are already assisting in their own programming and development; as this technique develops it is certain to extend the scope of computer capabilities.

How will these developments be exploited in the next half-century? It is probably impossible to be visionary enough to match reality, though the opportunities are obvious. With endless amounts of energy available where needed, and with automata to control machines and to substitute for or augment most mental labor and to extend greatly the human mind's best creative efforts, man can truly become master of his physical environment. One can even hope that the "thinking machines" will make it possible to understand and cope with the enormous and vexing social problems that the technological revolution is leaving in its wake. Possibly the most important aspect of these scientific and technical developments will be the assistance they will provide man in making adjustments to the environment which he has created—economic, political and social.

AEROSPACE AND NAVIGATION

Organized with the assistance of the IRE Professional Group on Aerospace and Navigational Electronics

Fifty Years in Aeronautical Navigational Electronics*

VERNON I. WEIHE†, FELLOW, IRE

***Summary*—The state-of-the-art in aircraft operations and in radio technology for the very early period of aeronautical navigation is given, and the technical evolution during the first twenty-five years of IRE is covered. Policy and organizational problems of the transition to the second twenty-five-year period are mentioned. A discussion is given of the World War II system developments, the introduction of pulse techniques and the race toward the microwave portion of the spectrum. This is followed by a discussion of self-contained systems. Illustrations are provided covering some of the more fundamental spatial characteristics of electronic navigation systems.**

Navigation and Power

Prince Henry the Navigator of Portugal (1394–1460), patron of voyagers and organizer of many serious projects to improve the science and practice of navigation, is credited with doing more than any other single person to make the 15th, 16th and 17th centuries the Great Age of Discovery. Except for this period the rate of progress in navigation during all prior centuries, and even to the 20th, was extremely slow. This probably can be attributed to lack of urgent need, since man could travel no faster than sail or animal power could propel him.

Even in the early twentieth century, during the fledgling days of aviation, designers concentrated on lift and stability while disdaining the less esoteric power approach as the "brute force" method. Yet the dynamic progress of aviation has been paced by the constantly increasing amount of power made available. Each new improved source of thrust spawned a new generation of higher performance aircraft and each, in turn, brought new requirements for navigational services.

But, lest we pass those early days too hastily, a quote from Talbot[1] on the status of navigation in World War I naval aviation may help us start from the beginning:

> When once the flying machine had indicated its possibilities in connection with land operations, it was only natural that endeavors should be made to adapt it to the more rigorous requirements of the naval service. But the conditions are so vastly dissimilar that only a meager measure of success has been recorded. Bomb-throwing from aloft upon the decks of battleships appeals vividly to the popular imagination, and the widespread destruction which may be caused by dropping such an agent down the funnel of a vessel into the boiler room is a favorite theme among writers of fiction and artists. But hitting such an objective while it is tearing at high speed through the water, from a height of several thousand feet is a vastly different task from throwing sticks and balls at an Aunt Sally on *terra firma;* the target is so small and elusive.
>
> Practically, it is impossible to employ the flying machine, whether it be a dirigible or an aeroplane, in this field.
>
> In operations over water the airman is confronted with one serious danger—the risk of losing his bearings and his way. . . . Many people suppose that because an airman is equipped with a compass he must be able to find his way, but this is a fallacy. . . .
>
> Unless the airman has some means of determining his position, such as landmarks, he fails to realize the fact that he is drifting, or even if he becomes aware of this fact, it is by no means a simple straightforward matter for him to make adequate allow-

ance for the factor. Side-drift is the aviator's greatest enemy. It cannot be determined with any degree of accuracy. . . . More than one bold and skillful aviator has assayed the crossing of the English Channel and being overtaken by fog, has failed to make the opposite coast. His compass has given him the proper direction, but the side-drift has proved his undoing, with the result that he has missed his objective.[2]

Aircraft of the wood, cloth and "bailing wire" period were not all-weather machines, and the number of them did not, of course, present a serious air traffic control problem. In addition, closing speeds were until very recently such that "see and be seen" was normally adequate to prevent air-to-air collisions over land. The earliest basic requirement was to find intermediate navigational checkpoints and terminal landing places or airports, while today's most urgent need is that of adhering continuously to a flight plan track for air traffic control, rather than for basic navigational purposes. A major challenge of our profession is to devise and introduce new electronic systems which can help maintain the flexibility and efficiency of air operations while drastically reducing the incidence of mid-air collision.

[2] Talbot, *op. cit.*, pp. 244, 245, and 246.

Early Radio Technology

During the first twenty-five years of the IRE, only continuous wave techniques were useful for navigation, and only in the relatively long-wave portion of the radio spectrum. Hence, antenna structures of practical dimensions provided low aperture, usually much less than one-half wavelength. This lack of aperture made high spatial sensitivity difficult to achieve, while the inability to differentiate between direct and reflected signals made acceptably accurate and stable navigational lines of position at times impossible to accomplish. In Figs. 1–3, navigation systems are categorized and chronologically related to emphasize first of all, the changes brought about by wavelength/aperture considerations; secondly, to point out the impact of the introduction of pulse techniques and most importantly to dramatize the explosive impact on navigational development produced by high performance aircraft requirements.

Early systems such as the aural-null airborne homing device or direction finder, and the LF/MF four-course radio range required the pilot to listen for signal nulls or to compare signal amplitudes. Atmospheric noise and the monotony of keyed tone signals produced consider-

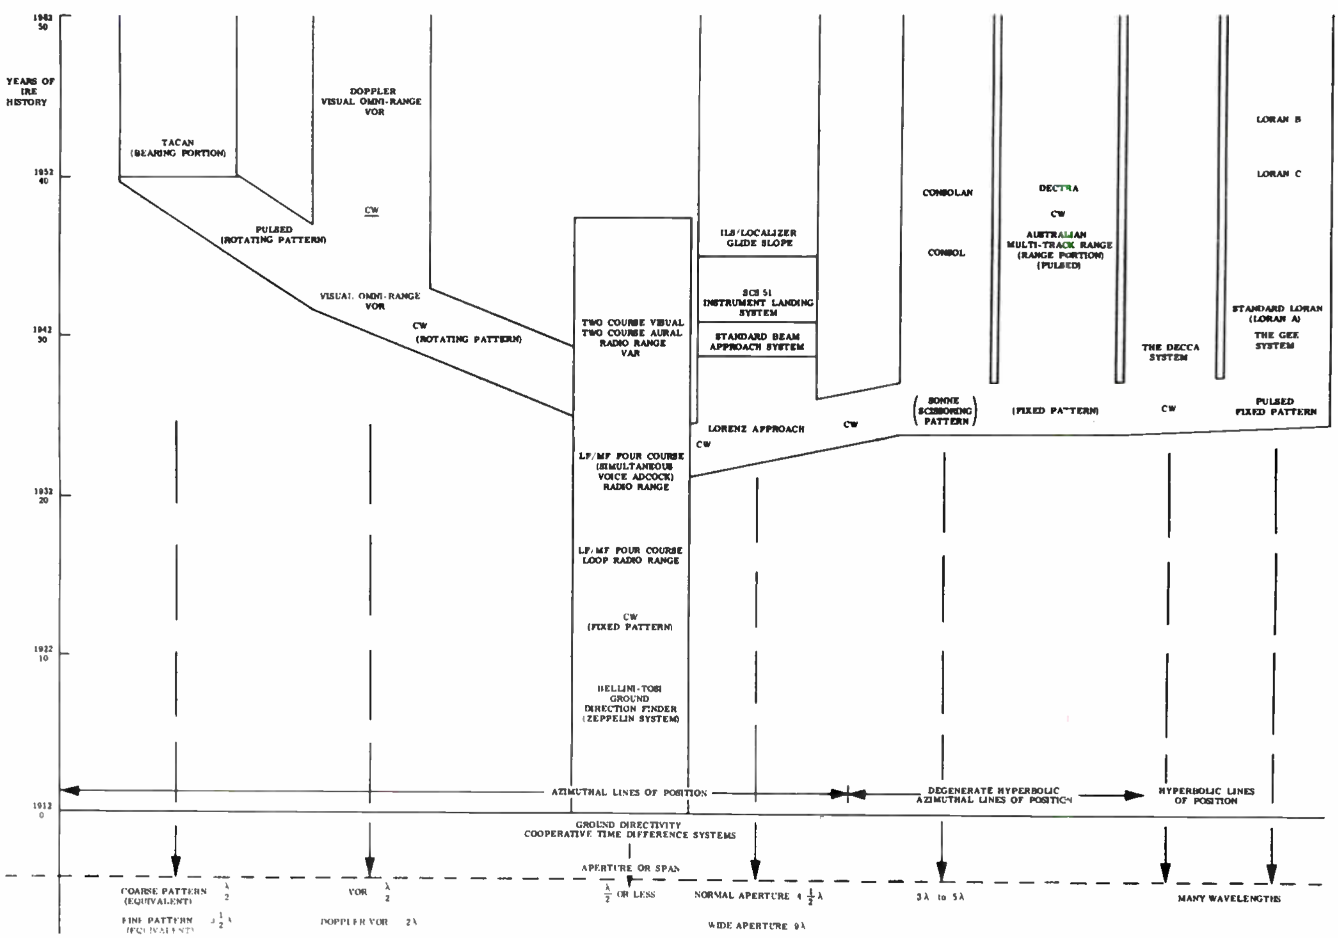

Fig. 1—Ground directivity—cooperative time difference systems.

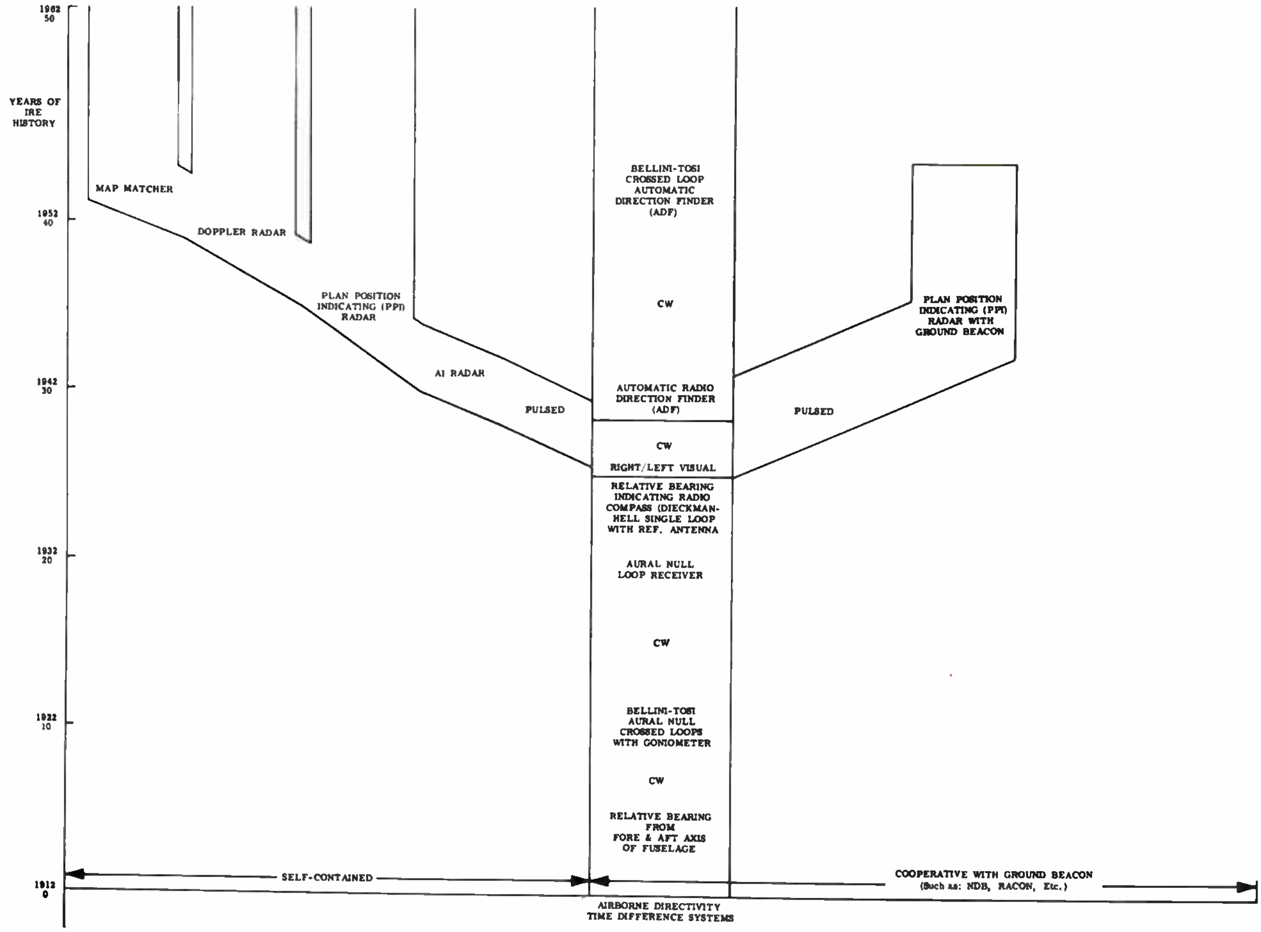

Fig. 2—Airborne directivity—time difference systems.

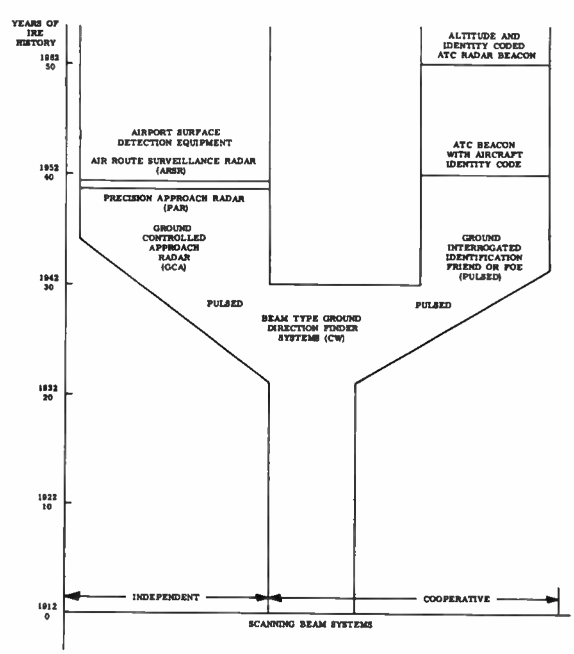

Fig. 3—Scanning beam systems.

able pilot fatigue, thereby emphasizing a requirement for the presentation of visual information in the cockpit.

This need caused development of zero-center meter systems. Such meters may have the needle at center, either when on-course or when the equipment is inoperative, hence are not considered to "fail safely." Later, zero-center meters were provided with flag alarm systems to indicate to the pilot the status of system operation, and in some cases the navigational signals were employed as servo inputs to provide "an active needle automatic follow-up" for presentation on an azimuth scale.

The need for cooperative lock and key relationships between airborne and ground portions of the system far in access of those for conventional radio communications soon became apparent. It became essential that transmitting and receiving units not emit or receive radio-frequency energy through extraneous paths, such as power leads, ground leads, chasses, etc. Only those antenna system relationships which were spatially sensitive were employed. For example, radio altimeters have been difficult to calibrate on more than altitude scale because of an inability to compare the reflected signal against a single reference. Leakage between transmitter and receiver within the equipment or within the installation wiring produced one reference, while direct signals between the transmitting aerial and the receiving aerial on the same aircraft provided another reference. The dynamic range, automatic gain control and phase characteristics of receivers now, for the first time, were required to remain uniform throughout the radio spectrum of the system and between severe environmental limits.

Cooperative Navigation Creates Organization and Policy Problems

National standards covering signal characteristics, tolerances, operational utilization, minimum acceptable performance criteria, and test standards had to be evolved. In the United States, many Presidential boards and committees were formed and the Radio Technical Commission for Aeronautics was created. This Commission, founded in 1935, still proveds a forum for all aeronautical interests—government, industry, and private—to exchange views and to recommend procedures and standards for the improvement of radio technical services to aviation.

The introduction of new navigational systems into aircraft must be accompanied by scores of prior agreements, since the number and type of aids used in the aeronautical service must be limited to a few broadly implemented standard types. Aircraft cannot change airborne equipment when flying from one country to another and, of course, "dead-heading" equipment during periods of non-use is detrimental to payload. Cooperating systems which require a ground counterpart, for practical reasons, must be more limited than other types, since administrations of many countries must install, operate and maintain the ground facilities. For airborne self-contained systems which radiate (*e.g.*, airborne radar and Doppler autonavigators), the problem is much simpler since radio-frequency channel licensing and airborne equipment certification only are involved. Much of the ponderous policy and administrative machinery necessary for ground equipment implementation and maintenance fortunately can be by-passed.

Continuous Wave vs Pulse Techniques

The start of the second twenty-five years of IRE coincided with the military build-up for World War II. Early emphasis on detection and early warning via radar produced an almost immediate employment of pulse techniques in electronic navigation. Real competition quickly developed between those who contended that navigation had a low information rate requirement and therefore should utilize very low bandwidth per channel and those who supported the full employment of pulse techniques in order to achieve multipath discrimination regardless of spectrum economy. This latter view was held regardless of the fact that in some instances techniques utilizing coding or repetition rates also had to be used as a means for providing navigational information.

Pulse techniques have two fundamental uses in electronic navigation:

1) to facilitate the measurement or display of distance through round-trip transit time of the direct wave when a multiplicity of targets or a multiplicity of sources is involved; and
2) to increase the accuracy of line-of-position determination through the reduction of multipath effects.

Feature 1) above is fundamental to radar and radar beacon range measurement and to distance measuring systems, while 2) is employed in hyperbolic systems (such as GEE and LORAN).

In continuous wave systems, the geographic line of position data at any point at any time is produced by the integrated total of all of the energy received, regardless of whether it is propagated over the direct path, indirect paths, or both. These effects are also very much influenced by the plane of polarization of the radio waves employed. For instance, the horizontally polarized component of the propagated wave is particularly detrimental to the performance of the loop radio range, causing multiple courses in regions of rough terrain and being particularly susceptible to course shifts resulting from ionospheric changes. The Adcock range was developed to assure improved course stability through minimization of these effects.

The navigational accuracy of CW aids can also be improved by transmitting on a number of wavelengths simultaneously or by increasing the aperture or span of the antenna array. The former method, although tried successfully, was not adopted because of poor spectrum and equipment economics. The latter method generally produced ambiguities which had to be resolved by including a less accurate subsystem to provide ambiguity resolution (*i.e.*, DECCA lane identification, CONSOL sector identification, and the 15-cps subsystem of TACAN).

Doppler systems of the type which systematically move a real or quasi-antenna through a span of several wavelengths obtain an increase in aperture without coincident development of ambiguous lines of position. The increase in aperture materially diminishes derogating multipath and related site sensitiveness (*e.g.*, Doppler direction finder, Doppler VOR). Systems of this type overcome serious disadvantages of CW systems without incurring some of the basic limitations of pulse systems.

In all but a few cases, equal performance can be had from either pulse or CW techniques, if equal cleverness is shown in system conception and development. Many of the better systems today utilize a combination of the two techniques either in the basic concept (LORAN B and LORAN C), in the measuring circuits, or in the safety monitoring subsystem. Certain other systems would be more useful if modified to include both CW and pulse techniques. For example, if TACAN had a CW feature like the audio channel of television, voice identification could supersede the somewhat archaic slow code identification method utilized; other uses also could be made of the available channel.

All accepted systems have relatively good sampling, integration, or correlation circuitry, evolved either through trial and error, or through theoretical analysis and development, yet little firm agreement exists concerning the superiority of one technique over another. CW signals are often squared and converted to pulses for measurement in airborne receivers or ground monitors, while pulse signals are often used to synchronize local sine wave generators to facilitate measurement of CW phase.

Full utilization of either seems to create unwarranted compromise, while full utilization of both seems, in some instances, to bring about considerable equipment sophistication. Sophistication can increase the cost and, in turn, decrease the number of potential users of a system. The unending competition between the CW and pulse systems proponents will no doubt improve both types of system; however, general agreement on the superiority of one over the other is not to be expected in the near future.

The Race Toward Microwaves

In addition to the introduction of pulse techniques, the impact of World War II also set in motion a vigorously supported development race to shorter and shorter wavelengths. By the end of World War II, microwave systems were in general use. Employment of shorter and shorter wavelengths made it feasible to obtain wider apertures with airborne and ground antennas of practical size. In the general case, wider aperture means improved geographic or spatial sensitivity and produces improved navigational accuracy.

In the line-of-sight bands, 100 Mc and above, means were also found for reducing or overcoming atmospheric and precipitation static difficulties, while increasing not only the number of radio frequency channels available, but the flexibility of their geographic employment. In some aeronautical services, the reduced coverage of line-of-sight limited systems (below line of sight and in the overhead cone) was preferred to the vulnerability to atmospheric and precipitation static and the susceptibility to long-range co-channel interference and multipath effects (VHF vs LF/MF aids).

Detection and Measurement of Spatially Significant Information

Earlier systems relied primarily on amplitude, in null detection and amplitude comparison forms, for sensing spatially configured signals, while later systems placed emphasis on phase comparison and pulse time difference measurements.

Unlike aural systems, visual systems require the establishment of measuring references, the formation of measuring scales, the application of these to the sensed signals, and visual presentation of the information to the user. In most pulse systems, reference signals are placed in time sequence with spatially varying signals, while in the CW systems the reference and variable signals are generally transmitted simultaneously, either on separate radio frequency channels or on different sub-carriers on the same radio channel.

Round-trip transit time of radio waves is extensively employed in primary and secondary radar (radar beacons) for the measurement and/or display of distance information.

Distance measuring systems are, in fact, multichannel, nondirectional radar beacon systems, wherein a multiplicity of aircraft are accommodated through the process of time variant or random airborne interrogation, rather than through azimuth scanning of a beam antenna.

Airborne Self-Contained Navigation—Doppler and Inertial

Janus, an ancient Italian deity, was regarded by the Romans as presiding over doors and gates, and over the beginnings and endings, and was commonly represented with two faces in opposite directions. The Janus airborne Doppler radar is so called because it points beams fore and aft. The reflected signals in the forward semicircle return with increased radio frequency, while those to the rear have lower frequency. Hyperbolic loci of equal Doppler frequency return are sensed to provide the pilot with indications of ground speed and drift angle. Through electronic integration and automatic computation, using as reference the heading subsystem of the aircraft, a very accurate self-contained automatic navigation service is made available. Airborne Doppler navigation was borne in the immediate post World War II period and is now common equipment on most long-range jet aircraft.

In the immediate future, inertial navigation will be employed on a broader scale. Doppler/inertial systems, where each subsystem improves the accuracy of the other, are apt to come into common use. Long-range scheduled air carrier flights have in the past twenty to thirty years primarily relied on the services of a professional navigator, and flights have been predicated on celestial rather than electronic aids to naviagtion. Now that Doppler autonavigator equipment with direct display to the pilot is coming into general use there is a decreasing need for the services of the professional navigator. As the heading reference subsystems (magnetic, inertial, or both) are improved, even more accurate autonavigator performance can be expected.

In contrast to cooperative electronic navigation systems, autonavigators can be employed anywhere in the world over land or sea and are not degraded by atmospheric, precipitation or auroral disturbances.

Airborne Astro Navigation

From the early Polynesian times, the surface navigator has employed the stars and planets for fix determination and heading reference with many types of instruments. The Polynesians knew which stars and planets passed over each island of interest and used a gourd with fluid as a horizontal reference to form a crude zenith sextant. On early long-distance flights, astronavigators soon learned to use a bubble rather than a sea horizon for a reference in determining star altitude. In World War II, astro domes were installed on most long-range multi-engine aircraft. In one high-altitude, high-performance aircraft, explosive failure of the astro dome in flight occurred with fatal results. The pressure differential propelled the navigator through the astro dome opening to his death in mid-Atlantic, thousands of feet below. The periscopic sextant was developed and placed into service, and until that time, a mere decade ago, electronics was not a predominant factor in classical astro navigation. The next step in the development was automatic astro-tracking, so that we now have automatically controlled and computed astro navigation. More recently, we have even violated the classical self-contained principle and are beginning to "hang out our own stars." In the TRANSIT system, the TRANSIT satellite is tracked by ground-based (Doppler) tracking stations. The using vehicle observes the satellite while receiving orbit-correcting signals from it.

As we move further into the space age, optical band radio and radar navigation systems, using navigational principles not unlike those of their predecessors chronicled here, will be developed and come into practical service. Only the time scale will be different; in today's development environment, one expects to finish in months tasks which formerly required years to complete.

The Air Traffic Control Equipment Subsystem—Present and Future*

P. C. SANDRETTO†, FELLOW, IRE

Summary—The air traffic control problem consists of operational, technical, and political elements. This paper, however, is confined to the technical (equipment) aspects of the problem. The equipment subsystem consists of five essential elements. These are: Type I—means whereby pilots of aircraft may know their positions and means whereby they may be able to conduct their aircraft over any arbitrarily chosen routes from terminal to terminal; Type II—means whereby a central decision-making entity may be able to know the position of all aircraft within its jurisdiction; Type III—means whereby the decision-making entity can determine instantly safe, nonconflicting flight procedures for all aircraft within its purview; Type IV—means whereby instantaneous safe-flight instructions may be transmitted unambiguously to all aircrafts concerned; Type V—means whereby action may be coordinated among the several central flight-instruction, decision-making entities. The paper lists the significant actions which have affected the air traffic control equipment subsystem. It gives the history of the various units which form the present equipment subsystem and forecasts the equipment that may constitute the future traffic control subsystem.

* Received by the IRE, February 16, 1961; revised manuscript received, April 17, 1961.

† U. S. Defense Group, International Telephone and Telegraph Corp., Nutley, N. J.

I. Introduction

THE air traffic control problem is a triad [1] for it consists of three problems that must be solved individually, otherwise there can be no solution to the whole. First, it is necessary to obtain an agreement among all air operating entities as to the rules, conditions, and methods by which they will operate and control (or order to be operated and controlled) the air traffic under their jurisdiction. Second, it is necessary to solve technical problems so that there may be constructed practical equipment which will perform within the framework of the air operations system. The solution of problems one and two, however, can result in a practical solution only when the political organizations which have been endowed with the appropriate statutory powers take steps to obtain the necessary agreements and implementing action to bring a system into being. It is evident, therefore, that within the space allotted to this paper, the air traffic control problem cannot be covered in all its details. For this reason, this paper is confined narrowly to the equipment aspect alone.

The air traffic control system is the means for controlling traffic which consists of a set of air operations procedures aided in their application by an equipment subsystem which is mainly (but not wholly) electronic. The air traffic control equipment subsystem is a collection of suitable equipment by which aircraft positions and movements are determined and through which the movements of the aircraft are controlled. Since this paper is written for engineers, it is directed at equipment, which is their principal domain, but it is necessary to emphasize that their best inventions will come to naught if the operational and political environment attending this equipment is ignored. Significant actions which have played a part in determining the character of the present air traffic control equipment subsystem are listed in Table I.

II. The Present Air Traffic Control Equipment Subsystem

To meet its requirements, the air traffic control equipment subsystem must consist of the following five sets of equipment:

Type I: Means whereby pilots of aircraft may know their positions (in three dimensions) and means whereby they may be able to conduct their aircraft over any arbitrarily chosen routes from terminal to terminal.

Type II: Means whereby a central decision-making entity may be able to know the position of all aircraft within its jurisdiction.

Type III: Means whereby the decision-making entity can determine instantly safe, nonconflicting flight procedures for all aircraft within its purview.

Type IV: Means whereby instantaneous safe-flight instructions may be transmitted unambiguously to all aircraft concerned.

Type V: Means whereby action may be coordinated among the several central flight-instruction, decision-making entities.

A. Type I Equipment

This equipment is navigation equipment which must serve in the en route long-distance zone, the en route short-distance zone, the approach and landing zone, and the airport zone. A discussion of the present equipment for these various zones follows, but reference to newer developments has been placed in Section III.

1) The En Route Long-Distance Zone: This zone is that portion of the air space in which aircraft are primarily served by radio aids spaced at intervals of 200 miles or more. There was little need for navigation equipment for the en route long-distance zone prior to 1935, for it was not until November of that year that the first transpacific airmail flight was made and not until 1939 that the first transatlantic airmail flight was inaugurated. As early as 1927, however, four-course, low-frequency radio ranges were installed [29] in the Hawaiian Islands and in San Francisco for the purpose of guiding flight over the Pacific. The station at each terminal could be heard at the opposite terminal, so the four-course radio range became the principal Type I equipment and was not supplemented in this zone with another aid until 1937 when airborne direction finding was installed on American aircraft. Pan American Airways developed a ground-based HF direction finder about 1936 and placed it in use in many parts of the world [30]. During the war, loran equipment was developed [31] and installed in many places throughout the world. Some of these loran chains were decommissioned immediately after the war, but a few years later new equipment [32] was developed and the coverage was extended [33] after about 1950. During the war, the Germans invented a LF azimuthal system known as "Sonne" [16], and they made several installations on the European mainland. This equipment was refurbished under the name of "Consol." In 1954, ICAO approved Consol for long distance use together with loran and nondirectional radio beacons. By 1960, the CAA had installed and commissioned Consol stations at Nantucket, R. I., and San Francisco.

Since the inception of transoceanic flying, the bubble octant has been the most important of the devices for navigation over transoceanic routes; however, in 1945 it was joined by the high-altitude radio altimeter [34] used in conjunction with the aneroid altimeter. In 1960, a few installations of the third self-contained aid (Doppler navigator) were made on aircraft in transoceanic service.

2) The En Route Short-Distance Zone: To fulfill the navigational requirements of the en route short-distance

TABLE 1 - SIGNIFICANT ACTIONS WHICH HAVE AFFECTED THE AIR TRAFFIC CONTROL EQUIPMENT SUBSYSTEMS

Date	Organization	Meeting Place	Chairman	Purpose	Remarks	Bibliographic Ref.
Nov., 1944	52 Nations	Chicago		To set up an organization of a technical and advisory nature.	Upon ratification of the Chicago convention, the International Civil Aviation Organization was formed and later became a branch of the United Nations.	2
Aug. 7-20, 1945	Third Commonwealth and Empire Conference on Radio for Civil Aviation	London	Viscount Swinton (Over-all) Sir Frederick Tymms (1) Sir Robert Watson Watt(2) (3)	(1) To establish communications procedures, regulations, preferred standards for radio equipment, (2) to select from military radio and radar systems those which should be installed on international routes, (3) to suggest a program of radio development to be undertaken in the Commonwealth and Empire and in the United States.	The program developed includes practically all of the items which today are being implemented. A pulse type omnirange with distance measuring equipment was recommended for development.	51
Feb. 4-8, 1946	U.S. Air Force	Washington, D.C.	General Curtis E. LeMay	To discuss all known systems for navigation and control of aircraft with a view towards (subject to national and international commitments and agreements) concentrating our development of those systems which appear most promising.	Several manufacturers presented proposals for coordinated air traffic control systems based on the technology which had developed during the war. Contracts were placed later for many of these systems. The CAA presented a "long range program" consisting of ILS, CW omnidirectional radio range, automatic communications and flight data posting (said to have been under development). Also proposed direct radio communications via VHF from aircraft to tower.	3, 5, 4, 6, 7, 8, 9, 10, 17
Aug. 20-27, 1946	Radio Tech. Commission for Aviation	Washington, D.C.	Howard K. Morgan	To develop recommendations for the United States policy on aeronautical telecommunications.	The program laid down was almost identical with that of Third CERCA but endorsed the VHF, CW phase comparison omnirange. Indicator signaling (ground-air radio link) also recommended.	11
Oct. 28 Nov. 11, 1946	COT Division of ICAO	Montreal	G/C Campbell	To recommend standardization of certain radio aids to navigation and communications.	Accepted ILS for installation not later than Jan. 1, 1951, at all international airports. GCA considered a supplemental standard where warranted. Major discussion centered around the VHF, CW omnidirectional radio range and DME. Recommended that standard Loran and Consol be retained. No single aid to air navigation for long range found to justify universal adoption.	12, 13, 14, 31, 16, 17
Jan. 22 - Apr. 4, 1947	Committee on Interstate and Foreign Commerce House of Representatives	Washington, D.C.	Mr. Wolverton	To study the problems involved in increasing the safety of air transportation.	The following quote is from the report of this group: "When we take the long-range view, it becomes apparent that individual devices do not constitute a coordinated system for safe air navigation. Sometime in the early 1950's there will be an urgent need for substantial and comprehensive improvement." This report lead to the establishment of Committee SC-31.	21
June, 1947 to Feb., 1948	RTCA Special Committee 31	Washington, D.C.	Phase 1 - Col. J. B. Duckworth Phase 2 - Capt. A. S. Born	To undertake a study of air traffic control for the purpose of developing recommendations for the safe control of expanding air traffic. Phase 1 - Development of basic air traffic control principles. Phase 2 - Development of recommendations regarding equipments and procedures required to implement the air traffic control principles.	Developed a plan for coordinated systems with bearing, landing, situation display, and airport surface navigation functions to be multiplexed on DME. Introduced the concept of digital computers with data links to constitute the automatic air traffic control equipment. Accepted an interim system which was essentially the system previously described by RTCA. The coordinated system was to require 15 years for complete development, installation, and training of operators, and was designated the ultimate system in contrast to the revised older RTCA plan designated the interim system.	22
1947 to Mar., 1948	Ad Hoc Committee on Navigation of the Joint Research and Development Board	Washington, D.C.	R. S. Damon	a) Determine the basic problems of military navigation of all types with regard to electronic aids. b) Determine what efforts have been made by the armed services to solve these problems in terms of research and development programs and the provision of experimental facilities. c) Ascertain the relation of the present military effort to solve the problems of navigation and control to that of the various civilian agencies active in this field. d) Recommend to the Joint Research and Development Board through the Committee on Electronics action that should be taken to promote safe and militarily effective navigation. e) Advise the Committee on Electronics on the feasibility of consolidating a national system of air navigation and traffic control with the air warning network.	Recommended the establishment of an organization for research, development, and standardization of the system described by RTCA Committee SC-31, the organization to be "An authoritative full-time planning and steering group consisting of a single representative from each of the departments of Commerce, the Navy, and the Air Force." This organization known as the Air Navigation and Development Board was established by a joint charter by the Secretaries of Defense and Commerce issued on November 2, 1948. It remained in existence until the Airways Modernization Board was established.	23
Jan. 11 to Feb. 26, 1949	Com. and Radio Aids Div. 3rd Session ICAO	Montreal	H. Costa	Foster further international standardization of certain navigation and communications facilities.	Specification for "The purpose of guiding development of UHF (1000 mc) distance measuring equipment accepted but not as an ICAO standard or recommended practice." Developed a GCA specification and refined further the ILS specification.	15, 19
Jan. 19 to Dec., 1950	Special Working Group 5, Air Traffic Control and Navigation Panel, Operational Policy Group - Air Coordinating Committee	Washington, D.C. Boston Wright-Paterson AFB Indianapolis USS Midway at Sea	A. W. Wuerker	To review and evaluate the SC-31 report, all air navigation and traffic control and navigation panel papers that deal with the common system, review and evaluate all available material pertaining to such items as the volume of present and anticipated air traffic and the characteristics of aircraft in use before 1963, and to establish operational policy and procedures for transition system implementation.	More than 200 persons participated in demonstrations and discussions. Work of this committee had the effect of bringing surveillance radar into use in daily air traffic control operations.	25
Apr. 24 to June 2, 1951	Comm. Div. of ICAO 4th Session	Montreal	R. Lecomte	Foster further international standardization of certain navigation and communications facilities.	Recommended where international air service required that 1000 mc DME be installed. Recommended extending standard Loran, Consol, and non-directional beacons for the long distance zone as required.	18
Mar. 9 to Apr. 9, 1954	Do 5th Session ICAO	Montreal	R. Lecomte	As above.	Recommended reviewing the operational objectives for standard long distance radio aids as established by COT Division. Recommended consideration of ground-air radio links known as air traffic control signaling system.	20
Early 1955 to Oct., 17, 1955	Special Working Group 13 Air Coordinating Committee	Washington, D.C.	Capt. Sam P. Saint	To find the way by which the advancement of U.S. operations can be brought about through the most modern operational and technological means.	Final report was published in March of 1957 and recommends use of defense radar in traffic control.	76
May 4 to Dec. 31, 1955	Aviation Facilities Study Group of the Director of the Bureau of the Budget	Washington, D.C.	Wm. Barclay Harding	Study U.S. Aviation facilities requirements for the next decade or two.	Recommended that a study should be made under the direction of an individual of national reputation with a broad understanding of civil and military aviation. President Eisenhower acted on this recommendation by announcing the appointment of General Edward P. Curtis on February 11, 1956.	77
May, 1957	System Engineering Team Office of Avia. Facilities Planning (Curtis Committee)	Washington, D.C.	Preston R. Bassett	To plan for meeting aviation facility needs in the U.S. for the next two decades.	Report of this committee described a new on the spot invention and was known as the Curtis report. In May of 1957, General Curtis wrote to the President recommending that the plan set forth by this committee be used as a basis for airways modernization and further that an independent agency known as "The Airways Modernization Board" be established. This Board was established on August 14, 1957, by public law 85-133. This Board remained in existence until it was absorbed as part of the Federal Aviation Agency which came into being on August 23, 1958, under public law 85-726.	27
Mar., 1957	Air Coordinating Comm.	Washington, D.C.	Louis S. Rothschild	To review the air traffic control systems and procedures in light of the introduction of jet aircraft and the existing defense situation.	Included the findings of Special Working Group 13 in a complete report which recognized Vortac and is the basis for the present air navigation and traffic control equipment program in the U.S. The Air Coordinating Committee was abolished on August 11, 1960, by executive order 10833.	26
1957	Working Group of European Air Space Coordination Committee of NATO	Paris		To study the problems of air traffic control in the upper air space over the six common market countries.	The six common market countries joined by the Benelux countries and Federal Republic of Germany joined by France and Italy drafted a convention to establish a permanent commission for air navigation security. The purpose of this organization is to standardize air traffic regulations, formulate common policy on radio aids, study technical progress on air navigation services, form an international agency to be known as Eurocontrol to provide air navigation services.	28
Feb. 10 to Mar. 2, 1959	Special Com/Ops/Rac Meeting of ICAO	Montreal	J. W. Stone	(Among others) to develop recommendations for standards and recommended practices and guidance material for short distance navaids.	Recommended that distance measuring equipment corresponding in principle to that specified by the U.S. (for its precision polar coordinate navigation system) should be adopted as the ICAO Standard for application as a complement to VOR.	78

zone, four-course radio ranges were installed [36] beginning in 1929. This equipment operated in the band of 200–400 kc. Since the number of equipments grew from 9 installations in 1929 to 378 in 1949 [37], it was necessary to reduce the power (and coverage) to allow for the use of the same frequencies simultaneously. Some LF nondirectional stations were installed in 1930 to mark the intersections of range legs but, beginning in 1939, these stations were replaced with markers [38] operating at 75 Mc. In 1938, however, it was required that aircraft carry direction finders, and as time went on, LF nondirectional stations were installed purely for use with these airborne direction finders. In Europe during the period extending to 1939, ground direction finders were the most important navigational facility. In 1937 there were seven direction-finder nets in Europe [39], each employing three stations for giving positions to aircraft from ground observation. At that time, however, eleven additional ground direction-finder nets were planned for installation. Upon outbreak of the war, about 100 four-course radio ranges were installed throughout the world. Fig. 1 shows the facilities installed for navigation in this short-range zone. While the RTCA 1945 meeting [11] had considered that the four-course radio ranges would be obsolescent in 1950, only 56 of these stations had been decommissioned by 1959.

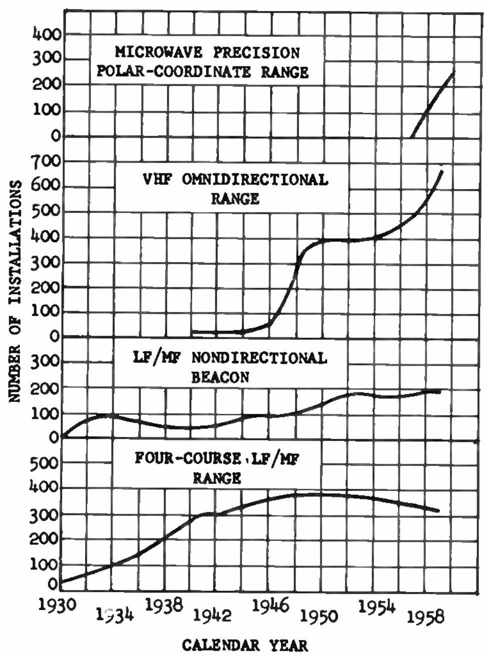

Fig. 1—Navigation equipment of the short-distance en route zone.

VHF radio ranges employing two visual and two aural courses [40] were installed beginning in 1940, but were later replaced with omnidirectional radio ranges. The VHF omnidirectional radio range (VOR) [41] program became an important factor in navigation for the United States short-distance en route zone in 1948, at which time over 300 units were installed. By 1959 the number had increased to 661 [37]. By 1960 the number of VOR's in other parts of the world had reached 279 stations. The mainstay of international navigation is the nondirectional beacon used with airborne direction finders. Over 200 stations are in operation at the time of this writing.

The RTCA program of 1945 envisioned the installation of a precision polar-coordinate system in 1955. Some installations were made by the military prior to that time. However, the civil program [24] began in 1957. By the end of 1960 this program totaled 343 stations. These stations (when commissioned) provide distance measurement to VOR equipped aircraft and precision bearing and distance to aircraft equipped with the complete microwave (Tacan) system [42]. Largely, due to installation by the military, about 170 precision microwave polar-coordinate ranges were in operation in other parts of the world (mainly in Europe).

3) The Approach and Landing Zone: Development of a so-called "blind landing system" was begun at the Bureau of Standards in the U. S. as early as 1928 [43]. A contract for a new development was placed by the Civil Aeronautics Administration in 1938 [44], but by 1941 the U. S. did not have ready for use a satisfactory low-approach system. In Europe in 1932, the Lorenz Company began development of a low-approach system [45] based on that outlined by the Bureau of Standards, and by 1939 this system (termed Standard Beam Approach System) had been installed throughout Europe and in some locations in South America. With U. S. entry in the war, the CAA development was completed by the U. S. Army Air Corps [13], and 500 equipments were manufactured in the period from 1942 to 1945. Installation of this equipment for civil use was begun in 1945. By 1959 a total of 174 stations [37] had been commissioned in the U. S. ILS was one of the first systems to be adopted as a world standard by ICAO in 1946 and more than 154 stations are installed external to the U. S. The world program is scheduled at 208 stations. A radar-beam approach system [46] was developed by the Radiation Laboratory of the Massachusetts Institute of Technology during the war and approximately 200 units were constructed prior to 1946. Installation of these devices for civil use began in the U. S. in 1947, and by 1959 a total of 11 were in operation [37]. The number in use by the military is far greater. Approximately 40 installations are in operation external to the U. S.

4) The Airport Zone: Little work has been done to install an effective guidance and control system for the airport zone. At the time of this writing, 10 radars operating at wavelengths of less than one cm have been installed in the U. S. for the purpose of detecting the movement of aircraft located on the surface of civil airports.

B. Type II Equipment

This equipment constitutes the means whereby a central decision-making agency may be able to know the position of all aircraft within its jurisdiction. From the time of the inception of air traffic control in 1935 to the war years, the only means provided for this purpose were reports by the pilots via HF radio transmitters. An airline pilot would report his position to a ground radio station owned by his company. The company personnel would, in turn, through the use of land-line telephony (often via a direct wire), pass the information to the local traffic control center. A similar procedure was followed for some of the military. Private flyers could, through the use of a frequency of 3105 kc, report their positions to LF radio range stations and could receive replies via the stations' normal navigational frequency. Communications were established from the aircraft to airport towers via the HF transmitter, and instructions from the tower were received on a frequency of 278 kc. About 1940, the airlines of the U. S. placed orders for VHF airborne equipment. However, the airline developments were taken over by the military prior to the U. S. entry into World War II. The RTCA had on February 8, 1937, discussed the desirability of employing VHF frequencies to replace the 278-kc communications used in airport control work [47]. Shortly thereafter, the U. S. Bureau of Air Commerce (the predecessor of the CAA) undertook tests at 125 Mc.

Aircraft positions could have been determined on the ground by networks of HF direction finders (as in Europe), and some work toward developing and installing such systems was conducted in the U. S. prior to World War II; however, these installations never became fully effective.

In the post-war era, RTCA Committee SC-31 recommended the utilization of primary radar [22] for the purposes of equipment of Type II as part of the interim system. For the ultimate system, it recommended the development of an elaborate secondary radar system. Special Working Group 5 [25] of ACC stated, "of all the aids now becoming available, airport surveillance radar is capable of making the most significant contribution toward increased safety and efficiency of operation." As a consequence of this recommendation, the CAA augmented its ground radar program. By 1959, 48 radars [37] were in operation in the U. S. serving the purpose of Type II equipment. The Standards and Recommended Practices of ICAO [19] first mentioned performance of surveillance radar in 1949, and this equipment is installed at civil airports throughout the world where heavy traffic is experienced. In the U. S. in 1957 Special Working Group 13 recommended [26] the inauguration of a program whereby information from military radars would be employed for civil and military air traffic control. This program was implemented, thereby greatly increasing the total radar coverage available for traffic control purposes.

The most significant change in means of Type II was the introduction of VHF communications between aircraft and control centers. The installation of such a system was begun in the latter part of 1950. Of course, transoceanic air traffic must continue to utilize HF communications although tests with directional arrays on the ground to provide communications with jet aircraft have shown ranges [48] over the North Atlantic up to 600 nautical miles. In Europe, some VHF direction-finding networks are employed to determine aircraft positions. In the U. S. (based on SC-31 recommendations), VHF and UHF direction finders [49] are used as a means for assisting in the identification of targets appearing on the radar scopes.

C. Type III Equipment

This equipment constitutes the means whereby the decision-making entity can determine instantly safe, nonconflicting flight procedures for all aircraft within its purview. As this is written, these means [50] are nonelectronic. By means of manual time and distance computers, the traffic controller determines when an aircraft will be over some specific fix. Another device is the flight progress strip. These strips list the number of the flight, altitude, and other pertinent information and fit into racks in time sequence of arrival over a check point represented by a rack.

D. Type IV Equipment

The means whereby safe, nonconflicting instructions are transmitted to the aircraft are the same means that are used for the pilot to report his position. That is, until the war years, communications from the ground to the aircraft took place via "company" or military stations via HF and to itinerant flyers via the LF radio range stations or LF tower stations. After the war, instructions were transmitted to pilots largely via VHF voice transmission except for transoceanic aircraft. Voice is also available on some VHF navigational aids. During the war the British developed an indicator signaling system [51] operating at VHF frequencies. This system was known as "Beechnut" and in the United States there was a parallel development called "Voflag." By means of this system, a series of pulses transmitted to the aircraft would cause visual indicators in the cockpits to appear with clearance messages inscribed on them (such as hold, proceed, climb, etc.). A system of this type was recommended by the RTCA meeting of 1946 for installation in 1948 but was never implemented.

E. Type V Equipment

The means whereby action may be coordinated among the several central flight-instruction, decision-making entities is of two different types. One of these is by direct-wire telephony (referred to as interphone). The second means is the teleprinter. In 1937 only 57 miles of interphone system were employed in the U. S. connecting 57 stations. By 1960, 167,821 miles of interphone were in use serving 4564 drops. The first interphone for control tower purposes was installed between 114 stations in 1939. By 1960, 404 stations were connected over a network of 49,906 miles. In addition to the wire service in the U. S., under the auspices of ICAO, radio teleprinter is being employed between many countries and a cable system is in process of installation between Canada and the United Kingdom to serve the needs of international air travel.

F. Conclusion

From the foregoing description of the equipment which constitutes the *air traffic control equipment subsystem*, it is evident that rather than to speak of it as a "system" it would be more accurate to say that it is an agglomeration of units with man providing the necessary flexible interconnections. The coordinated system mentioned in the Congressional Report of the 80th Congress and described in detail by RTCA Committee SC-31 was never implemented. SC-31 found that a factor of merit no greater than 67 per cent would result if the procedure employed was that of adding units to existing units, but its findings have not been heeded.

III. Forecast

Since events like those listed in Table I[1] doubtlessly will dictate the future systems, it is not possible to make a forecast with any degree of confidence. Therefore, the following is based on known developments and prejudices with which the reader may freely disagree.

A. Type I Equipment

This equipment is the navigation means for the four zones as follows:

1) The En Route Long-Distance Zone: The COT Division meeting in 1947 [12] found no system that could justify universal adoption, and looked to new developments to fill the requirements. In the years that have ensued, several systems [35], [53], [54], [55] have been developed which could meet most but not all of the requirements, but these newer systems have not been adopted. The lack of action in providing these aids leads to the conclusion that they have not really been needed. Yet air traffic control over the North Atlantic suffers from the necessity of each aircraft being spaced by departure times alone and, therefore, each carries with it thousands of cubic miles of air space. The increase in traffic will force the adoption of some aid. At the moment, tests are in progress attempting to determine the success of a VORTAC installation aboard weather ships. A VHF aid is advantageous for air traffic control use because it is unaffected by atmospheric and propagation anomalies such as those associated with the aurora borealis. It would be readily possible to install radio ranges capable of reception on existing equipment and operating in the VOR frequency band. It is predicted that transoceanic aids, at least for the North Atlantic, will utilize a technique similar to that of the present short-distance aids. Some loran C [35] installations are being made in various parts of the world. This device has been shown to have a ground-wave range over water of 1700 miles in the daytime and 1200 nautical miles at night, with probable errors of the order of 0.1 to 0.2 μsec. Sky-wave ranges are greater with correspondingly greater errors [56]. With such outstanding performance, then, what is the probability of loran C being accepted as the international standard? One can readily picture an international conference at which the proponents of the system would outline its range, accuracy, and the existence of certain networks. The opponents of the system would bring out 1) airborne equipment complexity and weight, 2) susceptibility of the low frequencies employed to propagation anomalies, 3) the necessity for locating cooperating stations in different countries (therefore, not under the control of a single responsible agency), and 4) the lack of automaticity and difficulty of adaption to computers and displays. The outcome of these discussions would lie solely in the laps of the techno-political gods.

In recent years there have been installations [57] of Doppler navigators [59] on transoceanic aircraft and also the development of inertial systems. There have been some forecasts [58] that these self-contained aids will replace the ground-based aids. While the Doppler navigator often ceases to function over calm water and its accuracy is dependent on the accuracy of the heading device employed [60], its ability to give ground speed and track makes it a valuable aid even though it is not associated with a positional computer. Inertial systems, although corrected by Schuler tuning so that their average errors [61] may be small, may at times have large instantaneous errors. The accuracy of the heading information which inertial systems provides has been sorely needed for flying ever since instruments were put on aircraft. Self-contained aids are not new to long-distance flying. The octant and the high-altitude altimeter have produced navigational performance of comparable accuracy to that provided by the Doppler and inertial systems, although not as conveniently. ICAO in the 6th Session of its Communications Division [79] said that it is extremely doubtful whether these aids alone could meet the needs of air traffic control. It is predicted, therefore, that both Doppler and inertial systems will become standard equipment on all aircraft that traverse the long-distance zone, but the requirement for ground-based aids for traffic control will not diminish.

2) En Route Short-Distance Zone: Experience of many years has shown the desirability of employing in this zone a precise navigation system and a homing device. With time, it is believed that the VORTAC system will perform the same function as that performed by the two older systems. As pictorial and course-line com-

[1] In March, 1961, President Kennedy issued a directive calling for a scientific, engineering review of aviation facilities and related research and development. This effort, known as "Project Beacon," was under the chairmanship of R. R. Hough. As of November 1, 1961, the report of this committee had not been made public.

puters are installed in aircraft, the desirability of obtaining both bearing and distance from the Tacan portions of VORTAC [62] with its higher accuracy [63] and lack of course scalloping will become evident, while the VOR will serve as a homer and for communications. It is forecast, therefore, that VORTAC will be the navigational aid for the short-distance en route zone for the next thirty years. Should it become necessary, it is possible to increase the accuracy of Tacan by one order of magnitude without too great a modification of the equipment.

3) The Approach and Landing Zone: To permit fully automatic landings in the fourthcoming years, there will be additions of equipment (such as the radio altimeter) and other improvements to the present low-approach systems. A large directional array has been developed [64] for use with the ILS (fixed-beam low-approach system) and has been in use by the U. S. Air Force for some time. The employment of this array so improves the localizer course that the use of automatic pilots for landings will force its adoption. Again, however, the necessity for using the localizer frequencies of 108 to 112 Mc for communication will force the replacement of this localizer with a similar device operating at a higher-frequency band.

The use of the frequency of 329.3 to 335 Mc for the glide slope equipment of the ILS has long been a detriment to optimum performance [65]. In the future, then, it can be expected that this equipment will be moved to a higher frequency (of the order of 5000 Mc). At the same time, techniques will be employed which will allow for selective glide slopes suitable for VTOL aircraft.

With the adoption of fully automatic landings [66], the radar low-approach system takes on greater significance. It will be mandatory that each automatic landing be monitored from the ground by a radar low-approach system. The radar low-approach systems currently in use have a data rate that is too low, and the complex wartime development has been made still more complex. It is predicted that the future will see the development of a simpler automatic landing monitoring ground radar with improved performance over anything heretofore employed for this purpose.

4) The Airport Zone: With improvements in en route flying and automatic landings, the bottleneck to the movement of aircraft will be at the airport. This bottleneck will so reduce the return from the high airport investment that a revolution will literally be caused in the development of navigation and control systems for the airport zone. A special signaling and detection system will be developed for operation on the airport surface so that aircraft may be guided to and from the loading ramps at top speed.

B. Type II Equipment

It has been shown that the means which has been enjoying the greatest increase in popularity in recent years and whereby the central decision-making agency may know the position of all aircraft within its purview is the surveillance radar located on the ground. At the same time the inherent weaknesses of the ground surveillance radar (even though it may be improved to indicate altitude) are very well known. Its data rate is too low; it is unable to determine the identity of its targets; targets are frequently obscured by precipitation and ground clutter, yet if MTI (moving target indicator circuit) is used, then orbiting aircraft disappear [67]. If the radar output is to be connected to a computer, it must be equipped with complex track-while-scan circuits. After all, radar is a development of twenty years ago and should be obsolescent. To remedy some of these defects, an airborne transponding beacon [68] was recommended by SC-31 and the combination of radar and beacon was to be obsolescent in 1961. The development of the beacon has been in process since at least 1948 and it appears only now that it will become standard for air-carrier aircraft. The primary radar program, even with beacon, is an example of a program that is "too little too late." There is in the U. S. a large network of defense radar that is now being used to furnish traffic control information. If the air-breathing threat to the nation's defense is determined to have disappeared, there will be no use for this radar [69] system except for traffic control. It might be argued that the high cost of telephone line rental from these radars, together with the high cost of maintenance and operation, would render this defense radar network uneconomical for traffic control use alone.

The above arguments tend to forecast the disappearance of primary radar in the air traffic control system, but quite on the contrary, radar is the only device that will be available for some time for this valuable purpose; consequently, it appears very certain that ground surveillance radar will be in the traffic system for at least thirty years hence.

The use of VHF reporting of position via voice will not disappear. Quite on the contrary, this system employed with high-accuracy ground direction finders [70] attached to digital computers will form a valuable aid, particularly to track those aircraft which will not be equipped with radar beacons. The importance of VHF for voice will render the proposed air-to-ground automatic reporting link [71] on these frequencies obsolete before the system ever comes into use. If, for no other reason than the fact that the airborne distance-measuring equipment interrogator has frequencies which are lightly used, air-to-ground automatic reporting will eventually find its place as a simple adjunct to this equipment [72]. As the interrogator performs its normal function in cooperation with already installed ground stations, the identity, altitude, and position of the aircraft will be conveyed to the ground where, over already existing telephone lines, this information will be relayed to traffic control centers.

C. Type III Equipment

An accurate forecast of the means by which the central decision-making entity of the future will determine nonconflicting flight procedures for all aircraft within its purview is that this equipment will consist of an electronic digital computer associated with suitable displays for which the man-machine relationship has been adequately solved. Such a forecast, although accurate, has little meaning unless the philosophy governing the procedures by which the aircraft would be operated is also forecast.

Perhaps the basic conditions underlying the air traffic control problem can best be understood by contrasting them with those for railroad operation. At each railroad terminal there are many sidings where the trains may be loaded and unloaded, but once out of a railroad terminal trackage is expensive and many miles of railroad right-of-way consist of only a single pair of rails. The condition just described is diametrically opposite to that for air operations. Airports require vast areas and very expensive runways. Only very few runways are present at the largest of our airports. Once away from the terminal area, however, the aircraft has unlimited space. If one observes the total number of aircraft in a flight between New York and Washington (over the world's heaviest density area), only very few aircraft will be seen during the entire flight. Why then is there an airways traffic control problem? It has been shown that if aircraft are allowed to fly at random that the probability of collision is very small. This probability is greatly increased by compacting aircraft on airways. A few freethinkers [73] in the air age have been pointing out that if the aircraft can be equipped with an effective collision avoidance system, they could fly where they will and in any number desired with a lower probability of collision than exists with the present system which is subject to error. It is not forecast that airborne true collision-avoidance devices will become practical within the next twenty to thirty years, although proximity and collision warning devices may come sooner. Experience at sea has shown that a mere proximity detector only increases the danger of collision. However, it is readily possible to develop and install a highly effective ground-based collision-avoidance system [74]. With the position reports relayed to a digital computer on the ground via the data links previously described, it is possible to send the pilots a proceed signal or a signal indicating a collision-avoidance maneuver. It is believed, then, that the future will see the elimination of the airways and the installation of ground digital computers which take their information from air-to-ground links that are automatically relaying the position of aircraft.

The above forecasts one type of digital computer but it has been pointed out that the difficult air traffic control problem lies not on the airways but at the terminals, so it is necessary to suggest the character of the digital computers that will solve the terminal problem. The popular solution to the terminal problem which has been proposed by many electronic engineers is to control (restrict) the traffic along the airways in order to solve the terminal problem. This control procedure is completely at variance with the characteristics of the aircraft and would force the aircraft to operate in such a manner as to solve the problem of the electronic engineer or the controller rather than solving the problem for the aircraft. It is conceivable that the aircraft at the terminals could be controlled entirely by automatic means. However, at terminals many instances occur which are the sources of potential accidents, and to allow for all of the possible contingencies that might occur, it appears that the present manual procedures which have been laboriously worked out through the years in actual practice will form the best basis for future operations. There is no reason why a very large amount of automation should not be applied. The communications systems between controllers are crude and the display systems have had no appreciable development to adapt them to the tasks for which they are used. It is forecast, therefore, that there will be a substantial automation assistance to the terminal air traffic controller in the future. Digital computers will update flight progress and compute release times for various terminal points and in other ways will relieve the controller of much of the labor, thus giving him a far greater degree of accuracy of control than he now has time to exercise. The machine will be used to monitor the actions of the controller [75] rather than vice versa.

D. Type IV Equipment

It is forecast that VHF communications will continue to be an important means whereby the instructions will be transmitted to the aircraft. There has been standardization among the military services of an indicator signaling ground-to-air link operating at UHF frequencies. Aside from the frequency space that is occupied by this type of communications, the weight and space penalty paid in the aircraft for its adoption is not great. At the same time, the amount of information to be transmitted from ground-to-air (in contrast to that required for transmission from air-to-ground) is not required to be too extensive. Data link from ground-to-air at VHF frequencies, therefore, will probably be adopted. Data link at 960 and 1215 Mc from ground-to-air has been demonstrated to be satisfactory and could serve for the collision-warning link, which has been mentioned in the previous section, to bring the output of the collision-avoidance computers to the aircraft.

E. Type V Equipment

If aircraft on the airways are to be allowed to fly as they wish only under the surveillance of ground-installed collision-warning systems, it will be necessary that these systems be capable of passing positional information from one to the other. The art of machine talking to machine is being developed rapidly, and such a system would be installed with the collision-avoidance system previously described. By relegating airways traffic control to the fully automatic means, the amount of information to be passed between terminals would be greatly reduced. Thus, there would be no need for an extensive augmentation of the teleprinter network which now connects terminal to terminal. By the use of indicator-type signaling directly to the face of the controller's console, much of the present voice communications via interphone would be eliminated.

F. Conclusion

The foregoing forecast is not based on any new and startling technological breakthrough. Having read in the public press for these many years of the seriousness of the traffic control problem, the reader might tend to conclude that 1) important technological breakthroughs have for years been awaited in order to solve this problem, and 2) that the writer is forecasting that the problem is unlikely to be solved. Neither of the above conclusions is correct. Quite on the contrary, the technology necessary to solve the problem has, since the war years, existed in a sufficiently advanced state to permit solution. The traffic control problem has not been solved because it consists in establishing agreements and actions among groups with divergent ways of thinking and divergent aims. It is hoped that in the reasonably near future these groups can agree on a common ***modus operandi***, for only this action is required to solve the traffic control problem very quickly.

Space Navigation*

ALTON B. MOODY†

Summary—**In space a successfully navigated craft must not only reach its intended destination, but must arrive there at the right time for rendezvous, and with a suitable velocity vector. Power limitations impose severe restrictions upon the amount of maneuvering that can be performed. Navigation techniques differ somewhat during the escape phase, in the vicinity of a planet and its natural satellites, during the midcourse phase of an interplanetary flight, and during the terminal phase. The most useful coordinate system is radius from a celestial body and some form of "latitude" and "longitude" on the sphere thus defined. Quantities measured are speed, direction, distance, acceleration, angles, and time. Of these, speed and direction of travel cannot now be measured to navigational accuracy. Position in space can be determined electronically, optically, and by inertial navigation, each under suitable conditions. Use of physical phenomena is not promising. A general-purpsoe digital computer will be needed. No order of magnitude improvement in state of the art is needed to produce a first-generation fully automatic space-navigation system, but considerable development work is required.**

INTRODUCTION

The Problem

NAVIGATION on or near the surface of the earth is usually considered successful if the craft arrives at the desired destination by a reasonably expeditious route. In contrast, space navigation is successful only if the space craft arrives at the desired destination at the right time to effect rendezvous with its target, and with a suitable velocity vector. The probability of recovering from a major mistake is remote.

The lack of adequate power to launch large payloads and provide the thrust needed to control their motions in space and return them to earth constitutes the principal limitation of space travel. It also dictates the requirement that the accuracy and reliability of any navigation system be very high. With a more satisfactory solution of this problem will come greater flexibility in space travel.

Space craft have been guided during powered flight extending over the first few minutes after liftoff. Following initial cutoff, positions near the earth have been determined by means of tracking facilities on the earth, and limited changes in orbits have been made by command from the earth. This is the extent of space navigation to date.

For the foreseeable future, space navigation can be considered in several phases or areas: 1) during escape, 2) near a planet and its natural satellites, 3) midcourse portion of a flight to another planet, and 4) terminal phase to an orbit or soft landing. Purposeful interstellar

and intergalactic flights, and beyond, will have to await the development of more efficient fuels and the solution of other formidable problems.

Kinds of Navigation

Terrestrial navigation techniques are often conveniently classed as piloting, dead reckoning, or celestial. The same classifications can be useful in space.

Piloting: Piloting is position determination relative to one's environment. Traditionally, it has involved the use of bearings, distances, map-matching in some form, etc. A prior survey to locate accurately the various landmarks used is essential. The application of electronics to navigation during the present century has largely eliminated the visibility limitation and has extended the range to provide coverage over much of the ocean areas.

Dead reckoning: Dead reckoning involves the extrapolation of a known position in accordance with assumed or anticipated motion during a given time interval. The basic elements of dead reckoning are velocity and elapsed time, or direction and distance. The fact that the velocity vector in space travel may be varying continuously does not alter the basic concept of dead reckoning.

Celestial navigation: Celestial navigation is usually defined as navigation utilizing celestial bodies. It is similar to piloting in that position is determined relative to points on the surface of the earth. But in celestial navigation these points, each vertically below a celestial body, are constantly in motion as the earth rotates. Thus, real time is involved even if the observer is stationary.

In space travel the use of any celestial body for navigation is usually considered celestial navigation. However, when celestial bodies are used as lighthouses and position is determined relative to them, the technique might more properly be considered a form of piloting.

Navigation Techniques

Escape Phase

Whether the escape phase starts at the launching pad, at a mobile launching site, from an orbit around a planet, or from a natural satellite, the position at the start of a space flight is known accurately. During the initial stage of such a flight, the desired trajectory is determined in advance. Position may be determined from measurements made either from the planet or aboard the space craft, but any detected deviations from the precomputed flight path can be corrected. When the desired velocity vector has been achieved, power is cut off and the space craft is on its way. The accuracy with which navigation is performed during this phase of the flight establishes, in large measure, the requirement for corrections later. For instance, it has been determined that, for a flight from earth to Mars, no subsequent correction will be needed to pass within 10,000 miles of Mars if the cutoff speed is accurate to 16 ft/sec and initial direction of travel is correct to 0°.01.

In the Vicinity of a Celestial Body

Here navigation consists primarily of determining position relative to that body or some part of it. In its usual form it consists of determining the distance from the body and the point on the surface of the body over which the craft is located. Position may be determined either by tracking from the surface of the celestial body, or aboard the space craft. Power is applied as needed to produce desired changes in the orbit.

Midcourse Phase

Normally, the time and place of rendezvous with the destination celestial body is determined in advance. With present chemical rockets of relatively low specific impuse, the planned trajectory is invariably a minimum power ellipse. In flight the position of the craft may be monitored by determination of position from time to time and comparison of this with the scheduled position. This is similar to commonly used techniques on the earth with one significant difference. As long as a terrestrial craft remains on the desired track and progresses toward the destination, it will arrive in due time. If the craft is ahead or behind schedule, the only effect is a revision of the estimated time of arrival (ETA). The original ETA can be maintained if the speed is decreased or increased as needed. In space navigation time is important in another way because the destination is not a fixed point and will be at the rendezvous point only for an instant. A change of speed of the space craft will change its orbit and may increase the discrepancy.

When discrepancies between the precalculated [dead-reckoning (DR)] position and the actual position are established, at least three possible correction techniques are available. The first is to return to the original schedule. To minimize the amount of fuel required, the return might be scheduled over a period of time. Several weeks is not unreasonable during an early portion of a flight of several months, but, if the period of time is too long, the delay in determining the effectiveness of the maneuver might result in a still larger correction later. If small continuous thrust were available, correction of DR positions might be essentially a continuous process. This technique requires a minimum of computation, but is somewhat wasteful of fuel. Fuel expenditure might be minimized by planned undercorrection to avoid possible overcorrection due to errors in position determination.

A second technique of correcting a discrepancy is to increase the correction period until it occupies the entire time remaining until rendezvous. To do this accurately involves the determination of a new orbit from the present position to the originally planned time and position of rendezvous. This is less wasteful of fuel but imposes a more severe computation problem. The thrust vector needed to change the present orbit to the new one requires computation of the present orbit. This may be determined, in increasing order of difficulty, by 1) present heliocentric position and present velocity vector, 2) three positions of the craft, or 3) two positions of the craft and the elapsed time between them. Although the first involves the simplest computation, the determination of present velocity vector can probably not be determined with adequate accuracy.

A third technique of correcting a discrepancy is to compute the new orbit to a new rendezvous point so as to involve minimum fuel requirements. If this computation proves to be beyond the capability of the computer aboard the space craft, solution might be obtained by a trial-and-error process, selecting successive rendezvous points (and corresponding times), until a minimum fuel expenditure is found to change the orbit from the present one.

A completely different technique for the midcourse phase involves the homing principle. Instead of following a precomputed ellipse from the origin to the destination, the craft travels first to some identifiable line through the destination, and then remains on this line until it reaches the destination.

Of various possible homing techniques, one that appears attractive for an interplanetary flight involves the radial line from the sun through the destination planet. The craft first follows an elliptical orbit until it reaches some plane through the radial sun-planet line. For minimum fuel consumption, the space craft should arrive in this plane with the same angular velocity as the destination planet, and with just enough radial velocity to reach its orbit. A properly directed thrust within the plane then moves the craft to the radial line between the sun and destination planet. The craft then applies thrust to eliminate motion across the radial homing line. Short periodic bursts of a chemical rocket may be adequate to keep the space craft approximately on the radial homing line, but the method will become much more attractive when low-thrust, high specific-impulse power plants, such as ion or plasma-jet propulsion, become available. It has been calculated that a continuous thrust of as low as 6×10^{-5} g is adequate to utilize this technique on a flight from earth to Mars. If the plane through the radial sun-destination planet line is also through the origin of the flight, one step might be eliminated.

One advantage of the homing technique is the simplicity of navigation involved. Once on the homing line, the craft need determine only that it is on the required line and moving in the right direction along this line. Position on the line might be determined by any device capable of accurately measuring angles near 0° or 180°. Crude successive measurements of distance or position would be adequate to establish the direction of motion if any reasonable doubt existed. Such position or distance measurement would be useful for establishing ETA at destination, but time would not be significant in terms of making or missing rendezvous.

Another advantage of this technique is that the destination planet might be approached at any desired speed, resulting in as much time as needed for making decisions and with relatively simple navigation during the terminal phase. In fact, along the radial approach line there exists a point where the centrifugal force and the gravitational attraction of the sun and destination planet exactly balance. A space craft could remain at this point indefinitely, with very small thrusts from time to time to correct for slight drift from this position. In approaching Mars from the earth's orbit, this point is some 600,000 nautical miles from Mars. This might well be used as a staging point for reconnaissance flights closer to the planet.

Terminal Phase

As the destination is approached, the leisurely tempo of the midcourse phase changes. The coordinate system is shifted from heliocentric to one centered on the destination object. Higher accuracy is needed, and this at a time when the astronaut may be subjected to relatively high g forces after having been weightless, or essentially so, for a long period. If the approach is from an elliptical path, computation of the space craft's orbit is made to determine the closest point of approach. As the path of the craft changes from a heliocentric ellipse to a hyperbola around the destination planet, the terminal phase is entered. Unless the closest point of approach is dangerously close, no thrust is applied before this point is reached, but the axis of the retro rockets is aligned with the velocity vector at the closest point. At this point sufficient thrust is applied to bring the space craft to the desired distance at the opposite side of the planet, and at this point additional thrust is applied as needed to produce the desired orbit. From this orbit a landing is made, if desired, by the technique selected in advance.

An alternative technique is to correct the approach orbit at some distance from the destination planet so as to arrive at the closest point of approach at the desired distance, and then apply the required thrust at this point to place the space craft in the desired orbit.

Measurements in Space

Quantities Measured

Space navigation involves determination of speed, direction, distance, acceleration, angles, and time.

Speed: Speed is a basic element of dead reckoning. In space navigation a knowledge of the velocity vector and position of the craft provides the information needed for a relatively simple determination of the orbit of the craft. Unfortunately, the determination of speed at any time during a space flight is not easily accomplished. Average speed between two established positions can be computed by means of the distance and elapsed times between the positions.

Rate of change of range can be used to compute speeds. In the vicinity of a celestial body, rate of change of range might be established by means of radar, providing radial speed determination with an error of the order of 1 per cent. Relatively close to a celestial body, the Doppler effect of a reflected CW signal can also be used to determine radial speed to perhaps 0.5 per cent, but with error introduced by unevenness in the surface of the celestial body and pointing error of the antenna if the beamwidth is less than the angle subtended by the body.

During periods of acceleration, either positive or negative, the speed increment can be determined by integration of acceleration.

Direction: Direction of travel, together with speed, constitutes the velocity vector which, with time, forms the basis of dead reckoning. Celestial bodies are used as references to indicate directions. Simple angle measurement related to such bodies can be used to determine the orientation of the space craft, but no technique is available for measuring directly the direction of motion of the craft to navigational accuracy. Measurement of the Doppler effect of radiation, such as visible light, from stars in different directions, or the observation of starlight, might provide a rough approximation. The most satisfactory method is probably the determination of direction from successive positions of the craft.

Distance: Distance traveled is a product of speed and elapsed time. Without knowledge of speed, the astronaut can resort to determination of distance by means of successive positions of his craft and elapsed time. When the space craft is moving toward or away from a celestial body, distance traveled relative to that body can be determined by successive measurement of distance from the body and elapsed time.

Distance from an object, particularly the celestial body forming the origin of the coordinate system in use, is a useful quantity in determining position. In the vicinity of a celestial body, distance from that body can be determined by radar, either primary or secondary, mounted either in the craft or on the celestial body. If mounted in the space craft, power requirements might be prohibitive, but could be reduced somewhat by use of relatively long pulse length. Slant range of a stable oscillator, either aboard the space craft or on the surface of the celestial body, can be determined by means of the frequency shift due to the Doppler effect, if the space craft is orbiting the celestial body within a few hundred miles of its surface. From a known point on the surface of a celestial body of known radius, the position of a space craft relative to the background of stars can be used with elevation angle to determine distance. Several indirect methods based upon observations of bodies of the solar system are discussed later, under position determination. A method useful over a wider range of distances is to measure the apparent angular diameter of a celestial body of known linear diameter. If the apparent diameter can be determined to an accuracy of one second of arc, the uncertainty of range from the sun at the distance of the earth will be about 42,000 nautical miles. At 100,000 miles from the earth, the error for the same accuracy of measurement is about 7 miles. An error as small as $0''.2$ may be possible in the measurement of diameter by optical means, and even smaller errors might be attained by the use of interferometer techniques. However, some error would be introduced by uncertainty or irregularities in the edge of the celestial body measured, and for accurate results some care might be needed in measuring the correct diameter in the case of a highly oblate body. A large error might be introduced by optical measurement of the apparent diameter of a body illuminated by reflected light if any part of surface toward the observer were in darkness, but this error might be reduced by use of infrared instead of visible light. The error by this technique increases with distance from the body.

Acceleration: Acceleration measurement during periods of thrust application is needed to establish the cutoff time. It is best determined by direct measurement, using suitable accelerometers. This is the primary function of an inertial guidance system during space flight.

Angle: Angle measurement is needed for determination of postion and for determination of the orientation of the space craft.

If the arc to be measured is small enough to be entirely within the field of view of the optical instrument, it might be scaled directly, using the reticle of the instrument. Another method would be to expose a photographic plate, as is frequently done at optical observatories on the surface of the earth, and use an optical micrometer to measure the arc on the developed plate. This would have the advantage of providing a permanent record of the measurement.

A somewhat different technique is required for measurement of angles between widely separated bodies. This might be done by pointing one telescope or star tracker at each body and measuring the angle between the axes of the two instruments. A single instrument could be used if some means were provided for marking the first line of sight. The space craft itself, if not rotating, might provide a sufficiently stable reference. A gyroscope is another possible means of marking the first direction while the optical axis is shifted to the second body. Mirrors or prisms might be used to bring the two bodies into optical coincidence, as is done in a sextant. Methods applicable at particular times might be used when one body of the solar system passes in front of or across the face of another body, or a photograph might be used to determine the position of a body relative to its background of stars.

Direct optical measures are perhaps the most accurate, errors as small as $0''.2$ or less probably being practical. Such measurements in space are free from the troublesome effects of atmospheric refraction. However, they are subject to several errors, as follows.

1) Optical center: Observation, to be accurate, must be made on the center of a celestial body. When only part of the surface is illuminated, or if the albedo differs over the exposed surface, an error is introduced. The complete elimination of this error may not be practical,

but the use of infrared instead of visible light might increase the accuracy. A somewhat similar error may be introduced when a double star is observed.

2) Motions of bodies of solar system: An appreciable time is needed for light to travel from the celestial body to the observer, during which the body moves a short distance. This is easily corrected by allowing for the time of travel of the light.

3) Aberration: A celestial body observed perpendicular to the direction of travel appears to be displaced in the direction of motion of the observer. This can amount to an error of several seconds of arc, but if the speed is known to 0.1 nautical mile per second, and the direction of travel is known to within a few degrees, the correction can be computed. One advantage of photographing a body against the background of stars is that no correction need be made for aberration because all bodies in the line of sight are displaced together.

Time: Time is needed for determining position by measurement of relative positions of bodies of the solar systems, for comparing a precomputed dead-reckoning position with a measured fix to determine the extent of any discrepancy, for determining future positions of objects when an orbit to a rendezvous point is to be computed, and for determining speed by means of distance traveled between two positions with a known elapsed time between them.

An ordinary high-grade chronometer should provide time to an accuracy of one part in 10^5. This is adequate for many purposes of space navigation. For greater accuracy, a quartz-crystal clock might provide time with an error as small as one part in 10^{10}, or slightly smaller. For even greater accuracy, of perhaps one order of magnitude or better, an atomic clock might be practical. Fast moving bodies of the solar system, such as the inner natural satellites of some of the planets, provide a means of determining time if the position of the space craft is known. Relative positions of various bodies of the solar system can be used by any of several techniques discussed under Position Determination.

Position Determination

The Situation

Position determination in space is analogous to position determination on the surface of the earth, with two significant differences:

1) *Third dimension:* On earth navigational position is essentially two-dimensional. The third dimension, the radius vector of the earth, is established, and minor variations due to location of the craft above or below this surface are too small to be significant. Because of the need for determining the third dimension in space, three quantities are needed to define a position. Where a single observation on earth provides a line of position, in space it defines a surface. On earth the intersection of two lines of position define a point, and, where lines intersect in more than one point, a third line may be used to eliminate the ambiguity. In space the intersection of two surfaces of position provides a line of position, and a third surface may be needed to resolve an ambiguity. An additional surface with a different origin is generally needed to establish a position in space.

2) *Time:* On earth time is needed for celestial navigation because of the rotation of the earth. It is not needed for piloting, except as it affects the motion of the craft. In space the opposite is generally true. Unless a position is desired relative to a particular place on a celestial body, time is not needed for celestial navigation relative to the celestial body itself. In space piloting, where position is determined by measurements made on bodies of the solar system to determine position within the solar system, time is needed because of the orbital movements of the bodies.

Coordinate Systems

The coordinate system generally considered most suitable for space navigation is similar to the equatorial system on earth, with the addition of the radius vector. Thus, in three-dimensional space a position report consists of distance from the center (sometimes the surface) of a celestial body, some form of "latitude," and some form of "longitude" on the sphere established by the radius vector.

The celestial body used as the origin of such a system varies with the situation, and will probably change during different phases of an interplanetary flight. During escape and for all navigation near a planet and its natural satellites, the planet is usually most suitable, although a natural satellite might be preferable under some circumstances. During the midcourse phase of an interplanetary flight, the sun is the logical origin. During the terminal phase, the destination celestial body becomes the origin. If flights are eventually made beyond the solar system, some other origin might prove useful.

Near the earth the equatorial system of coordinates (latitude and longitude) is used invariably to locate position on the sphere defined by distance from the earth. A similar set of coordinates with respect to some selected reference meridian on another celestial body will prove useful. However, when position relative to a celestial body itself is desired, rather than to its surface features, an external reference direction such as the sun or a star might be selected as an origin for "longitude."

This is generally done when heliocentric coordinates are used. The ecliptic is a suitable reference "equator." The vernal equinon may seem the obvious choice for origin of the "longitude" measurement in this system, but it has two serious disadvantages. No bright visible body defines it, and it moves at the rate of more than 50 seconds of arc per year. The perihelion or aphelion of the earth's orbit is similarly disadvantageous, although the rate of motion is slower. The most satisfactory point is probably a bright celestial body near the ecliptic, with a small component of proper motion parallel to the ecliptic. Spica, with a component of proper motion along the ecliptic of some 0″.02 per year, has been suggested as suitable for this purpose.

Optical Methods

Optical methods provide the most versatile and generally the most reliable techniques for determining position, particularly during the midcourse phase of an interplanetary flight.

On the earth measurement of the angular altitude of a celestial body above the horizon provides a circle of position on the surface of the earth. Two such circles provide a fix, and a third resolves any ambiguity. In space, measurement of the angle, at the observer, between the lines of sight to a body of the solar system and a star provides a conical surface of position with apex at the body of the solar system. Two such cones with apex at the same body provide a radial line of position, and a third removes any reasonable doubt as to which of the two lines of intersection of the two cones constitutes the line of position. If the origin of the coordinate system in use is at the apex of the cones, the line of position establishes the "latitude" and "longitude" of the space craft.

A special case of the usual celestial line of position on earth occurs when the circle of position established by observation of the altitude of a celestial body shrinks to a single point with the celestial body in the zenith. In space the determination of the position of a body of the solar system against the background of stars establishes a line of position radial to that body. If the body is the origin of the coordinate system, "latitude" and "longitude" are established. The position of a body relative to the background of stars can be obtained by photography or by measurement of the arcs from the center of the body to several stars near the line of sight to that body. If the body has an appreciable apparent angular diameter, the mean of measurements to opposite sides establishes the measure to the center. Close to a celestial body an infrared scanning system might be useful in establishing the center of the body.

The position of the space craft on the line of position, established by measurement of angles between stars and a body of the solar system, or by locating the zenith among the stars, can be determined by any of the methods of finding distance from the origin body, discussed earlier, or by measuring the angle between a star and a different body of the solar system, thus establishing another cone with a different origin, intersecting the line of position at two points. If reasonable doubt exists regarding which intersection represents the position of the craft, it can be resolved by another observation. Accurate time would be needed for this technique, unless two observations were made in which case the method might be used to establish time. Radial lines of position from two bodies, however established, fix the position of the craft. Three such position lines provide a means for determining time.

These are celestial navigation techniques. Several piloting techniques are available. Distances from three bodies of the solar system provide three spheres intersecting at the position of the space craft. A fourth sphere would remove any possible ambiguity and provide a measure of time. The angle between two points in a plane defines an arc of a circle with the straight line through the two points constituting a chord of the circle. If the two points are bodies of the solar system, in three-dimensional space, the measurement of the angular separation of the two bodies, as observed at the space craft, defines a surface of position formed by rotating the arc around the chord as an axis of rotation. The intersection of this surface with another formed in any manner constitutes a line of position.

With any of the methods discussed, allowance is needed for proper motion of stars. This is simply a matter of updating the ephemeris. Parallax of some of the nearer stars, too, might introduce a small error. Although the ephemerides provided by the Naval Observatory are sufficiently accurate for terrestrial navigation, some improvement in positions of bodies of the solar system may be needed for accurate space navigation, Also, because the size of the astronomical unit in terms of linear units in use on the earth is known only to an accuracy of some two parts in 10^5, a serious systematic error will be present until this accuracy can be improved. In general, "latitude" and "longitude" can be determined to somewhat greater accuracy than radius, particularly when distance is determined by measurement of the apparent angular diameter of a body.

Electronic Methods

Various electronic methods of position determination might be available in the vicinity of a celestial body. Measurement of distance from a body has been discussed. An electronic system providing space-oriented directional information (perhaps of the VORTAC or consol type) or hyperbolic surfaces of position (such as loran or Decca) is theoretically possible, but does not appear to be practical except very close to the celestial body on which the system is located. The short base line would be a severe limitation. If synchronized transmitters were placed on different celestial bodies, such as the earth and the moon, the rotational and orbital motions of the bodies would introduce serious problems.

Further, any method relying upon electronic or other equipment on the celestial body would severely limit the regions in which such techniques would be available, at least during the early periods of space travel. Any method requiring measurements made on the celestial body and transmitted to the space craft would be dependent upon maintenance of communications with the celestial body.

Thus, electronic systems of the type familiar to earth navigators can be expected to be of limited application, near celestial bodies, particularly the earth. However, because the volume of space travel near the earth will probably be comparatively heavy compared to traffic well beyond the moon, the possibility of utilizing earth-based electronic systems should not be overlooked. A precedent has already been established in the various forms of electronic tracking that have been utilized.

Inertial Navigation

As discussed earlier, inertial navigation can be expected to be used only during periods of thrust, particularly during escape from the earth, orbit corrections in flight, and during approach and landing.

When the approach is to some body other than the earth, knowledge of the gravitational force of the body will be needed. The drift of gyros during a long space flight might limit the effectiveness of an inertial system, but stellar supervision could be provided. Another technique would be to mount the inertial components directly on the space craft and replace the stable platform with a computer. Large gyro torquing rates, instrument fabrication, and computer requirements would be problems to be overcome in such a system.

Physical Phenomena

Physical phenomena such as magnetism, gravity, cosmic radiation, ion streams, or solar pressure offer possibilities for measurement of lines or surfaces of position, direction, speed, or time. These have been investigated, but with the knowledge available none are considered useful at this time. The most promising is the application of the Doppler effect to natural radiation in the visible spectrum for determining the velocity vector of the space craft. Although much development work remains to be done before this technique can be evaluated, the development of the laser offers some promise of success. Somewhat less probable is the measurement of the aberration of light or other radiation from stars to determine speed perpendicular to the direction of observation.

Data Processing

The mass of data to be processed during a space flight constitutes a problem of considerable magnitude. A study of this question indicates that the optimum solution is probably a general-purpose digital computer that can be programmed for the various computations anticipated during the flight. Rapid advances in computer technology indicate that within a few years the size and power requirements might be reduced to values compatible with space-craft limitations.

Conclusions

Although a considerable amount of research and development work is needed to provide adequate, reliable space navigation systems, it appears that no order of magnitude advances over present state of the art are needed to produce a workable first-generation space-navigation system. Such a system could probably be fully automatic, although some functions might be performed manually if this is determined to be desirable. In any event, human monitoring and a manual back-up system appear desirable.

No one technique is best for all situations. Therefore, the technique or combination of techniques selected for any one space flight should be chosen to suit the circumstances.

Section 2

ANTENNAS AND PROPAGATION

Organized with the assistance of the IRE Professional Group on Antennas and Propagation

Early History of the Antennas and Propagation Field Until the End of World War I, Part I—Antennas*

P. S. CARTER†, MEMBER, IRE, AND H. H. BEVERAGE‡, FELLOW, IRE

Summary—The prediction by Maxwell in 1865 that electric oscillations in a circuit produce electric waves in the surrounding space stimulated scientists to devise experiments to detect the presence of these waves. Following the classical experiments of Hertz in 1888, many attempts were made to communicate at a distance by electric waves. Marconi was the first to demonstrate a complete workable system. His success was largely due to his clear understanding that high antennas with top loading were essential to transmitting signals over considerable distances. Since the early transmitters utilized spark gaps directly between the antenna and ground, the wavelength of the energy radiated increased as the dimensions of the antenna increased. This naturally led to the idea that long wavelengths were required for operation over long distances, particularly during daylight as indicated by Marconi.[5] Thus, the usefulness of short waves for long-distance communication during daylight was destined to remain unknown until some 30 years later when Marconi himself pioneered the development of long-distance communication with short waves. The development of various types of long-wave antennas is described to the end of World War I.

IN 1865 James Clark Maxwell, by mathematical reasoning, predicted that electric oscillations in a circuit produce electric waves in surrounding space, and that these waves travel with the velocity of light.

Professor Amos Dolbear of Tufts College, Medford, Mass., was granted a patent in 1882 for a wireless system which consisted of an induction coil with one terminal of the secondary grounded, and the other terminal con-

nected to a condenser. A microphone and battery were connected to the primary of the induction coil. A similar arrangement was proposed for reception with a telephone receiver and battery connected between a condenser and ground. While Dolbear's arrangement had some of the elements later used with success by Marconi, there were no electrical oscillations of high frequency. Consequently, any transmission would be due to induction rather than to radiation.[1]

It remained for Heinrich Hertz to prove the existence of electric waves in space as predicted by Maxwell. The first true antenna appears to have been used by Hertz in his classical experiments at Karlsruhe in 1887. His antenna consisted of two flat metallic plates, 40 cm square, each attached to a rod 30 cm long. The two rods were placed in the same straight line, and were provided at their nearer ends with balls separated by a spark gap about 7-mm long. The spark gap was energized by a Ruhmkorff coil. In order to detect the radiated waves, Hertz employed a receiving circuit consisting of a circular loop of wire broken by a microscopic gap. The radius of the loop was 35 cm, which was found by experiment to be the proper size to be in resonance with the oscillator.[2]

After Hertz had succeeded in proving that the action of an electric oscillation spreads out as a wave into space, he planned experiments with the object of concentrating this action and making it perceptible to greater distances by putting the oscillator in the focal plane of a large cylindrical mirror. With this arrangement, he performed his classical experiments with polarization, refraction, and reflection of electromagnetic waves.[1]

Sir Oliver Lodge, on June 1, 1894, delivered before the Royal Institution a lecture entitled, "The Work of Hertz." In this remarkable lecture he described, among other things, the filings coherer with automatic tapper, the connection of the coherer to a grounded conductor, and the method of detecting distant thunderstorms by connecting the coherer to a grounded gas-pipe line. Lodge estimated that the apparatus would respond to signals at a distance of half a mile.[3]

In 1895 Professor Popoff of Kronstadt set up apparatus designed for the study of atmospheric electricity. He used the metallic filings coherer developed by Professor Branly of Paris in 1890. One terminal of the coherer was connected to a metallic rod extending above the housetop, and the other terminal was connected to earth, so that electric currents produced by atmospheric electricity were conducted to earth through the coherer. He included a bell which sounded when an atmospheric discharge was received. The bell was so placed that its hammer, while in vibration, also struck the coherer, causing it to decohere. He also included a telegraphic registering apparatus in shunt to the bell, so as to obtain a written record of the duration of each electric disturbance. In a note dated December, 1895, Popoff said, "I entertain the hope that when my apparatus is perfected it will be applicable to the transmission of signals to a distance by means of rapid electric vibrations—when in fact a sufficiently powerful generator of these vibrations is discovered."[3,4]

The practical application to wireless telegraphy of the principles discovered by Maxwell, Hertz and others awaited the genius, skill, and forceful initiative of Signor Guglielmo Marconi. In 1896 Marconi filed a provisional specification, and in 1897 complete specifications for a system of wireless telegraphy, including a spark transmitter and a receiver utilizing an improved coherer. One terminal of his transmitter and corresponding receiver was connected to an elevated wire, and the other terminal was connected to earth. Marconi's success was to a great extent based on his understanding of the importance of the elevated antenna. In a lecture before the Royal Institute of Great Britain in 1908,[5] Marconi stated:

> My early tests on wireless transmission by means of the elevated capacity method had convinced me that when endeavoring to extend the distance of communication it was of little utility merely to increase the power of the electrical energy applied to the transmitting circuits, but that it was necessary to increase the area or height of the transmitting and receiving elevated conductors. As it was economically impractical to use vertical wires of very great height, the alternative was to increase their size or capacity, which, in view of the facts I had first noted in 1895 seemed likely to make possible the efficient utilization of electrical energy.

Obviously, as the length and capacity of the elevated antenna was increased, the wavelength was also increased. This led to the idea that, for long-distance operation, long waves (low frequencies) should be used, particularly during daylight. Marconi stated in his lecture, "Apparently the amplitude of the electrical oscillations and the length of the waves radiated have much to do with the interesting phenomena, small amplitude and long waves being subject to the effect of daylight to a less degree than large amplitudes and short waves."[5] Thus the usefulness of short waves for long-distance communication was destined to be unknown until some 30 years later, when Marconi himself pioneered in the development of long distance daylight communication with short waves.[5,6]

In 1901 Marconi erected a large cone-type antenna at Poldhu in Cornwall for an attempt at signaling across the Atlantic. This antenna was wrecked by a storm in September, 1901. The transmitting antenna actually used at Poldhu during the experiments in transmitting to Newfoundland consisted of 50 vertical copper wires supported at the top by a horizontal wire stretched be-

tween two masts 157 ft (48 m) high and about 200 ft (61 m) apart. These wires converged together at the lower end in the shape of a large fan. The wavelength was 1200 ft (366 m) and the actual power for the production of the waves was about 15 kw. In Newfoundland Marconi used an antenna supported by kites. He stated:

It was soon discovered that an ordinary syntonic receiver was not suitable, although at one time a number of doubtful signals were recorded. I therefore tried various microphonic self-restoring coherers placed either directly in the aerial or included in the secondary circuit of the oscillation transformer, the signals being read by telephone.

On December 12, 1901, the signals transmitted from Cornwall were clearly received at the prearranged times. In many cases a succession of S's being heard distinctly, although in consequence of the weakness of the signals and the constant variations in the height of the receiving aerial, no actual message could be deciphered. The following day, we were able to confirm the result. The signals were actually read by myself and by my assistant, Mr. G. S. Kemp.[5]

In a note in the *Electrical World*, December 21, 1901, it was stated that the letter S was sent from 3 to 6 P.M. GMT or 11:30 A.M. to 2:30 P.M., St. John's time. Considering the time of day, the stated wavelength of 1200 ft (366 m) and the insensitivity of the coherer, this was a remarkable achievement. In 1901 means for measuring the wavelength of radiation were very crude. It is quite possible that the wavelength actually used at Poldhu was considerably longer than 1200 ft.

The same Poldhu transmitter was used in February, 1902, to transmit to the SS *Philadelphia* which had the receiving antenna fixed to the main mast, the top of which was 200 ft (61 m) above sea level. Good results were obtained on a syntonic receiver, and the signals were all recorded on tape by the ordinary Morse recorder. Readable messages were received from Poldhu to a distance of 1551 miles, S's and other test letters as far as 2099 miles at night.[5,6]

In 1902 antennas were constructed at Poldhu and Cape Cod, Mass., consisting of four wooden lattice towers, each 210 ft (64 m) high erected at the corners of a square of 200 ft (61 m) on a side. The towers carried insulated triatic stays from which a conical arrangement of 400 copper wires was suspended. The wavelength used was 3600 ft (1100 m). The antenna at Poldhu was shortly afterwards extended by the addition of wires sloping downwards, umbrella fashion. This arrangement was a considerable improvement. By the adoption of much longer waves than had been hitherto employed, namely a wavelength of 14,000 ft (4270 m or 70 kc), it was possible to telegraph over a distance of 550 miles with an expenditure of about 1 kw.[5]

The first commercial service across the Atlantic was established in October, 1907, between Clifden, Ireland, and Glace Bay, Newfoundland. The antennas consisted of a flat top with multiple wires fed at one end. The wavelength was 12,000 ft (3650 m).[5]

By 1907 the advantage of using top-loaded antennas was widely recognized. In 1910 the Telefunken Company constructed an antenna at Nauen, Germany, in the form of an umbrella. The central tower was 100 m high, supported by a carefully insulated ball at the base. The tower served partly to support the entire antenna and partly as a current carrier in conjunction with a bundle of wires with which it was connected.

In 1911 this tower was increased to a height of 200 m, but in April, 1912, during a severe storm, this tower collapsed. Shortly thereafter, the construction of an entirely new antenna and tower was undertaken. Another umbrella-type antenna was erected by C. Lorenz at Eberswalde, Germany.[7]

In the United States an umbrella-type antenna was erected at Brant Rock, Mass., by the National Electric Signaling Company (tower height—130 m).[7] During 1913 and 1914, several long-wave stations were erected in the United States for overseas radio communication. The Telefunken Company of Germany erected a station at Sayville, N. Y., with an antenna of the umbrella type supported by a central insulated tower about 500 ft (152 m) in height. A counterpoise consisting of 56 wires 16 ft (5 m) above ground was provided.[8] Another antenna of the umbrella type was erected by German engineers at Tuckerton, N. J., utilizing a central tower, insulated at the base, having a height of 825 ft (250 m).[9] The American Marconi Company erected stations at New Brunswick, N. J., Marion, Mass., Bolinas, Calif., and Kahuku, Hawaii. The Marconi transmitting antennas were of the so-called Marconi-bent type, consisting of a flat top with the horizontal portion containing a number of wires 5000 ft (1530 m) long supported by triatics 600 ft (183 m) long suspended between adjacent masts. Thirteen tubular guyed masts 400 ft (122 m) high were used.[10]

By 1914 the U. S. Navy had over 50 shore stations and 250 ship stations in operation.[11] The first high-power station to be put into operation by the Navy was the famous "NAA" at Arlington, Va., in 1916. Other high-power stations for the Navy were in the process of construction at several other points, including San Diego, Calif., Pearl Harbor, Hawaii, Cavite, P. I., and Guam. Most of the Navy high-power stations used antennas suspended between three self-supporting towers 600 ft (183 m) high spaced in the form of a triangle 1100 ft (336 m) along the base, each of the other sides being 1000 ft (304 m) between towers.[12]

Prior to the start of World War I, the techniques were available for establishing transoceanic radio communication over distances of several thousand miles. Several of the stations described above were on the air making tests, some with spark transmitters and others with continuous waves utilizing Poulson arcs or alternators.

The start of the war in August, 1914, soon interrupted all attempts at establishing an international commercial radio service. During the war years, the development of high-power radio facilities continued, primarily for military purposes.

Also during the war, in addition to the stations mentioned above, the U. S. Navy constructed high-power stations at Darien (Panama Canal Zone),[13] Annapolis, Md., and elsewhere. The Navy also installed arc transmitters at the former German stations located at Sayville, N. Y.,[8] and Tuckerton, N. J.[9]

In cooperation with the U. S. Navy the General Electric Company installed Alexanderson alternators at the Marconi station located near New Brunswick, N. J. An important feature of the New Brunswick station was the multiple tuning applied to the Marconi antenna, which increased the efficiency from 1.85 per cent to about 14 per cent. This development is described elsewhere in this issue.[14]

In Europe the power and efficiency of the station at Nauen, Germany, was considerably increased. The principal long-wave stations which were in operation before the end of the war were as follows:

Germany—Nauen (POZ) and Hanover (OUI) using alternators.

England—Carnarvon (MUU) using Marconi timed-spark transmitters.

Norway—Stavanger (LCM) using Marconi timed-spark transmitters.

France—Lyon (YN) and Lafayette (LY) using arc transmitters.

After the war, several of the European stations mentioned above were used for commercial service, mostly to the United States.

The History of Radio Wave Propagation Up to the End of World War I*

CHARLES R. BURROWS†, FELLOW, IRE

Summary—**Hertz in the 1880's demonstrated electromagnetic wave propagation predicted by Maxwell from his equations in 1864. Heaviside and Kennelly postulated the ionosphere to explain Marconi's historical transatlantic reception of radio waves in 1901. Austin derived the first formula for radio propagation in 1911 from experimental data in the kilometer wavelength range taken in the daytime.**

Much theoretical effort was expended on the effect of the electrical properties of the ground but the problem was not resolved until a later date. Watson, however, cleared up the problem of diffraction around a perfectly conducting sphere in 1919.

Up to the end of World War I, it was generally believed that radio transmission improved with increase in wavelength so the experimental data is concentrated in this region.

THE HISTORY of radio-wave propagation began in 1864, when Clerk Maxwell [1] introduced the concept of dielectric current to satisfy the equation of continuity. This added symmetry to the equations that now bear his name. From these "Maxwell Equations," he deduced the existence of electromagnetic waves that would be propagated with the velocity of light.

In the 1880's, Heinrich Hertz [2], experimenting with the spark discharged from a Leyden jar, demonstrated that the effect was propagated at a distance so as to cause a spark to occur across the terminals of a receiving antenna. In these experiments he produced the electromagnetic waves predicted by Maxwell. In describing his experiments, Hertz used the concepts of rectilinear propagation, polarization, reflection and refraction.

On the theoretical side, Hertz [3] calculated the field from a rectilinear current element, and Abraham [4] calculated the field from a half-wave dipole. Hack [5] plotted the fields around rectilinear antennas half wavelength, full wavelength and three-half wavelengths long, based on the formulas of Abraham [4]. Rudenberg [6] calculated the radiation resistance of the dipole which made possible the expression of attenuation as the ratio of the power radiated from one antenna to the maximum power that could be extracted from the receiving antenna [7].

Blondel [8] pointed out in 1898 that the effect of the earth on a vertical antenna was to produce an image of the antenna, an approximation good for long waves. Hence, for moderate distances the field was found to be inversely proportional to the distance. Experimental evidence for this was obtained by Tissot [9] in 1906.

In the 1890's, Heaviside interpreted the propagation of electromagnetic energy along a pair of wires as a guiding of the wave energy, a concept also used by Hertz during this period. Hertz discovered that by

† Datronics Engineers, Inc., Bethesda, Md.

forming the inducing circuits, so as to become what is now known as a Hertzian dipole, the radiation was greatly increased. In January, 1897, Marconi [10] was able to greatly extend the range of radio wave propagation by employing a vertical grounded antenna, hence demonstrating the superiority of vertical polarization over horizontal polarization for propagation up to several hundred miles on the longer waves.

The successful reception of radio signals across the Atlantic by Marconi [11] on December 12, 1901, introduced much speculation as to the mechanism of radiowave propagation around the curvature of the earth. Three mechanisms were proposed and seriously considered for several decades: 1) ionospheric propagation, 2) guided propagation by means of a surface wave and 3) diffraction into the earth's shadow [12]. To explain the first mechanism, Kennelly [13] in America and Heaviside [14] in England independently postulated [15] the existence of an ionized region in the upper atmosphere that would reflect the radio waves back to earth. Eccles [16] showed mathematically how this ionized region could bend the waves back to earth. In view of our present knowledge, this was the mechanism responsible for Marconi's transatlantic reception.

Zenneck [17] gave credit to Blondel [8] and Lecher [18] for the concept that radio waves were of the nature of surface waves. In 1907 Zenneck [19] showed that the interface between two dielectrics, such as earth and air, could support a surface wave. In 1909 Sommerfeld [20] studied the problem of the propagation of electromagnetic waves from a Hertzian dipole in the interface separating media of two different dielectric properties. In his formulation he had a component which corresponded to a cylindrical surface wave which at great distances over dielectric ground predominated and was the same as Zenneck's surface wave. From this he concluded that radio waves would be guided around the curvature of the earth. He believed that the effect of the imperfect conductivity of the earth (which introduced cylindrical divergence described as a surface wave) would probably be intensified by the curvature of the surface and hence might counteract attenuation of the waves by the curvature. Ten years later Weyl [21] investigated the same problem, but his answer did not explicitly include the surface wave component of Sommerfeld. He, however, believed that quantitatively his results were the same as Sommerfeld's. Many years later Burrows [22] discovered that these two formulations, in fact, differed by exactly the surface wave of Sommerfeld, and, in collaboration with his associates, L. E. Hunt and A. Decino, conducted the crucial experiment which showed that Weyl's formulation was correct and that the surface wave of Sommerfeld did not exist. Later Rice [23] and Niessen [24] independently found the source of the error in Sommerfeld's work—the incorrect choice of the square root of a complex quantity in an intricate mathematical derivation.

The problem of the diffraction of radio waves around the earth's curvature occupied the efforts of several of the leading mathematicians for many years before Watson [25], in 1919, pointed out the errors of the earlier investigators and presented values for the diffraction of radio waves around a perfectly conducting sphere. Much later Van der Pol and Bremmer [26] generalized Watson's solution to take into consideration arbitrary ground constants, and Gray [27] extended the work to include horizontally polarized antennas.

In 1902 Marconi observed that the same transmitter had a longer range at night, sometimes having a range two and a half times the daytime range. This was the first observation of atmospheric absorption by the ionosphere. Austin's [28] measurements confirmed this and showed that the nighttime propagation was irregular. Marconi [29] observed that when part of the propagation path was in darkness and part in daylight, the signal was weaker than the steady daytime signal. This was followed by stronger signals when it was sunset over the entire path and preceded by stronger signals just before sunrise at the eastern terminal. When it was nighttime over the entire path, the signals were stronger and variable. Signals were stronger in the daytime on 7000 meters than on 4000 meters, but the sunrise and sunset maximums were stronger on the shorter wavelength.

Austin [28] gave us our first formula for radio wave propagation [30]. It was an empirical formula representing the summary of experimental data for the propagation on wavelengths in the kilometer region over the sea during the daytime. It is

$$I_r = 4.25 \frac{I_s h_1 h_2}{\lambda d} \exp\left(\frac{-0.015d}{\sqrt{\lambda}}\right)$$

where the currents are in amperes and lengths in kilometers. I_r is the current in the vertical antenna of height h_2 resulting from a current I_s in an antenna of height h_1, separated by a distance d on a wavelength λ. Hogan's [31] experiments confirmed Austin's formula and showed that it was valid over a greater range of distances.

Austin's formula corresponds to the usual formula

$$E = \frac{120\pi h_1 I_s}{\lambda d}$$

for the field propagated along a perfectly conducting plane [7] multiplied by an exponential absorption factor. Austin's formula showed that the exponential attenuation factor was proportional to the distance and inversely proportional to the square root of the wavelength. In Watson's [25] theoretical formulation for the diffraction of radio waves around the curvature of the earth, the exponential attenuation factor is inversely proportional to the cube root of the wavelength. In a later paper [32], he considered the effect of the ionosphere, which then changed the dependence on the wavelength from the cube root to the square root.

On the longer waves (in the kilometer range) the propagation was studied as a function of wavelength, ground conditions, time of day and season. The strength of signals on a wavelength of 1000 meters at a distance of some 200 km was found to be maximum in winter and minimum in summer with a variation of a factor of about six [33]. Daytime transmission over land on 3500 meters was more attenuated than over sea and depended on weather and time of year [34]. Shorter waves (2500 meters) were more attenuated than longer waves (3500 meters). Taylor [34] attributed the increase in attenuation in spring and summer to poorer conductivity which he attributed to the breaking up of the ground by frost and cultivation. Kennelly [35] discussed the influence of solar radiation on radio propagation. The dip both at midsunrise and at midsunset with reinforcement both before and after each dip were explained by reflection effects at the shadow wall.

The first report of selective fading was made by Dr. de Forest on the observations of the federal telegraph operators on their transmissions between Los Angeles and San Francisco, a distance of 560 km on long waves [36]. They observed that the mark wave would fade on 9.7 kc while the space wave some 5 kc lower in frequency remained normal.

In 1915 the AT & T and Western Electric Companies, in cooperation with the United States Navy, demonstrated voice radio communication between Arlington, Virginia, and Hawaii and Paris. On November 29, 1915, signals from Nauen, Prussia, were copied in Honolulu, a distance of 9000 miles [37].

Many high-power radio transmitters were put in operation during the war. Little is available in regard to the radio-wave propagation resulting from them, except that transmissions were successful.

Growth of the Antennas and Propagation Field Between World War I and World War II

Part I—Antennas*

L. J. CHU†, FELLOW, IRE

Summary—**The advances in antenna theory concepts and designs between World War I and World War II are summarized. Rapid growth of world-wide and regional broadcasting and point-to-point radio communication stimulated the design of high-power low-frequency transmitting antennas of reasonable efficiency, directive-wave antennas for signal-to-noise improvement in low-frequency reception, rhombic and V-shape wave antennas and arrays of various types for directive short-wave transmission and reception.**

Introduction

The development of antenna techniques and theory during the period between World Wars I and II was motivated by two major events. The first was the rapid growth of radio communication in the form of world-wide and regional broadcasting and point-to-point communication. The second was the development of power-generation techniques toward higher and higher frequencies. In this paper the major antenna advances during this period are outlined. A number of other advances are regretfully omitted. Among these are the engineering aspects of antenna development, the improvment of direction-finding aircraft and marine antennas and the "scattering" and "diffraction" theories, which were not treated as antenna problems during that period and exerted great influence on microwave antenna development during World War II.

Fundamental Theorems

The foundation of antenna theory was solidly laid out before World War I. Maxwell's equations were valid for the purpose of antenna analysis. Hertz-vector and magnetic-vector potentials were used extensively to calculate the radiation from electric currents. Poynting's theorem was applied to determine total radiated power from antennas and their radiation resistances.

Carson [1], [2] and others extended Lorentz's reciprocity theorem for electromagnetic field to antenna terminals. Their contribution to antenna theory was immeasurable. Aside from other applications, it allowed us to specify the receiving characteristics of an antenna in terms of its transmitting characteristics. Before Carson's work, receiving antennas were sometimes analyzed as such by questionable procedures. After Carson's work, the analysis of receiving antennas as distinguished from transmitting antennas practically disappeared from the literature of the subject.

At the turn of the century, A. E. H. Love and H. M. MacDonald formulated the mathematical procedure for replacing a given current distribution by equivalent surface currents over an arbitrary surface, enclosing the given current distribution to obtain identical field outside the surface. This "equivalence theorem" was rediscovered by Schelkunoff [3], and applied to the problems of radiation from open ends of a coaxial line and waveguide. The engineering significance of the equivalence theorem lies not so much in its formal exactness. It provides a self-consistent procedure for calculating the external field from the aperture type of antenna, such as the horn, reflector, and lens, for which a reasonable approximation of electromagnetic field can be made over a closed surface that includes the "aperture."

VLF Transmitting Antennas

To achieve world-wide reliable communication, a number of VLF antenna systems were installed and in operation in the 1920's. Following Alexanderson's design procedures, these antennas consisted of top-loaded vertical down leads connected to huge coils over elaborate ground systems. The top loading serves not only to provide a greater effective height for the down leads, but also allows a large current in the down leads to radiate up to 250 kw at 15 kc without voltage breakdown. The measured radiation efficiency at this frequency for some of the systems is as high as 26 per cent [4].

Wave Antennas

The most significant discovery of the capability of the wave antenna was made by Beverage [5]. With a no. 14 rubber-covered wire, six miles long, laid in the scrub oak and sand of Long Island, he observed a significant increase in signal-to-noise ratio from Europe when the

* Received by the IRE, July 31, 1961; revised manuscript received, November 1, 1961. This work was supported in part by the U. S. Army Signal Corps, the Air Force Office of Scientific Research, and the Office of Naval Research.

† Department of Electrical Engineering, and Research Laboratory of Electronics, Massachusetts Institute of Technology, Cambridge, Mass.

receiver termination was at the remote end and ground termination at the other end nearer to Europe. Concurrently, C. W. Rice and E. W. Kellogg concluded, on purely theoretical grounds, that a long horizontal antenna pointed in the direction of the sending station would constitute a unidirectional receiver, provided that the receiver were placed at the end of an antenna remote from the sending station, while the other end was grounded through a noninductive resistance equal to the surge impedance of the antenna. These discoveries were followed by an exhaustive experimental and theoretical study to establish the "Beverage antenna" as an effective and practical directional antenna for low-frequency reception.

The analysis of the Beverage antenna by E. W. Kellogg was an analysis of it as a receiver. As a transmitting antenna, one would find traveling-wave solutions along the antenna. The natural continuation of the development of wave antennas was carried out by RCA, Bell Laboratories, Inc., and the International Telephone and Telegraph Company, in the forms of V and rhombic antennas [6], [7]. The peak of the radiation pattern of a traveling-wave current along a straight conductor lies along a cone that is coaxial with the conductor. The angle of cone is a function of the conductor length measured in wavelength. By arranging the conductor in the form of an inverted V above ground, a rhombic in free space, with proper termination impedance at the end opposite the input terminal to minimize reflection, the cones of maximum radiation intersect with equal phase in a direction along the axis of the antenna, when the angles of the antennas are properly chosen.

While traveling-wave antennas inherently possess a broad-band characteristic both in input impedance and directivity, the other type of wave antenna developed during this period made use of standing waves to achieve the broadside effect. The Marconi-Franklin antenna is a typical example. Quarter-wave shorted transmission lines or lumped high-impedance circuits were inserted in series every half-wavelength along a straight conductor to set up a standing wave along the conductor, with phase reversals at the inserts. This method results in a narrow-band broadside array.

Antenna Arrays

For a decade after World War I, investigations of multiple-element antenna systems were carried out by many workers in the United States, Great Britain, France, Germany and Japan, both experimentally and theoretically. This development took two distinct directions. The first recognized the coupling of field from the excited element to the parasitic elements that are not connected circuitwise to the transmitter or receiver, and the resonant phenomena of a linear conductor. By choosing a proper length for the parasitic elements, the phase of the current induced relative to that of the excited element could be controlled to form a directive beam along the axis of the array [8]. The well-known "Yagi" is one example. The mutual coupling among elements was reduced to a multiterminal circuit problem by England and Crawford [9]. Calculations of self-impedance and mutual impedance were carried out by Carter [10], who started from the field viewpoint. Carter made ingenious use of Carson's reciprocity theorem.

The second significant development of linear-array theory was based upon assumed relative current distributions of a uniformly spaced array of identical elements. In 1928, Bohm [11] published experimental and theoretical polar diagrams of broadside and end-fire arrays. For an array of many elements, it was found that the mutual coupling does not play an important role in determining the relative current distribution of elements that are connected together through a transmission-line system. Southworth [12], before his fundamental work on waveguides, made an exhaustive theoretical study of three-dimensional arrays of uniformly spaced elements of constant current amplitude and constant phase difference between adjacent elements in any one of the orthogonal directions. With R. M. Foster's help, he evaluated the gain of the array and applied it to many special cases of importance.

Not all arrays developed before World War II were uniformly spaced. To conform to the area coverage assigned by the FCC to a broadcasting station, the technique of antenna synthesis or beam shaping was developed after 1930. To obtain specified patterns, the problem was to determine the coordinates of the towers, which were used as radiating elements, and their complex currents and then to design the proper matching and transmission network to achieve the desired relative currents [13].

One of many significant developments during this time was MUSA (multiple unit steerable antenna) by Friis and Feldman [14]. Their work laid the foundation for a new technique of antenna design, which now is known as electronic scanning. This antenna system consists of six identical rhombic antennas uniformly spaced colinearly. Each rhombic is connected to a detector and then to three IF variable phase shifters of RC type in parallel. The outputs of the three sets of phase shifters from the six rhombics are combined to feed three receivers. Each set of phase shifters is mechanically arranged to produce progressive phase shifts to give equal phase at the receiver for signals coming in at a given direction. The system was designed for point-to-point high-frequency communication between New York and London, with a view toward achieving signal-to-noise improvement and eliminating fading resulting from multipath transmission.

A significant contribution was made by Hansen and Woodyard [15] in the design of end-fire arrays, which led to the investigation of super-gain antennas after 1940. By allowing 2.94 radians of additional phase shift along a conventional end-fire array of linear phase variation, they found a decrease in beamwidth and an improvement in gain by a factor of 1.82. The theory was subsequently proved experimentally. A conventional end-fire array has a total phase difference between end elements of $2\pi/\lambda$ times the length of the array.

Linear Antenna Theory

Most of the antennas that were in use at the beginning of World War II were designed with wires and towers. Their designers used quasi-static theory, transmission-line theory, Hertz-vector and experimental data. Many theoretical investigations of impedance and other characteristics of linear antennas had been carried out between 1930 and 1940. The work of Carter [10] and Labus [16] was based upon assumed current distribution and the EMF method. From the assumed current distribution, the component of electric field tangential to conductor surface was computed. The integral of the component of the complex Poynting vector normal to the surface of the conductor was considered to be the complex power output at the input terminals. This method yielded rather accurate results, except when the input terminals were near the current minimum. It was then recognized as an electromagnetic boundary-value problem. Stratton and Chu [18], extending the work of Page and Adams [17], used a prolate spheroidal model for a linear antenna and expanded the wave function into the orthogonal series of spheroidal wave functions. King [19] and Hallen [20] formulated the boundary-value problem of a linear antenna as an integral equation of the current distribution itself. Perhaps, the most illuminating approach to the problem was made by Schelkunoff [21]. He used, initially, a biconical horn model, which supports, among others, a TEM mode of transmission in the space enclosed by the cones, and matched the field to the spherical wave functions outside the biconical horn. It demonstrated that conductors in a linear antenna serve to guide the electromagnetic waves, and expelled the illusion created by the EMF method that the radiated power was emitted from the conductor.

Electromagnetic Horns

The development of waveguides in the middle of the third decade led, naturally, to the development of electromagnetic horns [22]–[24]. By tapering cross-section dimensions of waveguides, one obtained sectoral, pyramidal, and conical horns. The dominant mode of propagation in the waveguide is transformed into the corresponding mode in the horn with cylindrical or spherical wave front. At the aperture, the wave leaves the horn and diffracts to form a directive beam. For a given length of horn, the beamwidth reaches a minimum at a critical flare angle. The introduction of electromagnetic horns paved the way for the engineering use of the aperture type of antenna, which, today, dominates the microwave field.

Radio-Wave Propagation Between World Wars I and II*

STEPHEN S. ATTWOOD†, FELLOW, IRE

Summary—**The period between World Wars I and II, 1918 to 1941, is particularly noteworthy for the significant developments that led to a comprehensive understanding of the factors that control the propagation of radio waves through the atmosphere. In slightly over two decades it became possible to identify the basic physical mechanisms with the aid and correlation of theory and experiment, so that by the end of this period it was possible to prepare predictions of future propagation conditions covering a wide variety of frequencies, transmission paths, for day and night, and seasonal variations.**

During the entire period, numbers of scientists were working toward the calculation of field strengths of radio waves propagated by both the ground wave and the ionosphere. Watson's paper in 1918 initiated the ground wave calculations by considering the propagation over a perfectly conducting sphere. It was soon recognized that the ground could not be treated as perfectly conducting, and the theory of propagation for an imperfectly conducting ground was not produced in usable form until the 1937–1941 period. Watson's predictions for field strengths in the shadow zone proved to be much lower than experimental values. This led to increased interest in the ionosphere as a possible explanation.

Effective work on ionospheric problems began in 1924 with the development of the Eccles-Larmor theory of electronic behavior. The effect of the earth's magnetic field extended this theory to include doubly refracting layers and ionospheric layer anistropy. There soon were developed experimental techniques that determined the existence of layers and their electron density variations. The rate of accumulation of data was greatly increased by the development of automatic ionosondes. From the data accumulated came increased understanding of the effects of solar flares, physical processes, diurnal and seasonal variations of propagation.

Tropospheric propagation is discussed briefly since most of the developments were made during World War II and lie outside the scope of this paper.

DURING this period the study of the propagation of radio waves led to a marked increase in the understanding of the physical mechanisms and the evaluation of signal strengths over a wide range of frequencies, with varying ground and atmospheric conditions. The study fairly naturally divides into consideration of the ground wave at all frequencies, ionospheric propagation at frequencies of about 30 Mc and below, and tropospheric propagation above 30 Mc and up into the microwave range of thousands of megacycles.

The Ground Wave

The ground wave is defined to include those factors affecting the propagation of radio-wave energy through the atmosphere and along the surface of the earth, excluding any ionospheric effects, or tropospheric effects other than standard refraction. Among the factors of prime importance are: 1) diffraction of the wave energy around the curve of the earth, 2) refraction or bending of the waves in passing through the atmosphere, 3) reflection from the earth's surface, with consequent phenomena of interference between direct and ground-reflected rays, and 4) absorption of energy by the earth and in the atmosphere. The latter proves to be significant only in the microwave range.

At all frequencies, electromagnetic energy is diffracted into the geometric shadow of an obstacle, the amount increasing with decreasing frequency. In the radio-frequency range, diffraction yields significant and usable signal strengths in the shadow zone beyond the geometric horizon of the earth. The mathematical problem of calculating the diffraction field strength in the shadow zone of the earth was attacked by many mathematicians over 15 years with resulting divergent answers. The first significant *break-through* was produced by Watson[1] in 1918, who showed that waves radiated by an antenna on the surface of a *perfectly conducting sphere* would be attenuated exponentially at great distances. The numerical values of field strength predicted by Watson under these conditions proved to be far lower than known experimental values. This discrepancy promoted increased interest in the ionosphere as a mechanism that might explain the wide divergence in the mathematical and experimental values of field strength, particularly in the kilocycle range of frequencies.

Meanwhile Austin[2] and others, over a period of years, had collected a considerable amount of quantitative field strength data in the LF and VLF frequency ranges. The results were summarized in the now-classical Austin-Cohen formula. This formula proved quite satisfactory as a basis for the engineering design of long dis tance LF and VLF circuits.

Interest in the behavior of the ground wave per se tended to diminish until the advent of MF broadcasting in the 1920's, when the strength of the wave in both the interference region and the shadow zone over an *imperfectly conducting earth* became of importance in the

allocation of frequencies to a rapidly increasing number of broadcasting stations.

This problem was solved completely during the years 1937 to 1941, covering pertinent factors such as heights, gains and spacing of the antennas, both vertical and horizontal polarization, arbitrary ground constants, and *standard* refraction of the *average* atmosphere. With standard refraction the radio-wave rays are curved downward with a radius of curvature equal to four times the actual earth radius. Passing over important mathematical contributions, it is possible to list only those authors and publications that contributed directly to the production of universal field strength curves. These are Eckersley and Millington,[3] van der Pol and Bremmer,[4] Burrows,[5] Gray,[6] Burrows and Gray,[7] and Norton.[8]

Ionospheric Propagation

Following Marconi's success in 1901 in transmitting signals across the Atlantic, Kennelly and Heaviside postulated the existence of a conducting (ionized) layer in the earth's upper atmosphere and suggested that such a layer might cause the waves to follow the curvature of the earth. After it became clear that diffraction could not explain the substantial field strengths actually received at great distances, increased attention was directed to this proposal of an ionized region.

The theory of radio-wave propagation through the ionosphere is based on work by Eccles[9] in 1912, on the ionizing effect of solar radiation, and on the effective refractive index of an ionized medium. Larmor[10] in 1924 re-examined the work of Eccles and others and ascribed the major part of the refractive effect to the presence of free electrons in large numbers. The Eccles-Larmor theory, as later extended and developed by Appleton,[11] Hartree,[12] and others to include the effect of anisotropy due to the earth's magnetic field, is now considered the basic theory of radio-wave propagation in the ionosphere. This work was later extended by Booker[13] and others to cover oblique propagation in a nonhomogeneous ionosphere.

The Eccles-Larmor theory leads to the concept of an effective refractive index n less than unity in an ionized medium; in the simplest theory $n=\sqrt{1-(Ne^2/m\epsilon_0\omega^2)}$, where ω is the radian wave frequency, ϵ_0 is the mks free space dielectric constant, N is the number of electrons per cubic meter and e and m are the electronic charge and mass. In terms of the wave frequency f, $n=\sqrt{1-(81N/f^2)}$. 81 N is the so-called critical frequency, now known as the *plasma frequency*. Since $n\leq 1$, a radio wave going up into the ionosphere encounters a decreasing refractive index and, therefore, is bent back toward the earth according to the usual refraction law. The maximum height it reaches is that corresponding to N_{max} given by

$$N_{max} = \frac{1}{81} f^2 \cos^2 \theta$$

where θ is the angle of incidence on the bottom of the ionosphere.

Absorption in the ionosphere is accounted for by including ν, the number of times per second each electron collides on the average with neutral molecules. This modifies the relative dielectric constant slightly, but adds a conductivity term that results in absorption of energy and consequent attenuation of the wave.

Again using the simplest theory and making suitable approximations, the absorption coefficient α is proportional to ν and to N but is inversely proportional to the refractive index n. Thus maximum absorption can occur at two different levels: one where the product νN is a maximum with $n\approx 1$, the other where n is a minimum. The first case (nondeviative absorption) occurs in the lower ionosphere, the second (deviative absorption) occurs in the upper ionosphere for near-vertical inci-

dence propagation, where $n \approx 0$ at the level of reflection.

Experimental evidence for the existence and the properties of the ionosphere were soon forthcoming. In 1925 Appleton and Barnett[14] proved the existence of a reflecting layer and calculated its height by measuring the angle the down-coming ray makes with the earth. With the transmitter and receiver separated an appreciable distance, the problem becomes one of simple triangulation.

The most significant and useful experimental technique is that of Breit and Tuve.[15] These authors in 1926 used transmitting and receiving antennas practically side-by-side, and sent a succession of HF pulses of short duration (30 to 100 μsec) at regular intervals (1/30 to 1/120 sec) up to the ionosphere and measured the time delay of the returning pulses. Assuming velocity c, the virtual height of the ionospheric layer (actual heights are somewhat less) returning the pulse of a given frequency is readily calculated. Continued experiments using different frequencies have enabled experimenters, using in conjunction the Eccles-Larmor relations, to measure the variation of electron densities with height in the various regions of the ionosphere, namely E, F_1 and F_2, ranging in height from about 100 to 400 km, and electron density maxima from less than 10^{10} to 4 times 10^{12} electrons per cubic meter.

Theory and experiment have shown that the ionosphere layers are doubly refracting as a result of interaction with the earth's magnetic field. Waves moving horizontally as well as vertically are split into ordinary and extraordinary groups that move in different paths with different velocities, and return to earth at distances beyond the so-called skip distance that exceeds the reception distance by the ground wave.

A big step forward resulted from the development by Gilliland[16] and others of sweep frequency ionosphere sounding equipment. These were the prototypes of the present day *ionosondes* that consist of transmitting and receiving sets in which the frequency is continuously varied from 500 kc or so to 15 or 20 Mc at an appropriate rate, generally proportional to the logarithm of the frequency. Modern ionosondes can sweep the MF/HF spectrum in a few seconds. The virtual heights are recorded as a function of frequency photographically by an oscillographic recorder. Fig. 1 is a typical example of the records that may be obtained for the E, F_1 and F_2 layers. The use of automatic recorders led at once, and ever since, to an enormous accumulation of factual information showing normal and frequently abnormal ionospheric behavior. Centers for the collection and study of this material were established in England, the United States, Canada and Australia.

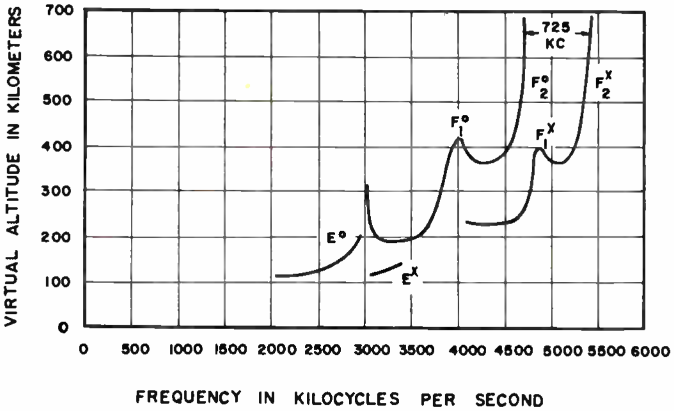

Fig. 1—Typical ionosonde record. Superscripts o and x correspond to the ordinary and extraordinary rays resulting from interaction of the wave with the earth's magnetic field. The sudden changes in height correspond to the critical frequencies of the layers.

As a result of the extensive theoretical and experimental work during the 1930–40 decade an extensive body of knowledge was built up regarding the structure of the ionosphere and its effect on the propagation of radio waves. This involved a number of disciplines: solar physics and ionizing radiations, atomic and molecular processes in the upper atmosphere of the earth, terrestrial magnetism and auroral phenomena, as well as terrestrial-radio communication over both long and short paths. The International Polar Year in 1932–33 represented a great world-wide cooperative effort among nations to obtain geophysical data, a large part of which directly added to the understanding of the ionosphere. Direct solar-ionospheric relations were discovered, such as ionosphere storms and solar-flare disturbances characterized by radio blackouts. Observations during solar eclipses led to the determination of recombination coefficients in the ionosphere. The important correlation between the sunspot cycle and electron densities in the ionosphere was discovered.

Especially significant, from the standpoint of radio communications, was the work directed toward calculation and prediction of radio-propagation conditions from the ionospheric observation. Seasonal, diurnal, and sunspot-cycle variations were established, and a beginning made on the delineation of the geographical distributions of the ionosphere. This would later be greatly extended by the network of observatories established during World War II. Ionospheric absorption measurements were begun, as well as the study of atmospheric radio noise, which generally sets the lower limit on usa-

ble high frequencies for long distance communication.

The general picture resulting from this work indicated an ionosphere that was highly variable, turbulent and patchy, and had unpredictable variations, but nonetheless had sufficiently regular characteristics so that, within certain limits of apparently random variations, reasonably reliable radio propagation predictions could be made.

It became possible, for oblique angle incidence, to calculate and disseminate information regularly about the maximum usable frequencies (MUF) and the lowest usable high frequencies (LUHF) for given paths and to predict the probable occurrence of ionospheric storms. In 1943 the Interservice Radio Propagation Laboratory of the National Bureau of Standards published the IRPL Radio Propagation Handbook under the guidance of the director, Dellinger, and the assistant director, Smith. The Handbook reappeared in expanded form in 1948 as "Ionospheric Radio Propagation," National Bureau of Standards Circular 462.

Excellent review articles for the period between Wars I and II were written by Mitra,[17] Mimno,[18] Dellinger,[19] and Dellinger and Smith.[20]

Tropospheric Propagation

The term Tropospheric Propagation refers to the effects of the earth's lower atmosphere on the field strengths of radio waves, with particular attention being given to the VHF, UHF and SHF frequencies, and also to various atmospheric conditions that produce nonstandard types of refraction. The atmospheric effects, due to temperature and moisture vapor gradients, are not particularly noticeable at frequencies below about 30 Mc because of the predominance of the ground-wave and ionospheric propagation modes. In fact, frequencies above the MUF were commonly called line-of-sight frequencies because they were useful only out to the radio horizon.

In the middle of the 1930–40 decade, with the advent of increasing use of VHF, attention was called to the effect of the troposphere on radio propagation[21] by several kinds of observations, chief among which were fading of VHF signals in and beyond the radio horizon, and extension of VHF ranges to several horizon distances, as evidenced by amateur radio contacts and unexpected interference from distant stations.

There appeared to be a noticeable relation between these transmissions and the weather, although little was accomplished in quantitatively explaining or predicting the effects before World War II, when it became extremely important to understand the vagaries of long-range radar performance at VHF and UHF, and later, SHF. Most of the work up to 1940 was concerned with studying the types, rapidity, and depth of fading and attempting, with only moderate success, to correlate the results with meteorological data.

Measurements of the temperature and moisture vapor gradients, made prior to and during the early period of World War II, showed the existence of atmospheric ducts. These ducts were found to exist at times upward a few hundred meters above ground, and at other times might exist as elevated layers. The ducts appeared to act somewhat like leaky waveguides. With sufficiently high frequencies, and with ducts of adequate thickness and strength to cause nonstandard refraction, the wave energy could be propagated largely inside the ducts and follow the curvature of the earth far beyond the radio horizon.

The full appreciation of this type of HF propagation was not developed until the war period itself. This period is outside the scope of this paper. Publications summarizing the work on atmospheric ducts and high frequencies done during the war are available.[22]

Contributions to the Antenna Field During World War II*

L. C. VAN ATTA†, FELLOW, IRE, AND S. SILVER‡, FELLOW, IRE

Summary—**During World War II intensive efforts of radio engineers and physicists resulted in the invention of many new types of antennas and in advances in fundamental antenna theory. The paper presents the results of this work in relation to the principal problem areas that were recognized during that period: 1) sidelobe suppression; 2) beam-shaping techniques; 3) beam-scanning techniques; 4) broadbanding; 5) antenna siting. In each of these areas major advances were made, both in operating hardware and in theoretical understanding.**

I. Introduction

The developments in the antenna field during World War II, the result of intensive and combined efforts of radio engineers and physicists, were marked by the invention of many new types of antennas, and also by advances in fundamental antenna theory. Indeed, the whole subject of microwave optics was born and grew to maturity during the war years. A review of the field leads us into many different directions. In choosing the subjects for this short résumé we have arranged the material, including theoretical considerations, according to certain operational developments. Because the achievements were so largely the result of the combined efforts of many people in the United Kingdom, Canada, and the United States, we have avoided ascribing any development to a particular person, even though in a few instances this would have been possible.

The review is divided into five sections: 1) sidelobe suppression, which relates to developments based on the concept of flat phase fronts; 2) beam-shaping techniques, which utilized new developments in microwave optics; 3) beam-scanning techniques; 4) broadbanding; 5) antenna siting, a subject of great importance in realizing the optimum performance of the systems and in measuring the characteristics of antennas.

II. Pencil Beams and Sidelobe Suppression

The first operational concept in the design of antennas for radar applications was that of providing a narrow beam whereby targets could be located with high precision in azimuth and elevation. The pulse technique of radar, of course, provides the range information, and the combination of beam and pulse techniques yields the three coordinates of the target in space. The operational requirement, based on the searchlight concept of optics, required not only that the main beam be narrow, but also that the sidelobe structure be kept low to avoid the ambiguity of targets detected on the sidelobes. Two main approaches were taken to achieve a narrow beam: the use of optical devices, lenses and reflectors, having the property of transforming a family of rays from a point source into a family of parallel rays; and the use of discrete arrays of elements based on the principle of interference.

The directive antennas to produce a main beam circularly symmetric about the axis utilized a paraboloid of revolution with a primary feed at the focus. In order to achieve maximum forward gain out of a given aperture the distribution in the field over the aperture should be uniform in both amplitude and phase. However, the sidelobe structure is determined by the distribution of amplitude within the uniform phase constraint, and a major aspect of the theoretical work in this field was the study of the interrelation between the aperture distribution and the entire radiation pattern of the system. This greatly enlarged the understanding of diffraction theory over what had been available prior to the war. It also led to a rediscovery of long forgotten monumental contributions made to the field of optics over a hundred years ago.

Much effort was devoted to the realization of a feed system having, on the one hand, the characteristic of a point source, that is, generating a spherical phase front, and, on the other hand, a power pattern which would properly illuminate the paraboloid. When the coaxial line was the preferred form of transmission line, the natural choice of primary radiator was the dipole and, in particular, the reflector-backed dipole. Dipole feeds did only a fair job of illuminating the reflector since they produced unequal illumination in the orthogonal planes, and hence asymmetry in the mainlobe. In addition, their considerable backlobe radiation had deleterious effects on gain and near-in sidelobe characteristics of the final pattern.

As was indicated, it is necessary to trade sharpness of the main beam for sidelobe reduction. The general result established was that the aperture illumination should be tapered by some 15 db between the center of the aperture and the edge. The half-power width of the main beam is given by $\theta = k\lambda/D$, where λ = free-space wavelength, D = diameter of the aperture; designs were developed for circular apertures which yield values of k in the range $1.2 \leq k \leq 1.5$ with near-in sidelobes down 20 to 25 db from the peak intensity of the mainlobe.

The availability of higher power, the move toward higher frequency and the toleration of heavier antenna structures, especially airborne, led to the use of rectangular uniconductor waveguides and compatible feed systems. The development of these waveguides and horns is certainly an outstanding feature of antenna work during World War II. Sectoral horns derived from rectangular waveguides by flaring in one or the other of the two principal planes of the guide, composite sectoral horns derived by flaring first in one plane and then in the orthogonal plane, and pyramidal horns derived by flaring simultaneously in both principal planes were developed for various applications. By virtue of the flexibility available in the design of a horn feed, it was possible to illuminate a reflector more effectively and to achieve improved performance with respect to backlobe and sidewise radiation. Three horn-feed types are shown in Fig. 1.

A major development in reflector design that accompanied the use of horn feeds was that of directing the axis of the horn pattern onto the reflector at an angle to the reflector axis. The reflector is then cut along an equi-intensity contour, again at an edge illumination some 15 db below the peak value over the aperture. Since the phase center of the horn remains at the focus, the phase distribution over the aperture remains plane yielding a directive beam. The importance of the technique is its flexibility in controlling sidelobe levels while retaining the required mainlobe characteristics. Such an antenna is shown in Fig. 2.

Operational needs arose for beams having mainlobes not circularly symmetric but of different beamwidths in two orthogonal planes, one very narrow to retain high resolution in the plane of scan, and the other relatively large to give extended coverage in the orthogonal direction. Such beams are known as *fanned* beams, and basic diffraction theory shows that they can be obtained by using rectangular or elliptical apertures with a corresponding ratio of their principal dimensions. The aperture illumination problem remains that of providing a uniform phase and a tapered amplitude distribution to control the sidelobe level; the horn feed solved this problem. Fig. 3 shows a paraboloid of revolution cut into an elongated elliptical shape and fed by a flared horn.

Another family of antennas designed to produce fanned beams consists of a parabolic cylindrical reflector between parallel plates illuminated by a sectoral horn feed at the focus. The exit pupil of the system is then a narrow rectangular aperture. Such antennas, known variously as cheese or pillbox antennas, served as ends in themselves or as line sources for illuminating larger parabolic cylinders, as shown in Fig. 4.

Microwave lenses were used in Germany prior to the war and were investigated extensively in the United States during the latter years of the war. In most military applications, however, lenses were not competitive with reflectors because of such factors as reduced gain, higher sidelobes, frequency sensitivity, greater weight and unfavorable shape. One development of note, however, must be mentioned in this survey. It was recognized that the dispersive property of a waveguide could be used in creating a medium having an effective index of refraction less than unity. The waveguide or metal-plate lens thus came into being but did not find actual application during the war. Fig. 5 shows an early type of waveguide lens.

Linear arrays also received a great deal of attention. The designs which were built around the coaxial line utilized dipole radiators, and there were many ingenious configurations devised for beacon antennas and related operational systems. Basically, however, these antennas were adaptations of ideas and developments already in use in radio-communications and direction-finder systems before the war. The distinct war-period contribution to the array system was the slotted waveguide array. The theory of slot radiators was developed extensively, and here it is appropriate to state that the basic work was largely provided by groups in the United Kingdom and Canada.

The excitation of a slot in the wall of a rectangular waveguide can be controlled by its position on the wall and the orientation of the axis of the slot with respect to the axis of the waveguide. It is this flexibility that makes possible the relatively easy control of excitation along the array. Of the many developments that were made in this field, the so-called Dolph-Tchebycheff array deserves special recognition. In this type of array the amplitude distribution along the array is related to the coefficients of a Tchebycheff polynomial. The result is a beam having all sidelobes of equal amplitude and therefore the narrowest beamwidth consistent with a prescribed sidelobe level. Sidelobe levels 30 db below the mainlobe peak were obtained, and in later developments following the war even lower sidelobe levels were achieved.

III. Beam Shaping

The operational requirements that motivated the design of fanned-beam antennas became rather quickly more demanding with respect to the more efficient utilization of the available power in air-search systems and more uniform ground illumination in airborne navigational and bombing antennas. One solution to the problem was obtained by the use of an extended feed in the focal plane of a paraboloid reflector. Each element of the feed produces a beam displaced from the axis by an angle proportional to the displacement of the element from the focal point. The resultant of the overlapping beams is a flared beam. High resolution in the transverse aspect is preserved until the coma aberration overrides the collimating property of the reflector. The theory of aberrations was advanced markedly in the course of this developmental program. The antenna on the left in Fig. 7 achieves a shaped beam by means of a three-horn distributed feed.

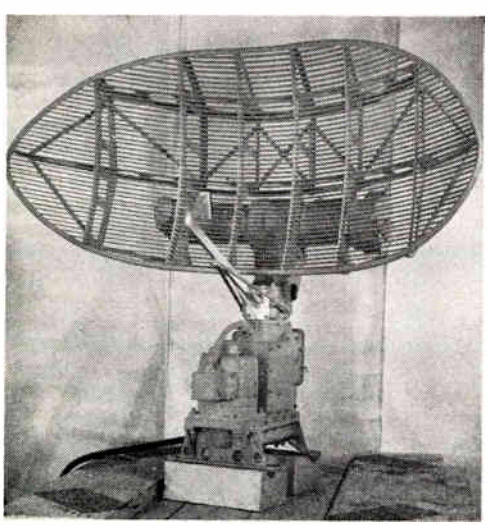

Fig. 2—Antenna with asymmetrically cut reflector.

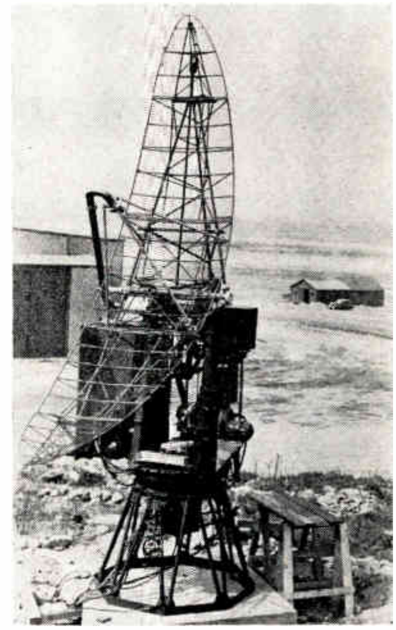

Fig. 3—Fanned-beam antenna.

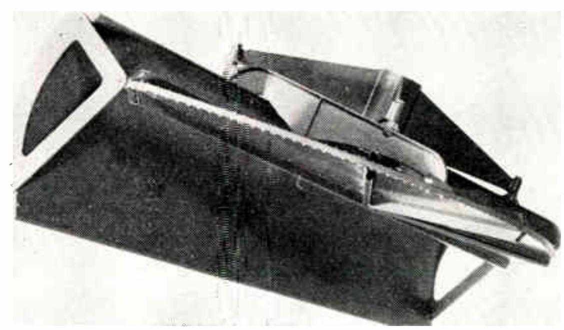

Fig. 4—Pillbox antenna feeding a cylindrical reflector.

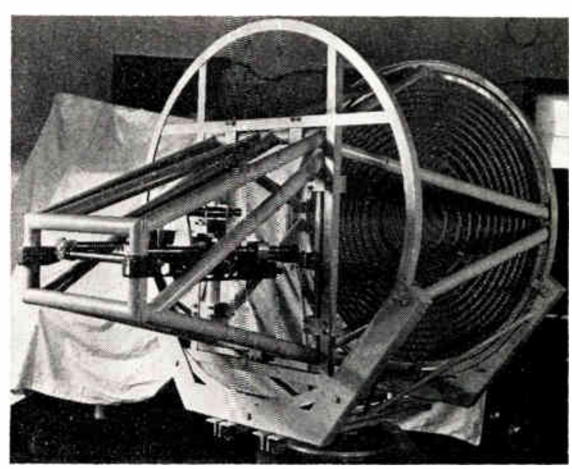

Fig. 5—Waveguide lens antenna.

The outstanding development, however, was the production of cylindrically curved phase fronts over the aperture of the antenna. By developing a phase front which is a section of a generalized cylinder, it is possible to obtain a flared beam which, in the transverse aspect, retains sharpness over large flare angles. The coma effect is eliminated since the rays are necessarily perpendicular to the generator of the cylinder. Both the underlying concepts and the realization of the system were major advances in microwave optics.

The requisite phase front was realized in several ways. One system utilized a line source feeding a cylindrical reflector whose cross section was designed to produce the dispersion of the ray system required for the flaring of the beam. The line source was aligned to be parallel to the generator of the reflecting cylinder. The sidelobe level in the transverse planes is determined entirely by the amplitude distribution along the line source. Both pillboxes and arrays were used as line sources, and all of the techniques for controlling sidelobe levels derived from flat phase fronts can be used in the design of the feed. (Fig. 4 represents this type of antenna.)

A second type of system utilized a point source feed with a modified paraboloidal reflector. The earliest form was made up of a split paraboloid of revolution with one section displaced relative to the other, so that the resulting phase front had a large amount of third-degree phase error. Advances in theory, however, led to a new type of reflector whose curvature varied from point to point so as to fit the ray requirements completely over the entire range of the beam. The complexity of the resulting surface was more than balanced by the simplicity inherent in the point source feed. This type of reflector, referred to as the doubly curved reflector, was used increasingly toward the end of the war. Fig. 6 shows an operational antenna of this class.

IV. Beam Scanning

A radar system must be able to scan its directive beam at a rate compatible with information rate called for by operational requirements. This must be accomplished while preserving resolving power and an effective SNR. Among the outstanding contributions made to the antenna art during World War II, were the developments in scanning techniques.

The obvious method of scanning by moving the entire antenna had soon to be superseded by other techniques as antennas became larger, and as higher scanning rates and complex scanning patterns became needed. In essence, the scanning problem is one of changing the orientation of the phase front at the aperture of the antenna. This must be done with minimum distortion of the phase front to preserve the structure of the beam. The various rapid-scanning techniques which were invented can be designated by the war-time categories as optical scanning, phase-shift scanning, and frequency-shift scanning.

In optical scanning only a part of the antenna is

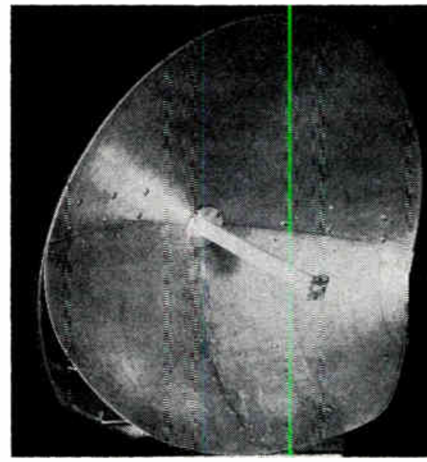

Fig. 6—Shaped-beam antenna employing a modified paraboloidal reflector.

moved. For example, the feed of a parabolic reflector can be moved off axis in the focal plane to obtain a limited angle of scan. In particular, the feed may be displaced slightly and then spun about the axis to achieve a conical scan. The differential signal from either side of the cross-over point yields a high accuracy of pointing and a convenient tracking signal.

The Robinson Roll antenna (right-hand antenna in Fig. 7) was the most ambitious application of the displaced-feed technique. The reflector had a long focal length in one plane and a relatively short focal length in the other. The feed was located at the far focal point, but was confined in one plane between parallel plates to meet the short-focus requirement. Moving the feed between the plates and parallel to the aperture then provided a scan in one plane. The final invention was to fold the plates in such a way that the oscillatory feed motion was replaced by a circular motion.

One system which was developed to effect the same purpose as conical scanning is essentially a data-processing technique. It uses a stationary feed system comprised of four feeds clustered in a square about the axis. These, when fed all in-phase and in out-of-phase pairs, form a central or sum lobe and two split or difference lobes in orthogonal planes, respectively. By using the sum lobe in transmission and the difference lobes and the sum lobe simultaneously on reception and comparing signals, one obtains a superior tracking antenna.

Three different examples of phase-shift scanning deserve mention. The Navy Mark 8 fire-control antenna (Fig. 8) scanned in an azimuth sector the beam formed by a two-dimensional array of "polyrod" endfire radiators, by separately controlling the phase to each vertical bank of radiators. This control was accomplished by rotating impedance elements in the circularly polarized field of cylindrical waveguide sections. In the Foster scanner a linear variation in phase was accomplished by control of physical path length; a wave between parallel plates was conducted around a variable portion of the circumference of a cone. The Eagle antenna was a

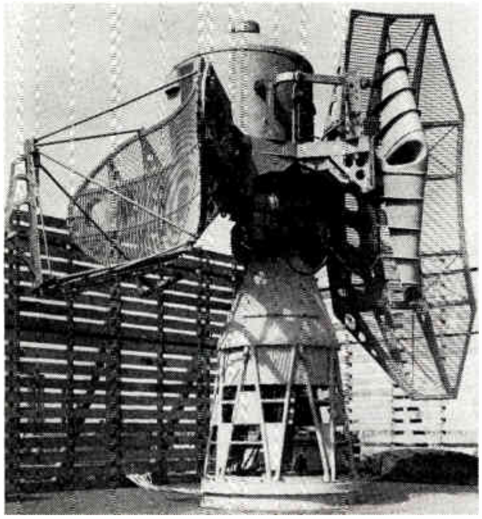

Fig. 7—Shaped-beam antenna (on the left) and Robinson Roll scanning antenna (on the right).

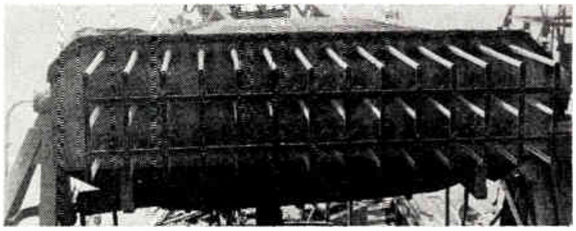

Fig. 8—Mark 8 "polyrod" scanning antenna.

linear array of dipole elements fed from rectangular waveguide. A linear-phase variation was obtained in this case by varying the major dimension of the waveguide and, hence, the optical path length between radiating elements.

Frequency-shift scanning makes use of the fact that the wavelength, and therefore the phase, along an array of radiators fed from a waveguide depends upon the frequency of the radiation. The scanning effect can be amplified by using a frequency-sensitive waveguide and by wrapping or folding the guide between radiators. This technique was explored during the war but did not find extensive application until later because of lack of frequency flexibility in available radio-frequency power sources.

V. Broadbanding

In the early days microwave power sources, even though designed for a spot frequency, came off the line with a spread in frequency. Later an even greater spread in frequency was required to reduce friendly jamming and to make enemy jamming more difficult. For these reasons the RF system, including the antenna, had to perform satisfactorily over a band of frequencies. Studies of a large variety of systems led to a clearer understanding of the factors limiting impedance bandwidth and of the methods of combining mismatches to cancel one another.

In the case of the antenna, satisfactory performance required that any of the essential antenna characteristics be maintained within certain limits over the specified band. These characteristics included power gain, beam-width, sidelobe level and, in the conical scan pattern, the cross-over level. The characteristic of greatest concern, however, in those days of the sensitive magnetron was the impedance of the antenna.

A constant impedance mismatch, even if large, could be corrected by a transformer at the magnetron, but a mismatch that varied widely and rapidly with frequency had to be eliminated or compensated at the point of origin. Frequency-sensitive mismatches resulted primarily from the combined effect of a series of discontinuities distributed along the RF line. Antenna mismatch was most serious since the antenna was farthest from the RF source.

Feeds for paraboloid reflectors were matched first independently of the reflector. Dipole feeds from coaxial lines, with their associated chokes and directive dipoles or plates, were relatively frequency sensitive with many critical dimensions requiring elaborate adjustments. Horn feeds from waveguides were basically better matched with fewer critical dimensions and were more susceptible to calculation.

The art of horn design reached an advanced state during the war years. If the waveguide was flared in both dimensions, the flare angles and their positions in the guide were chosen so that their discontinuities tended to compensate each other and also that caused by the mouth of the horn (see Fig. 1). Final correction was accomplished by capacitive or inductive strips at or near the mouth of the horn, or better, in some cases, by the thickness and placement of a plastic cover over the horn.

When the feed was placed in the reflector, an additional discontinuity resulted from reflection back into the feed. In some cases this discontinuity was corrected by a small plate placed a fraction of a wavelength in front of the vertex of the reflector. The size and placement of the vertex plate could be calculated from the geometry and the feed pattern. The vertex plate saw limited use, however, because it disturbed the aperture illumination and increased sidelobes. The ideal solution was found in the asymmetrically cut reflector (see Section II) which took the feed out, or almost out, of the reflected beam. In this case the feed was located at the focal point but directed off-axis approximately toward the center of the reflector area.

The reflector mismatch was much more serious in cylindrical reflectors, such as pillboxes fed by horns or long cylindrical reflectors fed by linear arrays. For these antennas it was essential that the feed be removed from the reflected beam. This was accomplished for the pillbox by the use of the folded pillbox or by the "hoghorn." In the folded pillbox the feed at one level was connected to the linear aperture at another level by a parabolic bend. In the hoghorn the feed, still at the focus, illuminated half a pillbox with the aid of a guiding horn. Both of these pillbox modifications, however, introduced additional weight and a less satisfactory form factor. In the case of a cylindrical reflector illuminated by a long linear array, the reflected wave striking the array seriously disturbed both the impedance and the radiation characteristics of the array. Therefore the array had to be kept well out of the path of the reflected wave.

The long linear array, in which only a small fraction of the incident power reached the far end of the array, was usually terminated in a load. This so-called nonresonant array provided a relatively good impedance match since the reflections from successive elements could be made to curl up into a small resultant mismatch at the input to the array. Short arrays, operated resonantly with a short-circuit termination, were more frequency sensitive in their impedance. In both cases, of course, well-matched or individually compensated radiating elements greatly improved the over-all performance.

VI. Antenna Siting

An antenna tested under relatively "free" conditions was found to perform quite differently under operating conditions because of reflection of its radiation by the surroundings. Reflection back into the antenna affected its impedance match; forward reflection affected the mainlobe or sidelobe characteristics of its radiation pattern. Toward the end of the war great strides were made in understanding and solving the complex problems created by the installation of many antennas on a single ship or aircraft.

A shipborne antenna with a horizontal beam had its elevation pattern sharpened and split into multiple lobes, and its gain increased by reflection of half of the mainlobe by the sea surface. The over-all effect was not simple since the reflectivity of the sea surface depends on wavelength and polarization of the radiation, angle of incidence, and sea state, and the combined pattern depends on height and orientation of the antenna.

A more complex installation problem was created aboard ship because many antennas were competing with each other in the presence of stacks, masts and superstructure for some semblance of free-space conditions. This so-called antenna-system problem was particularly severe for omnidirectional antennas. In the case of HF communication antennas, intercoupling between transmitting and receiving antennas and the sharply lobed patterns of individual antennas were known only through operational experience, so that maintaining satisfactory HF communications required black art of a high order. Radars were frequently installed in pairs with their antennas fore and aft or port and starboard in order to achieve complete azimuthal coverage.

Military aircraft also presented a serious antenna-system problem. Antennas for navigation, short- and long-range communication, and radar competed for favorable sites in the face of increasingly severe aerodynamic restrictions as aircraft speeds increased. The radar antennas, aircraft intercept or bombing and navigation, had the additional problem of operating through a radome, a plastic housing necessary for aerodynamic reasons.

The radome problem first presented itself dramatically when a naval aircraft search radar was found to be blanked out in certain sectors. This was found to be due to reflections from the radome back into the RF system pulling the frequency of the magnetron out of the pass band of the receiver. This impedance effect continued to be the most serious consideration. Under certain conditions, however, refractions and forward reflections could distort the mainlobe and introduce objectionable sidelobes.

Radome wall designs included the thin wall (zero-thickness approximation), the sandwich wall (two thin skins spaced a quarter wavelength apart by plastic foam), and the half-wave wall (a solid, high-density wall, one-half wavelength thick). During the war much attention was given to the sandwich wall, but shorter radar wavelengths, higher temperature requirements, and more severe microwave optical requirements eventually favored the half-wave wall.

Antenna siting problems were first encountered in connection with measurements made in the course of antenna development and test. With directive microwave antennas, measurements of the pattern and impedance were normally handled separately. For impedance measurements, satisfactory results could be obtained merely by pointing the antenna out through a large open window. For pattern measurements, especially since there was considerable interest in measuring low-level sidelobes, it was necessary to have transmitting and receiving antennas facing each other across a considerable distance from elevated vantage points, so that reflecting surfaces were well out of both beams. As antenna apertures increased, the minimum pattern range also had to be increased according to the relation $R_{min} = 2D^2/\lambda$, where D was the maximum dimension of either transmitting or receiving antenna.

Radio-Wave Propagation During World War II*

KENNETH A. NORTON†, FELLOW, IRE

Summary—**Many publications have appeared which describe the very extensive wartime radio-wave propagation research. References to some of these summaries are given which cover some aspects of this research as carried out in the United States, England, the U.S.S.R., Japan and Germany. These summaries are most complete for the work done in the United States, England and Japan.**

A summary is then given of some of the wartime research in the United States on direction finders and the polarization of downcoming ionospheric radio waves. This is followed by some heretofore unpublished material on Japanese ionospheric research which, by way of example, clearly indicates that an April, 1942, paper by Maeda, Uyeda and Shinkawa contains the first definite identification and interpretation of the F2-layer longitude effect. Finally a brief summary is given of a few selected topics in propagation research which arose out of the wartime development of radar.

I. Introduction

BECAUSE of the importance of radio to the efficient conduct of many military operations, an intensive effort was made during World War II to understand and to predict the nature of radio-wave propagation. Thus great advances were made in the application of such information to radio communication, radio direction finding, and radar. For the improvement of communications and direction finding, these advances were primarily in the prediction of ionospheric propagation and atmospheric noise levels. As regards radar, our knowledge of propagation characteristics was extended initially from about 100 Mc in an abrupt jump to 3000 Mc (*S* band) and later to 1000 Mc (*L* band), 10,000 Mc (*X* band) and 25,000 Mc (*K* band). This wartime research, begun in these higher frequency bands in England and later conducted vigorously in the United States, Canada, New Zealand and Australia, increased the usable portion of the radio spectrum by a factor of 250. Thus, immediately after the war it was possible to make extensive use of this new knowledge in the establishment of such peacetime services as FM and TV broadcasting, microwave radio relays and aircraft communication and navigation services.

Prior to World War II, the study of radio-wave propagation was confined to a few small laboratories scattered throughout the world. During and subsequent to the war, these activities were expanded many fold and now represent a continuing activity of relatively enormous extent. In a brief article of this kind, it will not be possible to mention more than a few of the highlights of this extensive research. Fortunately, several good summaries are available in the literature.

* Received by the IRE, January 2, 1961.
† Radio Propagation Engineering Division, National Bureau of Standards, Boulder, Colo.

A large part of the research in the United States on radio propagation was conducted under the auspices of the National Defense Research Committee [1], and summaries of this research were issued by the Columbia University Press for distribution by the War and Navy Departments. The reports in this series of interest in connection with radio-wave propagation are contained in the "Summary Technical Reports" of Division 13, Electrical Communication, Division 14, Radar, and the Committee on Propagation. The Division 13 report is in four volumes, of which vols. 1, 2A and B contain some discussion of propagation. Volume 1 includes a discussion of the direction of arrival of downcoming ionospheric radio waves, and the bibliography lists several reports dealing with polarization errors in high-frequency direction finders and studies of the polarization of downcoming ionospheric radio waves which have not subsequently been published elsewhere; a summary is given in the following section of this paper. Volume 2A includes a discussion of the effects of hills and trees on radio propagation and a brief discussion of ionospheric propagation. Volume 2B deals with electronic navigation systems. The Division 14 report on radar contains a bibliography dealing with radio propagation. The NDRC Committee on Propagation published a three-volume report which gives extensive coverage of the work conducted during the war; in particular, volume 3, entitled "Propagation of Radio Waves," should be in the library of all serious students of this subject. In addition to these summary reports, the NDRC also sponsored the well-known Radiation Laboratory Series [2], and the following volumes of this series contain information on radio-wave propagation: vol. 2, "Radar Aids to Navigation," edited by J. S. Hall; vol. 4, "Loran," edited by J. A. Pierce, A. A. McKenzie, and R. H. Woodward; vol. 13, "Propagation of Short Radio Waves," edited by D. E. Kerr; vol. 24, "Threshold Signals," edited by J. L. Lawson and G. E. Uhlenbeck. The NDRC also sponsored the publication in two volumes of "Very High Frequency Techniques" [3], which were compiled by the staff of the Radio Research Laboratory of Harvard University.

Dellinger and Smith [4] published an excellent review of the developments in radio sky-wave propagation research and applications during the war, and Gladden [5] published a history of vertical-incidence ionosphere sounding at the National Bureau of Standards.

In England good summaries of wartime propagation research were published by Appleton [6], Tremellen and Cox [7], and Smith-Rose [8]. A most valuable source of war research results obtained in England is "Meteorological Factors in Radio-Wave Propagation," a Report of a Conference held on April 8, 1946, at the Royal Institution in London by the Physical Society and the Royal Meteorological Society.

Bailey [10] has prepared a thorough report on the very extensive Japanese research on radio-wave propagation before and during World War II; the ionospheric research portion of this report is summarized in Section III of this paper.

As regards Germany, a good review of their scientific activities during the war is given in the "FIAT Review of German Science" 1939–1946 [11]. However, there is very little discussion of radio propagation in this review; pertinent books in this series are: "Electronics Including Fundamental Emission Phenomena," vols. 1 and 2, by G. Goubau and J. Zenneck; "Geophysics and Geodesy," vols. 1 and 2 by J. Bartels; "Meteorology and Physics of the Atmosphere," by R. Mügge.

In an effort to obtain a balanced account of the research on propagation in the U.S.S.R. during this period, I solicited the assistance of Vladimir A. Kotelnikov who responded as follows:

> I received your letter with the request for information about the investigation on the propagation of radio waves carried out in the Soviet Union during the period of the Second World War. I am sending a list of fundamental work on the ionospheric and tropospheric propagation of radio waves belonging to this period. The questions which interest you in greater detail are discussed in the review by B. A. Vvedenskii and A. V. Sokolov, "Investigations of Tropospheric Propagation of Meter, Decimeter and Centimeter Radio Waves in USSR," published in *Radio Technika and Electronica*, vol. 2, no. 11, pp. 1375–1389, November, 1957; and likewise in the articles "Investigations of Propagation of the Radio Waves Along the Surface of the Earth in U.S.S.R.," by M. P. Doluckanov, pp.1344–1359, and in A. N. Kazantzev, "Investigation of the Ionospheric Propagation of Radio Waves in USSR," published in the same issue on pp. 1360–1375. These articles are accompanied by extensive bibliographic lists.

Enclosed with his letter were references [12]–[29] which, together with the above, appear to cover the more significant research carried out in the U.S.S.R. during the war.

II. Studies of Polarization Errors in Direction Finders and the Polarization of Downcoming Ionospheric Radio Waves

Work in long-distance radio location and direction finding at the National Bureau of Standards began in the Radio Section in Washington, D. C., which during World War II became the Interservice Radio Propagation Laboratory (IRPL), and afterwards the Central Radio Propagation Laboratory (CRPL), now located at Boulder, Colorado.

A direction finder may be responsive to vertical or horizontal polarization or to both polarizations phased in various ways, but one polarization may produce an undesired response which causes an error in the reading. This undesired response is a function of the geometrical properties of the instrument, its mountings and various accessories, such as RF cables. A combination of modes in the downcoming ionospheric wave results in more or less random polarization. From instant to instant the relative amplitudes and phases of the wanted and unwanted components of the arriving wave keep changing, causing the polarization error to change.

It is difficult to compare direction finders and evaluate their polarization errors by observing sky waves, for which bearings depart from their true great circle values for a variety of causes. Thus some simple test technique was desired which would offer an estimate of the polarization-error propensities of any particular direction-finder design. The first test of this type had been evolved by Barfield in England [30]. A balloon with a target transmitter and antenna producing a circularly-polarized wave at a downcoming angle of 45° was placed near the equipment under test. The polarization error observed was called the *standard-wave error*.

At NBS a group under the late H. Diamond [31]–[39] devised techniques whereby pickup factors for the desired and undesired polarizations were determined from fixed target transmitters. These pickup factors were then treated analytically in accordance with a procedure designed for each type of direction finder and polarization errors determined for any set of conditions.

In the case of the simple Adcock antenna, the desired polarization is parallel to the plane of incidence and the undesired polarization is normal to the plane of incidence. The plane of incidence is the plane normal to the ground which contains the incident downcoming ionospheric ray.

The pickup factor for a wave polarized parallel to the plane of incidence was called h. That for a wave polarized normal to the plane of incidence was called k. If h and k were known then the polarization angular error ϵ could be determined (in the notation used by the Diamond group) from

$$\tan \epsilon = \frac{k}{h} \frac{E_n}{E_{pz} \cos \psi},$$

where E_n is the resultant total vector electric field component normal to the plane of incidence (*i.e.*, horizontal polarization) after combination of the incident and ground reflected wave, and E_{pz} is the resultant total vector-electric-field component parallel to the plane of incidence and normal to the ground after the combination of the incident and ground-reflected wave components. ψ is the angle of elevation at the ground of the downcoming ray.

A figure of merit ϵ_0 was proposed for a direction finder which may be determined from $\tan \epsilon_0 = (k/h)$; it is clear that a direction finder may be less subject to polarization errors the smaller the value of ϵ_0.

The advantage of the method was that h and k could be measured on the ground. One type of error called *radiator parallax* occurred in measuring k in direction finders like the balanced H Adcock. This was due to a net unwanted vertical pickup in the system when a horizontal dipole was used as a source of perpendicular polarization. In the case of spaced vertical loops another type of error called *controlled parallax* was studied. The forward tilt component of the target transmitter's magnetic vector produced an unbalanced voltage in the system. Both of these errors in measuring h and k could be minimized by increasing the distance to the target transmitter.

In support of this experimental work, a comprehensive theoretical study of the polarization of downcoming ionospheric radio waves was made by the author [40]. Extracts from the conclusions to this report are given herewith. Its principal purpose was to provide a picture of the nature of the polarization of downcoming ionospheric radio waves with emphasis on those characteristics which affect the operation of a direction finder. It was found convenient to separate the study into two parts: 1) a study of the polarization of the downcoming waves before they reach the surface of the earth, and 2) the modification in the polarization caused by the fact that the wave collectors of the direction finder are placed near the ground so that the resulting wave at the direction finder consists of both a direct wave and a wave reflected from the ground.

For a study of direction finding, the polarization of a downcoming wave is adequately described when we can specify the ratio of the intensities of the components of the electric and magnetic fields polarized parallel and normal to the plane of incidence and the relative phase between these components. It was found that, at very high frequencies, the magnitude of the ratio (E_{nd}/E_{pd}) in the downcoming wave varies from a value much less than one to a value much greater than one, the median value of this ratio being one; for one per cent of the time it is greater than 10, and for one per cent of the time it is less than 0.1. These results follow from the assumption, which is reasonable at very high frequencies, that the normal and parallel components of the downcoming wave are each random variables, independently Rayleigh distributed in time about the same median value; on this assumption it follows that the magnitude of the ratio (E_{nd}/E_{pd}) will exceed q with a probability $p=1/(1+q^2)$. At very low frequencies (E_{nd}/E_{pd}) is distributed over a narrower range of values; its median value will be much less than one when the transmitted wave is polarized parallel to the plane of incidence at the ionosphere and will be much greater than one when the transmitted wave is polarized normal to the plane of incidence at the ionosphere. Near the gyro-frequency the extraordinary wave is absorbed in the ionosphere and the ratio (E_{nd}/E_{pd}) becomes equal to the constant value $R_d \exp(-iB)$ which is the limiting value of the ratio (E_{nd}/E_{pd}) for the ordinary downcoming wave as it emerges from the ionosphere. Just below the maximum usable frequency only the extraordinary wave returns to the earth and the ratio (E_{nd}/E_{pd}) becomes equal to the constant value $(1/R_d) \exp\{-i(B-\pi)\}$. At very high frequencies the relative phase between E_{nd} and E_{pd} is random, whereas at very low frequencies values of the relative phase near B are more probable when the transmitted wave is polarized parallel to the plane of incidence, while values near $(B-\pi)$ are more probable when the transmitted wave is polarized normal to the plane of incidence. Near the gyro-frequency the relative phase becomes equal to the constant value B, and just below the maximum usable frequency the relative phase becomes equal to the constant value $(B-\pi)$.

For wave collectors near the ground, the effect of the ground is to suppress the normal component in favor of the parallel component of the resulting wave under most circumstances. When the elements of the direction finder responsive to the undesired normal components of the resulting wave are buried underground as in the shielded U direction finder, this suppression will be very large indeed so that a direction finder should be comparatively free from polarization error. On the other hand, when a direction finder is to be operated primarily at the shorter distances so that the elevation angles of the downcoming ionospheric waves are large, the parallel components of the downcoming waves will be suppressed in favor of the horizontal components for wave collectors above the ground and a direction finder designed to operate on these latter components, such as one with spaced vertical magnetic-dipole wave collectors, would be expected to have some advantages. When, as in most direction finders, the parallel component of the electric field (or the normal component of the magnetic field) is the desired component while the normal component of the electric field is the undesired component, there will be less polarization error when the direction finder is located over soil with the largest possible value of the index of refraction, n, *i.e.*, over soil with the highest possible dielectric constant and conductivity. In Part 4 of Norton [40] a simple method for measuring these ground constants is described.

The problems arising when testing a direction finder by means of fields transmitted from a source at a comparatively short distance away were also discussed in Part 4. Due to the great complexity of the fields at distances less than one wavelength from a transmitting antenna and the lack of any reasonably simple, yet accurate, relations for the field at these short distances, it is considered desirable to keep the source for testing the direction finder at a distance greater than one wavelength. It was shown that, owing to the presence of a surface wave from the nearby transmitter which is absent in the case of the downcoming ionospheric waves, tests for determining the magnitude of the polarization error of a direction finder can only be made for high elevation angles, unless the source is removed to a very great distance, or unless appropriate correction is made for the effect of the surface wave. In general, it would appear that the National Bureau of Standards' method of testing a direction finder for polarization error is to be preferred; in this method the polarization of the test wave is measured at the direction finder, and the direction finder performance is then calculated using the relations given in Part 3.

The method of calculating the electric field corresponding to the magnetic field as measured by a loop antenna is also given in Part 4.

A direction-finder site should be on very level land with uniform ground conductivity. It was proposed that information of value concerning a proposed site could be obtained very easily and rapidly by transmitting from a vertical magnetic dipole and measuring the ground constants at various points on the site using the method described in Part 4 [40].

Since the electric and magnetic fields at a depth Δ below the surface of the earth are of interest in connection with the operation of some types of direction finders, expressions were given for these fields in this paper. These results anticipated the treatment of this subject and the problem of transmission from underground antennas given in a 1951 thesis by Moore, a revision of which has recently been published [41], in reports by Banös and Wesley [42] and in papers by Wait [43] and others.

The above rather extensive summary of this work has been given since it has not been published subsequent to declassification.

There is continuing interest in the problem of ionospheric radio-wave polarization. In 1950 Aden, de Bettencourt and Waterman [44] pointed out an error in the above report by the author; they showed that the major axes of the ordinary and extraordinary ellipses are not in general mutually perpendicular, but instead have the property that the sum of the angles which they make with the direction (normal to the plane containing the direction of propagation and the earth's magnetic field) is an odd multiple of $\pi/2$. A still more recent summary of this question is given by Murty and Khastgir [45].

The behavior of reflected downcoming ionospheric radio waves described above is to be expected when the ordinary and extraordinary wave components fade independently after traversing different paths through the ionosphere. This case is essentially different from the polarization fading of satellite signals which involve ordinary and extraordinary waves which follow essentially the same path in traversing the ionosphere; this latter phenomenon has recently been used by Little and Lawrence [46] to measure the electron content along the path through the ionosphere traversed by satellite signals.

III. Japanese Ionospheric Observations During the War

Shortly after the end of the war in October, 1946, a brief summary of Japanese ionospheric research was prepared by D. K. Bailey and N. Smith under the title appearing in the heading of this section. It was submitted to an English journal for publication, but no word was ever received from that journal relative to its acceptability and, as a consequence, this account was never published. It seems appropriate to include it in this historical summary and it is given here in full:

A substantial contribution to the scientific knowledge of the world is to be found in the work of Japanese scientists, during the war, on radio wave propagation.

This work is summarized in a recent report distributed by the Chief Signal Officer, United States Army Forces, Pacific, in Tokyo [10]. Besides abstracts of the research papers on radio propagation, the ionosphere, atmospheric noise, radiation, reflection, tropospheric propagation, antennas, direction finding, and diversity reception, this report gives also the results of vertical-incidence pulse ionosphere measurements of the usual *h'f* type made at many locations in Asia and the Western Pacific. These data and reports are now on file at the Central Radio Propagation Laboratory of the National Bureau of Standards and may be consulted for further details.

Particularly interesting are the ionospheric data. Observations of the *h'f* type were made between 1934 and 1945 at nineteen locations scattered throughout Eastern Asia and the Western Pacific, over periods ranging in length from ten months to ten years. It is of interest to note that only the developments of the Pacific War prevented the operation by the Japanese of eight additional stations in 1944 and 1945.

The stations actually operated by the Japanese are listed in Table I. In addition to these, the following stations were planned or under construction, but never actually operated:

Naha, Okinawa
Tainan, Formosa
Seishin, Korea
Hanoi, French Indo-China
Saigon, French Indo-China
Palembang, Sumatra
Kwajalein Atoll
Rabaul, New Britain.

The geographical disposition of the stations included in the Japanese program extended from Paramushiro in the north to Bandoeng in the south, and from Rangoon in the west to Kwajalein Atoll in the east. At the height of the program, in the spring of 1944, there were fourteen different stations in simultaneous operation—nearly one-third of the total number of stations in operation throughout the world at that time.

Nearly all the Japanese ionosphere data have fortunately been preserved. By far the most interesting feature of the data is the ample confirmation they provide for our previous ideas about the longitude effect in the *F2* layer. The data from the southern stations, at Hankow, San-Ya (Hainan), Rangoon, Manila, Palau, Penang, Singapore, Makassar, and Bandoeng are of particular interest, since they supply for the first time a nearly complete definition of the remarkable trough in daytime critical frequencies centered near the magnetic equator, and concerning which observations elsewhere, particularly in the Western Hemisphere, had provided little more than a suggestion of existence.

Particularly noteworthy is the fact that the Japanese first recognized the possibility that the *F2* layer of the ionosphere might exhibit different characteristics at the same local time and latitude in different longitudes, a behavior now generally termed the longitude effect, when they attempted to reconcile the data from Washington (lat. 39°N) with their data from Tokyo (lat. 36°N) and their Hokkaido observations (lat. 42.5 and 43.5°N) taken in June 1936 in con-

TABLE I

LIST OF JAPANESE IONOSPHERE STATIONS

Place	Operating Agency	Latitude	Longitude	Period of Operation	Last Available Data
1) Paramushiro, Kurile Islands	Navy	50.1°N	155.3°E	Nov, 1943–Sep, 1944	Sep, 1944
2) Shikuka, Karafuto	Navy	49.3	143.0	Oct, 1940–Dec, 1941	Dec, 1941
3) Tsitsihar, Manchuria	Army	47.3	123.9	Apr, 1940–Aug, 1945	Jul, 1945
4) Toyohara, Karafuto	Ministry of Education	46.9	142.8	Sep, 1942–Jul, 1944	Jul, 1944
5) Dairen, Kwantung	South Manchurian Railway	39.0	121.6	Dec, 1944–Unknown	Feb, 1945
6) Tokyo and vicinity					
a) Hiraiso	Ministry of Communications	36.4	140.6	Jun, 1936–Jul, 1945	Jul, 1945
b) Kokubunji	Ministry of Education	35.7	139.5	Aug, 1943–Dec, 1944	Dec, 1944
c) Meguro	Navy	35.6	139.7	Jun, 1934–Nov, 1940	Nov, 1940
d) Kaminoge	Ministry of Education	35.6	139.6	Jan, 1945–Aug, 1945	Aug, 1945
e) Hiratsuka	Navy	35.3	139.3	Dec, 1940–Apr, 1945	Apr, 1945
7) Hankow, China	Ministry of Education	30.7	114.3	Sep, 1941–Dec, 1944 (No observations, 1942)	Dec, 1944
8) San-Ya, Hainan Island	Navy	18.3	109.3	Jun, 1942–Jun, 1943	Jun, 1943
9) Rangoon, Burma	Army	16.8	96.5	Jun, 1943–Feb, 1945	Dec, 1944
10) Manila, P. I.	Army	14.6	121.0	Mar, 1944–Dec, 1944	Nov, 1944
11) Palau Islands	Navy	7.3	134.5	Jul, 1939–May, 1944	May, 1944
12) Penang, Malay States	Navy	5.5	100.4	Mar, 1944–Aug, 1945	Jul, 1945
13) Singapore, S. S.	Army	1.4	103.7	Feb, 1943–Aug, 1945	Aug, 1945
14) Makassar, Celebes	Navy	5.2°S	119.5	Jan, 1944–Oct, 1944	Oct, 1944
15) Bandoeng, Java	Army	6.9	107.6	May, 1943–Aug, 1945	Aug, 1945

nection with the solar eclipse of that month. In 1940 new stations were established at Tsitsihar, Manchuria (lat. 47.3°N) and Shikuka, Karafuto (lat. 49.3°N) which soon gave a sufficient body of data to permit a more detailed study of the longitude effect.

In April, 1942, the Japanese published a paper [47] giving the results of, so far as is known, the earliest quantitative as well as qualitative study of the longitude effect and attributing it to a geomagnetic influence. The freely translated title of the paper is "Differences of Ionospheric Conditions in the F2 Region between Two Points Lying in the Same Latitude but Having Different Longitudes." The paper, which is fully summarized in the Tokyo report [10], gives much attention to the preparation of contour charts of the critical frequencies of the F2 layer as a function of local time and both geographical and geomagnetic latitude. The writers found that the hitherto unreconcilable Washington observations could be satisfactorily used in Eastern Asia for the preparation of contour charts if the data were used at geographical latitude 60°N, the latitude having, in Japanese longitudes, the same geomagnetic latitude as Washington.

The Tokyo report [10] has the following to say in connection with failure of scientists outside of Japan definitely to recognize the longitude effect before 1943: "In fairness to the work on this subject done on the Allied side, it must be pointed out that the Japanese had nearly complete results of ionosphere observations made elsewhere in the world up to the end of 1941, whereas practically none of the Japanese work has been available before the present time. Nevertheless it is clearly necessary to assign the credit for the discovery of the longitude effect to the Japanese."

The Japanese ionospheric data now available go far toward filling in one of the three major gaps remaining, at the end of the war, in coverage of the land areas of the world by ionospheric observing stations. It is to be hoped that the future will see ionospheric stations in the other two gaps, which include temperate South America and Africa.

Somewhat later Bailey [48] published a more complete discussion of the geomagnetic nature of the F2-layer longitude effect. The existence of this longitude effect has always constituted one of the principal complications to the compact prediction of F2-layer maximum usable frequencies on a world-wide basis. Currently this is accomplished by publishing world maps [49], [50] for each even hour of the day and month of the year. In the near future a still more accurate method of prediction will be available; a first paper on this new method has been published by Jones and Gallet [51], and further papers are expected in the near future.

IV. Topics from the Propagation-Related Wartime Radar Research

The development of radar introduced a very large number of wave-propagation problems and at the same time provided a very useful tool for exploring some of these problems. These problems were for the most part associated with the matter of determining the maximum range of the radar for a target with a given effective echoing area and discriminating between the desired target and reflections from land masses or other objects [1], [2], [3], [8], [9]. A summary of the influence of some of these radar-propagation phenomena was given shortly after the war by Norton and Omberg [52].

The maximum range expected for a standard atmosphere was often shown in the form of a lobe diagram giving contours of maximum range in the vertical plane with distance as the abscissa and height above the curved surface of the earth as the ordinate. Such a plot indicated the gaps in coverage caused by interference between the direct and ground-reflected waves. When these two waves are in phase, the range reaches its maximum value, this maximum being determined by the transmitter power, antenna gain, a visibility factor and the operating noise factor. The concept of an operating noise factor was originated by North [53], [54], who showed that it depended not only on the noise factor of the radio receiver but also on the effective noise temperature of the radiation impedance of the receiving antenna. These concepts opened up a whole new field of research. Friis [55] introduced the concept of available power, thus obtaining a precise definition of the receiver noise factor which he called a *noise figure*. The author [56] has generalized these results to allow for image responses and for differing ambient temperatures of the various lossy components in the receiving system, thus obtaining a very general expression for North's operating noise factor and a general expression for the effective input noise temperature for a receiving system; this latter temperature has also been called an *operating* or *system* noise temperature. This operating noise temperature t_e is expressed in degrees Kelvin and provides a convenient measure, which is currently coming into widespread use, of the sensitivity of a receiving system. The operating noise temperature is related to the operating noise factor f and to an absolute arbitrarily-fixed reference temperature t_0 by $t_e \equiv f t_0$. Since f and thus t_e depend in general on losses or gains and image responses in various components of the receiving system and may also depend on the direction in which the receiving antenna is pointed, t_e can be identified with an actual temperature only by virtue of the fact that it has the dimensions of a temperature. This follows from the fact that the operating noise factor f is a dimensionless positive factor which is usually much larger than one but which may be very much less than one for microwave receiving systems employing low-noise receiving antennas and masers. The concept and method of calculation of an effective temperature of the receiving antenna have been described by Slater [57] and by Lawson and Uhlenbeck [58]. At frequencies of the order of 100 Mc and lower, cosmic and atmospheric noise determine the effective antenna temperature, whereas at higher frequencies the temperatures of the antenna foreground and of the absorbing constituents of the atmosphere usually control the antenna temperature; the effective temperature of an antenna pointed directly at the sun may be determined from its surface temperature of 6000° K and the antenna directivity as discussed by Southworth [59].

The most important gap in the radar coverage occurs near the radio horizon as a result of the weakening by diffraction of the radio waves in propagation over the curved surface of the earth. Under certain circumstances, however, radio waves at sufficiently high frequencies may be trapped in an atmospheric duct. This type of propagation was studied intensively during the war because of its great operational importance. A paper by Booker and Walkinshaw [9] provides a theoretical discussion of the main features of this interesting phenomenon. Duct propagation was found to be the normal mode throughout the day at sufficiently high frequencies over the sea, but at lower frequencies and for propagation over land trapping was a sporadic phenomenon.

Prior to and during the war, radio waves scattered from the troposphere were observed; a good summary of these early observations is given in a paper by Bullington [60]. Shortly after the war, these beyond-the-horizon fields were sometimes confused with the waves propagated via ducts, but research at NBS and elsewhere [60] soon established that these scattered waves were present even under standard atmospheric conditions when no ducting was expected. This led to the development of the Pekeris and Booker-Gordon theories of scatter propagation which will no doubt be discussed in a companion paper [61].

Finally, it is of interest to point out that radar reflections from the moon were first observed on January 10, 1946, by DeWitt and Stodola [62] using a war-developed radar set. Here again these observations opened up a new field of research which has recently had a revival of interest in connection with the current intensive investigation of outer space.

Advances in the Field of Antennas and Propagation Since World War II: Part I—Antennas*

E. C. JORDAN†, FELLOW, IRE, AND R. W. P. KING‡, FELLOW, IRE

Summary—**Progress in the quantitative understanding of antennas as circuit elements, transmitters, receivers and scatterers of electromagnetic radiation is reviewed briefly for the period 1945–1961. Advances in the design of selected radiating systems with special properties are indicated.**

Specific reference is made to the impedance, current distribution, and pattern characteristic of cylindrical dipoles, singly and in arrays. Particular developments touched upon include slot and surface wave antennas, microwave antennas and microwave lenses, super-gain antennas, and very large antennas and arrays for radio astronomy and satellite communication. Frequency-independent "angle" antennas and log-periodic structures are reviewed briefly.

Introduction

The WIRELESS transmission of signals depends critically on the radiating and receiving properties of antennas. In the period 1945–1961 significant advances were made in the quantitative understanding of the fundamental properties of antennas and many new and useful types of radiating systems were developed. In this brief review references can be made to only a small cross section of this rapidly growing field.

The Dipole Antenna

The basic radiating element is the dipole in the broad sense of a symmetrical center-driven conductor, half of such a conductor with its image in a metal screen as shown in Fig. 1 (or, by complementarity, a slot in a metal plane). The groundwork in the quantitative study of cylindrical, biconical, and spheroidal dipoles as boundary-value problems in electromagnetic theory instead of as sources with arbitrarily assumed distributions of current was laid in the years just preceding 1945. Research since that time has been extensive and so fruitful that the behavior of these antennas is now well understood in a detailed quantitative sense.

The transmitting and receiving properties of the cylindrical dipole have been determined theoretically in overlapping ranges by iterative, variational, Fourier-series, and Wiener-Hopf methods. The impedance is now known for antennas of any length over a broad range of ratios of radius to wavelength. Typical curves are shown in Fig. 2. A simple and quite accurate formula for the current when $kh=2\pi h/\lambda \leq 3\pi/2$ is

$$I(z) = \frac{j2\pi V}{\zeta\Psi \cos kh} \cdot [\sin k(h - |z|) + T(h)(\cos kh - \cos kz)], \quad (1)$$

where $\zeta = 120\pi$ ohms and where Ψ and $T(h)$ are complex coefficients that depend on the length and the radius of the conductor. Excellent correlation between theory and extensive series of measurements was achieved as soon as the interesting problem of end and coupling effects for various types of transmission lines had been solved and the properties of the idealized generators used in the theory were understood. Extensions of both the theoretical and the experimental techniques have been made

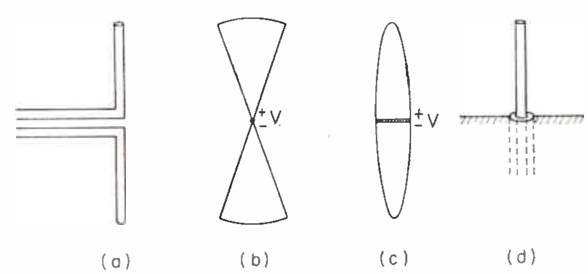

Fig. 1—(a) Cylindrical dipole driven from two-wire line. (b) Biconical antenna driven by idealized point generator. (c) Spheroidal antenna driven by idealized slice generator. (d) Cylindrical half dipole over conducting image plane.

to cylindrical antennas in dissipative media including their application as probes to study ionized regions in space. The response of dipoles to voltage pulses has also been studied theoretically and experimentally.

Corresponding progress has been made in the study of asymmetrical, folded and special antennas, as well as of the closely related loop antenna both with and without a ferrite core (which behaves like a magnetic dipole when electrically small).

The power transferred to the load of a cylindrical receiving antenna in an arbitrarily polarized plane-wave field incident from any direction has been obtained from an analysis of the distribution of current (which differs significantly from that in a transmitting antenna). The directional properties and the EMF in an equivalent circuit are expressed in terms of a complex effective length. The scattering of electromagnetic waves from variously loaded cylindrical antennas has been analyzed and measured; in particular, the back-scattering cross section has been determined for a thin dipole of any length.

The complete electromagnetic field of the driven dipole with an assumed sinusoidally distributed current was well known in 1945. More correct fields have since been obtained with the current given by (1) and from the application of the reciprocal theorem to the quite accurately known effective length of the receiving antenna. For very long antennas a Wiener-Hopf solution has yielded good results. Measured field patterns are in satisfactory agreement with theory.

Many of the properties obtained for thin cylindrical antennas have been translated to apply approximately to narrow slot antennas in a conducting plane with the help of the principle of complementarity. Advances similar to those summarized for the cylindrical dipole have also been made for biconical and spheroidal antennas.

Dipole Arrays

An unlimited variety of directional patterns may be achieved with suitably designed arrays of dipole antennas in air or slots in metal surfaces. In 1945 a very substantial knowledge existed about the properties of arrays of elements that are geometrically alike and are *assumed to have identically distributed* currents. Important advances in arrays of this type since 1945 include the proper choice of currents in the elements in order to achieve optimum relationships especially between the beamwidth and the minor lobe level, the use of elements that are of unequal length and unequally spaced in order to obtain broad-band properties, the development of methods for the synthesis and for the scanning of patterns, and new mathematical techniques that involve the application of potential theory and the treatment of the currents in the elements as sampled values of continuous functions.

Significant progress has also been made in the determination of the actual current distributions and the self- and mutual impedances of coupled elements in collinear, circular, and curtain arrays including Yagi, corner-reflector and special types of antennas. Except in arrays of half-wave dipoles and regular phase-sequences in circular arrays, the distributions of current along the several elements are far from alike, so that the actual field patterns with specified input currents may differ greatly from those predicted by conventional theory, especially with reference to the nulls and minor lobes. Distributions of current on a couplet of two full-wave elements with specified input currents, $I_{20}=jI_{10}$, are shown in Fig. 3 and the resulting field pattern in Fig. 4, together with the ideal pattern for identically distributed currents.

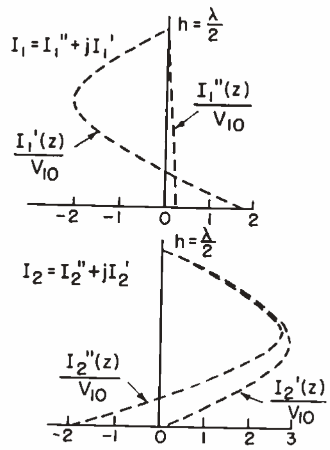

Fig. 3—Currents in the upper halves of the two elements of a full wave couplet; $I_2(0)=jI_1(0)$; $h/a=75$.

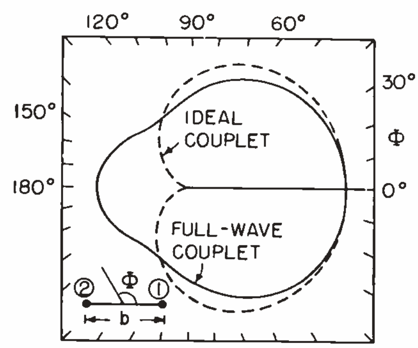

Fig. 4—Horizontal field pattern of couplet wjen $b=\lambda/4$; for ideal couplet with $I_2(z)=jI_1(z)$ and for full-wave couplet with currents shown in Fig. 3.

Surface Wave Antennas

Surface waves are associated with an interface between two media, their most important characteristics being the exponential decay of their field components in an equiphase surface perpendicular to the direction of propagation. The surface wave does not transmit power away from a lossless supporting interface unless the supporting structure is terminated or a discontinuity of some kind is introduced. The radiation pattern may be analyzed in essentially the same way as that of other aperture antennas from the field distribution in the terminal plane. For a nonuniform or modulated supporting structure there are, in addition, the radiation fields generated by the nonuniformities.

Although many of the characteristics of surface waves have been known for some time, not much attention was paid to practical uses in transmission lines and radiating systems until after the development of high-powered microwave oscillators during and after World War II. It was found that suitable interfaces that support surface waves generally consist of plane or cylindrical dielectric materials, such as sheets, rods or tubes as well as plane or cylindrical transversely corrugated metallic interfaces.

The dielectric rod antenna has been extensively used both singly and in arrays (see Fig. 5). It may have a square or circular cross section and may be excited in one of several possible surface-wave modes. The maximum of the radiation pattern is along the axis of the rod.

Corrugated end-fire antennas were developed where a higher degree of rigidity and heat resistance was required (see Fig. 6). In many cases it has been found possible to support the surface wave by means of corrugations in the aerodynamic structure itself. The corrugations are filled with a suitable dielectric material so that streamlining of the aerodynamic body is undisturbed.

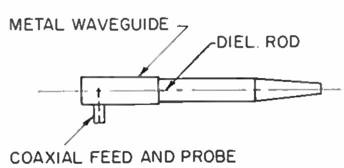

Fig. 5—Dielectric rod antenna.

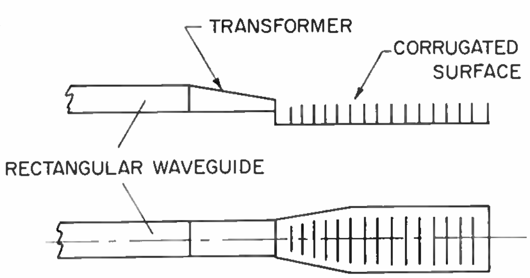

Fig. 6—Corrugated surface antenna.

Other antennas whose behavior may be quite well understood in terms of surface-wave modes are the Yagi and helical antennas which support surface waves with a phase velocity that is less than the velocity of light. Radiation occurs only from the terminal plane or from other discontinuities such as tapers. Antennas of this type are useful where end-fire operation over a wide band of frequencies and low wind resistance are required.

Corrugated or dielectric-coated surfaces operating in the circularly-symmetrical cylindrical surface-wave mode have been designed for use as omnidirectional beacon antennas.

Microwave Antennas

Advances in microwave antennas have been associated with increased size, more precise beam shaping, and improved scanning capabilities. Conventional paraboloidal, spherical, and parabolic cylinder reflectors with apertures of several hundred wavelengths have been constructed. Primarily this development represents a mechanical achievement in maintaining close tolerances although automatic servomechanism control of the surface alignment is also in use. For scanning or multiple-beam operation numerous microwave systems have been developed from their optical counterparts. Microwave lenses have been constructed with artificial dielectrics of many forms, and recent advances in the polymer industry are making available a wide range of natural dielectrics suitable for this purpose. For beam scanning, the Luneberg lens is a particularly interesting type that has been developed in many variations. In its simplest form it is a dielectric sphere with the useful property that rays from a point source, located at any point on its spherical surface, emerge as parallel rays from the other side of the sphere.

Broad-Band Antennas

A highly significant advance in the antenna field since 1945 is the successful development of frequency-independent antennas. Before 1945, a bandwidth of 2 to 1 was considered large, and few antenna engineers would then have predicted the possibility of designing antennas with impedance and pattern characteristics that are *independent* of frequency over as wide a frequency band as the designer may specify (and, of course, is willing to pay for in terms of dimensional requirements).

The concept of frequency-independent antennas has been realized in two separate but related practical developments: equiangular structures and log-periodic structures. The first of these uses the "angle concept" which is based upon the observation that an antenna whose geometry can be specified entirely by angles should have characteristics which are independent of frequency. Of course, all such structures extend to infinity, so the problem is to determine which retain their frequency-independence when truncated to a finite length. (The infinitely-long biconical structure is an example which does *not* remain frequency-independent when truncated to form a practical antenna.) The equiangular spiral antenna of Fig. 7 was the first of a class of antennas which are frequency independent when truncated. The feed voltage is applied between the two arms at the center, and the decay of current is sufficiently rapid that the current is negligible at a distance of a wavelength measured along the arms. Hence, the antenna may be truncated at this length, and its characteristics will be frequency independent for all higher frequencies (up to that for which the diameter of the feed region becomes an appreciable fraction of a wavelength).

In a more practical version of this antenna the spiral arms are developed on the surface of a cone as shown in Fig. 8. This structure is frequency independent, and yields a desirable unidirectional, circularly-polarized beam, having its maximum off the apex of the cone. Antennas of this type have been constructed to cover a frequency band of more than 20 to 1.

Log-periodic structures have radiation characteristics that repeat periodically with the logarithm of the frequency and in addition, that do not vary greatly over a period. Such antennas are essentially frequency independent. One of the simplest of many types is the log-periodic dipole array. In this array adjacent elements have a fixed length-ratio τ, and adjacent spacings bear the same ratio. From the principle of scaling, whatever radiation characteristics result at a frequency f, must also result at a frequency τf, and indeed at all frequencies $\tau^n f$, where n is an integer. When appropriately excited (with phase reversals introduced between adjacent elements) a truncated version of this array radiates a single-lobe linearly-polarized beam directed toward the apex. In operation, the active region of the antenna remains near the element of length $\lambda/2$. As the frequency is increased the active region moves forward through the array.

If the dipole arms are slanted forward, the log-periodic resonant-V array of Fig. 9 results. With care such an array can be designed so that when the active portion runs off the front end with increasing frequency, it returns to the rear end in the $3\lambda/2$ mode, moves through the array and again returns to the rear to advance through the array in a still higher-order mode. By this means very large bandwidths can be achieved from a relatively short array.

Fig. 8—Conical balanced equiangular spiral antenna.

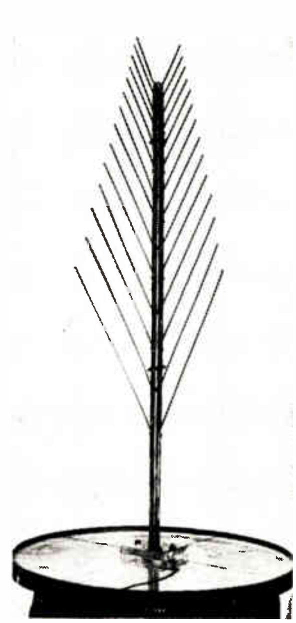

Fig. 9—Log-periodic resonant-V array.

Large Antennas and Related Problems

Applications in radio astronomy and in satellite tracking and communication have spurred the development of very large antennas and arrays. In radio astronomy where resolution can be more important than gain, large interferometer-type antennas, Mill's cross antennas, and synthetic arrays are in use. The latter, instead of using many elements simultaneously, use a fixed and a movable element to measure the relative phase and amplitude over the aperture of the equivalent array being synthesized. The data are stored and operated upon by a computer to yield information equivalent to that given by an ordinary array. In some large arrays utilizing many elements data processing techniques are being applied to combine the data from individual elements to produce a maximum of information.

During the 1940's it was demonstrated that there is no limit, theoretically, to the narrowness of the beamwidth obtainable from a given-sized aperture, or array. Although several excellent analyses showed conclusively the impracticality of these "super-gain" antennas, considerable effort was expended in some quarters to obtain a small degree of supergaining.

The advent of extremely low-noise receivers, using masers and parametric amplifiers, has introduced the antenna engineer to the notion of antenna temperature as a unit of measurement for the noise picked up by the antenna. The extremely low-noise temperatures seen by a microwave antenna looking at a "cold" sky has required that additional effort be devoted to reducing side and backlobes which "see" the warm earth. By careful design, antenna temperatures of less than 5°K have been achieved for an upward-looking antenna.

Radio Propagation Following World War II*

LAURENCE A. MANNING†, SENIOR MEMBER, IRE

Summary—Since the early 1940's the development of new propagation modes has greatly increased man's ability to communicate. Some of the outstanding advances are briefly reviewed.

Introduction

A REMARKABLE REVOLUTION has taken place since World War II in the field of radio propagation. In the early 1940's, the recognized modes of signal transmission useful for communications and broadcasting were principally 1) ground waves at MF and below, 2) ionospheric layer reflections, and 3) line of sight at VHF and above. These modes are still important, and many new developments have led to their more efficient use; however, a really surprising number of exciting new propagation modes have now arisen that enormously extend the communications capabilities that are open to us.

Orbiting Relays and Reflectors

Potentially the most significant development to radio propagation has been the growth of man's capability to launch artificial earth satellites. Using satellite relay stations, wide-band VHF and UHF communications become possible on a line-of-sight basis. The presence of signals depends only on the operation of man-made devices, and not upon ionospheric critical frequencies, or tropospheric conditions. The possible bandwidths are limited only by system sensitivity, so that such services as world-wide television are within reach.

Four principal forms of orbiting relays may be distinguished.[1] First is the active satellite repeater. This approach minimizes the power and sensitivity required by the ground transmitters and receivers and leads to the highest signal-to-noise ratios. If three such repeaters were placed in 24-hour orbits, communications would be possible between non-polar regions at all times. However, since a 24-hour orbit has an altitude of about 22,000 miles, a transmission delay of about one-half second would occur; such a delay would be objectionable for some applications. If an active satellite is placed in a lower and more easily achieved orbit, the time delay can be greatly reduced, but at the expense of reduced geographical coverage. However, a network of perhaps 100 active satellites in random polar orbits would make communication possible 99.9 per cent of the time and appears likely to be economically feasible.

A second form of satellite repeater has been achieved by orbiting a large, spherical, conducting balloon. Echo I, launched in August, 1960 by the National Aeronautics and Space Administration, was the first test of this technique. Because passive balloon reflectors of this type require high ground-system sensitivity, they lead to relatively small rates of information transmission. An alternative to the spherical balloon reflector is the use of resonant dipole elements. Several hundred million short resonant wires placed in orbit with slight differential velocities soon spread into an extended belt. The high reflectivity of the resulting belt of reflectors can be used to return signals near the resonant dipole frequency.

Although not man-made, the moon is an earth satellite which has been tested for communication purposes. Despite its great distance, its size makes usable signals possible. The moon has the merit of unique durability. However, the bandwidths are relatively limited, and reflected signals are delayed by nearly two-and-one-half seconds. When the moon is not in view, communication is impossible. Lunar reflections have been of importance principally in studies of propagation through the ionosphere, and in studies of the lunar surface.

Beyond-the-Horizon and Scatter Propagation

The applications of satellites as relays are just beginning to be felt. Tropospheric and ionospheric scatter propagation, on the other hand, have already assumed an important role in the communication scene.[2,3] Systems of meteor-burst propagation have been developed which promise certain advantages for some applications.[4]

Diffraction theory predicts that, at VHF and UHF, beyond-the-horizon signal strengths should attenuate very rapidly so that propagation over distances of several hundred miles should not be possible. During the early 1940's, as high power transmitters became available in these frequency ranges, it became apparent that beyond-the-horizon signals were well above the values predicted by diffraction. In some cases, the signals could be explained by trapping in an atmospheric duct or waveguide caused by certain meteorological conditions. However, in absence of ducting, a weak signal remained that has been attributed to scattering from ir-

regularities in the tropospheric dielectric constant. Tropospheric scatter communication has been found to be useful at distances up to about 600 miles, and with bandwidths of as much as several megacycles.

At distances of roughly 600 to 2300 km, VHF signals can also be scattered in useful intensities from irregularities in electron density in the lower E region. Discovery of ionospheric forward-scatter signals was a result of a conscious search for a new communications mode, and was envisioned as an extension of the theory of tropospheric scatter to ionospheric irregularities.[5] Unlike tropospheric scatter, the irregularities in refractive index causing ionospheric scatter are strongly frequency dependent, so that frequencies from 25 to 60 Mc are preferred. Bandwidths of 40 kc are quite feasible. Ionospheric scatter circuits are relatively immune to the blackout and storm effects that plague HF ionospheric circuits. High power transmitters, large antenna gains, and diversity reception are the rule.

Ionospheric scatter signals are made up in part of reflections from a continuous background of ionized meteor trails. Also present are less frequent bursts of signal strength caused by relatively large meteors. Intermittent communication has been shown to be feasible by transmitting condensed bursts of information whenever the signal level exceeds an arbitrary high threshold level. Closed-loop systems are used to determine when transmission is possible. Since signals are sent only when the path loss is low, relatively low power is needed. Because of the aspect sensitivity of meteoric echoes, the antennas are not directed along the great circle. Meteor-burst communication is useful for distances out to about 2000 km, and at frequencies up to about 200 Mc. A transmission delay of a fraction of a minute is associated with the intermittent rate of meteoric incidence.

Higher-Order Scatter Systems

Tropospheric and ionospheric scatter systems depend on a second-order effect, the fluctuations in refractive index in the troposphere or ionosphere. Recently a third-order scatter mechanism has been experimentally demonstrated in the ionosphere,[6] and calculations show that communications possibilities exist.[7] It was shown by Gordon[8] that a neutral plasma containing electrons will scatter weakly because of the randomness in the positions of the individual electrons. More careful studies have shown that the electrons follow the positive ions, and the number of positive ions within successive regions separated by a fraction of a wavelength is unequal because of their random motion. Energy is scattered in proportion to the amplitude of the component of irregularity of scale equal to the effective space wavelength.[9] These "incoherent scatter" signals are very weak, and were first detected from the F layer using 5-Mw pulses and an antenna array of 1024 dipoles. Calculation shows that, at frequencies of 100 to 1000 Mc, communication would be possible at distances of over 4000 km. Using a million-watt transmitter and 1000 m^2 antenna apertures, an average of 100 teletype channels could be supported with an error rate of 1 in 10^3. Propagation would be relatively unaffected by ionospheric blackouts.

Developments in HF Communications

Great progress has been made in use and prediction of the properties of ordinary HF ionospheric layer propagation. Of primary significance has been the gradual evolution of a world-wide ionospheric sounding network. Since the war, the Central Radio Propagation Laboratory (CRPL) of the National Bureau of Standards has made predictions of radio propagation conditions based on results from the sweep-frequency ionosondes in the system. The development of the "f chart" has greatly improved reporting of data from individual stations.[10] CRPL is now adapting the prediction process to computers, thus reducing the subjective element. Predictions are made not only of the normal propagation frequencies but also of the probable occurrence of storm conditions and fade-outs.

Progress has also been made in measurement of propagation conditions as they occur. The scatter-sounding technique is important in this regard. Pulse signals are transmitted to a distant point by way of the ionosphere. Upon striking the ground, energy is scattered back along the original path to the transmitter site. Presence of echoes at given frequency and range thus indicates the possibility of communication on a given circuit.[11]

VLF Propagation

Despite the venerable place of VLF and LF propagation in the history of radio, important developments have occurred in the field. Greater theoretical understanding has arisen because of experimental and theoretical work.[12] The mode theory of propagation between earth and ionosphere has been carefully developed and

[12] K. G. Budden, "Radio Waves in the Ionosphere," Cambridge University Press, London, England; 1961.

used to explain the experimental results. Pulse soundings of the ionosphere were made at LF for the first time soon after the war,[13] and quite recently the resonant properties of the concentric earth-ionosphere cavity has been demonstrated for the low order modes.[14] It is of interest that the fundamental frequency is about 7.8 cps, and the Q is about 4.

Study of the waveform of signals from lightning discharges led to detailed analysis of "whistlers," a highly dispersed form of atmospheric with energy return spread over a second or more. These signals were shown to propagate between northern and southern hemispheres along a dispersive guided path controlled by the geomagnetic field. Thus the signals extend several earth radii into space.[15] Man-made signals have also been transmitted using this mode.

Underlying Research

Back of the salient developments in propagation discussed above has been a tremendous and growing research effort, directed in large part to the physics of the troposphere and ionosphere.[16] One might draw fleeting attention to the development of refractometer techniques of tropospheric study, the enormous amount of work devoted to study of auroral ionization and polar propagation, and the study of ionospheric storms and polor blackouts. One should not ignore the development of techniques to measure ionospheric winds using drifting meteor trails, the fading properties of radio signals, or the drift and expansion of rocket-borne chemical releases. Nuclear detonations both below and above the ionosphere, as in the ARGUS experiment, have had far-reaching effects. Detailed study has been made of ionospheric layer formation, ionospheric composition, electron concentration, and the incident solar radiation. Rocket data has played a key role in the latter experiments. The list seems endless, and the literature is enormous.[17]

The Future

Very few of the developments of the past fifteen years were foreseen in advance. None the less, certain trends seem likely to continue. With the use of computers, communications channels are likely to be used by adaptive systems which control type of modulation, frequency, and directivity to match the propagation conditions. Computer control will be a must in organizing the use of satellite relays. The properties of the interplanetary environment and the ionospheres of other planets will be studied, and communications techniques adapted to the scale of the solar system. Our understanding of sun-earth relationships will grow, and with it an elucidation of ionospheric storm and auroral mechanisms. Finally, we will probably not leave the atmosphere as nature made it, but will find new ways to modify its propagation properties to suit our needs; already we have seeded the ionosphere with chemicals, shocked it with bombs, heated it with radio waves, and filled it with satellites. Next? Only dreams will tell.

The Future of Antennas*

M. D. ADCOCK†, SENIOR MEMBER, IRE, R. E. HIATT‡, SENIOR MEMBER, IRE, AND K. M. SIEGEL||, SENIOR MEMBER, IRE

Summary—**Although the rate and direction of advancement of the antenna field depends to a large extent on new inventions and techniques, and on the discovery of new materials, it is possible to indicate some of the trends which may be expected. The major advances in the near future will probably come in the areas of data-processing antennas and dynamic antennas. In the data-processing antenna, increased information is obtained by processing the signals available at the antenna terminals; in dynamic antennas, antenna performance is enhanced by time-modulating the aperture transfer function. It is likely that the most significant applications of data-processing antennas will be in the fields of radio astronomy and communications.**

Electronic scanning, another well-known technique of beam pointing, should lend itself naturally to the data-processing antenna approach, particularly since, for other purposes, the arrays will be used with computers. Such antennas will supersede movable large reflector types, for communication with space vehicles. Very large electronic scanning antennas will probably be built on the ground or on a horizontal plane, for minimum wind resistance. It may be expected, further, that electronic scanning arrays will be built in various shapes for installation on missiles or satellites.

In order to achieve larger antennas for increased tracking and communications capability, greater transmitted power, larger apertures, and natural geographic features may be used as foundation elements of the antenna. Canyons and cliffs, for example, could be used as reflecting surfaces if suitably coated. Ultimately, however, such techniques will be superseded by newer and more efficient developments. Somewhat further in the future, antennas for space communications will become extremely important. Work will no doubt be done on self-erecting antennas for automatic placement on the moon or planets, on antennas for the transmission of power from one location to another, on integral solid-state antenna elements, and on microwave-to-optical-to-microwave interplanetary communications.

THE AUTHORS in choosing to write about as yet unrecorded events, are sorely tempted to hedge their scientifically-based statements by pointing out the distinct possibility of science being strongly influenced by its inseparable and more unpredictable bedfellows, economics and human psychology.

Perhaps, sufficient hedgings can be had by saying that it takes a reckless or clairvoyant individual to predict the direction of future antenna research and development. In the antenna field, as in many other scientific programs, the rate and direction of advance depends to a large extent on new inventions, the discovery of new materials or the leveling of new requirements. During World War II, none of us would have predicted the development of an electronic scanning antenna using ferrite phase shifters. Who would have made a prediction five years ago that our 1961 antenna effort would include so much attention to antennas for space vehicles?

In spite of our lack of clairvoyance, we will attempt some predictions on the growth and the direction of growth for antennas of the future. Without doubt, improvements in materials and techniques will result in improvements in many types of antennas. Some of our estimates on expected trends on several antenna types will be discussed later. We predict, however, that the major advance in antennas will come in the field of data-processing antennas.[1] Such antennas, in more elementary forms and under different names, have been in use for years. An early example is the simultaneous lobing antenna in which the use of four feeds in a reflector provided more information on the location of a target than could be had from the use of a single feed. In this case and in many cases, data processing of the voltages available at the antenna terminal or terminals results in increased information on the nature of the target under surveillance or on the communication signal being received.

Other names used for closely related antenna work are "four-dimensional antennas"[2] and "dynamic antennas."[3] Work in this area also includes application of correlation techniques to antenna systems and the application of communication theory to antenna design. In fact, a symposium[4] was held under the latter name early in 1957. In dynamic antennas, the aperture transfer function is time modulated so as to obtain either enhanced performance characteristics or multiple beams or simultaneous scanning.

A notable example of past success in data-processing antennas is the synthetic aperture antenna system developed at The University of Michigan.[5] Here, the narrow antenna beam characteristic of a large aperture is obtained from a synthetic aperture produced by a small antenna. The energy received as the small antenna moves along a linear path is stored with the proper

phase factor. Periodically the stored energy is combined to yield the effect of a large aperture antenna.

In the four-dimensional antennas as discussed by Shanks and Bickmore,[2] time is used as the fourth dimension to obtain better antenna performance. One or more of the antenna parameters is time modulated to improve radiation characteristics of the antenna or to increase the information-handling capacity of the system. An improved radiation pattern can be achieved, for example, by time modulating the length of the antenna. This may be accomplished by switching the end elements of an array into or out of the antenna. The sidelobes of the shorter array may be made to coincide with the minimums of the longer array and will partially cancel each other when the two antenna patterns are combined or averaged over a time longer than the modulation period. A 10-db improvement has been achieved by a simple application of this technique. Shanks and Bickmore show that other modulation techniques can result in a multipattern antenna while another would allow for simultaneous scanning of a two-dimensional array.

Data-processing techniques can be applied to interferometer antennas quite effectively. Drane[6] has shown that it is possible to combine a linear array with a number of co-linearly aligned two-element interferometers and obtain a pattern having no ambiguities and a resolution equal to that obtainable from a continuous aperture as long as the entire system. This is accomplished by phase modulating the output signals from each two-element interferometer and adding them in a nonlinear detector to the linear-array output.

The basis, objectives, and applications of data-processing antennas have been widely discussed in the literature, only part of which is referenced in this paper. Our interest is in future developments in these areas. It is our belief that data-processing antennas will be used in many applications to add to the information that is obtained from a communication, radar or radio astronomy antenna. The area of greatest advances will be the areas of greatest payoff. One of these areas will be radio astronomy interferometer antennas; another will be in the closely related area of synthetic aperture antennas. It is believed also that these techniques will be used more and more in antennas for scatter communication. Electronic scanning antenna arrays should lend themselves quite naturally to data-processing techniques. Here it is possible to have information from each radiating element or from many combinations of elements. There is, therefore, infinitely more information available than may be ordinarily obtained from a single beam looking in a single direction. Data-processing innovations in such an antenna seem even more likely since it is probable that computers will be needed for other reasons in many future electronically scanned antennas.

Our opinion on the future of data-processing antenna techniques are in agreement with those of Shanks and Bickmore[2] who say,

> these concepts and techniques . . . represent one of the most interesting and promising new areas of investigation in the field of radiating systems. Without a doubt, the course of electromagnetic systems in the future will be influenced by this philosophy. However, effort in many different directions will be necessary to realize the full capabilities of these methods. Not only will extensive theoretical analysis be necessary on such problems as the accuracy, synthesis, procedures, etc., but in addition considerable component research and development is indicated.

Electronic scanning is the second broad area where we can expect great advances. Progress in electronic scanning during the past few years has been enormous but it is expected to continue in the future at a very rapid pace. This advance will be due, first, to the urgent need for large scanning antennas and, second, to the development and improvement of electronically controlled phase shifters. There is need for large electronically scanned antennas for communication with distant planets and space vehicles, for radio astronomy and for use in search and tracking of ICBM's.

Arrays which can be electronically scanned will be built to fill requirements which cannot be met by reflector-type antennas. With the 600-ft diameter parabolic antenna, Sugar Grove, W. Va. (Fig. 1), now being built, we are probably approaching the size limit of reflectors which can be scanned by rotating and tilting the reflector. Antennas of the future which must be capable of quickly beaming large amounts of power in

[6] C. J. Drane, Jr., "Phase-Modulated Antennas," Air Force Cambridge Res. Ctr., Cambridge, Mass., Tech. Rept. No. 59-138, ASTIA Doc. No. AD 215374; April, 1959.

one direction or another will be electronically scanned arrays. The maximum practical size of antennas of this type which require no moving parts and which are capable of being built in modular form is much greater than for reflector-type antennas. In antenna arrays, the power maximum will not be set by the power-handling capability of the waveguide used, since it will be possible to have many power oscillators, one for each radiating element or for each group of elements. They can be properly phased by low-power control signals, which will also serve to scan the beam by some suitable arrangement of electronically controlled phase shifters. A digital computer, associated with the antenna, will be the means for providing the intricate control needed for the phase shifter; the computer can also be programmed to cause the beam to scan in any desired sequence. Electronically scanned antennas of this type will, of course, serve as receiving antennas by switching the power oscillator out of the circuit.

For many applications, the large scanning arrays can be built in the most convenient and economical form, that is, on the ground or on a horizontal ground plane. This provides both the advantages of minimum wind resistance and a low silhouette which in turn is advantageous for camouflage purposes.[7] Scanning arrays have been built in a form to cover part of a sphere, cylinder, or cone.[8] This trend will be carried further by designing scanning arrays suitable for use on surfaces of more complicated geometry such as are found on aircraft, missiles, or satellites. Here again it may be desirable to use a computer to schedule the necessary phase and current values for the various elements for the desired scanning sequence. The use of electronic scanning on satellites will be particularly desirable because of the low energy required for scanning and also because the scanning of such an antenna without physical motion will eliminate any tendency to upset the stability of the vehicle.

From these optimistic predictions about the future of electronic scanning one should not conclude that all electronic scanning problems have been solved. On the contrary, some very difficult problems remain,[9] just two of which will be mentioned here. Although the problem of mutual coupling between elements is better understood as a result of recent work, there is yet no attractive method of preventing high sidelobes and beam deterioration due to mutual coupling for wide-angle scans. More work is also required on phase shifters; although several types are now in use, all of them are far from ideal.

In emphasizing the future importance and growth of electronic scanning arrays, it is not intended that the importance of reflector-type antennas be de-emphasized. This antenna, which has been called the "workhorse of microwave communications" will always be in demand for many applications. At the present time it is probably the most popular antenna for radio astronomy use due in a large part to its broad-band frequency capability. The large reflector antenna is now and will continue to be widely used for keeping in contact with space vehicles.

At least two 1000-wavelength aperture antennas are in planning or being built. In discussing one of these, the Lincoln Laboratory Radio Propagation Research Facility Antenna (Fig. 2), Ward[10] says that, "most people who have studied the problem feel that one cannot build an antenna of equal precision that is much larger than this (1000-wavelength) without resorting to point-to-point surface control." He further says, "there will always be an insatiable demand by the customer for more and more tracking and communication capability with corresponding pressures for greater transmitted power, larger antenna apertures, and more sensitive receivers. . . . Antennas will continue to get bigger, demands will be made for more and more accurate radiating and reflecting surfaces on these antennas." Our position is somewhat similar to this—namely, that the practical size limit for scannable reflector-type antennas has been reached, but due to the demands for larger and larger antennas, we will continue to build larger ones even though they are not "practical."

As has been said, it is doubtful if moveable reflector-type antennas much larger than the 600-ft NRL-Sugar

Grove antenna will be built. The designers of the largest reflector-type antenna known, the 1000-ft antenna in Puerto Rico (Fig. 3), are taking advantage of Mother Nature to help them with their reflector. The 1000-ft spherical surface is formed in a hollow in the earth. Scanning is accomplished by moving the feed. A corrected line source feed is used to minimize spherical aberration. We predict that there will be more and more use of natural phenomena to assist the antenna designer. This use will not be limited to parabolic or spherical reflector-type antennas. One fascinating idea that should have a great future is the plan by Morgan[11] to use an island in the ocean as an antenna. This and other methods of using the contrasting dielectric properties of the earth and sea water should go far towards the solution of some of the VLF and ELF antenna problems. Other attempts have been made to utilize the ocean to solve an antenna problem. Zucker has studied the possibilities of its use as part of a surface-wave antenna. Here, the lack of an effective method of launching the surface wave has been a handicap. It is believed that this idea will be made to pay off in the future to provide solutions to some of the communication antenna problems. Mountains have been used to support wires for VLF antennas. In the future, mountains, canyons, or cliffs may be used also as reflecting surfaces—perhaps for a corner reflector antenna.[12] These and other ideas will be pursued in the future to solve some of the very difficult ELF and VLF antenna problems. Included among these problems is that of transmitting underground and through the ocean for certain communication requirements.

Since we have just entered the space age, we can with complete confidence predict rapid advances in antennas for space craft. For vehicles at altitudes well above the atmosphere where there are no problems with attenuation due either to the atmosphere or to the plasma sheath generated by the moving vehicle, antenna development will certainly include the use of VHF's. Millimeter and submillimeter frequencies will be used since these frequencies will make it possible to obtain high gain and narrow beams with antennas small and light enough to be compatible with space vehicle load limitations. These frequencies will be used for space-to-space communications and for radar for moon landings and for space-to-space vehicle rendezvous. The antennas used for these applications will in many cases be miniatures of present-day antennas. For space-to-earth communications, lower frequencies must be used. Low-gain antennas for such use are already being operated on current satellites at 20, 40, 108 Mc and higher frequencies. With the stabilization of satellites, higher-gain antennas will be used with frequencies well into the microwave band. Applications will include both communication and radar uses. Collapsible reflector-type antennas erected by gas pressure or mechanical means will be used.[13] It is expected that considerable use will be made of slot or dipole arrays distributed over the surface of the satellite.

For the satellite in a plasma environment, there exists a very difficult antenna problem. This is an area on which a large amount of future antenna effort will be expended. We can be sure of this because the problem is difficult, the need is urgent, and the payoff is high. To mention just one application, it is important for the Mercury space capsule to be able to maintain space-to-earth communications continuously and this is particularly necessary during re-entry.

The antenna problems that exist during the re-entry phase are well documented in the literature.[14] Of prime importance are solutions to the problems of power breakdown, reflections at both the inner and outer plasma boundaries, and the attenuation within the plasma. Solutions to these problems will include the use of higher frequencies and higher power, transpirational cooling, careful shaping of the vehicle, and care in choosing the antenna location. It is expected also that a way will be found to take advantage of the plasma properties, *e.g.*, by using the plasma as an impedance transformer to outer space. There will still exist, however, the need for a breakthrough to arrive at a successful solution to this problem. It may be found that it is possible to excite the ion column behind the satellite as a leaky waveguide antenna.

There will also be work in the future on self-erecting antennas that can be dropped on the moon, or Mars, or Venus. No doubt some such antennas have been designed already. Future designs will be more sophisticated in mechanical design to provide needed gain and the ability to scan or perform other functions on command.

There will also be future studies on antennas for transmitting huge amounts of power from one location to another. These may be used, for example, to transmit power to a space ship. Such antennas will be characterized by having very high gain and the capability of handling unusually high power, probably by the use of multiple phased oscillators—one for each antenna element or group of elements.

Recently, it has been found possible to improve the performance of an array for certain applications by the use of nonuniform spacing for the elements.[15] This is a distinct advantage because it decreases the required number of elements and simplifies the feeding network and also results in lower sidelobes. This idea will be more fully investigated in the future.

Now that we have made speculations about the near future we might reach further out.

We foresee the use of arrays which will collect data. This data will automatically be processed in a digital computer and the array will be "rephased" and the information retransmitted. Thus we will invent systems which will first process the complete information received; second, determine the message of highest probability; and third, determine from the message and stored instructions its proper destination. We foresee arrays in which the signals from the various elements are not combined at radio frequencies, but where the usual coherent array phenomenon is duplicated by digital-data-processor techniques. Such an "array" will be as broadband as its individual elements; such an array will be ideally suited for nonplanar applications and, in addition, should provide versatility of operation superior in certain important respects to conventional arrays representing the present state-of-the-art.

We foresee the abolition of all metal radiating towers when they are used as dipole radiators. We foresee the use of ferrite-type materials for transmitting antennas to go with the present uses for receiving antennas. We believe the heat dissipation problem will be overcome with new materials and the "lost" heat will be partially recovered to be reused by the power source.

[15] M. G. Andreasen, "Arrays with Variable Interelement Spacings," presented at URSI Meeting, Boulder, Colo.; December, 1960.

We foresee the use of physical and chemical electron depletion processes at the conjugate point region in the ionosphere regulating the variation in electron density at the other conjugate point and thus producing lens effects which will allow us to focus energy into outer space. We will be able by these mechanisms to transmit energy into space at frequencies below the plasma frequency. We will also be able to focus energy into particular earth location from space at lower frequencies than now can penetrate the ionosphere.

Concerning reliability, we expect array elements individually backed up by solid-state blocks in such a way that several elements can be damaged or become defective without greatly degrading the system. Mutual coupling sensors will determine the malfunction and will automatically rephase the antenna to a new optimum.

Concerning sidelobes, we predict that we will find an irreducible minimum amount of energy that must be wasted by an antenna system. Antennas of the future will, of course, consider the surroundings as a part of the system.

As we pointed out earlier, we feel large reflectors will be on the way out and by fifty years from now will be "museum pieces" in the large. The search for natural reflectors will cease. We will decide for other reasons, possibly economic, possibly low noise of the background, where we want to locate our antenna. We will then obtain a precise three-dimensional map of the terrain and phase our array taking into account the geometry. Thus we will be able to obtain square miles of aperture at a cost much less than the large antennas presently being constructed. Twenty years from now we will be communicating with our explorers on Mars and Venus via advanced communication systems. It is not beyond reason to expect we will use microwave wavelengths to communicate to satellites which will retransmit the message at optical wavelengths to a satellite going around Venus which will retransmit at microwave wavelengths to the surface of Venus. We predict that in fifty years from now earth-to-earth communications will make use of an artificial ionosphere and replenishment rates with properties and gradients which will minimize the effect of solar activity and will be designed with communication reliability in mind. Thus the *golden years* of large reflector antennas will continue for perhaps ten to twenty years and then go the way of ancient mansions, well designed, but inefficient in a modern world. We hope this limb we have walked out on does not discourage sponsors of large antennas. There is much to be learned about the planets before we can maximize the probability of human survival on initial human landings on the moon and planets.

The Future of Propagation Research and Development*

HENRY G. BOOKER†, FELLOW, IRE

Summary—**It is predicted that the future of propagation research and development will involve: 1) world-wide radio communication via satellites, 2) greatly increased interest in the magnetosphere and the solar atmosphere, 3) greatly increased interest in the atmospheres and surfaces of planets, 4) a far wider interpretation of the notion of radio frequency, both at the lower and the upper ends of the spectrum, 5) extensive use of new methods for investigating the top side of the ionosphere by both reflection and scattering techniques, 6) the discovery of new phenomena by the use of large antennas, high-power transmitters and low-noise receivers, and, 7) greatly increased interest in the propagation of sonic and tidal waves in the atmosphere.**

PREDICTING the future in a field of research is unsafe to the point of being dangerous. However, it is an interesting intellectual exercise. That the science of radio propagation is undergoing important developments is illustrated by the reorganization that has recently taken place under the auspices of the U.S.A. Committee of the International Scientific Radio Union. A new U.S.A. Commission with the title "Magnetospheric Radio" has been established. The magnetosphere is the outermost part of the earth's plasma envelope where the distribution of charged particles is strongly controlled by the earth's magnetic field. The magnetosphere exists mainly above the level of maximum electron density in the F region. Ten years ago essentially nothing had been done to investigate the magnetosphere, whereas today it is the region where most satellites fly.

From a development standpoint the most striking advances in world-wide radio communication will undoubtedly be associated with the use of relay stations in satellites. Whether this will be true from the research standpoint, however, is more doubtful. Satellite communications will involve radio propagation problems of considerable interest extending from the lowest layers of the troposphere to the levels in the magnetosphere where relay satellites will fly. But to study these phenomena it will in all probability be better to make direct scientific investigations of the various levels of the atmosphere by methods not involving the satellite communication systems themselves.

One of the striking respects in which the field of radio propagation is expanding concerns the range of frequencies involved. Many of us can still remember the time when the radio frequency spectrum extended from something above 10 kc up to about 100 Mc or less. During World War II the frequency range was extended up to about 30,000 Mc. Now, however, we see the development of coherent sources of electromagnetic radiation at optical frequencies together with fibrous waveguides capable of handling these waves.

Nor is the extension in the range of radio frequencies solely in the upward direction. With the successful interpretation of whistlers[1] about ten years ago, we have been seriously concerned with the propagation of electromagnetic waves through the earth's atmosphere at audio frequencies. Moreover, at frequencies below the gyromagnetic frequency of atmospheric ions, these waves become the hydromagnetic waves studied originally by Alfvèn.[2] Hydromagnetic waves are now regarded as a likely feature of the geomagnetic storms that cause so much interference with radio communications. Pulsations in the earth's magnetic field are being actively investigated at frequencies well below 1 cps. It is clear that, in future, the expression "radio propagation" must cover the behavior of electromagnetic waves from optical frequencies down to a frequency of about 1 millicycle per second or less. Indeed we authors can derive some sly amusement from watching the editorial department of the PROCEEDINGS OF THE IRE wonder how to abbreviate "millicycles" to "mc" when for years they have been using this abbreviation for "megacycles."

The history of radio propagation has been punctuated by successive extensions in the range of communication beyond that originally anticipated. Except in the case of ionospheric scatter transmission,[3] these extensions in range have always been discovered experimentally, and a theoretical explanation has then followed. It is virtually certain that we may look forward to discovering a series of situations in which electromagnetic waves manage to do things not presently anticipated. Discovery of these unusual situations will be accelerated by the development of large antennas, of high-power transmitters and associated handling facilities, and of low-noise receivers.

Many of us can remember the time when all radio transmission took place below the level of maximum electron density in the ionosphere. The development of radio astronomy changed this situation somewhat, and the successful interpretation of whistlers brought about

[3] D. K. Bailey, *et al.*, "A new kind of radio propagation at very high frequencies observable over long distances," *Phys. Rev.*, vol. 86, pp. 141–145; April, 1952.

a spectacular change. We now look forward to an era when the top side of the ionosphere will be measured and monitored by satellite-borne ionospheric recorders[4] with something approaching the detail in space and time already achieved on the under side of the ionosphere. Moreover, we can look forward to similar radar investigations of the atmospheres of the sun and the planets, and to investigations of the various plasma phenomenon of space. In addition, the same techniques will provide information about the roughness and movement of the surfaces of the planets in the manner already achieved for the moon.

History has shown that a newly acquired ability to detect weak signals is one of the ways in which research in radio wave-propagation progresses. Repeatedly we have found that what was considered the regular mode of propagation did not disappear into the noise with increase of distance but merely gave place to some other mode of propagation that had hitherto been disregarded. The discovery of tropospheric scatter propagation is an example of this.[5] The same is true of the use of backscattering from thermal fluctuations to measure the height distribution in the magnetosphere of electron density and other parameters. This method is currently under development by Gordon[6] and Bowles[7] and presages a new kind of ionospheric sounder that could be used on a world-wide scale in the future. Indeed, if we persevere, we may even succeed in comprehending the long-standing enigmas of "sporadic E" and "spread F!"

Guidance of electromagnetic waves by various natural phenomena will also be a profitable field of investigation. Guidance of microwaves by the semipermanent radio duct existing near the surface of the sea, especially over tropical oceans,[5] was discovered during World War II, but comparatively little has so far been done to make practical use of the phenomenon. Guidance of radio waves between the northern and southern hemispheres round field-aligned irregularities of ionization in the magnetosphere has recently been suggested both on theoretical[8] and experimental[9] grounds. This may prove to be an important method for scientific investigation of the magnetosphere. Even as an unusual method of radio communication such guidance cannot be completely ruled out at the present time; perfect guiding along the entire length of a tube of the magnetic field is not required if large antennas are used at both ends. What may be achieved with guidance of electromagnetic waves along ionization irregularities aligned by magnetic fields, both in the earth's atmosphere and in the sun's atmosphere, cannot easily be predicted at the present time.

A considerable field of investigation also lies ahead in connection with the propagation of sound waves and tidal waves in the earth's atmosphere. There are many refraction problems that require investigation, and new methods are now available for generating these waves with quite large amplitudes. Hines[10] has suggested that irregular motions in the lower ionosphere are simply the result of sonic noise propagated upwards from below. He is probably right, and the nonlinear interaction between these waves probably constitutes the "turbulence" of the lower ionosphere. Anyone interested in radio propagation in the earth's atmosphere will be well advised to study tidal waves, sound waves, hydromagnetic waves, electromagnetic waves and light waves over the entire frequency range from less than one millicycle per second upwards and at all levels from the earth's surface up to well above the conventional ionosphere.

It is clear that propagation in the earth's atmosphere and in space is a field of investigation that is in no danger of running dry; and even if it should, there is the whole field of plasma physics to which we can turn our attention.

AUDIO

Organized with the assistance of the IRE Professional Group on Audio

A Century of Microphones*

B. B. BAUER†, FELLOW, IRE

Summary—**Of the various manifestations of a sound wave, the action of pressure on a diaphragm still is the universal means for detecting the presence of sound. The diaphragm actuates a transducer converting its motions into equivalent electrical waves. Innumerable transducers have been tried, but five are pre-eminent: 1) carbon, 2) condenser, 3) piezoelectric, 4) moving conductor, 5) moving armature.**

Important microphone improvements during the late twenties and the thirties have come about as a result of application of equivalent circuit analysis to acoustical structures. The principle of pressure microphones, pressure gradient microphones, combination microphones and phase shift microphones are described. Each of these has found an important niche in modern microphone applications.

A small number of important applications require super-directional microphones. Here three approaches are used: 1) reflectors, refractors and diffractors, 2) line microphones, 3) higher-order combination microphones.

In the future, improvements in design of directional microphones will continue. Wireless microphones are bound to increase in popularity. New methods of transduction based upon solid-state technology appear to be imminent. Unconventional methods of sound pickup may find wide use in space communication.

* Received by the IRE, January 2, 1962.

Introduction

As a SENSOR which transforms sound into energy form suitable for amplification and transmission, a microphone is among the most common and useful technological servants of mankind. At this writing, a century of effort has been devoted to inventing and perfecting the microphone. This paper is intended to provide a record of the basic contributions made during that time as well as to survey the engineering principles employed in the present day microphones. A brief look into the future will also be attempted.

Plan of This Paper

From the scientific point of view a microphone may be designed to sense any of the manifestations of the sound wave and to convey it to a transducer which will transform it into electrical energy. A sound wave is accompanied by the presence of an alternating excess pressure called the sound pressure p; the particles of air are subject to a to-and-fro motion which may be described by their velocity u and since the medium follows the adiabatic law there exists an alternating change in temperature as well as corresponding changes in density, dielectric constant, magnetic susceptibility and index of refraction. This paper is confined to those microphones in which the sound pressure or sound-pressure gradient are transformed into a force F by use of a diaphragm which, together with an associated electromechanical transducer, is set into motion resulting in generation of electricity. This is the method employed in earliest microphones, and it is virtually the universal method for microphone operation today. Because of their importance to proper understanding of microphones, brief descriptions of typical diaphragms and their interaction with the medium have been included in this paper.

Some of the other functions of a sound wave that have found significant but limited application in microphones are 1) the combined action of the particle velocity and the alternating temperature upon a heated fine wire[1] and 2) the combined action of pressure and particle velocity upon a cloud of ions.[2,3] Other possibilities have been considered: the change in dielectric constant or magnetic susceptibility of the air could be used to modulate the frequency of an oscillator;[4] the varying refractive index may be caused to modulate a light beam,[5] for example. Some of these functions may hold a key to microphone developments of the future.

Every conceivable means of electro-mechanical transduction has been combined with the vibrating diaphragm in an effort to produce "new and better" microphones. In this paper five basic transducers are described, any one of which will be found in virtually all of the present-day microphones: 1) Loose contact (carbon), 2) Electrostatic (condenser), 3) Piezoelectric (Rochelle Salt and Ceramic), 4) Moving conductor (moving coil dynamic and ribbon), 5) Moving armature (magnetic or reluctance). Many other means of transduction have been studied, tested and patented, such as, variable fluid contact,[6] movable vacuum tube elements,[7] piezoresistivity[8] point-contact transistors,[9] etc. To this date, these have not been widely adopted, but again these and newer methods of transduction may become important in future microphones.

Among the scientific tools of radio engineering, none has contributed as much to microphone development as the application of electrical circuit analysis to electroacoustical structures.[10] In employing the principles of this analysis, the operation of microphones is better understood and the groundwork is laid for future developments. It will be seen, for example, that some of the foregoing transducers are ***displacement responsive*** and others are ***velocity responsive*** (these terms arising from the generated voltage being dependent on the amplitude of displacement or the velocity of the diaphragm). Equivalent circuit analysis shows how to proportion microphone structures best to utilize these characteristics.

Diaphragms

Earliest among microphone diaphragms—perhaps because of its similarity to the eardrum—was a stretched flat membrane (actually a sausage skin) used by Reis[11] to actuate a loose metal-to-metal contact. A stretched flat membrane [Fig. 1(a)] made of metal or very thin metallized plastic is used in present-day electrostatic microphones. This diaphragm is typically clamped at its periphery by a ring 1.1 and stretched to any desired tension by a threaded ring 1.2.

The cross-sectional shape as a function of radius r taken on by a circular membrane of radius a made of nonrigid material uniformly stretched with tension T and loaded with a uniformly distributed pressure P is a paraboloid of revolution described by the equation

$$y = (Pa^2/4T)(1 - r^2/a^2) = y_{max}(1 - r^2/a^2), \qquad (1)$$

where y_{max} is the central or maximum displacement.[12] This equation is of interest since a stretched diaphragm used with condenser microphones commonly is subjected to uniform force of electrostatic attraction.

A flat diaphragm clamped between rings 1.3 and 1.4 or the like, is illustrated in Fig. 1(b). Used in early telephone receivers, this type of diaphragm is desirable where a great unbalanced pressure must be supported, but it also may be found in a modern electrostatic microphone.[13]

A more common arrangement for a flat plate diaphragm is shown in Fig. 1(c), where the diaphragm is held against a circular support edge 1.5 by a steady-state force, *e.g.*, magnetic attraction of transducer in a telephone receiver.

The previously described diaphragms are best adapted to drive a distributed acoustical load. When it

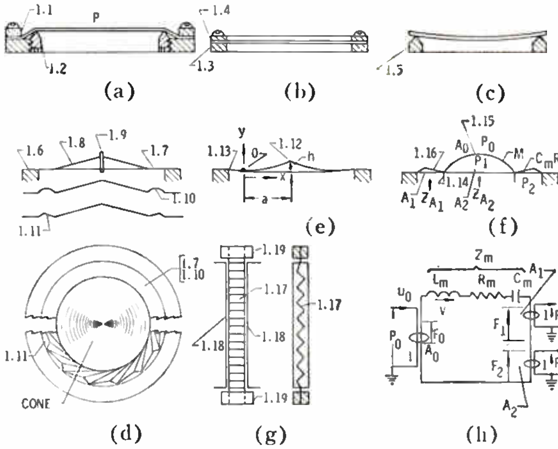

Fig. 1—Various types of diaphragms used in microphones.

becomes necessary to actuate a mechanical system from a point or a line, the diaphragm usually takes on a different shape so as to present an adequate *driving-point impedance* to the load.

Very commonly used for a point-drive is a cone diaphragm shown in three versions in Fig. 1(d). The edge of the diaphragm is effectively clamped or cemented against some support 1.6 leaving an annular portion 1.7 to flex in response to motions of the conical portion 1.8. The latter actuates a transducer through a drive-rod 1.9. The flat annulus gives way to a formed or corrugated annulus 1.10 when linearity of motion and freedom from spurious resonances at high frequency is required. A major advance in annulus design was achieved by Harrison[14] who invented a tangentially-corrugated annulus 1.11, shown at bottom of Fig. 1(d), and which is used at present in many moving-coil microphones and horn loudspeaker drivers.

A "curvilinear" diaphragm developed by the author for use with piezoelectric microphones a quarter of a century ago is now widely used with various point-drives. The goal is to provide a "nonbuckling" shape, that is, one that normally would be assumed by a pie-slice segment of a diaphragm supported at its apex and the circumferential edge and subjected to uniform pressure at one side. The desired shape may be defined approximately by the following equation:

$$y/h = (3/2)(x/a)^2 - (1/2)(x/a)^3, \qquad (2)$$

where the lowest point of the draw is at the origin *o* and *h* is the height at the apex 1.12. The contour may rise both toward the apex and toward the edge of support 1.13.

A "piston" diaphragm shown in Fig. 1(f) is practically universally used with moving-coil microphones and other transducers where force is transmitted at the circular line around the rim to a coil 1.14. The central portion of the "piston" 1.15 is of spherical shape. The annulus 1.16 commonly is tangentially corrugated after Harrison.

A ribbon diaphragm which also is a transducer was invented by Gerlach.[15] As used in a pressure-gradient microphone invented by Olson,[16] this transducer is made of corrugated aluminum ribbon 1.17 less than 0.0001-inch thick which either floats freely or is slightly stretched between two pole pieces 1.18. Electrical connections are made at the supports 1.19 to a high turns-ratio transformer.

From equivalent circuit point of view, the action of a diaphragm may be represented by Fig. 1(h).[17] The mechanical elements of the diaphragm, *i.e.*, mass M, compliance C_m and internal damping resistance R_m appear in the circuit as equivalent electrical elements to which forces derived from acoustical pressures are coupled by means of ideal $1:A$ transformers. The relationships between the pressure p and the force F developed upon an area A, and the volume velocity u and the linear velocity V resulting therefrom are correctly portrayed by the use of a transformer coupler, as may readily be verified from transformer equations. Normally the net areas on both sides of the diaphragm are equal, so that only two transformers (one for each side of the diaphragm) will be required. In the case of moving coil microphones the two sub-areas of the diaphragm in 1(f) separated by the coil from 1–14 are subjected to different pressures and are confronted by different acoustical impedances. In this case each independently acting area must be represented by its own coupling transformer. These transformers are merely aids to correct circuit analysis representation. Usually they can be deleted in the actual experimental circuit work.

Loose-Contact Transducers

Among the earliest devices intended for converting vibration into electrical impulses was Reis' loose metal-contact transducer[11] which is reported to have transmitted tones of different frequencies, but not intelligible speech. This latter event seems first to have been achieved by Bell, using a magnetic microphone, on June 3, 1875.[18] However, Bell's microphone proved not to be sufficiently sensitive for telephone work, and the experiments of Berliner,[19] Edison,[20] Hughes[21] and others soon thereafter introduced a long era of dominance for the loose-contact carbon transducer. To Edison goes the credit of being the first to design a transducer using granules of carbonized hard coal,[22] still used in present-day microphones.

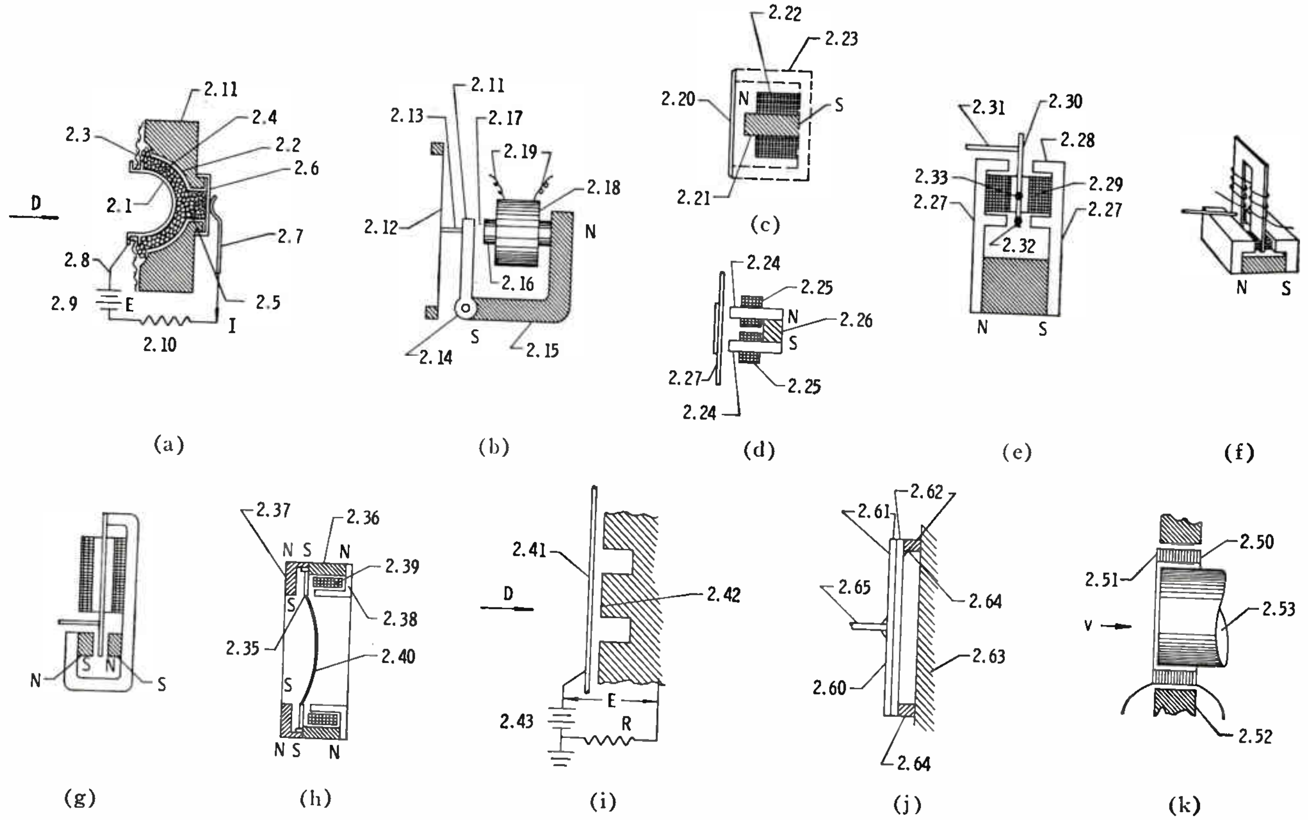

Fig. 2—Various types of transducers used in microphones.

The carbon granules are made of deep-black "anthraxylon" coal ground to pass a 60–80 mesh, treated chemically and roasted in several stages under a stream of hydrogen. This drives out volatile matter, washes out extraneous compounds, and carbonizes the coal. The last step of the process is magnetic and air-stream screening to eliminate iron-bearing and flat-shaped particles.[23]

Referring to Fig. 2(a), the modern carbon-granules transducer[24] is comprised of gold-plated metallic cups 2.1 and 2.2 attached to a diaphragm (not shown) and to a stationary back-plate 2.11, respectively. A fabric washer 2.3 encloses the carbon cavity which is filled with granules 2.4 through an aperture 2.5 capped with a contact 2.6. Leads 2.7 and 2.8 complete the circuit with a polarizing source of current 2.9 and a load impedance 2.10. Frequently, the load impedance is a primary winding of a step-up transformer. Variations of transducer resistance stemming from displacement D modulate the current I in the circuit. The incremental voltage developed across the load is proportional to displacement D.

The carbon-granules transducer not only has the distinction of being most widely used in microphones—every telephone in the world has one—but also of constituting its own amplifier of some 40- to 60-db gain. Its disadvantages are relatively high-noise level and distortion, instability caused by variation of the contact resistance of the granules with position and degree of packing, and a loss of sensitivity or "aging" under action of vibration. With the advent of economical and efficient solid-state amplifiers, the importance of the carbon transducer is bound eventually to diminish.

A brief mention should be made of a stretched diaphragm push-pull dual-button carbon transducer used in the early days of broadcasting because of its distortion-cancelling properties.[25] This microphone became outmoded during the early thirties as a result of advances in other types of microphones aided by electronic amplification.

Moving Armature Transducer

While claiming a record of first successful use for intelligible voice transmission, the "magnetic" transducer also can point with pride to continued service since its inception, principally in telephone receivers, and more recently again in microphones. Many different magnetic transducers have been designed. The type described in Bell's first patent application[18] of 1876 is shown in Fig. 2(b). An armature 2.11 is connected to a diaphragm 2.12 by a drive pin 2.13. The armature is hinged at 2.14 to a

[23] Production of carbon granules appears to a degree to be a "trade secret" but see, for example, J. R. Fisher, "Coal for transmitters," *Bell Labs. Rec.*, vol. 10, pp. 150–154; January, 1932. See also, W. E. Orvis, "Coal talks," *Bell Labs. Rec.*, vol. 10, pp. 200–204; February, 1932.

yoke 2.15. The yoke bears a pole-piece 2.16 forming an airgap 2.17 and carrying a coil 2.18 with terminals at 2.19. Bell's original idea was to interconnect two such transducers by means of a transmission line and a battery in the circuit which polarized the electro-magnets of both transducers. The generated signal voltage is proportional to armature velocity.

In 1877 Bell patented a notable improvement to the above structure in which he used a permanent magnet for purposes of polarization.[26]

The transducer of Bell is used to this day in telephone receivers in two modified forms shown here for reference. The one in Fig. 2(c) employs a combination diaphragm-armature 2.20 and a permanent magnet pole-piece 2.21 surrounded by a coil 2.22. A magnetic return cup 2.23 often is provided. A bi-polar form in Fig. 2(d) employs two pole-pieces 2.24, each provided with a coil 2.25 and a common permanent magnet 2.26. A Permindur pole-shoe 2.27 helps to carry the steady-state flux of the magnet. The above units have not been successful as microphones because the moving member requires sufficient heft to carry unbalanced dc flux and to support the steady-state forces which it produces.

A magnetically balanced-armature transducer, useful in microphones, was suggested by Siemens[27] and Watson,[28] but more definitely projected by Capps.[29] Shown in Fig. 2(e) an armature 2.30 within the coil carries the *differential flux only* stemming from motions imparted to it by the drive pin 2.31 connected to a diaphragm (not shown). The armature may be pivoted at a point 2.32 which results in a mechanically unbalanced structure, or at a point 2.33 which produces mechanical, as well as magnetic, balance.

In an attempt to dissociate as much as possible the steady state and the ac flux paths, the magnetic structure and the armature may be deformed, topologically speaking, until a straight-line pole-piece structure and a U-shaped armature form has been obtained, with great economy of dimensions.[30] This structure shown in Fig. 2(f) has found wide use in transistorized hearing aids in which miniaturization has become a most important virtue. A variation is shown in Fig. 2(g).

An improvement heretofore applied to a telephone receiver but with possible use in microphones is shown in Fig. 2(h).[31] In this arrangement, a ring armature 2.35 is maintained in an unsaturated condition by two ring magnets 2.36 and 2.37. The circuit comprising the alternating flux path includes a circular pole-shoe 2.38 and a circular coil 2.39. This transducer is well adapted to being driven by a piston diaphragm 2.40.

Magnetic transducers are characterized by the presence of a negative force-displacement function at the airgaps which has the dynamical form of ***negative stiffness***. The magnetization and saturation properties of the armature must be proportioned in such manner that the mechanical restoring stiffness of the armature and diaphragm are greater than the magnetic negative stiffness.[32]

Electrostatic Transducers

While Edison[33] and Dolbear[34] proposed the use of electrostatic transducers very early in this history of electroacoustics, it remained for Wente[35] to develop an electrostatic microphone that was truly a precision instrument. An electrostatic transducer is shown in schematic view in Fig. 2(i). A stretched flat conductive membrane 2.41 is arranged at a distance x from a back plate 2.42 defining an active area A. This produces a capacitor having a capacitance $C=kA/x$, where k is the dielectric constant of air. A polarizing potential difference E is provided from a source 2.43, connected to the electrodes through a very high resistance R. Thus a quasi-constant charge Q_0 is established on the capacitor where $Q_0=CE=kAE/x$. Solving for E,

$$E = (Q_0/kA)x. \tag{3}$$

Therefore the voltage across the condenser will vary linearly with the diaphragm displacement x. Because of the low-loss air dielectric, a capacitor transducer potentially is an extremely quiet, linear device.

In practice the spacing x is of the order of 0.001 inch, and the capacity of the microphone is around 25–50 $\mu\mu$f. Therefore, a very high impedance preamplifier at the transducer is required. The electrostatic transducer is most often used where highest quality is sought regardless of cost and inconvenience caused by the integral preamplifiers such as in recording and calibrations work. An electrostatic transducer also is characterized by presence of negative stiffness.

Moving Coil Transducer

While the early efforts and concepts in connection with moving-coil transducers are associated with the names of Cuttriss, Redding[36] and Siemens,[37] the credit for developing a wide-range practical moving-coil microphone goes to Wente and Thuras.[38] Referring to Fig.

[26] A. G. Bell, U. S. Patent No. 186,787; 1877.
[27] E. W. Siemans, German Patent No. 2355; 1878.
[28] T. A. Watson, U. S. Patent No. 266, 567; 1882.
[29] F. L. Capps, U. S. Patent No. 441,396; 1890.
[30] B. B. Bauer, U. S. Patent No. 2,454,425; 1948.
[31] E. E. Mott and R. C. Miner, "The ring armature telephone receiver," *Bell Sys. Tech. J.*, vol. 30, pp. 110–140; January, 1951.

[32] For example, see B. B. Bauer, "A miniature microphone for transistorized amplifiers," *J. Acoust. Soc. Am.*, vol. 25, pp. 867–869; September, 1953. In all transducers (other than loose-contact) any utilization of the generated electrical energy causes a reaction upon the transducer's mechanical impedance. In microphones, this effect is usually small, and is beyond the scope of this paper.

[36] C. Cuttriss and J. Redding, U. S. Patent No. 242,816; 1881.
[37] E. W. Siemens, German Patent No. 2355; 1878.
[38] E. C. Wente and A. L. Thuras, "Moving coil telephone receivers and microphones," *J. Acoust. Soc. Am.*, vol. 3, pp. 44–55; July, 1931.

2(k), the moving-coil is circular in shape and is attached at the rim 2.51 to a diaphragm (not shown) being supported and centered thereby in an air gap between pole-pieces 2.52 and 2.53. If the length of the conductor in the air gap is l and the flux density is B, and the diaphragm velocity is v, the voltage generated in the coil is

$$E = Blv \tag{4}$$

and hence, a moving-coil transducer is a velocity-responsive device.

Wente and Thuras based the development of their microphone and receiver upon equivalent circuit analysis. It is interesting to note that the circuit developed by them for a moving-coil receiver (where the goal is constant diaphragm displacement as a function of input voltage) is identical with the circuit to be used for a displacement-responsive (*e.g.*, ceramic) microphone.

A moving coil transducer is sensitive, rugged, provides good frequency-response and low noise, and at present is the "workhorse" among the microphones used for broadcasting and public-address applications. The low-coil impedance is suitable for operation with long cables, followed with a step-up transformer at the pre-amplifier, although in many microphones, a built-in transformer provides the proper impedance transformation right at the microphone.

Piezoelectric Transducer

In 1820 Becquerel described and observed piezoelectric effects[39] although a systematic study leading to modern understanding of these effects is credited to the Curies.[40] Nevertheless, piezoelectric microphones had not become practical until the invention of the "bimorph" Rochelle Salt transducer by Sawyer.[41] The "bimorph" ushered a quarter of a century era of dominance for Rochelle Salt crystals in low cost microphones, which (because of relatively poor stability of Rochelle Salt in severe climates) subsequently was to be challenged by polycrystalline Barium Titanate ceramics of Gray[42] and more recently by Lead Zirconium Titanate ceramics of Jaffe.[43] The shapes taken on by these bodies is that of a sandwich designated 2.60 in Fig. 2(j) consisting of two slabs of piezoelectric material 2.61 and 2.62 which are joined into an integral unit with appropriate electrodes. The element is attached to a reference frame 2.63 by raised portions 2.64, and driven by means of a drive-unit 2.65 which is connected to a diaphragm. The tension and compression in the beam combine with the polarization mode of the individual slabs to produce a potential difference in the electrodes as a function of displacement. Rochelle Salt bimorphs are available for actuation by torsion or bending stresses, while the ceramic units are usually of the latter variety.

Microphone Structures

Hunt[44] refers to the 1870's as "vintage years for electroacoustics." The inventions of the telephone and phonograph together with innumerable transducers to implement them occurred during those years. In the same manner, the 1930's, having seen the development of many a modern microphone, may be thought of as vintage years for microphones.

In studying the historical development of microphones it becomes evident that control over their directional capabilities has become increasingly important with time. In the following sections, we describe 1) *pressure microphones* which respond to sound pressure at one exposed surface of the diaphragm and (because sound travels around corners) are more or less equally sensitive from all directions; 2) *gradient* or *pressure-difference microphones* in which the diaphragm is exposed for differential action by sound pressure equally at both surfaces to achieve a bi-directional operation; 3) *combination microphones* which unite pressure and gradient concepts to achieve unidirectional action and 4) *phase-shift microphones* which achieve unidirectional action with a single transducer and acoustical phase-shift networks. Diaphragms and transducers in endless combinations have been brought together to produce a multitude of such microphones, but only a few basic examples can be given here.

Pressure Microphones

The electrostatic microphone of Wente[35] is one of the simplest, and, with modern refinements, one of the most effective of microphones. Its basic form is shown in Fig. 3(a). The microphone is composed of a flat stretched conductive diaphragm 3.1 attached to a box 3.2 so as to expose one surface to the external sounds. A stationary electrode 3.3 inside the box, placed close to the diaphragm, forms the electrostatic transducer.

The equivalent network analogy of the electrostatic microphone is shown in Fig. 3(b). Sound pressure acts upon the diaphragm through an air-load radiation impedance portrayed by an inductance L_a in parallel with a resistance R_a.[45] Thin films of air between the diaphragm and the electrode are squeezed in and out as the diaphragm vibrates to-and-fro resulting in damping action, the collective effect of which is represented by R_b and L_b. The fluid motion finds its way into the volume

[44] F. V. Hunt, "Electroacoustics," Harvard University Press, Cambridge, Mass., p. 37; 1954.

[45] Means of approximating air-load impedance with fixed elements is an important tool in the bag of tricks of the electroacoustician. For example, see B. B. Bauer, "Notes on radiation impedance," *J. Acoust. Soc. Am.*, vol. 15, pp. 223–224; April, 1944; R. C. Jones, "A fifty horsepower siren," *J. Acoust. Soc. Am.*, vol. 18, pp. 371–387; October, 1946; F. B. Hunt, *op. cit.*, p. 158.

of the recesses 3.4 which taken together define an acoustical compliance C_b.

A simplified equivalent circuit is obtained by dividing the mechanical impedance of the diaphragm by the square of the area A, which allows the elimination of ideal $1:A$ transformers [Fig. 3(c)]. The input voltage E_p replaces the sound pressure p. Since diaphragm displacement D is equivalent to the charge on a condenser $Q=CE$, it is a requirement in the equivalent circuit that the voltage E_0 remain invariant with frequency for constant E_p. This result is achieved if the combined series compliance of the diaphragm (C_mA^2) and of the volume 3.4 (C_b) comprise the controlling circuit impedance. In the microphone of Wente this condition was obtained by stretching the diaphragm to a high resonance frequency. A similar effect may come about by reducing the dimensions of C_b until the spring of the air becomes the controlling factor.[46] R_b and L_b are selected to damp the diaphragm resonance, to provide a "flat" response at high frequency.

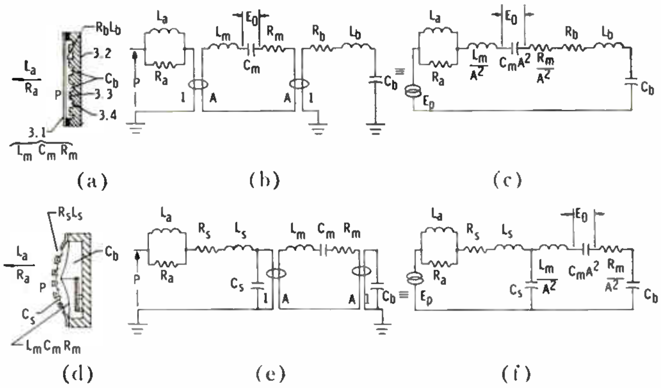

Fig. 3—Pressure microphone with displacement responsive transducer.

A piezoelectric microphone[41] in Fig. 3(d) is very similar in its equivalent circuit to the electrostatic microphone, except that a damping screen defining an acoustical resistance R_s and inertance L_s are added in the structure. The volume C_s between the screen and the diaphragm forms a part of the equivalent circuit mesh in Figs. 3(e) and 3(f). The mass, compliance, and resistance of the piezoelectric element and the diaphragm are lumped together and represented as L_m, C_m, R_m, respectively. A damping element or screen may be placed behind as well as in front of the diaphragm.

A different approach is taken in designing pressure microphones which use *velocity-responsive* transducers. Among the most elegant is the pressure-microphone portion of a combination microphone described by Olson in 1932.[47] In schematic cross section this microphone is shown in Fig. 4(a), its equivalent electrical network in Fig. 4(b), and a simplified version in 4(c). Because it is a design objective to make the *velocity* of the transducer invariant with frequency (and the electrical circuit counterpart of velocity is the current I), the circuit must be resistance controlled. This is achieved by the expedient of making all the mechanical and acoustical impedances small compared with the termination resistance R_b. The latter is obtained with a pipe or labyrinth filled with tufts of felt.

A more modern version of this microphone was described by Olson and Preston in 1950.[48] In this unit a pickup probe in the form of a small horn was added to the microphone to enhance its high-frequency response.

A major advance in pressure microphone design was

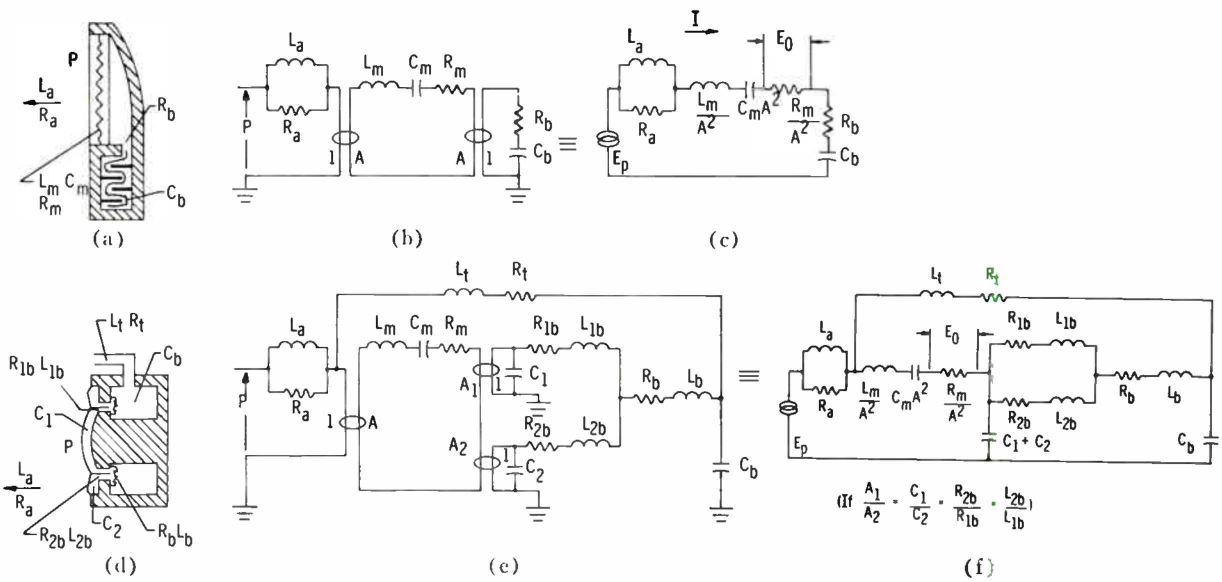

Fig. 4—Pressure microphone with velocity responsive trandsucer.

[46] The pressure-operated mode of Von Braunmühl and Weber microphone to be described is probably air-stiffness controlled, but also see T. J. Schultz, "Air-stiffness controlled condenser microphone," *J. Acoust. Soc. Am.*, vol. 28, pp. 337–342; May, 1956.

achieved by Wente and Thuras[38] with the invention of a moving-coil microphone shown in Fig. 4(d). The equivalent circuit is given in Fig. 4(e), and a simplified circuit in 4(f). It should be noted that the acoustical compliances C_1 and C_2 confronting the two portions of the diaphragm are interconnected by the acoustic impedances R_{1b}, L_{1b}, R_{2b}, L_{2b} defined by the circular slits between the coil and the magnetic structure, which form a resonant circuit capable of producing spurious response. Wente and Thuras encountered this problem and solved it by addition of a separate internal circuit mesh. However, by choosing the acoustical constants in accordance with equations at the bottom of Fig. 4(f),[17] the spurious resonance is prevented, and the simplified circuit 4(f) then correctly portrays the operation of the microphone.

Gradient Microphones

A number of illustrations and patent drawings of early microphones show diaphragms open on both sides for access to the sound waves, and in the early part of the century Pridham and Jensen[49] and Meissner[50] invented noise-cancelling microphones in which access at both sides of the diaphragm was provided for entry of noise, with preferential access on one side for speech sounds. Notwithstanding, the invention of a pressure-gradient ribbon microphone ("ribbon velocity microphone") by Olson[16] was an outstanding contribution to the art. This microphone is shown in schematic elevation in Fig. 5(a) and in plan cross section in Fig. 5(b). Olson designed the pole-pieces 5.1 and 5.2 to form a small baffle with an effective front-to-back air path d equal to $\frac{1}{2}$ the shortest wavelength of sound to be received. A ribbon transducer 5.3 was installed for free motion therebetween. The resulting action is shown by the phasor diagram in Fig. 5(e). The front and back pressures, designated as p_1 and p_2 are displaced in phase by an angle $(\omega d/c)\cos\theta$.

The equivalent circuit of the ribbon microphone is shown in Fig. 5(c), and a simplified circuit in 5(d). It is noted that by making the mechanical compliance of the ribbon sufficiently large, and the damping resistance sufficiently small, the inductive (mass) elements will become controlling. Lumping these elements into a single constant L, the acoustic impedance of the transducer may be expressed as $j\omega L$. Therefore, the velocity v (and consequently the output voltage E_0) is expressed by:

$$\begin{aligned} v &= j(\omega d/c)pA\cos\theta/j\omega L \\ &= (d/cL)pA\cos\theta. \end{aligned} \tag{5}$$

The output of a ribbon microphone, therefore, is in phase with the sound pressure, invariant with frequency, and proportional to the cosine of the angle of sound incidence. The polar response is the "cosine" pattern $\rho=\rho_{max}\cos\theta$ shown in Fig. 5(f). The power response to random sounds for this pattern is $\frac{1}{3}$ or the response of an omnidirectional (circular) pattern exhibited by pressure microphones.

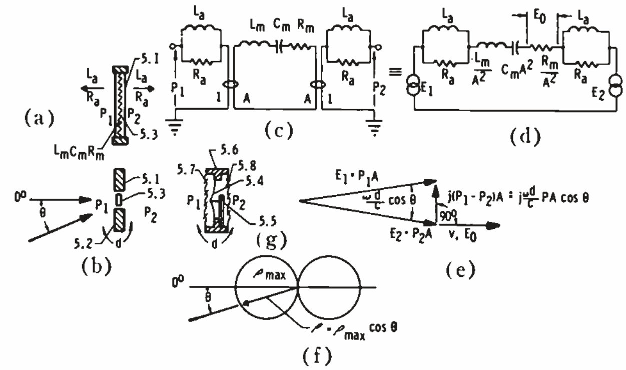

Fig. 5—Pressure gradient microphones.

A piezoelectric pressure-gradient microphone also can be constructed[51] as shown in schematic cross section in Fig. 5(g). A diaphragm 5.4 and a transducer 5.5 are housed in a round casing 5.6 with access to the atmosphere through damping screens 5.7 and 5.8. While this microphone had little commercial importance, it served as a stepping stone in the discovery of phase-shift microphones, later to be described.

Combination Microphones

The invention of the ribbon gradient microphone provided the necessary tool for the creation of a unidirectional microphone.[47,52] Such a microphone is shown in schematic cross section in Fig. 6(a). Two ribbons are provided with a common supporting frame 6.1. The ribbon 6.2 is freely accessible on both sides to form a pressure-gradient element with directional pattern expressed by the equation $\rho=\cos\theta$. The ribbon 6.3 is terminated by a damped pipe to form a nondirectional pressure microphone with directional pattern expressed by the equation $\rho=1$. Adding the two in equal half-and-half proportions produces a polar pattern $\rho=0.5+0.5\cos\theta$, which is a heart-shaped pattern or "cardioid." (The latter is a special case of the more general limaçon pattern $\rho=(1-k)+k\cos\theta$. The resulting directional characteristics are shown in Fig. 6(b).

A similar principle was employed by combining a piezoelectric pressure-gradient microphone with a piezoelectric pressure microphone to produce a cardioid pattern.[53] This latter unit incorporated a switch for selective choice of any of the three patterns. By combining a ribbon pressure-gradient with a moving coil pressure microphone, Marshall and Harry produced a very superior unidirectional microphone and endowed it

[49] Personal communication from the late P. Jensen.

[50] B. F. Meissner, U. S. Patent No. 1,507,081 (1924), filed March 12, 1919. In a recent personal communication, Meissner recounts attempts at intercommunication in open cockpit planes in 1916–17, leading to removal of back case from a Baldwin earphone (used as microphone) to provide equal noise access to both sides of the diaphragm.

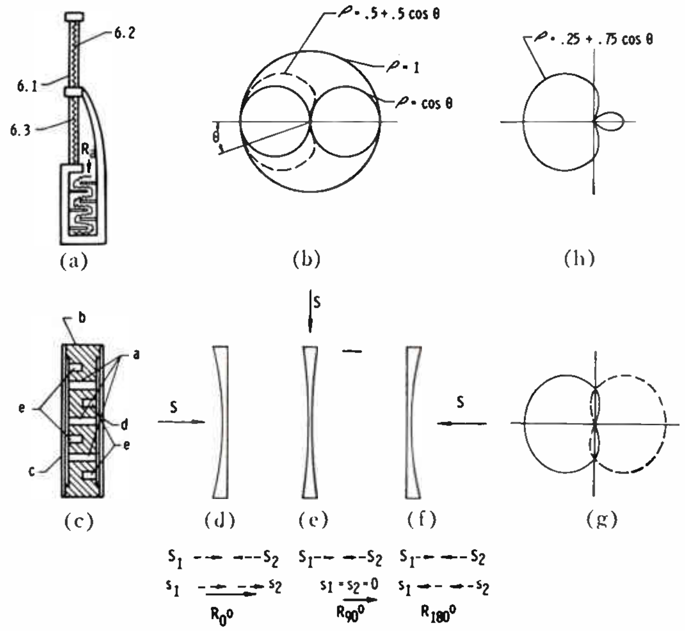

Fig. 6—Combination unidirectional microphones.

with six directional patterns.[54] It is to be noted that the pattern $\rho = 0.25 + 0.75 \cos \theta$, shown in Fig. 6(h) provides the lowest random energy pickup in the limaçon family: $\frac{1}{4}$ that of an omnidirectional pattern, while the pattern $\rho = 0.37 + 0.63 \cos \theta$ provides the greatest front-to-total random ratio of 93 per cent.[55]

The above microphones suffer from axial dissymmetry and production difficulty in the matching of two dissimilar units. In the newer designs they have been outmoded by simpler and more effective "phase-shift" microphones, later to be described.

A brilliant combination microphone based on the electrostatic principle was described by Von Braunmühl and Weber.[56] The principle of this microphone, according to the inventors, is as follows [Fig. 6(c)]: A brass circular body member b is provided with a series of holes *a through* the member and another series of holes *e part way through*. Two diaphragms c and d are fastened at the sides of the body, forming two electrostatic transducers. Assume first the condition of sound arriving at 90°. The sound pressure will merely push both membranes to-and-fro against the stiffness of the diaphragms and the air trapped within the body openings, by equal amounts denoted by the arrows S_1 and S_2 in Fig. 6(e). Now, let the sound arrive from the 0° direction; an additional pressure-gradient component will push both diaphragms and the air as a body (owing to the interconnection through the holes a) against the resistance of the film of air trapped between the diaphragm and the electrode faces. This latter effect is denoted by arrows s_1 and s_2. If the friction factor and the stiffness factors are suitably chosen, $S_1 = s_1$ and $S_2 = s_2$ and therefore only the front diaphragm c will move. By the same token, for sounds arriving from 180° direction only the rear diaphragm will be set into motion as shown in Fig. 6(f). The polar pattern exhibited by the front diaphragm, used by itself, will be a cardioid shown in solid lines in Fig. 6(g). If both diaphragms are connected in parallel, then the polar response of the combination will be omnidirectional or circular. While not so stated by the inventors, it is almost axiomatic that the rear diaphragm, by itself, will produce a reverse cardioid shown by the dotted line in Fig. 6(g); and if both diaphragms are oppositely polarized and their ac outputs summed, then a cosine pattern will emerge. The principle of Von Braunmühl and Weber is found to this day in electrostatic microphones used for recording and other high quality applications.

While Von Braunmühl and Weber envisioned the operation of their microphone as a combination of pressure and pressure-gradient functions, another way of looking at it, within certain limitations, is as a special case of a phase-shift microphone to be described next.

Phase-Shift Microphones

In attempting to balance the two damping screens of the structure in Fig. 5(g), the author noted that certain conditions of screen unbalance produced a small but decided unidirectional effect. In analyzing this phenomenon by means of equivalent circuit analysis it became apparent that acoustical phase-shift introduced by the networks was responsible. Soon thereafter the conditions were formulated for producing any directional pattern in the limaçon family with any transducer and an appropriate phase-shift network.

The invention is described in a parent patent[57] and four continuations-in-part.[58] The former outlines three different phase-shift networks which are the basis of practically all phase-shift microphones currently in use, and which are summarized in Fig. 7.

A piezoelectric phase-shift microphone is shown in Fig. 7(a). The microphone consists of a circular mounting plate 7.1 upon which is fastened a diaphragm 7.2 and a piezoelectric transducer 7.3. In the simplified equivalent circuit of Fig. 7(b) these are shown as defining an impedance Z_{am} which includes the air load. Sound waves for frontal (0° incidence) first impinge upon the diaphragm with a pressure p_1 traveling to the rear of the microphone through a distance d with a velocity c. The rear pressure p_2 lags behind p_1 by a phase angle $\phi = \omega d/c$. For any other angle of incidence θ, $\phi = (\omega d/c) \cos \theta$. Air flow into the volume 7.5 which defines an acoustical compliance C_2 is caused by pressure P_2 acting through the circumferential entry-port 7.4 which defines a resistance R_2 and inertance L_2. It is shown in the parent patent that *regardless* of the magnitude of Z_{am}, a cardioid pattern will be obtained if the

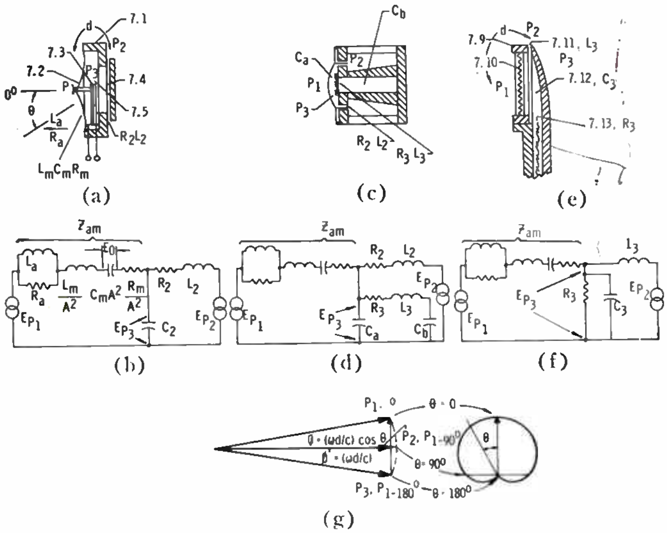

Fig. 7—Phase-shift unidirectional microphones.

elements of the network R_2, L_2, and C_2 are proportioned as follows:

$$R_2 = d/cC_2 \quad (6)$$

$$L_2 = C_2R_2^2/2. \quad (7)$$

In the above proportions, the elements R_2, L_2, and C_2 form a phase-shift network whereby the pressure P_3 within the microphone is equal to P_2 but is shifted in phase by an angle $\phi' = \omega d/c$. ϕ' remains unaffected by direction of arrival of sound. Referring to Fig. 7(g), and letting P_2 and P_3 remain stationary, as the source of sound rotates from the front to the back of the microphone, the phasor P_1 will describe a path from $P_{1-0°}$, to $P_{1-90°}$ and then to $P_{1-180°}$. The phasor connecting the ends of P_3 and P_1 plotted as a function of the angle θ will be a cardioid of revolution. By choosing properly the relative magnitudes of ϕ_0 and ϕ', any desired member of the limaçon family may be obtained. The above principle is employed in piezoelectric microphones intended for public address applications.

A moving-coil phase-shift microphone exhibiting cardioid operation is shown in Fig. 7(c), and its simplified equivalent circuit in 7(d). Here the impedances of the moving coil and the air load again are lumped together as Z_{am}. The phase-shift network is composed of the rear port resistance R_2 and inertance L_2, compliance of the volume under the diaphragm C_a, and within the magnet C_b, and the impedance of the interconnecting screen R_3 and L_3. Subsequently, Black[59] and Wiggins[60] modified this structure by providing multiple rear entry ports. This approach allows the use of stiffer diaphragm suspension than that used with the microphone in Fig. 7(d), and serves to improve sensitivity to mechanically transmitted noise.

[59] Black, U. S. Patent No. 2,401,328 (1946); filed January 16, 1943.

[60] A. M. Wiggins, "Unidirectional microphone utilizing a variable distance between the front and back of the diaphragm," *J. Acoust. Soc. Am.*, vol. 26, pp. 687–692; September, 1954.

Practically all unidirectional moving-coil microphones built today use one of the principles described in the preceding paragraph.

A third phase-shift network to be found in the parent patent is especially adapted for use with mass-controlled transducers, such as the ribbon transducer. Shown in Fig. 7(e) is a frame 7.9 and ribbon transducer 7.10, and a phase-shift network comprised of the following elements: entry port 7.11 which defines an acoustic inertance L_3, a volume behind the ribbon 7.12 which furnishes a compliance C_3, and a damped pipe which defines a resistance R_3. The front-to-back distance is again defined as d. This network can be solved analytically for the cardioid with the following result:[57]

$$L_3 = dR_3/c \quad (8)$$

$$C_3 = L_3/2R_3^2. \quad (9)$$

An improved version of this microphone was developed by Olson[61] in which the rear entry is adjustable for selection of polar pattern. Subsequently, Olson, Preston and Bleazey reported achieving a further improvement by taking a phase-shift ribbon microphone with a limaçon characteristic where $\rho = 0.3 + 0.7 \cos\theta$ and providing a damped cavity in the vicinity of the rear entry ports.[62] The above microphones have found wide use in public address and television broadcasting.

Super-Directional Microphones

Three approaches have been taken to provide microphones with directional characteristics sharper than those possible with limaçon patterns.

A. Reflectors, Refractors, Diffractors

From optical analogy, the idea of using a parabolic mirror for improved directivity must have occurred to various investigators. The microphone is placed at or near the focus of the reflector. The angular resolution for short wavelengths is given by Rayleigh's criterion,[63] as $\theta_r = 0.61\ \lambda/r$ radians, where λ is the wavelength, r the radius, and θ the resolution angle. The directional capability is very high at high frequency and nil at low frequency. Hansen[64] describes a parabolic reflector used with condenser microphones. Olson and Wolff[65] proposed a concentrator consisting of parabolic and conical sections arranged in the form of a horn. Aamodt and Harvey[66] devised a wide area electrostatic microphone which attains notable directivity simply because of its

large size. Further improvements in performance can be obtained by combining an acoustical lens[67] with a conical horn.[68]

B. Line Microphones

In 1939, Mason and Marshall described a microphone attachment consisting of 50 small tubes whose lengths vary by equal increments from 3 cm to 150 cm. These are assembled into a circular bundle and coupled to the diaphragm of a pressure microphone.[69] This microphone is roughly equivalent in directional effects to a 3-foot parabolic reflector, but with considerably less bulk and frequency dependence. The same year Olson described an improved line microphone in which directional characteristics were substantially independent of frequency, obtained by combining several multipipe units, each designed for operation over a given frequency range.[70]

C. Higher-Order Combination Microphones

It has been seen that subtraction of pressures at two points in space produces a gradient mode of operation described by $\rho = \cos\theta$. Subtraction of two gradient modes at two points in space will produce a second-order gradient, $\rho = (\cos\theta)(\cos\theta) = \cos^2\theta$. By continuing this process, in theory infinite improvement in directivity could be obtained in theoretically infinitesimal space.

A microphone with higher mode of operation was developed in 1938 and described in the parent phase-shift microphone case, U. S. Patent No. 2,237,298.[57] By providing an appropriate electrical network with two gradient transducers a polar pattern defined by equation $\rho = (1+\cos\theta)(\cos\theta)$ was obtained. The reissue patent 2,305,599[58] describes how the same effect may be achieved by subtraction of outputs of two spaced-apart cardioid microphones. Olson and Preston have carried out this work further by combining two special phase-shift microphones[62] with electrical networks to obtain a polar pattern defined by $\rho = (0.3+0.7\cos\theta\cos\theta/3)(\cos\theta)$.[71]

A second-order gradient differential microphone employing a single diaphragm and a case of suitable configuration was developed by Wiggins, for speech transmission from noisy environment.[72]

Future Developments

The art of microphone design still taxes the ingenuity of the physicist and the radio scientist. Despite the century of progress many problems remain unsolved.

Improved directional characteristics will continue to receive considerable attention. A "zoom" microphone, in which directional pattern can be adjusted to conform, say, to the optical angle of a television camera may find important use in the broadcasting industry. Light and highly effective directional microphones would aid with picking out the desired sounds amidst crowd noise.

The problem of an effective, reliable and inexpensive multichannel wireless microphone is yet to be solved. Such a microphone would be a boon to broadcasting, entertainment and similar industries.

One feels intuitively that we should be due for a "breakthrough" in transducer technology. Microphones especially suitable for use with transistor amplifiers and with sufficient sensitivity and low noise, figure to be useful in broadcasting recording and sound level meter applications would be very welcome.

Unconventional methods of sound reception will be further explored: Throat microphones already have been widely used in military actions, but they provide poor articulation. Microphones placed within the mouth, attached to the teeth, inserted in the ear canal and otherwise coupled to the skeletal structure of the head have already received considerable study.

Ultimately, lest we forget, speech is merely an end-product of the thought processes, and there is no reason why eventually these should not be directly picked up without the intervening aerial vibrations. One should not be surprised to see an Astronaut, someday, with a radio "thought" transmitter permanently implanted in his cranium. But then, alas, all this microphone development would have been in vain.

Acknowledgment

A debt of gratitude is due to the writers and historians who have documented the work of previous investigators well enough to allow this paper to be written without need of exhaustive original research. H. A. Frederick[18] and F. V. Hunt[44] in their respective publications have provided a wealth of historical material. Olson's encyclopaedic "Acoustical Engineering"[73] describes a great variety of microphones from the technological point of view, and it was an invaluable reference.

Back volumes of the *Journal of the Acoustical Society of America* and the IRE Transactions on Audio have been most useful in reviewing modern developments. Friends and associates too numerous to mention have been helpful with the location of references. To those of them who are still young enough reasonably to expect to celebrate the 100th Anniversary of the IRE, this article will hopefully be an acceptable starting point in appraising the progress in microphones that will have taken place during the next 50 years!

Loudspeakers*

HARRY F. OLSON†, FELLOW, IRE

Summary—**A loudspeaker is an electroacoustic transducer intended to radiate acoustic power into the air, the acoustical waveform being essentially equivalent to that of the electrical input. Electrodynamic, electromagnetic and electrostatic driving systems have been used for loudspeakers operating in air. However, during the past two decades the electrodynamic has overwhelmingly predominated in all applications for loudspeakers operating in air. The almost universal use of the direct-radiator dynamic loudspeaker in radio receivers, phonographs, magnetic-tape reproducers, television receivers, announce and intercommunicating systems is due to the simplicity of construction, small space requirements and the relatively uniform response-frequency characteristics. For small-scale applications the low efficiency of the direct-radiator loudspeaker is not a handicap. However, for large-scale high-power sound applications, the high-efficiency horn loudspeaker is particularly suitable because the amplifier requirements are reduced by an order of magnitude. For the future, the promising developments in loudspeakers appear to be in the field of motion control.**

Introduction

A LOUDSPEAKER is an electroacoustic transducer intended to radiate acoustic power into the air, the acoustical waveform being essentially equivalent to that of the electrical input. The transformation of electrical waves into the corresponding acoustical waves may be accomplished in a multitude of ways. At the present time, while practically all loudspeakers may be classed as of the diaphragm type, the essential essential difference resides in the method of coupling between the diaphragm and the air and the means for driving the diaphragm. The two extreme ends of the audio-frequency range are the most difficult to reproduce with efficiency comparable to that of the mid audio-frequency range. In general, loss of coupling between the diaphragm and the air occurs in the low-frequency range. Among the common methods employed to increase the low audio-frequency radiation from diaphragms are, namely, the use of large diaphragms, groups of diaphragms and various shapes of baffles, cabinets and horns. Loss of efficiency in the high audio-frequency range is due to a relatively large mass reactance as compared to the sound radiation resistance of air. The effective mass reactance may be reduced by multiple loudspeakers and horn couplers.

There are many possible transducers which may be employed to drive the diaphragm as follows: dynamic, magnetic, electrostatic, piezoelectric and magnetostrictive. In the direct-coupled loudspeaker systems with no diaphragm there are various electronic expedients for producing compression or motion of the air. Some of these have been used commercially.

The purpose of this paper is to present a brief historical review of the loudspeaker art, a technical exposition of the present state of loudspeakers and future possibilities.

* Received by the IRE, June 21, 1961; revised manuscript received, October 19, 1961.

† RCA Laboratories, Princeton, N. J.

Historical Review

Thousands of investigators have contributed to the science of electroacoustic transducers over a period of more than one hundred years. Therefore, it is impossible in this limited presentation to provide a complete historical account of the loudspeaker art because the main objective is to present the significant technical aspects of loudspeakers. In view of the fact that the dynamic or moving-coil driving mechanism has been the most important in terms of modern commerical utilization, the historical presentation[1] in this paper will be confined to this system.

The motor mechanism consisting of a circular coil located in a radial magnetic field was first disclosed by Siemens.[2] Lodge,[3] Pridham and Jenson[4] and others contributed to the suspension system. However, there were very few developments in loudspeakers in the twenty-seven years following Lodge's disclosure. A breakthrough in the dynamic loudspeaker was made by Rice and Kellogg[5] in 1925. The success of the development was due to their recognition of three physical factors with relation to the action and design of a direct radiator loudspeaker. The first is that the sound-power output of a loudspeaker is the product of the mechanical resistance due to sound radiation and the square of the velocity of the diaphragm. The second is that sound radiation from a small vibrating diaphragm gives rise to a mechanical resistance which is proportional to the square of the frequency. The third is a vibrating system which is mass controlled. It follows then that, if the fundamental resonance occurs below the lowest frequency of interest, the complementary variations of the second and third factors which control the sound output as given by the first factor conspire to provide a uniform response up to the frequency region at which the assumptions begin to fail. This was the contribution of Rice and Kellogg, and it continues to be the basic precept that guides the design of all direct-radiator loudspeakers.

[1] For those interested in a complete historical account of loudspeakers, the reader is referred to F. V. Hunt, "Electroacoustics," John Wiley and Sons, Inc., New York, N. Y.; 1954.

[2] E. W. Siemens, German Patent, No. 2355, filed December 14, 1877.

[3] O. J. Lodge, British Patent, No. 9712, filed April 27, 1898.

[4] E. S. Pridham and P. L. Jenson, U. S. Patent No. 1,448,279, filed April 28, 1920.

[5] C. W. Rice and E. W. Kellogg, "Notes on the development of a new type of hornless loudspeaker," *Trans. AIEE*, vol. 44, pp. 461–475; April, 1925.

Horn loudspeakers are used for applications which require high efficiency and large power outputs. The first use of horns in connection with loudspeakers is somewhat obscure. However, Webster[6] was the first to introduce the concept of acoustical impedance and to apply the theory to horns to show that a horn may be used as a marching device between the relatively large acoustical impedance of the diaphragm and the low acoustical impedance of air in free space.

The preceding all-too-brief history of loudspeakers includes only a few of the thousands of investigators whose contributions during the past century have made modern sound reproduction possible.

Driving Systems

All loudspeakers employ an electromechanical or electroacoustic transducer, termed a driving system, for converting electrical variations into the corresponding acoustical variations. The most common driving systems in use today are the electrodynamic, the electromagnetic, the electrostatic, the magnetostrictive and the piezoelectric.

In the electrodynamic driving system depicted in Fig. 1A, the mechanical forces are developed by the interaction of the current in the conductor and the transverse magnetic field.

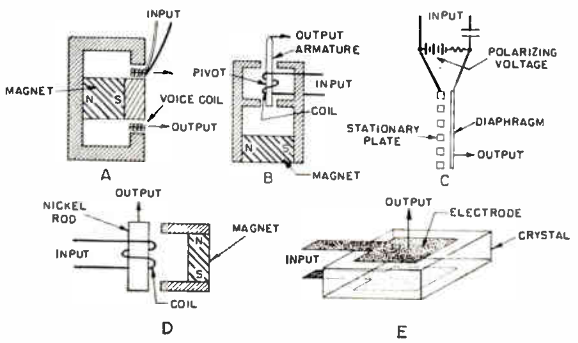

Fig. 1—Driving Systems. A) Electrodynamic. B) Electromagnetic. C) Electrostatic. D) Magnetostrictive. E) Piezoelectric.

In the electromagnetic driving system depicted in Fig. 1B the mechanical forces are developed from magnetic reactions. There are innumerable possibilities in the design of electromagnetic driving systems, but the most common arrangement for use in loudspeakers is the balanced armature system shown in Fig. 1B.

In the electrostatic driving system depicted in Fig. 1C the mechanical forces are developed from electrostatic reactions.

In the magnetostrictive driving system depicted in Fig. 1D the mechanical forces result from the deformation of a ferromagnetic material possessing direct magnetostriction properties.

[6] A. G. Webster, "Acoustical impedence and the theory of horns and of the phonograph," *Proc. Natl. Acad. Sci.*, vol. 5, pp. 275–282; 1919.

In the piezoelectric driving system depicted in Fig. 1E the mechanical forces result from the deformation of a crystal or ceramic having converse piezoelectric properties.

Electrodynamic, electromagnetic and electrostatic driving systems have been used for loudspeakers operating in air. However, during the past two decades the electrodynamic has overwhelmingly predominated in all applications for loudspeakers operating in air.

Direct-Radiator Dynamic Loudspeakers

The almost universal use of the direct-radiator dynamic loudspeaker in radio receivers, phonographs, magnetic-tape reproducers, television receivers, announce and intercommunicating systems is due to the simplicity of construction, small space requirements, and the relatively uniform response-frequency characteristic.

The vibrating system of a direct-radiator dynamic loudspeaker consists of a conical paper diaphragm coupled to a voice coil located in the air gap of a magnetic structure (Fig. 2). The voice coil consists of a cylindrical multilayer coil of aluminum or copper wire. In general, the resistance of the voice coil, depending upon the design, ranges from 1.5 to 100 ohms. The mass of the voice coil, depending upon the size of the loudspeakers, ranges from 0.1 to 4 grams. The permanent magnet is of the high-flux high-coercive type and may be an alloy of aluminum, cobalt, nickel and iron, or a ferrite of iron, cobalt, barium and nickel. The flux density in the air gap of commerical loudspeakers ranges from 3000 to 20,000 Gauss. The diameter of the cone of commerical direct-radiator loudspeakers ranges from 1 to 18 in. The mass of the cone from the smallest to the largest covers a range of 0.1 to 100 grams.

The inherent characteristics of the elements of the vibrating system and radiation load of a direct-radiator dynamic loudspeaker which conspire to provide a uniform response-frequency characteristic may be illustrated as follows.

A cross-sectional view, the voice coil circuit and the mechanical circuit of a direct-radiator dynamic loudspeaker are shown in Fig. 2. The total mechanical impedance z_{MT} in mechanical ohms, of the vibrating system at the voice coil is

$$z_{MT} = r_{MS} + r_{MA} + j\omega m_C + j\omega m_A - \frac{j}{\omega C_{MS}}. \tag{1}$$

where

r_{MS} = mechanical resistance of the suspension system (in mechanical ohms)

r_{MA} = mechanical resistance of the air load (in mechanical ohms)

m_C = mass of the cone and the voice coil (in grams)

m_A = mass of the air load (in grams)

C_{MS} = compliance of the suspension system (in cm/dyne).

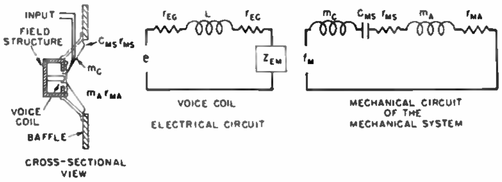

Fig. 2—Cross-sectional view, electrical and mechanical circuits of a direct-radiator dynamic loudspeaker mounted in a baffle. In the electrical circuit: e = the internal voltage of the generator. r_{EG} = the electrical resistance of the generator. r_{EC} and L = the electrical resistance and the inductance of the voice coil. z_{EM} = the motional electrical imedance. In the mechanical circuit: f_M = the driving force. m_C = the mass of the cone. C_{MS} = the compliance of the suspension system. r_{MS} = mechanical resistance of the suspension system. m_A = the mass of the air load. r_{MA} = the mechanical resistance of the air load.

Eq. 1 may be written as follows:

$$z_{MT} = r_{MS} + r_{MA} + jx_{MC} + jx_{MA} - jx_{MS}, \tag{2}$$

where

r_{MS} = mechanical resistance of the suspension system (in mechanical ohms)

r_{MA} = mechanical resistance of the air load (in mechanical ohms)

$x_{MC} = \omega m_C$ = mechanical reactance of the voice coil and cone (in mechanical ohms)

$x_{MA} = \omega m_A$ = mechanical reactance of the air load (in mechanical ohms)

$x_{MS} = 1/\omega C_{MS}$ = mechanical reactance of the suspension system (in mechanical ohms).

The mechanical resistance and mechancal rieactance of the air load may be obtained from Fig. 3.

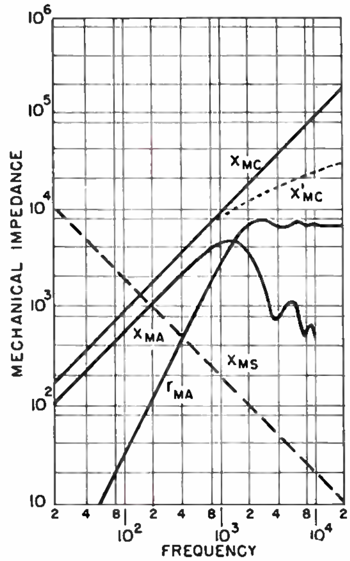

Fig. 3—Mechanical impedance-frequency characteristics of a direct-radiator dynamic loudspeaker with a cone 4 in in diameter. x_{MC} = the mechanical reactance of the cone and coil. x_{MA} = the mechanical reactance of the air load. r_{MA} = the mechanical resistance of the air load. x_{MS} = the mechanical reactance of the suspension system. x'_{MC} = the mechanical reactance of the cone and coil where wave motion occurs in the cone.

where

r_{ER} = component of the motional electrical resistance due to the radiation of sound (in abohms)

r_{EM} = total motional electrical resistance (in abohms)

r_{EC} = damped electrical resistance of the voice coil (in abohms).

The components r_{ER} and r_{EM} may be obtained from (2) and (3).

From (2)–(4) the efficiency (in per cent) of the loud speaker is

$$\mu = \frac{(Bl)^2 r_{MA}}{(Bl)^2(r_{MS} + r_{MA}) + r_{EC}\left[(r_{MC} + r_{MA})^2 + (x_{MA} + x_{MC} - x_{MS})^2\right]}. \tag{5}$$

The motional electrical impedance z_{EM} (in abohms) of the mechanical system is

$$z_{EM} = \frac{(Bl)^2}{z_{MT}}, \tag{3}$$

where

B = flux density in air gap, (in gauss)

l = length of the conductor in the voice coil (in centimeters)

z_{MT} = total mechanical impedance of the mechanical system (in mechanical ohms).

The efficiency of the loudspeaker is the ratio of the sound-power output to the electrical-power input. The efficiency, μ (in per cent) may be obtained from the voice-coil circuit of Fig. 2 and expressed as follows:

$$\mu = \frac{r_{ER}}{r_{EC} + r_{EM}} \times 100, \tag{4}$$

To simplify the discussion, assume that the mechanical reactance and mechanical resistance of the suspension system are zero. The mechanical-impedance characteristics of the mechanical system are shown in Fig. 3. Since r_{MA} is small compare to x_{MA} and x_{MC}, (5) becomes

$$\mu = \frac{(Bl)^2 r_{MA}}{r_{EC}(x_{MA} + x_{MC})^2} \times 100. \tag{6}$$

Referring to Fig. 3, it will be seen that x_{MA} and x_{MC} are proportional to the frequency, and r_{MA} is proportional to the square of the frequency. Under these conditions (6) shows that the output of a direct-radiator loud speaker is independent of the frequency from the fundamental resonant frequency up to the frequency at which the ultimate resistance obtains.

The efficiency characteristic μ_1 of Fig. 4 depicts the foregoing in a graphical manner. The efficiency characteristic μ_1 assumes a resonant frequency at 0 cps. If the mechanical reactance of the suspension system is included, the efficiency will be as depicted by the efficiency characteristic μ_2 of Fig. 4. In the high-frequency region the cone no longer vibrates as a single unit, and wave action takes place which lowers the mechanical impedance, as shown by the dotted characteristic x'_{MC} (Fig. 3). As a result, the efficiency in the high-frequency range is increased, as shown by the efficiency characteristic μ_3 (Fig. 4). The preceding illustration substantiates the physical principles of operation of the dynamic direct radiator loudspeaker as outlined in the historical section of this paper.

Another important characteristic of a loudspeaker is the directional characteristic, which depicts the response as a function of the angle with respect to some axis of the system. The directional pattern of a vibrating cone depends upon three principal factors: the cone diameter, the cone angle and the frequency. Other factors such as the paper pulp, the fabrication and processing of the cone, the voice-coil diameter and the cone suspension also influence the directional pattern, but to a lesser degree.

The directional characteristics of direct-radiator dynamic loudspeakers for cones of various angles as a function of the ratio of the diameter to the wavelength are shown in Fig. 5. The directional pattern becomes sharper with increasing frequency. However, the pattern is broader than that of a vibrating piston of the same diameter due to the relatively low velocity of sound propagation in the paper cone. A further consideration shows that the directional pattern becomes broader at the higher frequencies as the cone angle is increased, which is due to the delay between the sound emitted from the outside edge and the center of the cone which will increase as the angle of the cone is increased. As a result, the directional pattern will be broadest for the cone with the widest angle.

Frequency discrimination will be introduced for various angles with respect to the axis of the cone if the directional pattern varies with respect to frequency. A consideration of the data of Fig. 5 shows that a relatively uniform directivity pattern may be obtained by the use of different size cones graduated with respect to frequency. This is graphically illustrated in Fig. 6 in which a broad and uniform directivity pattern is obtained by employing a 15-in diameter cone to cover the frequency range up to 1200 cps and a $2\frac{1}{2}$-in diameter cone to cover the frequency range above 1200 cps.

As in all electronic systems, a loudspeaker exhibits nonlinear distortion. The principal sources of nonlinear distortion are as follows: nonlinear cone suspension system, inhomogeneity of the air gap flux in which the voice coil moves, frequency modulation of a high-frequency sound radiation due to large motion of the cone in the low-frequency range, and nonlinear distortion of the air due to the high sound level in close proximity to the cone.

The most troublesome, and in most cases the largest, source of nonlinear distortion in direct-radiator dynamic loudspeakers employing cone-type radiators is the suspension system. The nonlinear distortion due to the suspension system may be reduced to a negligible value by employing a low-resonance loudspeaker mounted in a completely enclosed cabinet, as shown in Fig. 7. If the compliance C_{MS} of the suspension is made large compared to the compliance of the air in the cabinet C_{MB}, the controlling negative mechanical reactance will be that of the compliance of the air in the cabinet. In this way the distortion introduced by the nonlinear characteristics of the suspension C_{MS} will be negligible.

In general, all of the other nonlinear distortions can be reduced to a negligible quantity. However, as in most electronic systems, the problem involves economics.

Speech and music are transient in character. Therefore, in order to reproduce speech and music faithfully the loudspeaker should exhibit excellent transient response. A tone burst simulates, to a first approximation, the transient nature of speech and music. Therefore, if an electrical tone burst is applied to the loudspeaker, the sound output will represent the transient response. The response of a loudspeaker for the range 400 to 3000 cps is shown in Fig. 8. There is a peak in the response at 800 cps and a dip in the response at 1100 cps. The sound output of this loudspeaker for an electrically applied tone burst is shown in Fig. 8. In the case of a peak in the response-frequency characteristic, there is a slow growth and a slow decay in the response of the loudspeaker to the applied tone burst. In the case of a dip in the response frequency characteristic, there is a rapid growth followed by a decrease in the output and then by an increase in the output. A measure of the transient distortion may be designated as the remaining response after the tone-burst signal has been cut off. In general, if the response frequency characteristic is smooth, the transient response will be good.

The diaphragms or cones of practically all direct-radiator loudspeakers are made of paper by a felting process employing a master screen having the shape of the diaphragm. The mixture of pulp and water is drawn through the screen leaving a thin deposit of compressed pulp. When this deposit is dried, it can be removed from the screen and the result is the finished diaphragm. The outside suspension system can also be felted as part of the cone.

The simple direct-radiator dynamic loudspeaker shown in Fig. 2 represents the most common and enjoys the greatest widespread use. However, there are many versions of the direct-radiator loudspeaker in which the principal objective is to provide improved performance over a wide frequency range. The most common of these systems is depicted in Fig. 9.

The direct-radiator loudspeaker mechanism is usually mounted in a flat baffle or some type of cabinet enclosure as shown in Fig. 10. A direct-radiator loudspeaker mounted in a flat baffle is shown in Fig. 10A. A rela-

tively large baffle must be used to obtain adequate low-frequency response, because the baffle cutoff is determined by the distance from the front to the rear of the mechanism. When this distance is less than a quarter wavelength of the sound wave, the response falls off rapidly below this frequency. In order to obtain good response to 70 cps a four-foot baffle is required. A direct-radiator loudspeaker mechanism mounted in an open-back cabinet is shown in Fig. 10B. This system is used in practically all radio receivers, phonographs and television receivers of both the table-model and console types. The fundamental resonance of the cabinet, acting as a pipe, connected to a loudspeaker mechanism produces considerable accentuation of the low-frequency response, and is termed *cabinet resonance*. A direct-radiator loudspeaker mechanism mounted in a completely enclosed cabinet is shown in Fig. 10C. This system will exhibit uniform response to about one-half octave below the fundamental resonance frequency of the combination of the mechanism and the cabinet. The accentuated response at the resonant frequency of the loudspeaker mechanism and cabinet can be reduced by the addition of sound absorbing material in the cabinet so that practically uniform response is obtained. A direct-radiator loudspeaker mechanism mounted in a cabinet completely enclosed save for a port is shown in Fig. 10D. The addition of the port accentuates the response in that portion of the frequency range in which the motion of the cone is in phase with motion of the air in the port. A direct-radiator loudspeaker mechanism coupled to one end of a long damped pipe in the form of labyrinth with the other end of the pipe opening in the front of the cabinet is shown in Fig. 10E. At the first half wavelength resonance, the velocity at the open end is in phase with that of the front of the cone. The radiation then is additive and the response is increased. An increase in response can be obtained over an octave. The increase of absorption with frequency can be used to control the radiation from the pipe in the frequency region in which the output of the loudspeaker and pipe are out of phase. A combination horn and direct-radiator loudspeaker are shown in Fig. 10F. The sound radiation in the low-frequency range takes place from the horn coupled to the back of the cone. The mid- and high-frequency sound radiation takes place from the front of the direct-radiator loudspeaker.

The efficiency of a direct-radiator dynamic loudspeaker is relatively low, being about 1 to 5 per cent. Therefore, the direct-radiator loudspeaker is not particularly suitable for installations requiring large amounts of sound power, as, for example, in large-scale high-power sound motion picture, sound reinforcing and public address systems, because the power amplifiers required to drive the loudspeaker become too large. Under these conditions, it is more economical to employ loudspeakers with high efficiency such as, for example, horn loudspeakers. With a horn loudspeaker it is possible to obtain an efficiency of 20 to 50 per cent. However, for reproduction in the average living room a relatively small amount of power is required to obtain an adequate sound level employing a direct-radiator loudspeaker. For the average listening sound-pressure level of 80 db the input power required is only 0.05 watt. A level of 100 db can be obtained with an input of 5 watts. Thus it will be seen that the direct-radiator dynamic loudspeaker is quite satisfactory for small scale applications.

During the past three and one half decades, more than 500,000,000 direct-radiator dynamic loudspeakers have been sold in the United States.

Horn Loudspeakers

A horn loudspeaker consists of an electrically or a mechanically driven diaphragm coupled to a horn. The principal virtue of a horn resides in the possibility of presenting practically any desired value of acoustical resistance to the driving system. The horn provides a matching means between the large acoustical impedance of a relatively dense diaphragm and the small acoustical impedance of the relatively light air.

The mechanisms in use today for coupling to horn loudspeakers are of the permanent-magnet dynamic type. These mechanisms may be classed as the large- and small-throat types. The large-throat mechanism shown in Fig. 11A resembles the direct-radiator mechanism. The diameter of the diaphragm ranges from 10 to 15 in. The voice coil is usually about 2 to 3 in in diameter. The flux density in the air gap is usually maintained at a high level of 15,000 Gauss to obtain a high order of efficiency. In general, the large-throat mechanism is used for reproduction in the low-frequency range. The small-throat type mechanism is shown in Fig. 11B. There are many ramifications of this design. The diameter of the diaphragm ranges from 1 to 4 in. The diameter at the throat of the horn ranges from $\frac{1}{4}$ to 1 in. The flux density in the air gap ranges from 15,000 to 22,000 Gauss. In some applications the mechanism shown in Fig. 12B may be used to reproduce the upper portion of the audio-frequency range, while the mechanism of Fig. 11A is used to reproduce the lower portion of the audio-frequency range. Under these conditions, an electrical network is used to allocate the power input to the loudspeakers. With a suitable horn, either of the mechanisms of Fig. 11 may be designed to cover the entire audio-frequency range.

Many types of horns are used in horn loudspeakers. A straight-axis large-throat horn is shown in Fig. 12B. A folded large-throat horn is shown in Fig. 12A. A straight axis small-throat horn is shown in Fig. 13B. A folded small-throat horn is shown in Fig. 13A.

The efficiency of horn loudspeakers may range from 20 to 50 per cent. Horn loudspeakers have been built which will deliver as much as 1 kw of the sound output.

Miscellaneous Loudspeakers

Direct-radiator and horn loudspeakers employing electrodynamic driving systems have dominated the loudspeaker field for more than three decades. Nevertheless a brief mention of other loudspeaker systems which have been commercialized is appropriate.

The magnetic driving system of Fig. 1B, coupled to a diaphragm, has been applied to both direct-radiator and horn systems. The magnetic loudspeaker was used in large quantities in the late twenties and early thirties. However, with the advent of high-coercive high-energy permanent magnets required in dynamic systems, the magnetic loudspeaker was displaced by superior dynamic loudspeakers.

The electrostatic or condenser loudspeaker has been in sporadic and limited commercial use for more than three decades. The electrostatic driving system was shown in Fig. 1C.

Commerical electrostatic loudspeakers for the frequency range above 7500 cps are built with a diaphragm of 0.001 in plastic with a thin metallic coating and a diaphragm area of a few square inches. The diaphragm rests directly upon the perforated metal back plate. The electrostatic loudspeaker is coupled directly to the vacuum tube in which the plate voltage supplies the polarizing potential. With an effective spacing of about 0.001 in, the sensitivity is comparable to conventional dynamic loudspeakers. This small spacing limits the maximum amplitude and confines the operation to a frequency range above 7500 cps.

Bilateral or push-pull electrostatic loudspeakers have also been commercialized. A diaphragm of one square foot is placed between two perforated plates with a spacing of 1/16 in. A polarizing voltage of 3000 volts is used. Since the directivity pattern of a diaphragm of these dimensions is quite sharp in the high-frequency region, two or more units are used and directed so as to obtain the required coverage. The use of the bilateral design makes it possible to extend the response to lower frequencies.

A throttled air-flow loudspeaker consists of a valve mechanism actuated by a dynamic or magnetic driving system. The valve mechanism modulates the steady air stream so that the undulations in the air stream correspond to the variations in the electrical input. The throttled air stream is usually coupled to a horn to improve the efficiency of the system. The throttled air-flow loudspeaker has not been commercialized to a significant extent.

A commerical thermoelectronic loudspeaker consists of an audio-modulated confined corona discharge coupled to a horn. The volume of air is expanded by the gas. Therefore, the system is essentially a constant amplitude device. For this reason the useful response range is confined to the high-frequency portion of the audio-frequency range.

Future Developments

The theoretical and practical superiority of the dynamic loudspeaker, established and maintained over a period of three decades, would appear to preclude the probability of any possible replacement by another system. Many improvements have been made in the performance of the dynamic loundspeaker in the past three decades. These have resulted in smoother response-frequency characteristics, more uniform directional patterns, lower nonlinear distortion, and superior response to transients. Work will continue in these directions. Among possible developments will be a feedback system for controlling the sound output. The most promising design for the low-frequency range is the pressure-control system shown in Fig. 14. The response can be controlled over the low portion of the frequency range which presents the greatest problem on obtaining low nonlinear distortion. The most promising design for the high-frequency range appears to be the motion control system shown in Fig. 15.

Other possible applications involve thermoelectronic and dynaelectronic systems, all of which involve the ionization of air. The thermoelectronic system has been described under miscellaneous loudspeakers. In the dynaelectronic system the air is ionized, and the ionized volume is set in motion by the application of an electric field corresponding to the signal.

Disk Recording and Reproduction*

W. S. BACHMAN†, FELLOW, IRE, B. B. BAUER‡, FELLOW, IRE, AND
P. C. GOLDMARK‡, FELLOW, IRE

Summary—**In 1878, Thomas Alva Edison built the first working phonograph but it remained for Berliner to bring together the various ideas which charted its future course. Major electroacoustical advances responsible for vast improvement in disk recording and reproduction took place during and after World War I, and into the twenties, such as the concept of mechanical and acoustical impedance, "electrical recording," folded exponential horn, and electromechanical pickup.**

Further advances occurred in the thirties: utilization of Rochelle salt crystals in phonograph pickups, the use of negative feedback in recording, as well as significant contributions to the theory of groove-stylus relationships. The end of World War II marked the beginning of "high fidelity" as a household word including developments of improved magnetic pickups, advances in measurements and calibrations, utilization of barium titanate transducers and improved record materials, and culminating with the introduction of long-playing records.

The fifties saw an ever widening use of magnetic tape for mastering, development of hot-stylus and variable-pitch recording techniques, and continued trend toward lightweight pickup design. These improvements, combined with ideas on binaural and stereophonic recording that have been dormant since the twenties and thirties paved the way to the introduction of stereophonic disks in 1957.

In the hands of the artist and the composer the advances in disk recording are leading to new art forms as well as to more faithful reproduction of great classics.

Introduction

IN AN ARTICLE for the *North American Review* of June, 1878, Thomas Alva Edison forecast that the phonograph would be used in ten ways. It was a remarkable prediction. Disk recording systems have been used in all of the applications, and multimillion dollar industries have been built around at least two of them, the reproduction of music, and office dictation.

Recording of telephone conversations, the teaching of elocution and other subjects, and talking books for the blind, these were also foreseen by Edison, but he long persisted in regarding the phonograph as primarily an office dictating machine. We believe that he would be shocked to know that the phonograph is used today for plays and poetry, comedians and preachers, sportscar roars and train whistles, and advertising and sales messages. Edison certainly would be aghast at records to relax by, to reduce by, and for dispersing birds or capturing mosquitoes, yet all these have been produced.

Specialized applications (even in dictating machines) are secondary in cultural and economic importance to the use of disks for recording and reproducing music. Our consideration here, then, shall be mainly entertainment disk recording and reproduction, its history and growth from an idea which sprang almost simultaneously in the minds of several men, and developed, through decades of strife, into today's giant record industry, which amounts to more than half a billion dollars a year.

Historical Note

Alexander Graham Bell's invention of the telephone, in 1876, drew attention to the problems of the reproduction of speech. One of those attracted was Thomas Alva Edison, who was all the more interested in the study of sound because he was partially deaf. Sometime in the fall of 1877, Edison wrapped a sheet of tinfoil around a cylinder, set a needle in contact with it, turned a crank to rotate the cylinder, and into a mouthpiece attached to the needle he shouted the nursery rhyme that begins, "Mary had a little lamb." After making a few changes, he cranked the cylinder again, and from the horn of the instrument he heard a recognizable reproduction of his voice. Thus was born the first phonograph. The date of invention was later recollected by Edison as August 13, 1877, but there is some question as to how precise that date is. We know, however, that the patent application was filed December 24, 1877, and the patent was granted on February 19, 1878.[1]

After almost a decade of preoccupation with other interests, during which he produced the incandescent lamp, Edison returned to work on the phonograph.[2] His improved model of 1888 employed an electric motor powered by heavy-duty batteries. Its advantages were derived from a constant speed for recording and playback, together with the superior qualities of wax rather than tinfoil as a recording medium. In 1888, the pianist, Joseph Hofmann, age 12, visited the Edison Laboratories. He became the first recognized artist to make a phonograph record.

On May 4, 1887, Emile Berliner applied for a patent[3] on what he called a "Gramophone," to distinguish it from Edison's phonograph of ten years earlier and from Bell's and Tainter's Graphophone of one year earlier.[4] The first figure of the drawings in Berliner's patent shows a record wound on a cylindrical support but by

1888, when he introduced his first model, he had changed to a flat-disk record.[5] The groove in this record had a lateral side-to-side movement, as against the vertical "hill and dale" system which had been employed by others. This lateral recording process was reminiscent of Leon Scott's phonoantograph, which used a diaphragm and hog bristle to trace a record of sound vibrations on lamp-blacked paper some thirty years earlier.

Berliner also used lamp-black as the recording medium, and combined this method with an etching process which permitted transfer of the original engraving to copper or nickel.[6] Thus Berliner achieved a permanent master recording, and for the first time mass duplication of records was possible.[7] No longer did artists have to repeat each number endless times.

By 1895, Berliner had developed a system utilizing many ideas of his own and others: Scott's lateral groove, his own flat disk, and a coating of Bell's and Tainter's wax. The system stood up as the industry standard for half a century, thus Berliner deserves a mantle as the father of disk recording and reproduction.[8]

Edison was again active in phonograph work at the turn of the century. He had tackled the problem of the wax mold used for the original, too. As a nonconductor, this master could not be electroplated. By 1903, he had worked out an ingenious duplicating process under which the original record mold of wax was placed in a vacuum chamber, with a piece of gold leaf suspended on either side. High tension electricity was then discharged between the two gold-leaf electrodes, while the record mold revolved. Upon this gold film, which faithfully adhered to all the original record grooves, a heavier deposit of another metal was then electroplated. The resulting original mold was a solid, durable negative, from which almost any number of positive copies could be duplicated.

Another early contributor to phonograph progress was Eldridge Johnson, who in the 1890's ran a small machine shop in Camden, N. J. By 1901, Johnson had so improved the disk phonograph that it sounded as good as the wax cylinder machine and had much greater volume.[9]

The conflicts during the early years of the phonograph industry, involving charges, litigation, intrigue, and publicity, are too numerous and too complex to treat here. Finally in 1902, all the companies and individuals who had patentable interests got together. Their settlement resulted in three dominant companies, Columbia (the Bell-Tainter interests), Victor (Berliner-Johnson), and Edison.

Electroacoustic Advances

The early efforts of the pioneers, Edison, Berliner, Bell, and others, were based on the empirical approach. Between the beginning of the twentieth century and the end of World War I, there was little progress made in the phonograph art. The War witnessed many advances in acoustical theory; the acoustical horn analysis of Webster,[10] and the concept of mechanical and acoustical impedance by Kennelly[11] and others ushered in the era of scientific electroacoustics; the phonograph was to be its most important beneficiary. The concurrent development of the electronic amplifier provided a further impetus to the art of recording and reproduction.

The best known early effort in that direction was the design of a phonograph recording and reproduction system by Maxfield and Harrison.[12] Their recorder was a magnetic transducer employing a loaded rubber transmission line as a damping element. Records of much improved modulation and clarity were now possible. With the new method of "electrical recording," the sound to be recorded was picked up by means of a microphone, amplified, and applied to the coil of the recorder or "cutter."

The reproducer of Maxfield and Harrison (subsequently licensed to the Columbia Phonograph Company and the Victor Talking Machine Company) was embodied in the so-called "Orthophonic Victrola," introduced in 1925. Together with the "rubber-line recorder" and a folded exponential horn, the system reproduced a frequency range of 100–5000 cps constituting a significant advance over other phonographs then available. It was not long, however, before the Brunswick and Majestic Companies began to offer phonographs employing electromechanical pickups which began to replace the acoustical phonograph. An electromagnetic pickup of the type used in the early phonographs was described by Kellogg.[13] The early pickups bore upon the record with a stylus force of several ounces, and represented but a slight improvement over the Orthophonic Reproducer. Their virtue resided in the ready control of volume and tone possible through the use of electronic amplification. Improved electromagnetic transducers

for disk recording and reproduction were developed during the thirties by Hasbrouck,[14,15] and others.

Vertical vs Lateral Recording

The lateral recording system adopted by Berliner and espoused by Maxfield and Harrison in the Orthophonic system established the lateral mode of modulation as dominant in home phonographs. The advantage of the moving coil system made itself strongly felt in the design of recorders and reproducers for high-quality applications, such as motion pictures and radio broadcasting. The type of system employed in these devices is exemplified by the moving-coil pickup described by Frederick.[16] The construction is similar to that of a moving-coil microphone, except that a conical diaphragm is used at the apex of which is installed a jewel-stylus tip which may be adapted to record or reproduce a phonograph groove. Since the moving coil normally moves axially the choice of vertical modulation is obvious. The moving-coil pickup was capable of tracking record groove modulation at forces of the order of ½ oz.

The use of negative feedback including the electromechanical system again must be credited to Maxfield and Harrison.[17] This principle was applied to the vertical recorder of Vieth and Wiebush in the mid-thirties[18] introducing the era of truly high-quality recording and reproduction of sound. There is no doubt in the light of the present-day knowledge that the presumed superiority of vertical over lateral recording in the mid-thirties stemmed more from the moving-coil feedback cutter and the moving-coil pickup, than from any basic advantage of the vertical system. This was made evident by the brilliant work of Pierce and Hunt published in 1938.[19] It was well realized by earlier workers that a problem arose because recording is accomplished with a flat-faced tool while playback takes place with a spherical-tip stylus. Pierce and Hunt made an important contribution by recognizing that any form of groove modulation could be represented by a normal sinusoidal modulation of the individual groove walls combined in appropriate phase relationship. They named the motion resulting from the tracing of a sinusoidally modulated surface by a spherical-stylus tip a "poid" and analyzed its harmonic components. With lateral modulation, the odd harmonic components of the poid are retained in the horizontal mode, while the even harmonic components cause a vertical motion of the stylus, which is commonly referred to as "pinch effect." With vertical modulation, all the harmonics, odd and even, remain. Simultaneously, Hunt and Pierce developed a moving-conductor lateral pickup capable of tracking 78 rpm records with a force of 2 grams, and envisioned the possibility of playing back 19 minutes of music on a 12-in 33-rpm record with a 0.75-mil-radius stylus. Further advances in the theory of tracing distortion were published by Lewis and Hunt in 1941.[20]

Hunt, Pierce, and Lewis had assumed for simplicity that the record material is unyielding. In 1941 Kornei[21] used the Hertz equation for calculating the deformation between the cylindrical groove-wall modulation and spherical-stylus tip, thus arriving at the playback loss (or gain) due to the dynamic interaction between the two. This work was extended further by Miller,[22,23] using a similar approach but correcting some of the assumptions of the Kornei analysis. Miller's result established the existence of a translation loss function G which is dependent on wavelength, and a pickup response function H which is dependent on playback frequency, thus providing a good fundamental basis for analysis of the playback process.

Development of Phonograph Reproducers

The role that was to be played by lightweight phonograph pickups in diminishing record wear and improving the performance of phonograph systems was already recognized during the early thirties. The perpendicular force required to hold a pickup in proper tracking engagement with the groove is directly proportional to the mechanical impedance at the stylus tip. This impedance is determined by the tip compliance, its mass, and its damping resistance. Development of low mechanical impedance pickups was greatly assisted by the introduction of the Bimorph Rochelle salt transducer element by Sawyer.[24] By coupling the pickup stylus to the Bimorph element using various types of elastomers and levers, a number of "crystal" pickups capable of tracking at 1–2 oz. were placed on the market.[25–27] Most of these had sufficient output to drive the first audio stage of a radio

set, thus ushering in the era of the popularly priced radio-phonographs.

After World War II, the trend toward lower force pickups was resumed. The relative ease with which substantial amplification was obtainable made it unnecessary to design the pickups primarily with high output in mind, and low mechanical impedance became an important goal of the designers, especially for the so-called High Fidelity applications. An important step in that direction was a variable reluctance pickup[28] capable of tracking at but a few grams. The armature took the form of a light elongated ferromagnetic member with the stylus attached at the free end and the magnetic pole pieces placed close enough to the stylus to generate, in effect, an output proportional to the velocity of stylus motion. A moving magnet pickup for 2-gram operation was described in 1957.[29] Subsequently, this moving magnet principle was applied to stereophonic pickups.

As a result of wartime research, piezoelectric properties of barium titanate ceramics were discovered and used in pickups,[30] as well as other transducers. These elements have properties similar to Rochelle salt, but without the temperature and humidity sensitivity of the latter. Subsequently, lead zirconium titanate ceramic was introduced by Gray,[31] providing a sensitivity and dielectric constant almost equivalent to Rochelle salt.

With the emphasis on low force pickups, the measurement of mechanical impedance at the stylus tip became of interest to pickup designers. Stylus-tip mass could be ascertained by weighing and calculation, but compliance and damping required measurement. A meter for ascertaining the compliance and damping factor by resonating the stylus compliance with a known force-driven mass was described in 1947.[32]

The tone arm which carries the pickup cartridge became the subject of intensive study from the geometrical and dynamical point of view. Even prior to World War II, it had been realized that the vibration of the playback stylus in a pivoted arm did not follow precisely the original vibrations of a cutter stylus moving in a straight line along the ways of a recording lathe. The difference could be minimized however, by curving the arm or offsetting the pickup head and mounting it appropriately with respect to the center of the record.[33] A mathematical analysis of this effect was contributed by Baerwald.[34] Subsequently, the geometry applicable to a variety of practical conditions was derived.[35]

With the development of "High Fidelity" instrumentation, the importance of the dynamics of the arm carrying the pickup head across the record was better appreciated. In 1951, an arm was developed in which damping in the form of a viscous substance was provided between two spherical surfaces eliminating resonance at low frequency.[36] "Dynamic" damping by provision of a viscous substance between the arm and the counterweight was introduced in 1957.[29]

The Development of the Lp[37] Record

In June 1948, the development of the 33⅓ rpm Long-Playing Record System was announced.[38] The relative specifications of the "Lp" records and the then current 78.26 rpm records are shown in Table I.

TABLE I

RPM	78.26 rpm	33⅓ rpm
Groove width	6 mil	2.6 mil
Groove bottom radius	1.5 mil	0.2 mil
Groove include angle	90°	90°
Stylus radius	2.5–3.0 mil	0.8–1.1 mil
Grooves per inch of radius	100	260 ave
Maximum groove/diameter		
12-in record	11½ in	11½ in
10-in record	9½ in	9½ in
Minimum groove diameter	3.75 in	4.75 in
Maximum playing time	5 min	22½ min
Tracking force	2 oz. max	7 gram max

Coincident with this announcement, a player was made available which met the required new specifications and which could be connected to existing phonographs. The development of the Lp system involved the combination of ideas and processes previously offered, as well as some new ones. New pickup lightweight and low cost drive mechanisms minimizing wow and rumble had to be developed to make the system practical for home use, including dual-stylus pickups to play either the 78 or the Lp records.

New methods of recording and mastering were evolved together with a new recording characteristic. Two important improvements followed: the "hot-stylus" recording technique[39] and the variable-pitch system of recording,[40] to be discussed later, which ultimately extended the recording time to 30 minutes per side of a 12-in Lp record.

Gradually, the Lp record became adopted for serious music and shows, since it allowed the playing of whole movements of symphonies without interruption.

Shortly after introduction of the $33\frac{1}{3}$ rpm record, the RCA Victor Company announced a 45 rpm, 7-in record playing 4 minutes per side, using groove and stylus specifications similar to the Lp.[41] The 45 rpm records became widely adopted for popular music.

Standardization of Response Characteristics

During the early days of phonograph development there were no means for performing acoustical measurements and most of the development work was done by listening and experimentation. Numerous phonograph "tone chambers" and styli made of various metals, cacti, etc., were sold under the claim of "producing a mellow tone." Not until the work of Maxfield and Harrison[12] were attempts made to establish the transmission characteristic of a phonograph system. Groove modulation was measured by means of a calibrated microscope. A more convenient method for measuring groove modulation velocity by observing the width of a light pattern reflected from a test record was described by Buchmann and Meyer.[42] Later, this method was modified, taking cognizance of the distance of the record from the observer[43] and employing diffraction[44] and interference patterns[45] of light to enhance the accuracy of measurements.

However, the question of what recording characteristic actually was used remained a trade secret for many years. It was not until the recording companies realized the mutual advantages of standardization that various standardizing bodies established Standard Recording Characteristics.[46] The result of these standards was not to diminish the performer's or director's artistic freedom, but rather to insure that the listener would be able to hear what was originally intended. In a parallel effort, means for evaluating and controlling distortion stemming from groove-stylus relationships were studied by Roys[47] and others.[48]

Stereophonic Recording

The possibility of modulating a groove in orthogonal mode so as to produce two tracks for independent modulation was envisioned by early workers, as evidenced by acoustical phonograph patents filed in the twenties.[49,50] Another attempt at two-channel recording, using electrical methods of recording and reproduction took place in the thirties.[51] In the instruments described, it was envisioned that one program channel would be recorded as a vertical modulation, and the other as horizontal modulation.

In a brilliant contribution to stereophonic recording in the thirties, Blumlein[52] not only envisioned the modern $45-45°$ recording method (where one channel is identified with a 45° motion of the inside groove wall, and the other channel with the $-45°$ motion of the outside groove wall), but also laid down the foundations of improved methods of stereophonic sound pickup and broadcasting. A. C. Keller and I. S. Rafuse[53] suggested a number of configurations for cutters and pickups for this system.

Development work which led to the final commercial introduction of stereophonic records as they are known today appears to have been going on simultaneously in various laboratories. Vertical-lateral equipment was under development and it had reached the commercial stage in 1957. The first to announce a commercial $45-45°$ recording system were Davis and Frayne, in 1957,[54] and it was adopted by the Standards Committee of the Record Industries Association of America (RIAA) as being technically superior to the vertical-lateral record.

In the $45-45°$ system, the two channels of stereophonic information are in effect two perpendicularly modulated channels, and therefore they contain all the harmonic components of the poid. To diminish this effect, a 0.7-mil-radius stylus is used for playing stereophonic records. Stereophonic records are recorded with the RIAA characteristics. Significantly, the stereophonic record standards were adopted prior to the commercial introduction of the system.

Artistic and Musical Considerations

In the original acoustical recording system, the nature of the recording equipment placed severe limitations on the choice of repertoire, and soloists were more readily accommodated than large ensembles. Electrical recording removed many of the limitations of acoustical recording and permitted successful recording of large orches-

tral groups as well as soloists. The early electrical recordings used a single microphone, and balance between the various performers was obtained by their relative positions and spacings.[55]

Recording in the early electrical era in America was influenced greatly by radio broadcast techniques which introduced the mixing of multiple microphones and the use of highly absorbent studios for both broadcast and recording. In contrast, many of the orchestral recordings made in Europe during this period were done in large reverberant concert halls, and the reproduced sound quality was generally considered superior to nonreverberant sound. Now the use of large reverberant halls and studios, as well as the mixing of artificial reverberation, has become almost a universal practice.

The artistic and musical aspects of recording appear to have evolved as a result of the technical facilities available which were developed for recording. In the acoustical recording days, there was little opportunity to consider whether the object of a record was to recreate an original performance on the basis of the listener being, in effect, transported to the hall or the performance being presented in the listening room. The advent of high quality microphones and loudspeakers made it possible to realize more nearly these philosophical approaches. Spectacular demonstrations of stereophonic sound were made by reproducing a program originating in one concert hall and carried by wire lines to corresponding loudspeakers in another hall where the listeners were located. This very closely approached the objective of placing the performers in the listening room.

Experiments with two microphones mounted in an artificial head and transmitting the individual signals to corresponding earphones, closely simulated the placing of the listener in the concert hall. The technique used in most musical recording lies somewhere between these two cases, in that the microphones are placed closer to the source than listeners would wish to sit during the actual performance. Many successful monophonic recordings have been made, however, with a single microphone quite distant from the sound source. In general, this technique lends itself to halls which are large and have agreeable reverberation characteristics.

The use of multiple microphones in recording raises a point of artistic judgment. The balance between choirs and soloists can be manipulated far beyond the possible range in a live performance. In some ways this may make it possible to approach more nearly the composer's wishes, although it can be argued that it may seriously violate his intent. The manipulation of the balance makes the recording an art form in itself. This is most evident in popular recording, and the artistic justification for it is seen in the widespread use of electronic aids in the live performance.

Mastering

In the early acoustical and electrical recording era the masters were made directly at the time of the performance. Frequently a duplicate master was made for playback, the unplayed one being processed to produce a master-matrix. The original recording was cut on wax, which would be seriously degraded by playback. Soon after the introduction of electrical recording, lacquer-coated metal disks instead of wax were used. The lacquer disks were more satisfactory for playback and with the development of improved reproducing equipment, it became practical to make original recordings on lacquers and re-record from them to make the master for processing. This was an important consideration since a replacement master could be provided in the not infrequent case where the original was destroyed in processing.

After World War II, magnetic tape machines became available in this country. Magnetic tape is a nearly ideal medium for studio recording because of the ease of starting, stopping, and playback without damage to the master, and its relatively long playing time. It was quickly adopted as the universal medium for original recording.

While most record companies made multitrack recordings of most important repertoire, their commercial exploitation was limited to pre-recorded tapes and it was not until the debut of stereophonic disks that intensive development of studio techniques for stereophonic recording were begun. Currently, it is common to do original tape recording on three-track machines, from which the stereophonic master as well as the monophonic master are derived. In the former, it is usual to feed the center-channel information in equal proportion to the left and right channels. The combination of editing and re-recording makes possible the addition of reverberation, the alteration of frequency characteristics, as well as changes in sound balance and acoustic perspective in the preparation of the final master tape.

Master Cutting and Processing

Early acoustical and even electrical recordings were cut mostly on shaved cake wax. Later, flowed wax on glass disks supplanted the cake wax. Following the flowed wax were lacquer-coated metallic disks. The latter were much more satisfactory for playback and gave added flexibility in handling.

The recording stylus made of sapphire is shaped much as a lathe thread cutting tool. It was found that in order to get a quiet cut on lacquers it was necessary to apply "dubbing" facets to the recording stylus.[56] Since these facets are an appreciable fraction of the recorded wavelength at the inner diameters, they interfered with satis-

[55] See for example, H. F. Olson and F. Massa, "Applied Acoustics," Blakiston's Son and Co., Philadelphia, Pa., 1934.

[56] C. J. LeBel, "Properties of the dulled lacquer cutting stylus," *J. Acoust. Soc. Am.*, vol. 13, pp. 265–273; January, 1942.

factory cutting of the highest frequencies. This problem became acute in the case of the Lp record. By applying heat to the cutting stylus,[39] it was found to be possible to use extremely small facets on the cutting edge of the stylus, providing a quiet groove with good, high frequency performance.

Processing

To produce records in quantity, it is necessary to make metal parts from the original cut disk, which is done by electro-deposition. This required the application of graphite powder or gold sputtering to render the surfaces conductive. The graphite process gave way to a far superior one in which pan silvering was employed. In this method, silver is precipitated on the master record much in the way it is done on mirrors. This process has been superseded by spray silvering, which is chemically similar to pan silvering, but is much more readily controlled. It is common practice to deposit nickel on the silvered master a few thousandths of an inch thick, and then build it up to 30–40 thousandths thickness with copper by electroplating. The master matrix is then stripped from the original. It can be used to press records, but it is usually passivated and put back in the bath to develop a metal positive which is called a mother. After a play test to determine its quality, it is passivated, put back in the electrolytic bath, and stamper plates are grown. While other metals are frequently used, it is common to make mothers and stampers of solid nickel. The quality of the surface produced in this electrodeposition process is quite remarkable. For an SNR of 60 db, the magnitude of surface irregularities must be less than one millionth of an inch. This SNR is closely approached in commercial pressings.

Specialized Applications

Dictation Machines

The use of phonograph recording and reproduction for dictation is one of the uses first envisioned by Edison for the phonograph, and indeed, until recent days the wax cylinders which were shaven after use were a common sight in business offices. Today most office dictation (other than that done on magnetic material) is done by embossing, rather than a cutting process. A blunt stylus presses against a moving vinylite disk or cellulose acetate belt, and is modulated by the voice of the user speaking into a microphone. A pickup converts the displacements into electrical currents for playback. The quality of the embossed groove so produced falls short from that of a cut groove, but is sufficient for the purpose intended.

Automobile Phonograph

In 1955, an automobile phonograph system was developed.[57] A special 7-in record, turning at $16\frac{2}{3}$ rpm, and containing up to 45 minutes of music, or one hour of speech on each side was used. 500 and 600 grooves/in were employed and the stylus of $\frac{1}{3}$-mil radius exerted a force of approximately 2 grams on the disk. The pickup cartridge was mounted in a balanced and heavily damped arm, and pivoted to permit handling records without scratching. The phonograph was suspended on elastic mounts to permit operation in the moving vehicle.

Talking Books

One of the ways in which Edison, in 1878, forecasted that the phonograph would benefit mankind was phonographic books, which would speak to blind people without effort on their part. Today, two major organizations are making disk records available to the blind. The Library of Congress, Division for the Blind, handles literary material, but generally excludes textbooks. Recording for the Blind, Inc., a national, nonprofit organization, records textbooks for blind students, primarily college and postgraduate. The two organizations, which cooperate but do not duplicate services, sponsored the development in 1958 of an $8\frac{1}{3}$ rpm Talking Book system.[58] The Talking Book record plays two hours on each side. The record has approximately 650 grooves/in and uses a stylus of $\frac{1}{4}$-mil radius and approximately 2-gram force. The frequency response of this experimental Talking Book system extends to approximately 5000 cycles, suitable for speech.

Film Recording and Reproduction*

M. C. BATSEL†, FELLOW, IRE, AND G. L. DIMMICK‡

Summary—**In a historical summary of motion-picture sound recording and reproduction, some of the technical problems and solutions are discussed, starting with the conversion of silent motion-picture studios to sound studios. During the early years, both the sound-on-disk system (Warner Vitaphone) and the sound-on-film system (Fox Movietone) were used. The film recording method was in its early development stage and the sound quality was relatively poor, but it had many inherent advantages which ultimately led to its universal acceptance.**

The first commercially successful photographic sound recording system used a variable intensity modulator known as the Aeo-light. This was later replaced by the ERPI light valve which is still in use today. The optical system used with the light valve is shown, and certain photographic requirements for linear recording are discussed.

The variable area recording system is the outgrowth of the Duddell oscillograph. The oil damped galvanometer was replaced by a magnetic-type optical modulator, and a more effective optical system was developed. Several sound tracks produced by this unit are shown. Noise reduction methods required by both the variable area and variable density recording systems are described.

An unusual type of sibilant distortion caused considerable difficulty in the early variable area sound tracks. The nature of this distortion and the means of correcting it are given.

Although magnetic recording is one of the oldest methods known, it came into its own during World War II. Its potential importance to the motion-picture industry was quickly recognized. The editing, re-recording and reproducing systems play an important part in the over-all process. Many problems had to be covercome before satisfactory performance was assured.

Introduction

SOUND-PICTURE recording and reproduction techniques employ many branches of physics and technology. The early conversion of silent motion-picture studios to sound studios required the development of compatible processes and equipment, and the training of technicians, as well as the construction of new facilities. New stages were required to exclude outside noise and to eliminate undesired reverberation. Cameras were noisy, requiring the development of camera enclosures that were effective noise suppressors but permitted required mobility. Laboratory processing of films had to be established on a controlled basis. Special microphones and booms for moving them, to follow action, were necessary developments. Systems for operating cameras and recorders in synchronism were required.

Extensive facilities for re-recording from several sound films synchronously to make new composite negatives were required. Special editing equipment was necessary to make it possible to cut and splice sound and picture films, retaining synchronization.

Reproducing equipment had to be developed that would be suitable for attachment to motion-picture projectors. The problem of obtaining constant speed at the sound-reproduction point had to be solved. Loudspeaker systems had to be developed that could reproduce speech in auditoriums and theaters with the effect of intimate audience relationship with actors in close-up scenes. This was necessary because the acoustics of large auditoriums and especially existing motion-picture theaters produced disturbing reflections or echoes. Many were too reverberant and required modifications.

Because of the cost of establishing facilities and trained personnel and the uncertainty of studio management regarding the popular appeal of motion pictures with sound, the large producers were not enthusiastic about undertaking the expensive step. As a result of lagging interest in the motion pictures by the public, Warner Bros., in 1926, decided to test the popularity of sound pictures. To minimize the cost of the venture, this studio arranged to have Western Electric develop the necessary equipment to synchronize disk-recording machines with cameras that were housed in booths to suppress the camera noise. Arrangements were made with the Victor Talking Machine Company to do the recording in their facilities and with their personnel. The Victor Talking Machine Company was a Western Electric licensee, and their studios were equipped with Western Electric recording equipment.

Western Electric developed motor drives for theater projectors and disc turntables. These were mechanically connected to the same constant speed motor system. Essentially standard public address system amplifiers and loudspeakers were used. The first picture produced was "Don Juan." In October, 1927, "Jazz Singer" followed and was a success.

The public reaction was so enthusiastic that the large theater chains wanted equipment immediately to play the pictures. Western Electric agreed to lease equipment to them. As a result of the success of the first pictures, Warner Bros. installed disk-recording equipment in their studios. This system was called Vitaphone. It was destined to be supplanted by systems that recorded the sound as photographic images on the same film the picture was printed on. Having demonstrated the popularity of sound pictures and developed the equipment, the industry proceeded with great speed to convert studios for sound-picture production.

In 1928 many "sound stages" were built in Hollywood, new men, new tools and new technicians entered the

scene. In early 1929 there were 16 recording channels in Hollywood. By the end of the year there were 116.

During the early years of sound-motion picture, both the sound-on-disk system (Warner Vitaphone) and the sound-on-film-system (Fox Movietone) were used. Disk recording was much more highly developed, and was immediately capable of high quality reproduction in the theater. From the standpoint of production flexibility, ease of handling, and assured synchronization of sound and picture, the disk method left much to be desired. The film recording method was in its early development stage and the sound quality was relatively poor at the start, but it had many inherent advantages which ultimately led to its universal acceptance.

Variable Density Recording

The first commercially successful photographic sound recording system (Fox Movietone News) used a variable intensity method of modulating a beam of light to expose the film negative. The gas-filled lamp known as the Aeo-light had an oxide coated cathode, and its intensity could be modulated over a considerable range by varying the anode voltage, at audio frequencies, between 200 and 400 volts. The Aeo-light was mounted in a tube which entered the camera at the back. Directly against the film was a light restricting slit which passed a beam about a tenth inch long and 0.001 inch high, placed between the picture and the sprocket holes. The Aeo-light could produce a sufficiently high intensity to expose the sensitive negative films used for picture taking. The system worked quite well for news photography, where the sound and picture were taken simultaneously on the same camera. For studio photography, however, there was need for separate but synchronized picture and sound cameras to permit the flexibility of multiple picture cameras, and the separation of the sound and picture recording facilities. The separate sound camera could use higher definition, lower sensitivity film, and thus improve the quality of the sound.

To meet the need for a higher intensity, higher quality variable density sound recording system, Electrical Research Products, Inc. (ERPI), a subsidiary of Western Electric, introduced in 1927 a complete recording equipment utilizing a light valve (Fig. 1) as the sound modulator. An optical system (Fig. 2) permitted the illumination of the light valve ribbons by the image of a high-intensity incandescent lamp. The space between the ribbons gave the effect of a variable width slit focused upon the film by means of a high resolution lens. Modulation of the valve occurred when current passed up through one ribbon and down through the other, and vice versa.

After sound had thus been recorded upon a film negative and this had been developed, it could be recovered by scanning the track with a fine light beam and permitting the transmitted light to fall upon a photocell. This process did not necessarily result in high-quality

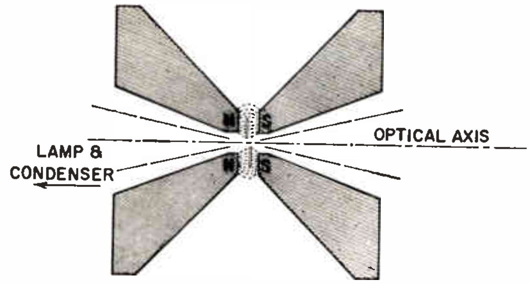

Fig. 1—Light valve ribbon and pole piece arrangement.

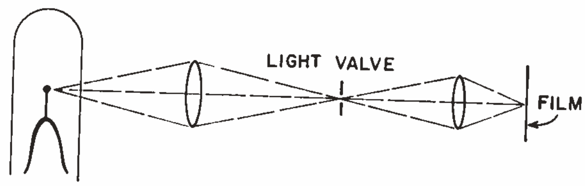

Fig. 2—Optical system for light valve recording.

sound recording because the transmission of the negative did not bear a linear relation to the exposure. Instead, T_n varies as $(1/E_n)^{\lambda n}$ where E_n is the negative exposure, T_n is the negative transmission and λn is an exponent referred to as the negative "gamma" or development factor. However, there is a tendency for the nonlinearity or distortion in the negative to be reduced in contact printing. It can be shown that the transmission of the print T_p varies as $E_n^{\lambda_n \lambda_p}$ where λp is the "gamma" of the prints. If the product $\lambda n \lambda p$ can be made to equal unity, the print transmission will bear a linear relation to negative exposure, and distortion will be eliminated. In normal practice the negative is developed to a gamma of about 0.4 while the print is developed to a gamma of about 2.5, thus satisfying the above conditions for low distortion.

Variable-Area Recording

In 1928 RCA Photophone, Inc., was formed to exploit the sound-on-film developments that had taken place at the General Electric Company and the Westinghouse Company. The variable-area system developed at GE was chosen as the basis for a product design. Variable-area recording systems may be considered to be an outgrowth of the Duddell oscillograph in which a tiny galvanometer swings a spot of light back and forth across a moving film and traces a picture of the wave shapes of the electric currents sent through the galvanometer. Fig. 3 shows the essential optical arrangement of the oscillograph. For sound recording the narrow wavy line was not satisfactory, and a modification of the optical system was made to produce a track like that shown in Fig. 4. When in reproduction a track of this type is scanned by a fine uniformly illuminated beam of light, the transmission to the photocell bears a linear relationship to the modulating current in the galvanometer.

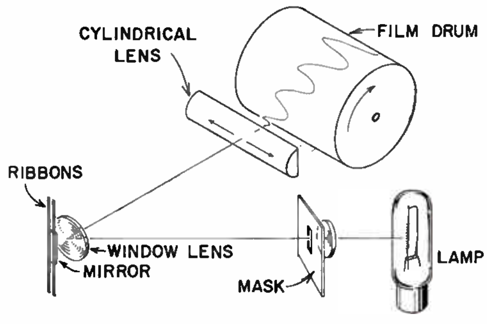

Fig. 3—Optical system of Duddell oscillograph.

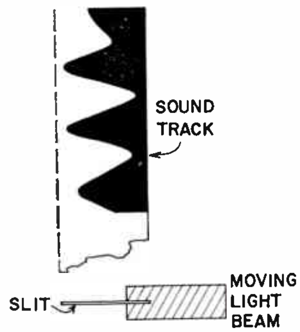

Fig. 4—Variable-area sound track.

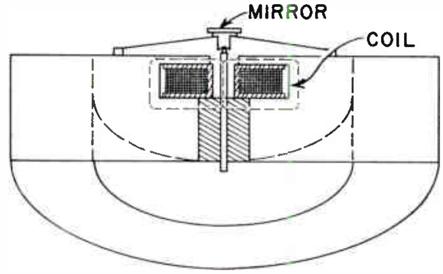

Fig. 5—Magnetic recording galvanometer.

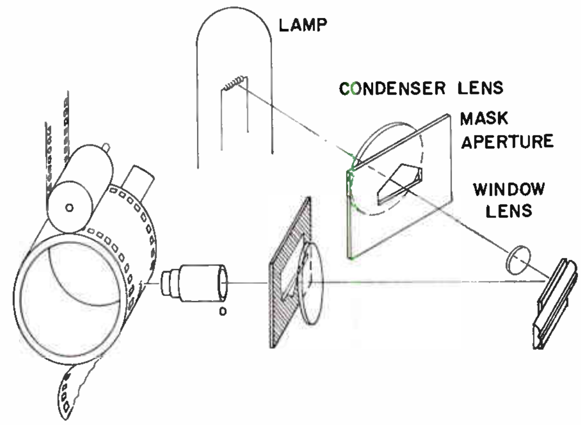

Fig. 6—Optical system for variable-area recording.

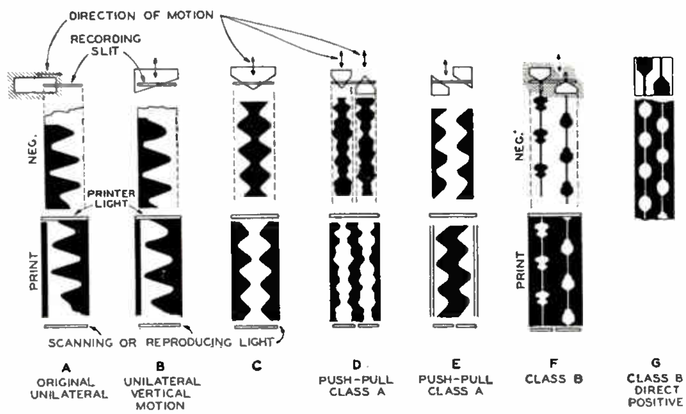

Fig. 7—Types of variable-area sound tracks.

The first generation of variable-area recorders used an oil-damped Duddell oscillograph galvanometer and an optical system to produce a track like Fig. 4. It soon became apparent, however, that the very small 0.017″ ×0.060″ oscillograph mirror was seriously limiting both the brightness and contrast of the optical image used to record the sound track. The oil damping was also very sensitive to temperature, and this caused difficulty when recording in hot or cold climates. Intensive development over the next several years resulted in a new recording galvanometer of the magnetic type (Fig. 5) with a modulating mirror having about twelve times the area of the mirror on previous galvanometers. To take full advantage of this new modulator, a new optical system (Fig. 6) was developed to provide a high-quality recording image with sufficient intensity to record on slow, high-resolution film. Further investigation showed that even higher resolution of the recorded sound track could be obtained by the use of an ultraviolet filter in the light path of the optical system. Since the film emulsion was sensitive to ultraviolet light, but heavily absorbed it, the end result of the UV filter was to concentrate the image on the surface of the emulsion and to prevent scattering of light and reflection from the film base.

An important advantage of the recording optical system shown in Fig. 6 was that the system was readily adaptable to making various types of track. The light spot moved transversely to the slit instead of parallel to it. By making apertures of different shapes, and focusing these upon the slit, many types of sound track were made on the same recording system. These are shown in Fig. 7.

Noise Reduction

The signal-to-noise ratio of a normal variable-density or variable-area sound track is only about 35 db, and the noise increases with film usage. It was recognized from the start that a much higher SNR is needed to accommodate the dynamic range of sound called for in the theater. A great deal of effort has gone into the solution of this problem. In the case of variable density recording, the principal cause of noise is the "graininess" of the developed film. This causes random variations in the transmitted light, which gives rise to a soft hiss in the reproduction. For a typical film and developing condition, the relation between noise level and film density is shown in Fig. 8. Density is defined as the logarithm of the reciprocal of the transmission. It will be noticed that on the straight portion of the curve, 0.3 change in density (2 to 1 change in transmission) results in a 6 db change in noise.

In the case of the variable area sound track, the dark portion transmits a negligible amount of light and contributes in a minor way to the noise. The clear area of the track is not completely transparent, but contains some grains of silver, imbedded particles of dirt and scratches. These are the sources of the noise, which is of a distinctly different character from the noise in a variable density track. The dirt and abrasions give rise to numerous "ticks" and "pops," the number of which vary directly with the width of the clear area. The measured rms value of the noise changes 3 db for each 2 to 1 change in clear area.

The light transmission through an unmodulated sound track is analogous to the RF carrier in an unmodulated radio transmission. This is normally 50 per cent of the transmission required for the sound peaks. It is obvious, however, that if the recorded amplitude is only 10 per cent of the peak value, the average value of the carrier need only be 5 per cent. The noise resulting from a 5 per cent carrier is much less than that resulting from a 50 per cent carrier. The noise reduction system, which has been in constant use over the past 32 years, depends upon an automatic circuit and mechanism for supplying just enough carrier to support the amplitude of modulation being recorded. When there is no modulation, the track transmission is reduced to a minimum value of approximately 5 per cent of its peak. The effectiveness of this system depends upon the fact that ground noise is most objectionable when the modulation is low. An improvement of 10 or 12 db in SNR is obtained by this method.

Two variable area sound tracks with ground noise reduction are shown in Fig. 9. One of these [Fig. 9(B)] was made with an optical system which employed a bilateral shutter to restrict the clear area of the track is required. The other track [Fig. 9(A)] was made with the optical system shown in Fig. 6. A special "bias" winding on the recording galvanometer permits the clear area to be reduced as the modulation decreases. Current for activating either the shutter or the bias winding is obtained by applying the audio-frequency voltages to a rectifier, and then filtering the rectified current, so that at no time does it change rapidly enough to contribute audible noise in the reproduced sound. The design of the filtering system involves a compromise between clipping the tops of the waves (in the case of a quick increase in sound amplitude) and moving the shutter or bias current fast enough so that the motion itself becomes audible. In variable density systems, noise reduction is accomplished by automatically darkening the sound track print when the modulation is low. The light valve shown in Fig. 2 accomplishes this by bringing the ribbons of the valves closer together by means of a biasing current obtained as described above.

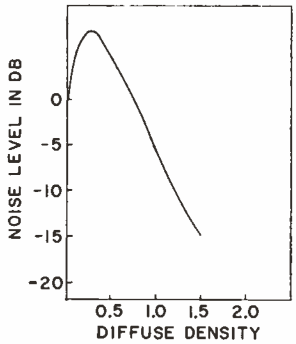

Fig. 8—Relation between density and noise.

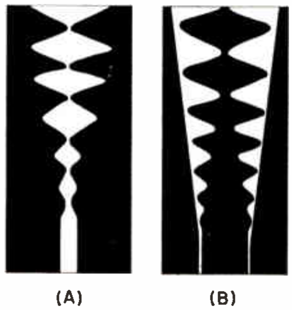

Fig. 9—Variable-area sound tracks with noise reduction.

Optimal Processing of the Variable Area Negative and Print

From the beginning it was recognized that the processing of a variable-density sound record must be carefully controlled in order to maintain a uniform sound level and to minimize harmonic distortion. Many of the early investigators believed, however, that the variable area method avoided this problem because the modulated track was a true graphical picture of the sound waves. In the low- and mid-frequency range this argument was valid, but at high frequencies, where image spreading is of a magnitude comparable with the recorded wavelength, careful control of the processing is needed to optimize the frequency response and to eliminate cross modulation. Fig. 10 shows how the shape of a recorded HF sine wave is affected by exposure of the negative. When this negative is printed, two opposite effects are present. The negative wave-shape distortion is reversed in the printing operation, and more distortion is introduced by image spreading in the print emulsion. Since these two effects are of opposite sign, they may be made to cancel at certain negative and print densities.

The harmonics produced by wave-shape distortion of the higher frequencies have practically no effect on the quality of the reproduced sound. The resultant change in the average transmission does however give rise to a very serious impairment of sound due to cross modulation. When a HF wave is modulated at a LF rate, which happens during the sibilant sounds in speech, cross modulation results in the introduction of a LF signal not present in the original speech. When variable area sound is not correctly processed, the "S" sounds are accompanied by an explosive LF blast which is intolerable. Soon after the nature and cause of this distortion were understood, a method was quickly devised for eliminating it through optimal processing of the negative and print.

An electronic test set was built to provide a 9000 c sine wave, amplitude modulated at 400 c rate. At the end of a normal sound recording "take," a few seconds of this special test signal is recorded. After the negative is processed, the test film is cut off and put through the printing operation several times at different print densities. The test print is then played through a 400 c filter and the 400 c amplitude is plotted against print density. The correct print density is that which gives a minimum of 400 c output. This is a very sensitive and a very practical test method which has been used at many movie studios and sound-processing laboratories for more than twenty years.

Magnetic Recording

Although magnetic recording was one of the oldest methods known, it was not until World War II that this form of recording came into its own. During this period there was developed in Germany a fine grain, low-noise, magnetic oxide, and a process for uniformly coating it on a thin flexible base ¼ inch in width. Use of this new tape in properly designed recorders and reproducers resulted in sound quality which was higher than had previously been obtained from either the film or the disk method. Immediately after the war some of the German recorders were demonstrated in this country, and the potential impact of magnetic recording on the motion-picture industry was quickly recognized. The theory of magnetic recording is covered in a separate article[1] and will not be covered here.

Early in 1948, oxide coated 35 mm film became available for use in motion-picture sound recording. It was then possible to convert photographic sound recorders to combination units capable of recording either magnetic or photographic sound. Many recorders were converted as quickly as possible and were tried in motion-picture sound studios for original "takes." Fig. 11 shows the arrangement of the "tight loop" film path, the optical recording barrel and the magnetic heads, in an early recorder built by RCA. The tests of magnetic recording in the studios were immediately successful, not only because of its high-quality and large dynamic range, but also because magnetic film provided a more flexible and a more economical means of recording. Since re-recording of all original "takes" to a composite photographic negative was already the accepted practice in the industry, little inconvenience was caused by the change.

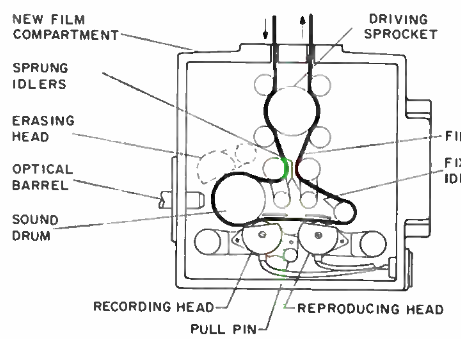

Fig. 11—RCA optical-magnetic recorder.

Editing and Re-Recording

Motion pictures are produced by photographing and recording short scenes or takes. Usually more than one take is made of each scene. These takes are viewed by the production staff daily and a final selection of preferred takes is made. There is then the task of assembling these takes to produce the final picture.

The sound is recorded on a separate film from the picture. At the start of each take synchronizing marks are made on both picture and sound films. These are usually made by means of "slap sticks." After the camera and recorder are up to synchronous speed, each being driven by a sync motor on a common power supply, the sticks are photographed while being struck together. The sound is recorded simultaneously. The take number and picture identification are also displayed in the picture when the "sticks" are photographed.

The editor and film cutters receive these rolls of sound track and picture after they are developed and printed. Some convenient means of viewing the picture and listening to the sound is necessary. For this purpose a small projector and sound reproducer was developed. This became known as a Movieola. It is standard throughout the industry. It is operated by the film cutter. It can be run backward and forward at variable speed as well as the standard 24 frames/second speed, and is convenient to thread.

The sound recording that is made simultaneously with the picture is usually dialogue only. Sound effects and music are recorded separately; in fact libraries of sound-effect recordings were established for frequently needed sounds. Facilities were necessary for re-recording the original sound (dialogue) and simultaneously adding sound effects and music as required for the finished production. Music is played on a scoring stage. This is usually a stage of adequate size to provide, when properly treated with absorbing and reflecting materials, acoustical characteristics to satisfy the needs for various types of music.

A re-recording installation consists of a number of sound reproducers or play-back machines, mixers, amplifiers, monitors and a recording machine. Electrical filters are available for modifying the response-frequency characteristic of the audio-frequency band. The use of a high-pass filter in transmission circuits for dialogue recorded on a stage, for example, may be used to eliminate rumble caused by traffic, etc., thus eliminating the need for a stage that is completely vibration-free. Reverberation chambers are employed to enhance certain sound effects. In these cases the amplified output of a reproducer is supplied to a loudspeaker in a reverberant chamber. A microphone is installed in the chamber and its amplified output is available at the mixer controls.

During each re-recording operation one reel of dialogue film is run, along with all sound effect and music films that have been supplied by the cutting room. Sound effects and music are spliced in blank film to make the same total footage as the dialogue reel, and to insure that each passage is reproduced at the proper time. The re-recording mixer controls are manipulated so as to produce the desired sound in the monitor. This usually requires running the films a number of times while suitable adjustments of gain and audio characteristics are determined. When these tests show the results to be satisfactory, the films are rerun and the combined output is supplied to a recording machine where the negative for the release print is made. The several reproducing machines and the recorder are driven by Selsyn motors which lock all rotors in a fixed angular position at stand still, and maintain this relationship while accelerating and running. This permits threading all films to start marks for proper synchronization.

Film stock used for sound recording is similar in characteristics to stock used for positive prints of pictures. It is fine grained in comparison to picture negative film. It is designed to reduce light scattering in the emulsion, thus improving the resolution. The equipment used in the re-recording installation is the result of a great amount of development work to produce the needed characteristics and to optimize the operating procedures. The design of gain controls and volume indicators are examples of items that are very important. Filter designs, methods of insertion, etc., are also important aspects of mixer and control facilities.

Reproducing Systems

The most difficult problem to solve in reproducing systems was that of uniform motion of the film at the sound take-off point. The film is a flexible material subject to warpage and shrinkage. It is driven by sprockets that engage perforations whose spacing may vary with shrinkage. When film is drawn past the take-off point by a sprocket, there is usually a modulation of the sound at a frequency corresponding to the rate of sprocket hole engagements. The shaft on which the sprocket is mounted must be driven through a mechanical filter to eliminate speed variations introduced by gear teeth involved in the driving system. The first systems employed sprockets at the film take-off point. Musical reproduction was not smooth, however, and development of mechanisms to improve film drives continued. The solution was to wrap the film around a smooth drum attached to a shaft having a flywheel on it. The flywheel-drum assembly was driven by the film which was held in contact with the drum by a pressure roller or by tension. When a pressure roller was used in connection with very low friction bearings, the stiffness of the film in the conventional film-path provided adequate elasticity to absorb frequency variations introduced by the driving sprockets. The flywheel assembly was damped by having a flywheel coupled to the assembly by means of an oil film. This damper prevented LF oscillation of the system.

In systems employing tension to obtain traction of film on the drum, spring-pressed idlers were employed. The springs provided elasticity to absorb variations in speed. The flywheel was solidly secured to the drum shaft. Damping of system oscillation was obtained by dash pots attached to the idler arms or other means of providing viscous friction.

Photoelectric cells of the caesium variety were employed to convert the varying light produced by the shuttering effect on the scanning light beam. Incandescent lamps were employed to produce the light. The development of caesium photocells, with high sensitivity in the red, permitted the lamps to be burned at low temperature, thus resulting in long life. Before the caesium photocell was available, potassium cells were used. Lamp life was a serious problem because the cells were only sensitive in the blue region.

Acoustical Problems in Recording

To simplify the problem of recording dialogue as the action is photographed, sound effects, etc., are generally excluded, so that the most effective microphone placement for natural quality and perspective can be obtained.

Sets usually are assemblies of flat surfaces of convenient dimensions for ease of assembly. Many of these are hard surfaced and reflect sound. Reflections can cause distortion or echoes. Through the use of microphone booms to provide flexibility and rapid movement of the microphone, and through the use of microphones having suitable directional properties, the operator who is responsible for the recorded sound can obtain an appropriate perspective. When it is difficult or impossible to do so, the sound may be recorded after the picture is made by having the actors watch the picture and speak the lines so their lip movements and sounds are synchronized.

The development of microphones having a cardiod-shaped directional pattern was a valuable contribution to the solution of the problems encountered in dialogue recording. The insensitivity to sounds to the rear of the microphone served to reduce the pick-up of "set" noise on the stage due to manipulation of equipment during the action. The uniform sensitivity of the microphone throughout a wide front angle made the placement of the speakers less critical.

The sound level of speech in theaters is reproduced considerably higher than the original sound because of the audience noise and other noise present in theaters. This change in sound level results in an increase in LF loudness to the listener. Also, reverberation in theaters reinforces the vowel sounds in comparison to the sibilants. Compressors that act with sufficient rapidity to suppress vowel sounds, and to increase gain during sibilants, have been effective in producing recordings that are easy to understand when heard in theaters. Before compressors were used, recordings that were excellent in small rooms were frequently very difficult to understand when heard in motion-picture theaters.

It is necessary to change the frequency characteristics of the recording system when the original sound is to be amplified as heard by the audience. Loud sound is satisfactory when reproduced through a linear system. Speech spoken softly, when amplified, is not natural. The low frequencies should be reduced as well as the higher-frequency sibilants. Some actors or actresses, when speaking softly, emit sibilant or hissing sounds that have a larger amplitude than the vowels. The required frequency characteristics are effected automatically through the use of a proper arrangement of filters and a fast-acting compressor amplifier.

Conclusion

The trend today is to employ magnetic recording for original takes. Magnetic materials are applied to perforated film, thus requiring a minimum modification of systems. Essentially the change is to replace the optical systems and modulator with the magnetic recording head, or in the reproducer, to replace the lamp, optical system and photocell with a magnetic reproducing head.

The magnetic recording is used to produce a photographic negative by re-recording, to make prints for general release to theaters. For release prints to theaters having stereophonic reproducing systems, the prints have magnetic sound recorded on strips of magnetic material that have been applied to the film, and which are capable of withstanding the picture developing process.

Current Problems in Magnetic Recording*

MARVIN CAMRAS†, FELLOW, IRE

Summary—**The past decade has seen great advances in techniques and in applications of magnetic recording until, at present, many of the empirical methods have been forced to their limit. Important future developments depend on a better understanding of fundamental processes which, as yet, have hardly been explored. This paper discusses some of the explanations and theories that are of current interest with regards to the playback process, the recording process, the record medium, ac bias, and noise. Limitations of the theories and avenues for further exploration are suggested.**

ALTHOUGH the principles of magnetic recording are easy to explain qualitatively, there is great difficulty in constructing a quantitative picture. Yet a quantitative or at least a semiquantitative understanding is necessary in order to guide one into fruitful areas for further improvement. There has been considerable work in this field, but much remains to be done Difficulties arise from:

1) The complexity of magnetic field distribution in and near tapes and heads.
2) The nonlinear nonreversible character of magnetic record materials.
3) The action of high-frequency bias combined with the recording signal.
4) Interaction of the above.

As a note of caution, it should be pointed out that many analyses are derived for a specific configuration of head and tape, and may not apply to other configurations. Simplifying assumptions are often made at the outset, which are forgotten by the time one has emerged from several pages of mathematical ritual; and the results thereby acquire an unjustified status.

* Received by the IRE, December 11, 1961.
† Armour Research Foundation of Illinois Institute of Technology, Chicago, Ill.

For simplicity, the examples in this paper deal with the most usual case of powder coated tapes and coil type confronting-pole heads as in Fig. 1. Transverse and vertical recording, flux sensitive heads, solid metal tapes, etc., may be handled in a similar manner.

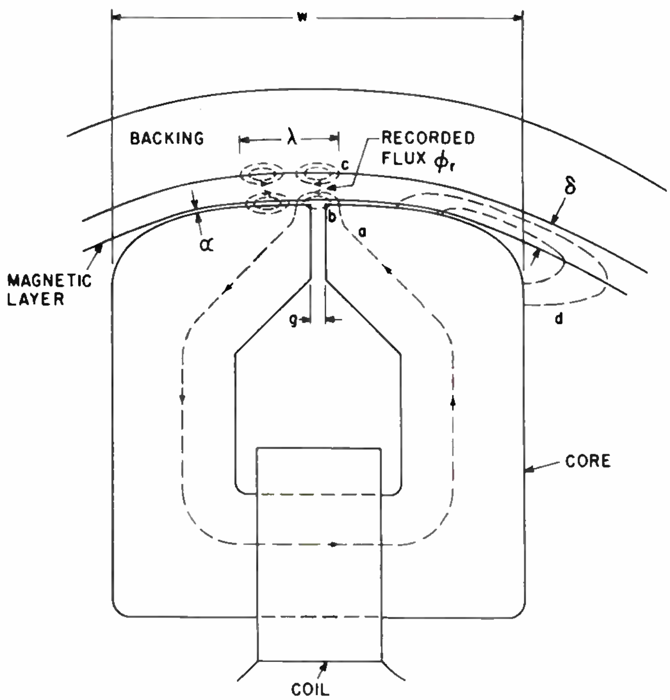

Fig. 1—Head-tape configuration.

The Playback Process

The fundamental concept of the playback process is very easy to understand. Our record is a multipolar permanent magnet. We move this past a transducer head which gives us an electrical output corresponding to the magnetic field of the record. The most common form of transducer has a coil with N turns of wire arranged so that it links *part* of the record flux ϕ_r. Let m be the fractional part of the recorded flux that threads the coil. The induced voltage is then

$$E = mN \frac{d\phi_r}{dt}.$$

The real difficulty comes in trying to predict m; and this is what papers in the field are all about. It turns out that m varies with frequency, wavelength, gap size, geometry of polepieces in the head, permeability of the head, permeability of the record, thickness of the record, direction of magnetization, space between head and record, and on many other factors.

Typical geometry for a popular configuration of tape and head is shown in Fig. 1. Even prior to an exact analysis, one notes that of the total retained flux, only the part a links the coil, while b and c take alternative paths. When the recorded wavelength λ is decreased in size so that it approaches the gap dimension g, there is a cancellation effect that causes the output to go through zero. On the other hand, if the recorded wavelength becomes longer than the gross dimension of the head w, an appreciable portion of the coil flux must complete its path through air as at d and much of it is lost altogether, so that the head becomes very inefficient. One expects also that the part of the tape layer in direct contact with the head is more effective than the outermost layer, and that spacing the record away from the gap is detrimental to high-frequency response.

The playback process has been treated mathematically by making a few simplifying assumptions. Usually these are:

1) That the remanent flux is low enough so that only linear changes take place in the pickup head.
2) That the remanent flux is unaffected by presence of the playback head; or that it is affected a constant amount which does not depend on the variables being studied.

In addition, it is sometimes assumed:

3) That the recorded layer has negligible thickness; or that layers of different spacings from the head act independently of other layers.
4) That the magnetic permeability of the head core structure is infinite, while that of the record member is unity.
5) That sine wave analysis is adequate for describing complex wave recordings.

A powerful tool in theoretical analysis is the reciprocity principle, which states that the sensitivity function of a head on playback is proportional to the recording field function of the same head with unity current through its coil. The relation has been used by Wallace,[1] Westmijze,[2] Gilbert,[3] Fan,[4] and others, and in its most general form may be expressed by the relation

$$E = kvN \frac{d}{dt} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \overline{M} \cdot \overline{H} \, dx \, dy \, dz$$

where

E is the playback voltage,
$\overline{M}$ is the vector magnetization at any point,
$\overline{H}$ is the vector field of the head at any point for unit current in its coil.
The dot product represents the product of the components of each vector in a given direction.
N = number of turns on the pickup coil,
v = velocity of the tape,
k = constant of proportionality.

[4] G. J. Y. Fan, "A study of the playback process of a magnetic ring head," *IBM J.*, vol. 5, pp. 321–325; October, 1961.

The integration is taken throughout all space symbolically, but the only region of interest is within the magnetized tape layer. The case for a wide tape record is simplified by treating it as a two-dimensional problem; or even further simplified to a one-dimensional problem by assuming negligible thickness of the tape layer.

One may consider tape effects separately from head effects. The tape magnetization is quite complex, as will be appreciated from the next section. The head effects are a geometrical problem in field mapping.

One of the most interesting of head phenomena is the gap effect, since the finite gap size is often the most important limitation on recorded density. This effect was previously analyzed for scanning apertures in photographic sound on film,[5] and a similar function was also found for magnetic recording. In its most elementary form the relation is

$$m' = \frac{\sin \frac{\lambda}{g}}{\lambda/g}.$$

Westmijze[2] derived a more exact relationship for gap loss in the head of Fig. 1. His result is rather complex and is best expressed graphically, as in Fig. 2, where it is compared with the simpler formula. According to Westmijze's formula the output drops to zero when the gap length g is about 0.89 times the recorded wavelength, making the effective gap length about 1.12 times its physical length. It is also interesting that this result is independent of spacing between the tape and head. In practice, the factor of 1.12 is unimportant since the mechanical tolerances of small gaps may give variations greater than this.

As indicated by the maxima near 1.5 λ, 2.5 λ, etc., a head will give output at wavelengths shorter than the scanning gap. Use has been made of this principle in working out a "long-gap" method for measuring surface induction of tapes. From theoretical considerations[2] the response in this case is as shown in Fig. 3, where the output rises at a six db/octave rate for frequencies below the first null. At higher frequencies the line connecting the peaks rises at a two db/octave rate. Unfortunately it turns out that for best results the straightness and parallelism of the gap-defining edges of such a long-gap head must be as exact as for a short-gap head of similar short wave response; so that in most practical applications one might as well make the gap as small as possible and avoid the dips.

In playback of very short wavelengths another important factor is the loss due to even the slightest separation between the record and the head gap.

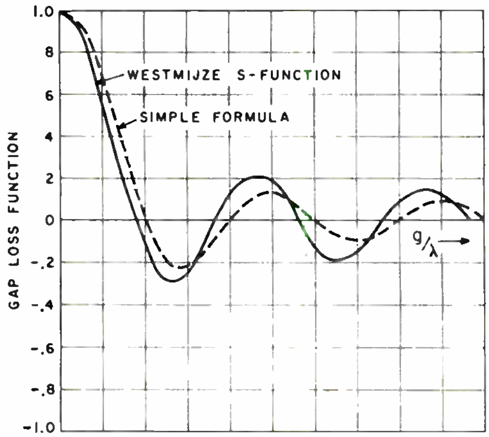

Fig. 2—Loss in output at short wavelengths due to finite gap size.[2]

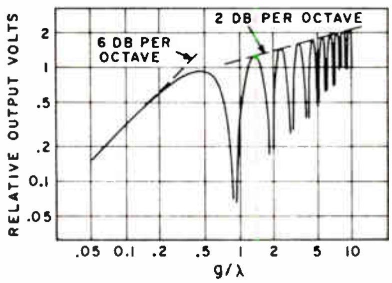

Fig. 3—Output of a long gap head.[2]

Wallace[1] derived a simple relation for this effect:

$$\text{spacing loss, db} = 54.6 \frac{\text{separation}}{\text{recorded wavelength}}.$$

This means that if a 15-kc response is desired at a record speed of 1 7/8 in per second (λ = 0.000126 in), a spacing of 0.00005 in gives a 22-db loss.

Experimental work in recent years has given results that are explainable by the presence of an 0.00006 in spacing.[6] There are several theories as to how this comes about. One explanation is that a surface layer of low permeability forms on heads made of permalloy and similar stress-sensitive core materials. Another is that an air film forms between the head and tape, especially at high speeds. However, such a separation has been observed even in a vacuum; so it is possible that the tape bounces enough to assume a net separation from the head.[7] Usually such an elaborate explanation is not required; mechanical imperfection in both the head and the tape are sufficient to prevent perfect contact.

Electrical engineers are familiar with an analogous situation where it is a rule-of-thumb that a butt-joint in a magnetic circuit acts as if it were at least 0.001 in long, no matter how carefully made. The usual explana-

tions are surface effects, stresses, etc. But the machining and grinding accuracies on transformer core sections are also of this order, and mask the more subtle effects. When the cores are really made accurately, as in head manufacture, gaps of less than 0.001 in are obtained.

If the magnetic record has appreciable thickness, then the very short wavelengths are not coupled efficiently to the head gap and there is, in effect, a "spacing loss" within the record. This has been termed the *thickness loss*[1]. When the above described losses are taken into account, one obtains for the head of Fig. 1:[2]

$$\phi = \phi_r \left[\frac{1 - e^{-2\pi\delta/\lambda}}{2\pi\delta/\lambda} \right] \left[e^{-2\pi\alpha/\lambda} \right] \left[S\left(\frac{\pi g}{\lambda}\right) \right] \cos 2\pi \frac{v}{\lambda} t,$$

where

ϕ is the flux which threads the coil for a sinusoidal signal,
ϕ_r is the maximum remanent flux (assumed constant for all wavelengths),
S is the gap loss function of Fig. 2,
α and δ are the spacing and tape thickness, as in Fig. 1,
v is the tape velocity,
t is time.

The first bracketed term accounts for the thickness loss. The second term is the spacing loss, and third term is the gap loss.

The effects on the response curve of different factors has been plotted in Fig. 4. An ideal record should have a rising response as in curve 1, diminished by appropriate factors from curves 2, 3, and 4; the result being a curve that resembles Fig. 3 to the left of the first null. But a perfect record is not obtained in practice because of the recording process, erasing effects, self demagnetization, core losses, etc. Hence an actual over-all response is always below that of Fig. 3, especially at high frequencies.

Certain applications, such as memories for computers, depend on the recording and playback of step functions, or of pulses. A very interesting analysis by Hoagland[8] showed that when a step function is played back the output waveform gives a picture of the field function of the head. Eldridge[9] used this relation to investigate the field of a head, especially the effect of spacing, tape thickness, and field strength on the sharpness and location of pulses. He concluded that the horizontal component of magnetization was by far the most important, the vertical components having little effect. It appears that pulses are a useful tool for investigating

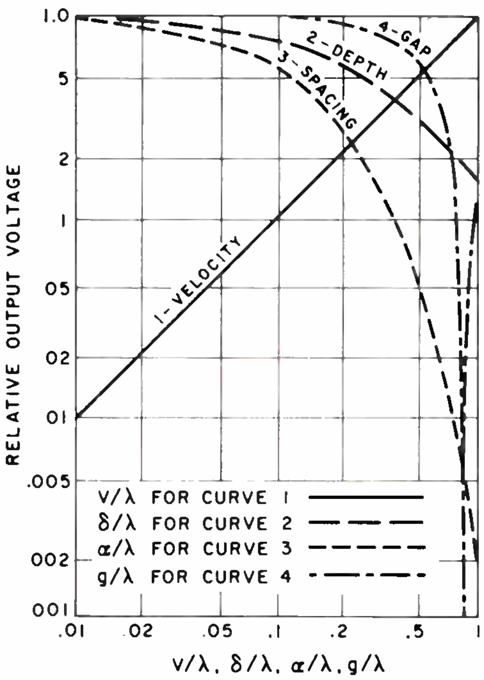

Fig. 4—Effect of tape velocity, thickness, spacing, and gap size on output.

the recording process even where one's interests are in sine wave recording.

On the other hand Kostyshyn[10] used the equations for sinusoidal recordings, but applied Fourier analysis to handle pulse recording. His method was adapted to machine computation, and he calculated the pulse width, recording demagnetization, and output EMF for changes in gap size, tape thickness, bit density, and head-to-tape spacing.

To summarize: the tools for analyzing the playback process are well developed, and the problem is mainly to apply them to realistic situations. This cannot be done if, for example, the magnetization within the record is not accurately known.

The Recording Process

To record on a tape, one applies to it a magnetic field strong enough to leave it permanently magnetized. For maximum information density the recorded regions should be as small as possible, and it has been found that the arrangement of Fig. 1 is excellent for this purpose. The degree of magnetization should be proportional to the input signal if distortion is to be avoided, and this is accomplished by a biasing arrangement. Direct current biasing is well understood,[2] but has disadvantages of noise and distortion, so that ac bias is almost universal in high-quality recorders. For the special cases of step or pulse recording, linearity is not required, and bias is omitted.

Unlike the playback process where linear reversibility makes it the joy of the mathematician, recording depends on hysteresis of ferromagnetic materials whose very nature is nonlinear and nonreversible. In addition, there are head and tape geometry effects and the nature of high-frequency bias. These must be considered simultaneously. It is not sufficient to analyze them separately and to superimpose the results.

One approach is a step by step analysis for a definite tape, head, bias, and signal. This is laborious, especially since it must be repeated a large number of times if one is to ascertain the effects of each variable. A situation of this kind is ideal for computer programming. Computer studies of this kind have been made for specialized instances of biasless pulse recording,[10] but not for the more difficult and more interesting general case where sine waves or complex waves are recorded with the use of high-frequency bias.

The results of such analyses should check closely with test data. Here again much work remains to be done, since agreement is not good. We may only guess at the reasons: perhaps not all the important elements were considered; possibly some of the theoretical relations do not hold in practice; perhaps the values of some parameters were incorrect.

Of all the factors that enter into magnetic recording the action of ac or high-frequency bias is the most intriguing, because intuitively one would not expect it to work, and because its operation is complex and obscure. Almost every investigator in the field has been dissatisfied with previous explanations, and the more venturesome have contributed their own versions which have in turn been rejected by their successors.

What takes place is as follows: If a signal field is applied directly to an unmagnetized record the residual magnetization vs applied field characteristic (B_r vs H) has the form shown in Fig. 5, which is an unsatisfactory output-input curve for linear recording. But if we add a weak signal field to a strong high-frequency bias field, and apply the resultant as in Fig. 6(c) to the record, then we obtain the input-output curve of Fig. 7, which has excellent linearity. The bias frequency, generally about 30 to 200 kc, does not appear in the output.

In explaining ac bias two approaches have been most common. The earliest suggestions were based on a physical picture of what might be happening to the magnetic elements in the record. Carlson and Carpenter[11] said that the bias had "the effect of agitating the recording element so as to greatly increase the sensitiveness of said element to feeble signal impressions." They were interested primarily in sensitivity to wireless-radio telegraph signals, and apparently did not realize that there might be conditions where the retained flux would be linearly related to the input signal.

[11] W. L. Carlson and G. W. Carpenter, "Radio telegraph system," U. S. Patent No. 1,640,881; August, 1927.

Later analyses were made in terms of the hysteresis loops of the magnetic record material,[12] [13] or its B_r vs H (residual induction vs applied field) characteristics.[14-17] For these it was not necessary to consider the mechanism of what took place at the domain level. The problem was reduced to: Given a family of magnetic characteristic curves and a complex sequence of applied magnetic fields. Find the magnetism retained by the record after it has been subjected to these fields. An analysis along these lines shows that the addition of a strong high-frequency field to the signal gives a linear output vs input characteristic.

Some explanations use the B_r–H curve such as Fig. 5 as their starting point. In so doing they assume (often tacitly) that the record is moving fast enough to present fresh tape at the recording point even for the bias frequency; in other words, the bias is recorded together with the signal. The reason for this is that the B_r–H curve is valid only if the polarity of the applied field never reverses; if the field does reverse, a B–H loop forms and the B_r–H curve no longer applies.

Holmes and Clark[14] used the B_r–H characteristic to plot the waveform of output, compared with a sinusoidal signal input. Their example showed distortion which they indicated might be reduced "by a more judicious choice of bias and audio signals." Camras[15] made a more complete graphical analysis on the basis of actual magnetic B_r-H data of a recording material, deriving the output-input curves, and showing how they varied in linearity and sensitivity as the bias and signal levels were changed. Montani[16] observed that if the rising portions of the B_r-H branches could be approximated by second degree functions, then the distortions would cancel out when the positive and negative cycle contributions were averaged. Zenner[17] set up a polynomial equation that fitted a B_r-H curve, and then operated on it with a function representing the sum of bias plus signal frequency terms. The result, after eliminating the high-frequency components, was a faithful reproduction of the input signal. Recent analyses by Bedford[18] and by Sebestyen and Takacs[19] are based on recording of the bias frequency, and on the pulse width modulation of the recorded bias which results when the signal is added. Such pulse width modulation is inherent also in the model of Bauer and Mee.[20]

While these explanations are valid as far as they go, they do not tell why ac bias still operates, and operates very well, under conditions where the bias is not recorded. In most recorders the resolving power of the head-tape system is inadequate to register the high-frequency bias, which goes through several reversals during the time an element of tape is in the recording gap field. One analysis which does not require that the bias be recorded is given in Camras[12] where minor hysteresis loops at bias frequency were followed as the bias plus signal decayed when passing out of the head-gap. A plot of the final magnetization versus input gave a straight line as in Fig. 7. A different analysis, based on the sloping sides of major hysteresis loops was made by Toomin and Wildfewer.[13]

There are those who feel that manipulation of characteristic curve can never get to the heart of the matter, and that a satisfactory understanding of ac bias is possible only in terms of electron spins and molecular interactions. So we return again to a physical picture, but an incredibly more complicated one than in early days.

In a magnetic record we have an aggregate of magnetic domains which are reversing in direction of magnetization for each reversal of the alternating bias field as long as the field strength is well above the coercive force of the material. As the record leaves the head, the field weakens until, at a certain point, it can no longer reverse the domains. If the domains were magnetically identical we should expect them all to remain saturated in the direction of the last cycle preceding this critical field strength. This is contrary to experience, since a record which has been subjected to a decaying ac field retains practically zero net magnetization. With the above record, if we should add a signal which varied slowly with respect to the bias frequency, the record would be left in a state of either positive or negative saturation depending on the polarity of the added signal. The output vs input curve would then be as in Fig. 8 which is also contrary to experience.

The output versus input curve actually obtained has a finite slope as in Fig. 7. A logical explanation might be that the domains are not all alike magnetically, but have a statistical range of coercive forces. Closer examination reveals the surprising fact that even with a range of coercive forces we still get the infinite slope of Fig. 8 rather than the finite linear range of Fig. 7. This may be seen from a practical example. Let us consider a mixture of magnetic domains having all possible coercive forces from zero to infinity. We now subject them to an ac bias field of 300-oersteds peak value combined with a signal field which is momentarily positive by 30

oersteds, and reduce both fields to zero at a linear (or any other) rate as shown in Fig. 9 over an indefinitely large number of ac cycles. Those particles with a coercive force above 330 need not be considered, since they are not altered by the maximum field and are small in population. Particles with a coercive force of 330 will be magnetized by the positive cycles which reach 330, but will not be reversed by the negative cycles of 270. Hence they will remain positively magnetized. A particle with coercive force of 135 undergoes a series of reversals up to the time T_2; after this time the negative field is too weak to cause further reversals, but the positive peaks of 165 are effective, so the particle with a coercive force of 135 remains positively magnetized. Similarly a particle with a coercive force of 90 will remain positive after time T_3. It is apparent that under these conditions the input versus output curve will still be as in Fig. 8. A more careful analysis including such factors as higher coercive particles, thermal agitation, and rapid field decrement, will indeed make the slope less than infinite, but hardly enough to account for the experimental results.

Early studies of the action of combined ac and dc fields on ferromagnetic materials were made by Steinhaus and Gumlich.[21] Their conditions were different from the ones encountered in magnetic recording, but they obtained characteristics resembling the ones of Fig. 7, which they called ideal magnetization curves. Their explanation followed a line of reasoning similar to the one given above, and they arrived at the conclusion that the curve should have an infinite slope as in Fig. 8.

Westmijze[2] pointed out the differences between ac bias recording and ideal magnetization curves. He gave a very illuminating explanation for the finite linear slope of the Fig. 7 characteristic, by supposing that the magnetic elements could assume various degrees of permanent magnetization. Corresponding to a given strength of retained magnetization, each element has an internal demagnetizing field opposite to the field that caused the retained magnetization. Under the influence of combined bias and signal fields, the element acquires just enough permanent magnetization so that the internal demagnetizing field cancels the external signal field. This concept gives a satisfying qualitative picture as to why the retained magnetization should be directly proportional to the signal; for as the signal changes, the recorded magnetization must adjust itself accordingly to maintain an equilibrium of zero field inside the element.

Independent single domain particles which are saturated in one direction or the other, do not satisfy the condition that permanent magnetization is acquired by degrees, and some other mechanism must be relied on. Woodward and Della Torre[22] filled this gap by showing that in recording tapes the particles are not independent, but have considerable magnetic interaction, and that such interaction explains the shape of the Fig. 7 characteristic. They made use of an ingenious technique which allowed them to measure and to plot both the interaction and the net magnetic differences among particles in actual tapes, as a statistical distribution. To do this they applied the method of Preisach,[23] where each magnetic particle is represented on a diagram by a point whose abcissa is the field required to switch it negatively (H_-), and whose ordinate is the field required to switch it positively (H_+). Fig. 10 shows the coordinate system and indicates where particles of different hysteresis loops would be plotted. Particles not under unbalanced influences are represented by points lying along a 45° line, with the ones requiring stronger switching fields being farther from the origin as indicated by progressively wider hysteresis loops *B*, *A*, and *C*.

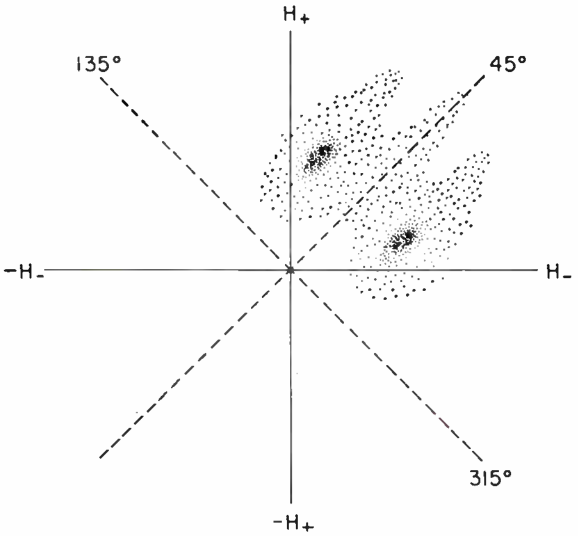

Fig. 10—Preisach coordinate system showing hysteresis loops of particles plotted in various areas.

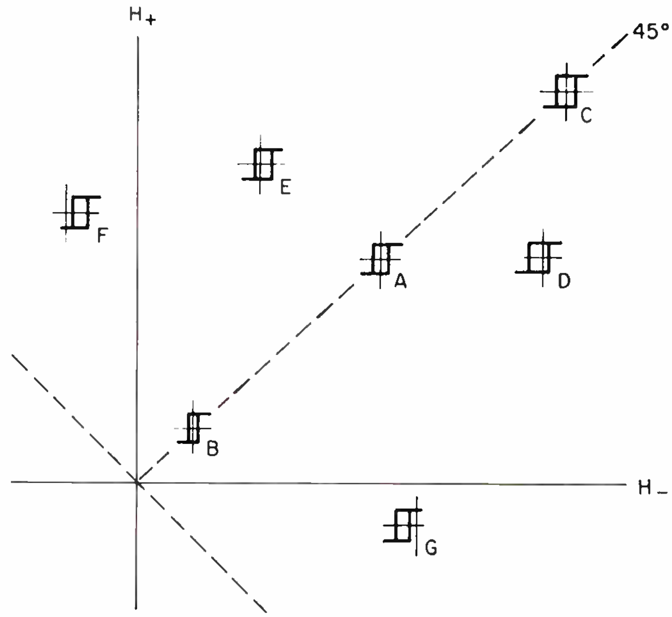

Fig. 11—Distribution function of particles in a magnetic tape (after Woodward and Della Torre).

In general, every particle will have neighbors whose magnetization modifies the over-all externally applied field. The influence of such neighbors may give rise to unbalanced conditions represented in regions D and E in Fig. 10, where the positive and the negative switching fields are unequal. In extreme cases, the unbalance may be high enough to displace the hysteresis loop from its axis, so that remanence in the region F is always positive, and in the region G is always negative. Since the magnetization of the neighbors is also changing during the magnetizing process, we cannot assign a permanent point on the diagram to any individual particle, but statistically a certain percentage will be in a selected area.

Once the distribution function given by such a diagram is known for a magnetic tape, its characteristic curve as of Fig. 7 can be plotted. The distribution function for samples of commercial gamma oxide tape was derived by Woodward and Della Torre from experimental data obtained by measuring the residual magnetization on a tape after it had been subjected to various combinations of ac and dc fields. They obtained results, shown roughly in Fig. 11, with marked peaks in regions well removed from the 45° line, signifying a high degree of unbalanced interaction among particles.

Some points lie in the second and fourth quadrants, just across the H_+ and H_- lines. Mathematically, there is also the area between 135° and 315° in the second, third, and fourth quadrants where the magnetization switches in a direction opposite to the applied field. Whether this is a forbidden region is not certain. Conceivably the applied field might upset a group of domains in such a way that their strong local influence would switch a domain oppositely to the applied field. At least one plot of Woodward and Della Torre showed a population in the third quadrant, which they obtained by extrapolation from the first quadrant.

Daniel and Levine[24,25] also carried out extensive work, both theoretical and experimental, with anhysteretic magnetization and with Preisach diagrams. They measured the "bulk" anhysteretic properties of recording tapes and came up with a set of constants that could be used to predict the recording sensitivity, the ac bias field required, and the maximum output. These are:

η_m—the maximum anhysteretic susceptibility, defined by maximum slope of the m vs H curve

H_0—the minimum ac bias field amplitude that produces an η of half η_m

S—the saturation value of m.

The Preisach distribution derived from their bulk measurements on recording tape, and shown roughly in Fig. 12, has a pear-shaped distribution with a single region of maximum density on the 45° line near a field of 240 oersteds.

Eldridge[26] has pointed out that the demagnetizing field relied on by Westmijze would only subtract from the applied field, but would not overcome it, and hence any applied field should still produce saturation were it not for the interaction fields. He reasoned that the anhysteretic magnetization curve of a material (which resembles that of Fig. 7) was really a plot of the cumulative distribution of interaction fields, since the abcissa represented an applied field which overcame interaction

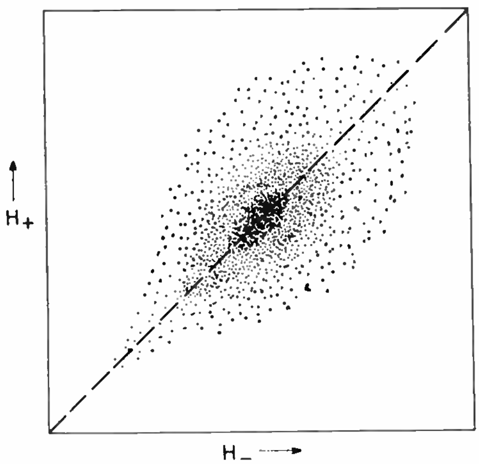

Fig. 12—Distribution function of particles in a magnetic tape (after Daniel and Levine).

fields of a certain number of domains and the ordinate represented the number of domains which had been overcome. He derived a distribution function from theoretical considerations, and showed that its form agreed closely with experimental measurements on tape. He found that the root mean square value of interaction field σ_{H_i} was proportional only to the magnetization intensity I_s of the bulk material:

$$\sigma_{H_i} = 2.9\, I_s \text{ total, or}$$

$$\sigma_{H_i}(x) = 1.7\, I_s \text{ in the } x \text{ direction.}$$

Summarizing, we may say that the premise that the domains are not alike magnetically does not, by itself, explain the B_r–H curve; but when the interaction between such domains is considered, a very good approximation to actual conditions is obtained. In the example of Fig. 9, at high ac bias fields all the domains are reversing their magnetic polarity together, but as the field decreases some of them become "set" and remain magnetized in one direction, while others of lower coercive force are still reversing. The first domains to become set will favor the polarity of the signal field (which may be considered constant since it changes slowly compared to the ac bias field). These first magnetized domains will now produce local fields which oppose the signal field; so that neighboring domains are subjected to the combined influence of the signal field and the local field of adjacent domains. Where the local fields overcome the signal field, a domain will become magnetized in a direction opposite the signal field, and a certain percentage of these opposite domains will exist. If the signal field is made stronger it will upset a greater and greater number of local situations in its own favor. If the signal field becomes weaker the self-balancing action of local fields tends to keep the net magnetization low, but statistically always in the direction of the signal field.

The result is that after being subjected to a field function as in Fig. 9, a record member is not saturated in one direction, but is magnetized in proportion to the signal field. To verify that it is a linear proportion in the region of the origin Eldridge[26] plotted his theoretically derived cumulative distribution function, and found it to be very close to experimental values for tape.

Another subject of prime interest is the magnetic field geometry in the tape during recording, and particularly the sequence of fields encountered by an element when it passes across the recording gap. As in the playback situtation, this must be analyzed for each type of head. The type shown in Fig. 1 is usually chosen because of its importance. Its external field has already been analyzed for the playback case. Unlike the playback case, the record on an element is not proportional to the integrated field but is influenced mainly by the highest field and by the last field encountered before it leaves the influence of the gap. This has given rise to the rule that head gaps need not be as small for recording as for playback, since in recording "only the trailing edge counts."

Armed with the head field configuration, the magnetic properties of the tape, and an assortment of simplifying assumptions, one may proceed to analyze the over-all recording process. A straightforward approach was used by Begun[27] who plotted the field variation versus time for different distances into the magnetic recording layer, and used the B_r–H curve to predict the resultant magnetization. This is an extension of the graphical analyses, which though accurate, does not give a physical picture that satisfies everyone. Stein[28] analyzed the recording of sine waves without bias, and came up with the interesting observation that the recording point begins at the trailing edge of the gap and progresses to the leading edge during the course of each half-cycle of recording field. Thus the magnetization moves contrary to the direction of tape travel, then jumps forward to begin another half-cycle. A similar effect was shown by Bauer and Mee[20] who devised a model to illustrate the recording process. At the recording gap they consider a "bubble" of magnetization. Inside this bubble magnetization can take place; outside the bubble the field is too low for recording. As the recording field increases and decreases, the radius of the bubble becomes larger or smaller. As seen from Fig. 13, when the bubble is expanding, it reaches out to the left, beyond the trailing polepiece, and upwards, thus magnetizing portions of the tape which would not have been magnetized with a constant radius of bubble. (It also expands to the right, beyond the leading edge, but here the tape would have become magnetized anyway as it passed through the bubble.) When the bubble is shrinking the leading edge becomes the important one, defining a boundary where tape is not magnetized which would have been magnetized with a constant radius of bubble. It might be

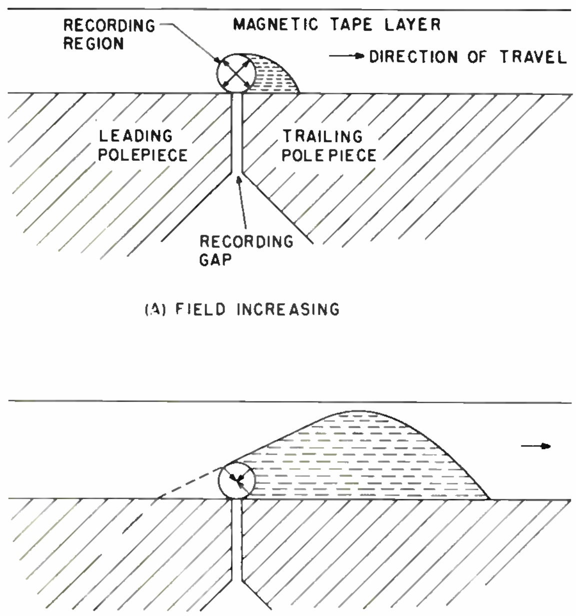

Fig. 13—Sine wave recording without bias (Bauer and Mee model).

expected that at short wavelengths, corresponding to rapid movement of the bubble wall compared to tape speed, some interesting effects would occur. Stein[28] analyzed the results of movement of the recording point under somewhat different assumptions.

When the Bauer and Mee model is used to show the effects of ac bias they obtain a pattern such as Fig. 14, where the signal expands the width of either the positive or the negative bias pulses. The model gives a qualitative explanation of output vs bias, but predicts a rapid drop in output if the bias amplitude or the bias frequency are increased, which does not conform to experiment. The authors admit that in these instances the model has gone beyond its limits of usefulness. Despite its limitations, the model shows that ac-biased recording on a moving tape can take place regardless of the mechanisms of finite anhysteretic magnetization, although we know such magnetization to be a fact from direct measurements on bulk material.

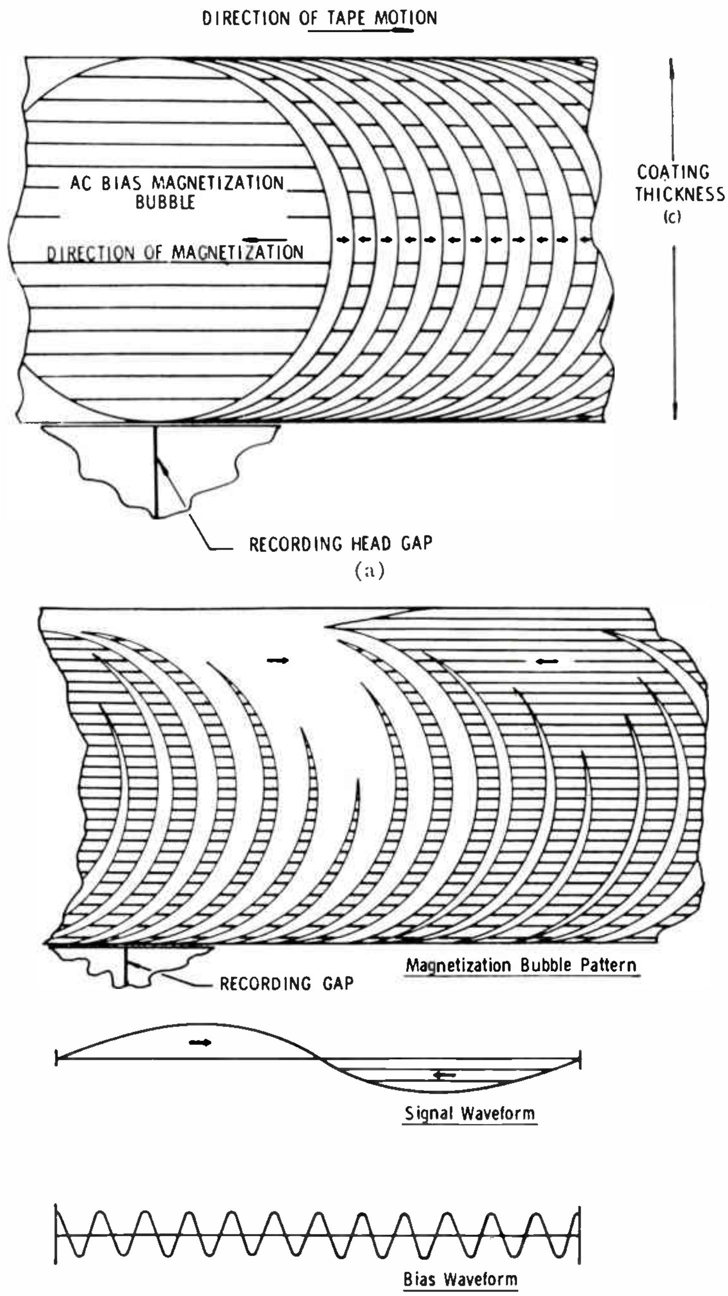

Fig. 14—AC bias recording. (a) Zero signal. (b) Long wavelength signal. (From Bauer and Mee.[20])

Noise in Magnetic Recording

When an unrecorded tape is played through a reproducing system, the noise level at the output will increase, compared to the noise level under identical conditions where the tape is not being scanned. Certain effects are noteworthy:

1) The least amount of noise is generated by a virgin tape or by a "bulk-erased" tape which has been demagnetized by subjected the entire reel of tape to a slowly decreasing field of power-line frequency.
2) Tapes erased with the erase head of a recorder may be several db noisier than bulk-erased tapes.
3) Tapes which have been scanned with a biased recording head (no signal present) are usually about 2 to 10 db noisier than either of the above.
4) The presence of a signal (including dc) will usually increase the noise in proportion to the signal level, typically about 10 db, but in severe cases as much as 20 or 30 db. This is called modulation-noise, and disappears when the signal is removed.
5) If the track width is changed the noise changes as the square-root of the width, while the signal changes directly as the width. Cutting a track in half reduces the signal-to-noise ratio 3 db.

6) Increasing the tape speed increases the over-all noise level and the high-frequency portion of the noise spectrum.

Even under best conditions, noise level from the tape itself is the limiting factor of a system, the amplifiers being considerably quieter.

A logical approach to analysis of noise is to find the response elicited by a single pulse, and then to sum the effects of a random assortment of such pulses forming a noise distribution. An early study of noise in magnetic recording was made on this basis by Wooldridge,[29] who derived the noise spectrum (noise power versus frequency) from theoretical considerations. He also derived the frequency response curve in the same way, and predicted that it would have the same form as the noise spectrum, provided that: a) the noise was caused by many random magnetic irregularities passing by the pickup gap; b) the pickup polepieces had negligible effect on tape magnetization; c) the random irregularities in the tape had small dimensions compared to the size of pickup gap. Measurements of frequency response and the noise spectra showed these to be alike, so that Wooldridge concluded that assumptions a), b), and c) were valid.

He then calculated the noise voltage that should result from a tape made up of saturated domains having completely random directions of magnetization. Under such conditions the noise would be about 1000 times as high as was actually observed. This indicated that the domains were not randomly magnetized, but in fact were arranged so that they cancelled out 99.9 per cent of each other's fields when the tape was demagnetized. Saturating the tape increased the noise 10 to 20 db without changing its spectrum. This was accounted for by postulating a greater degree of local disorder among the domains.

A theoretical analysis of the effects of variations in head-tape separation and in tape thickness during playback was made by Gilbert.[3] He also analyzed the case of sinusoidal tape irregularities, which could be useful for complex irregularities by application of Fourier series.

Wetzel[30] showed noise spectra taken in the presence of a recorded signal in which bands of noise were present near the signal frequency components. These might be explained by modulation noise effects. Periodic speed flunctuations in the tape drive under such conditions can also superimpose frequency modulation effects which modify the spectral distribution.

Glendon[31] obtained a great deal of data on noise spectra of modern tapes in a modern recorder, giving the results as a function of type of erase, backing and coating thickness, mylar vs acetate material, orientation, and tape speed. He reached no unexpected conclusions, but his results are useful in checking different noise theories.

In a recent paper Hammon[32] discussed noise problems occasioned by the trend to narrower and more closely spaced tracks. He was especially interested in modulation noise and showed spectra obtained under various conditions, including longitudinal vibration of the tape at 5 kc in the vicinity of the head.

Snow[33] pointed out that in practical situations the over-all noise spectrum of a recorder used for audio must be considered in relation to masking noises which are always present in the ultimate listening environment. Under proper conditions a recorder with a signal-to-noise rating of 50 db might effectively have a 70-db ratio.

Conclusions

Of all problems in the analysis of magnetic recording, the theory of the playback process has been treated most satisfactorily and most adequately. Others such as the recording process and noise are currently being developed, but a definitive treatment has not yet been evolved.

Electroacoustic Measuring Equipment and Techniques*

LEO L. BERANEK†, FELLOW, IRE

Summary—**Since 1876 electroacoustic measuring equipment and techniques for its use have advanced from a primitive state to an advanced engineering science. This paper discusses sound-level measurements and primary techniques for the calibration of microphones. It covers systems and techniques for the measurement of the steady-state and transient response of amplifiers, microphones and loudspeakers. Means for shock-wave calibration of microphones and for measurement of nonlinear distortion and complex waveforms are also described.**

ELECTROACOUSTICS as a field of engineering was born in 1876 with the invention of the telephone. Microphones and earphones developed rapidly after 1880, following the invention during the previous decade of the carbon-button, moving-iron and moving-coil types of transducer. The moving-coil loudspeaker was invented in 1878. The most prevalent instrument for measuring sound was the human ear, which measured sound intensity, frequency response and nonlinear distortion better than the more objective means of that day. It was not until after the turn of the century that electroacoustic measurements as we know them today came of age.

I. Sound-Level Measurements

In 1908 the first report on the relative measurement of sound pressure by electronic equipment was published. G. W. Pierce, in an experiment described in the literature,[1] used a Bell magneto-telephone receiver (also a carbon button) as a microphone, together with a tuning condenser, a step-up transformer, a molybdenite (MoS_2) rectifier, and a galvanometer. He said that with this apparatus he had examined the sound "intensity" in different parts of various auditoriums and had observed the whistle of a distant train on the galvanometer scale.

A precision method for measuring the mean-square magnitude of the particle velocity in a plane-wave sound field was invented by Lord Rayleigh in 1882 and is still being used for free-field primary calibrations of laboratory pressure-gradient microphones.[2] This method makes use of the fact that a steady torque is exerted on a thin, small disk suspended in a sound wave by a fine quartz fiber or phosphor bronze wire. A Rayleigh disk is not practical for field measurements, because of its sensitivity to drafts and winds. Nor was it very useful in laboratories, until oscillators and loudspeakers were devised to create relatively intense sound waves.

High-quality equipment for the measurement of sound became practical with the advent of the vacuum-tube amplifier (about 1915). Within two years engineers at the Western Electric Laboratories (later the Bell Telephone Laboratories) had perfected the electrostatic (condenser) microphone[3] and an absolute technique for calibrating it, the thermophone method.[4] The condenser microphone has very low internal noise compared with a carbon-button microphone, and a more uniform response over a wider frequency range than a magneto-telephone receiver. This equipment was valuable in the laboratory, but at first it was delicate to transport and unreliable in the presence of high humidity.

By 1925 sturdy vacuum-tube amplifiers were available, and the condenser microphone had been conditioned against the effects of high humidity. Portable sound level meters were developed.[5,6] In 1930[7] the range of these instruments extended from 60 to 9000 cps. However, they were expensive and heavy.

Until about 1932 the only light-weight instruments for the field measurement of sound were the audiometer and the tuning fork, with which the subjective loudness of a sound could be compared with the loudness produced at the ear by a tone of known and adjustable sound pressure level.

The modern low-cost portable sound-level meter came into use prior to 1935. It was made possible by the advent of the piezoelectric (crystal) microphone of the diaphragm type, and by improved batteries and smaller-sized vacuum tubes. This type of sound-level meter has remained standard for 25 years. Improved types using transistorized circuits, miniature batteries and condenser microphones are recently available. Sound-pressure levels can now be measured with an accuracy of one to two decibels between 20 and 15,000 cps with a light-weight sound-level meter having an average battery life of 100 hours.

Electronic means for analyzing sound waves were available in the early 1930's and have been improved continuously since that time. These include continuously variable, narrow-band, heterodyne frequency analyzers with crystal filters, step-wise variable octave, one-half-octave and one-third-octave band filter sets and constant-percentage, continuously variable, adjustable-bandwidth filters achieved by means of feedback circuits.

The most significant advance in the accurate measurement of sound pressure was the reciprocity method for calibration of linear, reversible microphones (transducers).[8-11] As seen in Fig. 1, the simplest embodiment of this principle[12] is the production of a spherical wave by the transducer (acting as a source) and the detection of this wave after reflection from a nonabsorbent plane wall by the same transducer (acting as a microphone). It can be shown mathematically[12] that the ratio of the open-circuit voltage e_{oc} produced by the transducer (when acting as a microphone) to the free-field sound pressure p_{ff} (that would exist in the reflected sound wave if the microphone were not there) is given by

$$\frac{e_{oc}}{p_{ff}} = \sqrt{\frac{e_{oc}}{i_T}\,\frac{4\lambda d}{\rho_0 c}}\, e^{-j(\pi/4-kd)}, \qquad (1)$$

where e_{oc} is the open-circuit voltage in the receive condition; p_{ff} is the free-field sound pressure acting to produce the open-circuit voltage; i_T is the current in the transducer acting to produce the wave in the transmit condition; λ is the wavelength of sound; $\rho_0 c$ is the characteristic impedance of air; d is the distance between the acoustic center of the transducer and the wall; and $k=2\pi/\lambda$.

The accuracy of the calibration depends only on the length of the path d and the measurement of the ratio of a current to a voltage.

II. Steady-State Response of Electroacoustic Equipment

Amplifiers and Filters

The standard method of measuring the response of an amplifier as a function of frequency is to connect a signal generator to the input and a meter to the output of the equipment under test. The sinusoidal signal is set to each frequency of interest at a constant level and the indicated output noted. These data can also be taken automatically by sweeping the signal source over the desired frequency spectrum and feeding the output to a graphic-level recorder which is linked to the sweep. For systems that are substantially flat within the frequency range of interest, this method is satisfactory. When measuring systems with a large attenuation at some frequencies in the range of interest, an instrument is used which comprises a signal generator connected to the input, and a wave analyzer, and graphic-level recorder connected to the output.

In order for an amplifier to produce minimum distortion of complex signals not only must it have a frequency response that is essentially flat over a wide frequency range, but it must also have a linear phase shift as a function of frequency. Equipment for the direct measurement of phase in the audio range is available from many manufacturers.[13]

Microphones

The following measurements are frequently made on microphones:[14,15]

1) Free-field frequency response, *i.e.*, open-circuit voltage vs frequency for a constant free-field sound pressure.

2) Directivity vs frequency.

3) Electrical impedance vs frequency.

4) Self noise vs frequency.

5) Linearity vs level.

6) Stability with time and environmental conditions.

The *frequency response* of a microphone is almost always determined by measuring its output after placing it in a sound field which previously had been adjusted to a known value with the aid of a standard microphone. The sound field is generally either a free, progressive,

[13] Typical instruments for the direct measurement of phase are the AD-YU Phase Meter of the Electronics Laboratory, Inc., of Passaic, N. J., and Acton Laboratories, Acton, Mass.

plane wave or is diffuse.[16] Free, progressive plane waves are produced by a loudspeaker in an anechoic (echo-free) chamber or outdoors. A diffuse sound field is obtained in properly designed reverberation chambers. Measurements of the open-circuit output voltage are made as a function of frequency with the sound-pressure level (measured before introduction of the microphone) held constant. The phase response is seldom measured.

Directivity patterns are measured in a free, progressive plane-wave sound field with the microphone oriented in space at all angles θ and ϕ with respect to the direction of travel of the wave. For those microphones that have symmetry of response about an axis, the directivity patterns are determined for angles θ alone.

The *electrical impedance* of a microphone is measured with an appropriate impedance bridge. Because the impedance includes the electrical resistance and reactance plus the reflected mechanical and radiation resistance and reactance, the measurements must be made with the microphone in a defined acoustical environment. The magnitude of the electrical impedance as a function of frequency can be determined by supplying a constant current to the microphone and measuring the voltage drop across the terminals.

Self noise is the limiting noise arising from the resistive portion of the electrical impedance. It is generally more easy to calculate it from a formula than to measure it:

$$e_{\text{total}} = \sqrt{4kT \int_{f_1}^{f_2} R\, df}, \qquad (2)$$

where

e_{total} = rms open-circuit self-noise voltage in the total band between f_1 and f_2 cps

k = Boltzmann gas constant = 1.37×10^{-23} joule/°K

T = absolute temperature in degrees Kelvin (°K)

R = resistive component of the electrical impedance of the microphone in ohms, in general, a function of frequency.

Microphone *linearity* is generally measured only for instances where sound-pressure levels well above 100 db *re* 0.0002 dyne/cm² are to be encountered. Apparatus for producing high sound levels, relatively free of distortion at the diaphragm of a microphone, have been described in the literature.[17]

The characteristics of some general-purpose microphones commonly used in audio measurements today are shown in Table I.[18]

Loudspeakers

Loudspeakers are more difficult to measure than any other component of an audio system. The difficulty arises from the radiation and resonance characteristics of the diaphragm from which the sound emanates. Typically the diaphragm (if a direct-radiator loudspeaker) has a diameter of the order of one foot. If the diaphragm were a flat surface in an infinite baffle with all parts vibrating in phase, it would begin to show directivity at frequencies near 400 cps. At frequencies above 1500 cps such a diaphragm would become very directional and would exhibit secondary radiation lobes. Actual loudspeaker diaphragms do not vibrate in one phase, but exhibit mechanical resonance conditions at frequencies above several hundred cycles.[19] These resonances are evidenced by lines of zero motion and by areas of out-of-phase motion on the diaphragm. The observable acoustical results are irregularity with frequency in the power output and in the directivity patterns. The type of baffle (enclosure) used also affects the frequency response and the directivity patterns because of resonances inside and sound diffraction outside the enclosure.[20] Horn loudspeakers exhibit similar difficulties, but at higher frequencies. Finally, the room in which a loundspeaker is located affects its response and directivity, so that there is no one set of measurements that characterizes a loudspeaker in all environments.

The steady-state measurements commonly performed on loudspeakers are as follows:

1) Sound pressure level on axis vs frequency, measured in an anechoic chamber or outdoors in free space.
2) Directivity vs frequency.
3) Impedance vs frequency.
4) Power-available efficiency vs frequency.

To determine the on-axis frequency response of a loudspeaker, measurements are generally made in an anechoic chamber.[21–24] Measurements in a space free of room characteristics have the advantage of being well defined and repeatable. For large loudspeaker systems, the open space in the room should approximate 25 ft in all directions, and the sound absorption lining should not be less than 4 to 5 ft deep on all walls. The test microphone is generally located between 5 and 15 ft from the loudspeaker. Typical response curves for an 8-in loudspeaker are shown in Fig. 2.[24] The frequency scale on the graph paper shown is logarithmic below 2000 cps and linear above. (This is not standard.)

The directivity patterns are determined at each frequency either by rotation of the loudspeaker on a turntable or by movement of the microphone on a spherical surface surrounding the loudspeaker. Typical directivity patterns for an 8- to 12-in loudspeaker and a 30-in horn are shown in Fig. 3.

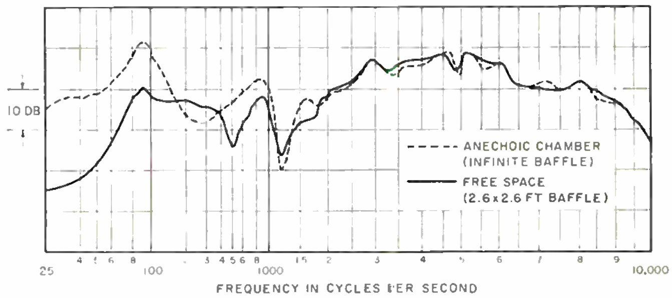

Fig. 2—Frequency-response curves of an electrodynamic loud-loudspeaker; microphone 1 m from the reference plane, constant voice-coil voltage.

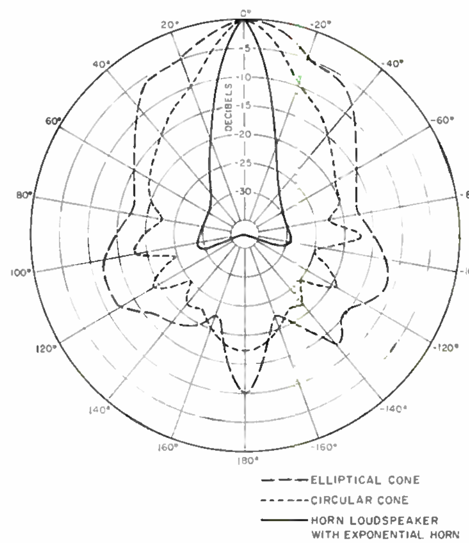

Fig. 3—Directivity patterns of three types of loudspeakers at 5000 cps.

The electrical impendence (including the reflected mechanical and radiation impedance) may be measured using a suitable impedance bridge. If only the magnitude is desired, the voltage drop across the terminals may be measured as a function of frequency for a constant signal current applied to the terminals.

Power-available efficiency in per cent is defined as 100 times the ratio of the total acoustic power radiated by the loudspeaker to the power developed by the driving amplifier in its nominal load resistance. This quantity is determined by, first, measuring the electrical power available from the amplifier for a particular gain setting. For example, if the 16-ohm terminals of an amplifier are to be connected to a nominal 16-ohm loudspeaker, the

[24] P. Chavasse and R. Lehmann, "Procedures for loudspeaker measurements," IRE TRANS. ON AUDIO, vol. AU-6, pp. 56–57; May–June, 1958.

load resistance R connected to the amplifier should be 16 ohms. The power available is defined as

$$P_e = \frac{e^2}{R}, \quad (3)$$

where e is the voltage developed across the resistance R. The total acoustic power radiated is determined by removing the resistance R from the terminals and substituting the loudspeaker for it without changing the gain of the amplifier. The sound intensity I in watts/cm^2 is determined at a number of points in space[25] by measuring the mean-square sound pressure p^2 in (dynes/cm^2)^2 and using the formula

$$I = \frac{p^2}{\rho c} 10^{-7} \text{ watts/cm}^2, \quad (4)$$

where ρ is the density of air and c is the speed of sound in cgs units ($\rho c \doteq 41$ dyne-sec/cm^3 at 72° F and 750 mm Hg). Then the total acoustic power W_a radiated is

$$W_a = (1/\rho c)10^{-7} \int p^2 dS \text{ watts},$$

where dS is an element of area on a spherical surface enclosing the loudspeaker, and the integration is carried out between 0 and 2π in the general case or between 0 and π if hemispherical radiation only is being determined.

III. Transient Response of Electroacoustic Equipment

Amplifiers

The need for measurement of the transient response of amplifiers has decreased considerably because of the improvement in components and circuitry. Transient behavior is easily calculated from steady-state frequency response and phase measurements. With modern feedback circuits linearity over a wide dynamic range is possible.

Microphones

The transient response of most modern microphones is superior to that of loudspeakers. Microphones used to measure sonic boom and explosive sound waves are calibrated by a shock-tube technique.[26]

Loudspeakers

Transient measurements on loudspeakers are of great importance because loudspeakers generally exhibit resonance peaks in their response curves and widely varying phase characteristics. One manner in which transient distortion is measured was first advanced by MacLachlan[27] and refined by Shorter[28] and Corrington.[29] By this method tone bursts of 4 to 20 cycles are produced at a given frequency (see Fig. 4). The electrical input signal is turned on and off as the sine wave goes through zero. The duration of time between any two tone bursts equals the length of one burst. The loudspeaker must be operated from a source with the same internal impedance at the amplifier with which it will be used, because the internal resistance of the amplifier usually affects the duration of the transient, at least at low frequencies. The electrical input to the amplifier and the acoustical output of the loudspeaker are recorded by an oscillograph. The transient distortion is determined by recording the output wave in the interval of time between two input bursts. The energy of this distorted wave is determined and compared with the energy in the output wave in the interval of time when an input tone burst was on. The relative transient distortion is the difference in decibels between the output energies in the two equal-length time intervals. The test is repeated for each frequency of interest.

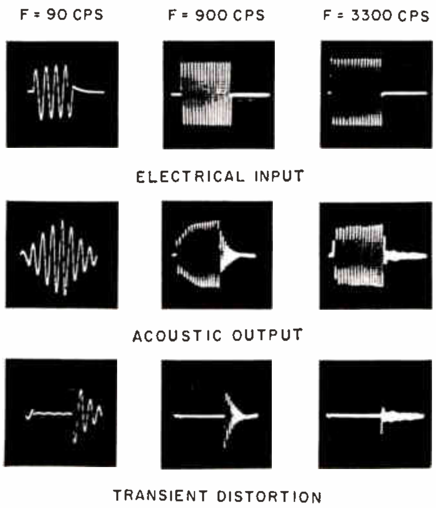

Fig. 4—Transient distortion for an 8-in direct-radiator loudspeaker.

Corrington reports very good correlation between such measurements of transient distortion on loudspeakers and subjective listening tests. He says that, when the transient distortion is more than 18 to 20 db down by the above test (using a 4-cycle pulse below 300 cps and a 16-cycle pulse above) the loudspeaker is comparable to the best obtainable. In addition, whenever

the curve of transient distortion vs frequency exhibits peaks, listening tests reveal an unpleasant sound, even though the frequency-response curve might be quite smooth. This test is not sensitive enough for use on high-quality amplifiers.

By Shorter's technique the decay time of the transient following the cutoff of the input signal is measured. Obviously, there is a positive correlation between his measurements and those of Corrington, and his subjective listening tests also bear this out.

IV. Measurement of Nonlinear Distortion in Electroacoustic Equipment

Methods for measuring nonlinear distortion in electroacoustic equipment may be divided into two major groups, *harmonic* and *intermodulation*. For the harmonic method [see (a) of Fig. 5][30] a single sinusoidal signal A is supplied to the equipment under test. Signals C, D, etc., in the output are harmonically related to the input signal and are measured and used to specify the harmonic distortion. For example, the second-order (C/A), the third-order (D/A) or the total rms distortion $[(C^2+D^2)/(A^2+C^2+D^2)]^{1/2}$ may be determined. In the intermodulation methods[31–33] *two* sinusoidal signals are applied to the input [see (b) and (c) of Fig. 5]. Then all signals in the output with frequencies different from those at the input are measured. If the system is nonlinear, harmonics of the sine-wave frequencies will be produced and, in addition, components which are not harmonically related to either of the driving signals. Since speech and music already contain a number of harmonic components, additional harmonics introduced by the audio system are probably not as objectionable as new components not harmonically related to any of the original components. By the SMPTE method, signals C_1, D_1, C_2 and D_2 of Fig. 5(b) are measured. By the CCIF method, signals C and D_1 are measured. The harmonic and nonharmonic components appear not to bear a fixed relation to each other for some types of audio systems.[31] Hence, it is generally agreed that one or the other of the two intermodulation methods is preferable to the harmonic method.

Aagaard concludes from analysis and listening tests that the SMPTE intermodulation method is the logical choice. The CCIF difference-frequency method, using only the (f_2-f_1) term, may be grossly misleading for a system with a symmetrical transfer characteristic. On the other hand, if the second-order component $2f_2-f_1$,

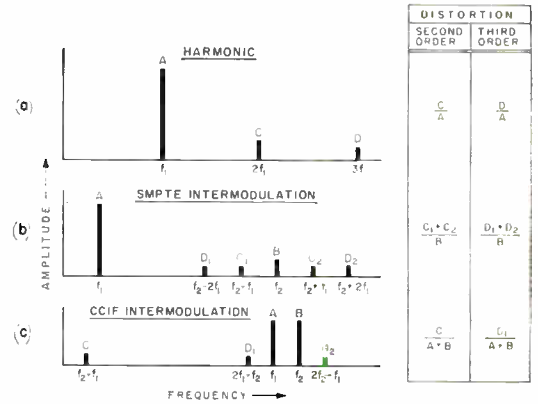

Fig. 5—Methods of measuring nonlinear distortion. (a) Harmonic. (b) Intermodulation method of SMPTE. (c) Intermodulation method of the Comité Consultatif International des Communications Téléphoniques à Grande Distance.

i.e., D_2 of Fig. 5(c), is measured, the CCIF method is the only really satisfactory way to determine nonlinear distortion near the upper-frequency limit of a system. In evaluating the results allowance must be made for the fact that the SMPTE method gives a numerical value 5 to 6 times that obtained with the CCIF procedure.

On highly nonlinear systems, or on systems that are amplitude limited (peak-clipped), such as hearing aids, a rough measure of distortion is the nonlinearity of the plot of the output signal level vs the input signal level. The point of nonlinearity in this curve is most quickly observed if a peak meter is employed.

In all cases it is wise to supplement the distortion measurement with oscillographic observation of the output waveform. This procedure not only gives an indication of the shape of the transfer characteristic, but it also reveals other defects such as instability.

V. Measurement of Random and Impulse Signals

Three types of rectifier characteristics commonly used when measuring random noise are 1) mean-square, 2) linear, and 3) pseudo-peak, all three normally calibrated to read alike when measuring a single sine wave.

Mean-Square (Square-Law) Indicating Instruments

A square-law device delivers an average current to a load that is 0.707 of the peak value of a sine wave. It indicates correctly the square of the standard deviation of the probability distribution curve of a random noise.

Average Indicating Instrument

A linear full-wave device delivers an average current to a load that is 0.636 of the peak value of a sine wave. If its output is adjusted upward by a factor of 1.11, it will, when measuring a sine wave, deliver the same output to a load as a square-law rectifier. When so adjusted and when measuring a random noise, it will deliver to a load a current that is about a factor of 1.13 (1.05 db) lower than that delivered by an rms meter.

Peak Indicating Instrument

A basic type of peak indicating instrument is shown in Fig. 6. Let us assume that E is a signal comprising a number of inharmonically related sine waves or a random noise. Then the ratio of the voltage E_b at the output of the peak indicating instrument to the true rms value of the signal E is shown by Fig. 7.[34] We see that for a high ratio of rectifier to series resistance (R_b/R_r) a pseudo-peak meter when measuring a random noise reads 5 to 8 db higher than an rms meter, provided both are calibrated to read alike on a sine wave ($n=1$). Only for $R_r/R_b \doteq 0.1$ would an rms and a pseudo-peak meter read approximately alike for a random-noise input.

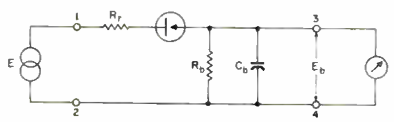

Fig. 6—Schematic diagram of a peak-indicating voltmeter.

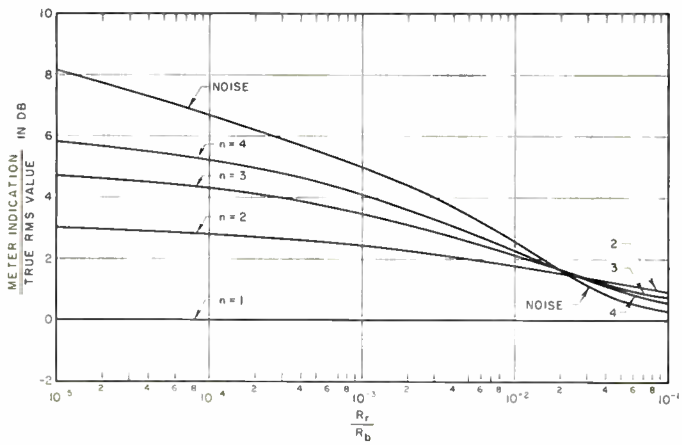

Fig. 7—Indication of a peak-reading meter relative to the true rms value of n equal, inharmonically related sine waves, and of white noise. The source impedance was assumed zero in constructing these curves, but can be taken into account by including it as part of R_r.

Impulse (Impact) Noise Meter

The time history of an impulse noise can be obtained from high-speed oscillographs or by photographing the trace on an appropriately calibrated oscilloscope. The energy-density spectrum can be obtained by appropriate filtering and integration. An impact (impulse) meter, such as the General Radio type 1556A, is relatively compact and can be used in the field or at the output of a magnetic tape recorder.[35] It measures 1) the peak level, and 2) a time-averaged level of the sound pressure. From 1) and 2) an estimate is obtained of the duration (decay time constant) of an impulse.

VI. Conclusion

A present-day view of the broad subject of electroacoustic equipment and techniques for measurement in the audible range of frequencies has been presented. Measurements of sound fields, loudspeakers, microphones, amplifiers and filters have been discussed. The quantities measured were the steady-state, transient and nonlinear correlates of the behavior of systems as judged by listeners. The methods are also applicable to situations where listeners are not involved. No attempt has been made to review subjective means for appraising audio systems.

In the next decade we may expect the digital computing machine to change radically our concepts of measurement. To fully utilize the capabilities of such machines, we need better electroacoustic transducers—particularly loudspeakers—with uniform frequency response and broad directivity patterns over a wide range of frequencies.

Speech Communication Systems*

WINSTON E. KOCK†, FELLOW, IRE

Summary—**Telephone, radio broadcasting, public-address and bandwidth conserving systems are discussed with particular attention being given to the latter two. The relation of certain properties of hearing (*e.g.*, the Haas effect) to public address system design is reviewed along with several bandwidth conserving techniques including speech interpolation systems and vocoders.**

Introduction

SPEECH communication systems can be divided conveniently into four categories: telephone, radio broadcasting, public-address and bandwidth conserving systems. Telephone systems seek high intelligibility and reasonable naturalness while maintaining economy in bandwidth. Radio broadcasting, first limited in bandwidth by channel spacing, later achieved high fidelity capability with the advent of FM and TV broadcasting. Public-address speech systems possess no serious bandwidth limitations but encounter problems in room acoustics. Speech-bandwidth compression systems utilize certain properties of speech to achieve an economy in bandwidth. These four categories will be discussed in turn.

Telephone Communication Systems [1]

The first telephone systems were limited in bandwidth by the transducer capabilities. Highly resonant telephone receivers achieved high sensitivity but imposed a limitation on the intelligibility of the speech transmitted. The first vacuum tube amplifier was installed between New York and Baltimore in October, 1913, and this type of amplifier later led to the development of carrier-current telephony, whereby several telephone conversations could be transmitted simultaneously in different parts of the frequency spectrum. A typical carrier system (*e.g.*, the type K) provides 12 channels within a bandwidth extending from 12 kc to 60 kc. The actual speech band within each of the 12 transmission circuits extends from approximately 300 to 3400 cps. With the advent of the coaxial cable and its extremely wide-band capability, a new carrier system (the type L) was developed, capable of varrying 600 voice channels on one coaxial circuit. Further development of the coaxial cable and the introduction of the microwave relay systems such as the TD-2 (a typical tower is shown in Fig. 1), led to even greater sophistication in carrier concepts, typically the L-3 carrying 1800 voice channels in one circuit.

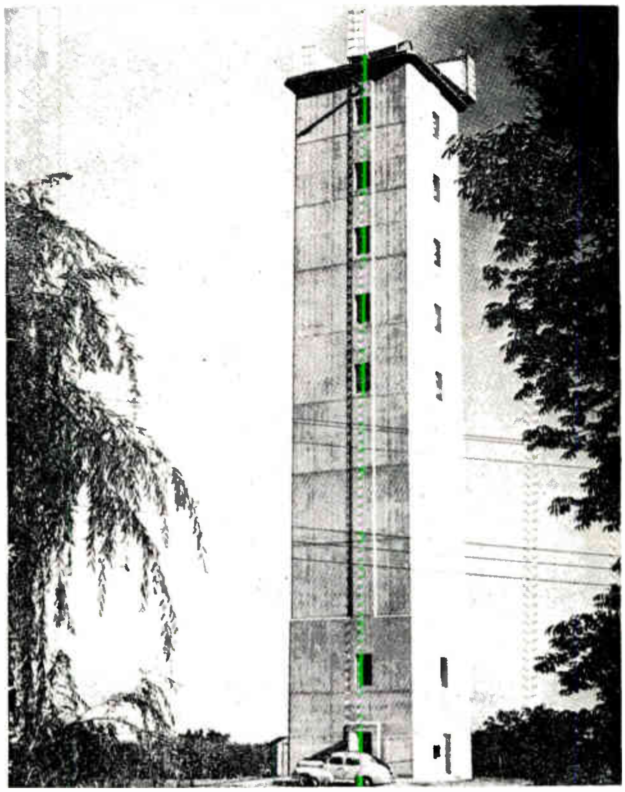

Fig. 1—Microwave radio relay circuits, exemplified by this Bell System TD-2 repeater tower, carry thousands of speech transmission channels on one radio circuit. The horn-lens antennas atop the tower, with a gain of 40 db and a beamwidth of 2 degrees [2], employ delay lenses [3] which were later found to be effective for directing the acoustic speech waves issuing from loudspeakers [4].

Early radio broadcasting with its 5-kc frequency band acquainted radio listeners with rather good quality electronic speech and an improvement in telephone speech quality accordingly seemed desirable. Better carbon microphones and improved telephone receivers such as the ring-armature receiver [5] were developed to improve the naturalness and intelligibility of telephone speech.

During this period of improvement in speech fidelity many experiments were conducted in various acoustical laboratories to determine the relations between audio bandwidth and intelligibility. Fig. 2 shows how the upper and lower limits of bandwidths affect intelligibility or articulation [6]. Monosyllabic word lists, referred to as phonetically balanced or PB lists, are used in listener tests to determine the quality of various transmission circuits. Such tests are particularly useful in evaluating speech bandwidth compression systems to be discussed later.

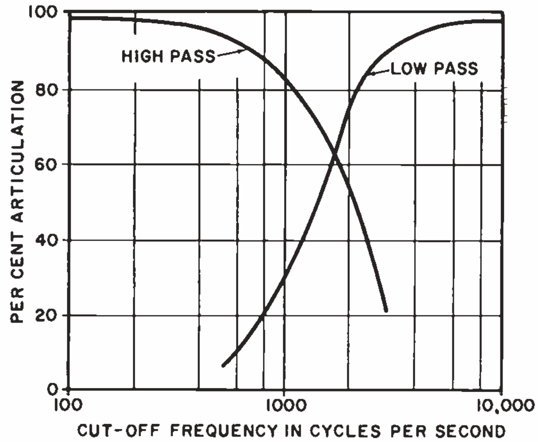

Fig. 2—Band-limited speech exhibits fairly high intelligibility (per cent syllable articulation) even with the low-frequency cutoff at 400 cps and the high-frequency cutoff at 4000 cps. [6]

Radio Broadcasting Systems

The spacing of radio channels set 5000 cycles as the limit of the audio spectrum to be encompassed in radio broadcasting. This constituted a moderately sizeable extension of the bandwidth used in telephone circuits, and, because of the state of the art in audio reproducing systems, it appeared adequate at the time. Recent developments in microphones, recording systems, and loudspeakers, however, permit electrical sound reproducing systems to encompass the full range of audibility of the ear, and this has made quite evident the limitations imposed by the 5000 cycle radio broadcasting channels. When frequency modulation broadcasting came into being, an audio channel of 50 to 15,000 cycles was selected; the audio channel for television broadcasting also covers this range. Obviously, such a frequency bandwidth can only be used effectively if the receiver loudspeakers and associated electronics are adequate. Since this is often not the case, network TV programs frequently have their 15,000 cycle audio channel transmitted over the narrower AM voice circuits. With the arrival of two-channel stereophonic recording and reproducing, it was only a matter of time before FM broadcasting standards were decided upon (April, 1961) permitting two-channel stereo to be broadcast (compatibly!) over FM stations.

Public-Address Systems

In the transmission of speech from a microphone on a lecture stand to loudspeakers in an auditorium, the problems of achieving good fidelity rest not in the bandwidth requirements, but rather in the acoustics associated with the hall or auditorium. Several recent developments which are pertinent to this problem are worthy of discussion here.

An effect called the precedence or Haas effect is now in wide use. It had long been recognized that both the relative nearness and the relative loudness of a sound source were pertinent in causing it to appear dominant over another source. Only recently, however, were the factors involved in this phenomenon thoroughly investigated. In 1951, H. Haas determined that if two sound sources are radiating the same signal, and the signal from one is delayed 5 to 35 msec relative to the other signal, the ear perceives the sound as coming almost entirely from the undelayed source [7] (Fig. 3). So great is this effect that the delayed source in many instances must be increased in intensity by many decibels in order that the listener be cognizant of its existence.

One of the first applications of this effect was its use in the public-address system installed in St. Paul's Cathedral in London [8], [9]. In previous systems the use of multiple loudspeakers resulted in large portions of the audience being aware that the amplified sound came from the loudspeakers instead of from the lecturer himself. In the St. Paul's installation the signals transmitted by the microphone in the pulpit are delayed (before being amplified and fed to the many distributed loudspeakers) so that the direct signal from the pulpit arrives at all audience positions in the cathedral before any loudspeaker signal can arrive there (Fig. 4). A listener thus imagines that the perceived sound comes from the pulpit rather than from a nearby loudspeaker. In addition to maintaining realism, the St. Paul's installation improved word intelligibility at the rear of the Cathedral from 52 per cent to 85 per cent [8].

Another effect which has been found useful in its application in public-address systems is the use of directional loudspeakers or directional-loudspeaker arrays. Many loudspeakers radiate in all directions and in an auditorium they create an excessive amount of reverberation through sound striking the ceiling and other undesirable areas. By modifying the radiation pattern of public-address loudspeakers, much can be done to increase the direct signal to the listener. In some instances the directivity of loudspeakers has been improved through the use of acoustic lenses [4], some of which are modifications of lenses originally developed for focusing radio waves [10] (Fig. 5). Another approach has been to employ vertical-line arrays of loudspeakers

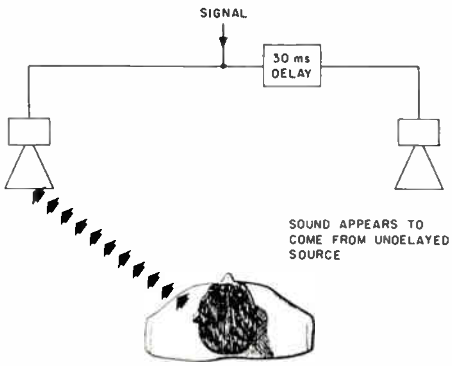

Fig. 3—Because of the precedence or Haas effect, the same sound issuing from two sources appears to come from the one with least delay.

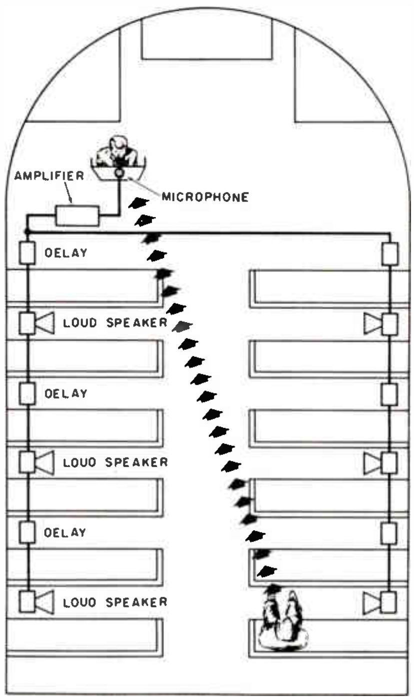

Fig. 4—An auditorium public-address system provides greater realism and intelligibility of delays as required by the Haas effect are introduced in the loudspeaker lines.

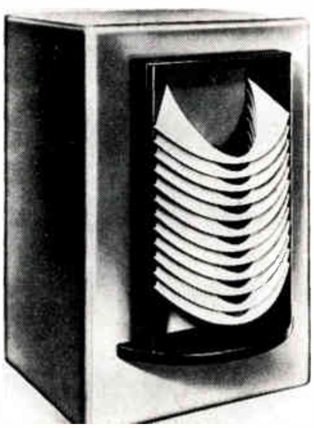

Fig. 5—Public-address system loudspeakers can provide maximum coverage with low reverberation if their directional patterns are properly modified as, for example, by the acoustic lens portrayed here.

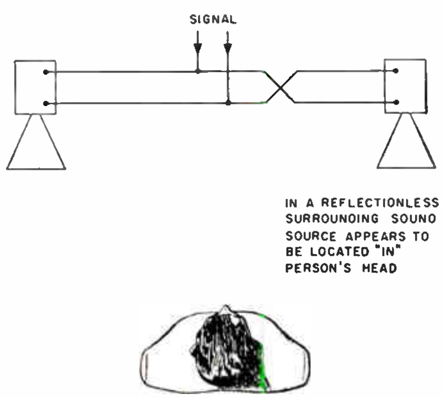

Fig. 6—In surroundings with low reflection, improper poling of two public-address system loudspeakers can create queer listening conditions for persons located along the center line.

permitting high directivity to be achieved in the vertical plane (thus concentrating the sound in the plane in which the audience is located) and low directivity in the horizontal plane (thereby covering the entire audience). Such loudspeaker arrays are employed in the St. Paul's Cathedral installation mentioned above [9].

Another effect which has been investigated recently is of importance in public-address systems employing two spaced loudspeakers. A listener equidistant from the loudspeakers observes that the quality of the speech he hears is quite dependent upon the relative poling of the two loudspeakers; as indicated in Fig. 6, the words actually seem to originate within the listener's head when the speakers are oppositely poled. The effect is most noticeable in a free space room or outdoors. When single frequency tones are employed in this situation, "phantom" sources can be localized [11], [12] but for broad-band signals the listener is quite confused [13]. R. L. Hanson and the author attributed the quite striking effect to the presence of a pronounced null for all frequencies along the exact center line plus the many high-frequency maxima and minima located near the center line. At certain frequencies this creates high intensity signals in one ear relative to the other, an effect otherwise achieved only by the sound being extremely close to one ear.[1]

Speech-Bandwidth Compression Systems

Savings in speech-channel capacity benefit expensive transmission systems (such as the transatlantic voice cable) and those communication systems where added voice-channel capacity cannot otherwise be obtained (such as in aircraft communications). Thus in the case of the transatlantic cable, a doubling of the number of speech channels would be equivalent to installing a second cable; the economic importance is obvious. In aviation communications, added channels could mean added traffic capability which might not otherwise be possible.

Bandwidth conserving systems can be divided into two categories: those dependent upon properties of the speech envelope and those dependent upon the frequency structure of speech. The first exploits the nature of speech conversations, in particular, the fact that in a normal two-way conversation each talker uses his circuit for only a fraction of the time. Accordingly, if the free channel time of an individual talker is interpolated among additional talkers an appreciable increase in the number of channels can be achieved [16], [17]. The second technique takes advantage of certain properties of the speech signal so as to permit adequate information on the quality and characteristics of the talker's voice to be transmitted over a narrower frequency band. When one considers the voice mechanism, one is not surprised to find that voiced speech is a relatively simple form of signal containing only one fundamental and one series of harmonically related overtones. This fact has led many to explore various sorts of speech-bandwidth reducing schemes.

Inasmuch as the time assignment interpolation system is now being employed on transatlantic voice cables [18], it will be reviewed first. Measurements on actual telephone working circuits indicate that the average activity is no more than 35 per cent to 40 per cent of the time that the circuit is busy at the switchboard. Since long distance circuits use separate pairs of wires and separate carrier channels for the two directions of transmission, it follows that each one-way channel is on the average free for 60 to 65 per cent of the time. When a large number of channels are operated as a group, variations in individual activity time average out and the law of probability serves to minimize mutual interference. In the operation of a system called TASI (time assignment speech interpolation) each of the lines from the toll switchboard is equipped with a special detector capable of recognizing, within 5 msec or less, the presence of speech sounds. When this detector operates, a switching network automatically connects that particular line to an idle channel and simultaneously sends a coded signal instructing the distant receiving terminal to connect that channel to the proper listener. This time sharing plan, connecting a talker to an available transmission channel for the duration of a talk spurt, has been able effectively to double the number of channels available in the 36 channel undersea telephone cable [19]. The first TASI system was put in service between White Plains, New York and London, England in May, 1960.

We turn now to systems making use of the frequency structure of speech. The first steps in this direction were taken almost 40 years ago when K. W. Wagner first created electronically the vowel sounds of speech [20]–[22]. It was about that time that experimenters were discovering that vowel sounds are dependent upon the shape of the resonant cavities in the vocal tract. Wagner employed a periodic series of pulses to excite resonant electrical circuits whose frequency and damping corresponded to the resonances present in the vowel sound. Fig. 7 portrays how vocal resonances (called formants) are excited by the glottal puffs originating at the vocal cords. A similar effect is present in many musical instruments [23]. During the 1930's the pioneering work of Wagner was extended by Homer Dudley who developed techniques for creating speech manually (the voder) [24] and for recreating speech from electrical signals obtained from an electronic speech analyzer (the vocoder) [25]. Dudley's vocoder system, shown in Fig. 8, might be likened to two high-speed electronic computers, one at the sending end and one at the receiving end. At the sending end, an analyzer ascertains what frequencies are present in the incoming speech signal, decides whether the sound is voiced or unvoiced, and measures the pitch of the signal if voiced. Since transitions from one sound to another occur quite slowly, the information

[1] Schodder [14] employed the Lauridsen effect [15] for another explanation of what he called the "Kocksche Wiedergabeweise (!)."

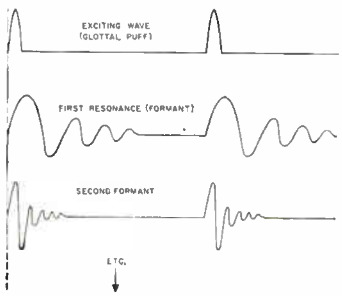

Fig. 7—Most speech-bandwidth compression systems make use of the fact that voiced sounds are combinations of the vocal cord wave (glottal puff) and several "formants," generated by the glottal puff acting on the resonant air chambers in the vocal tract.

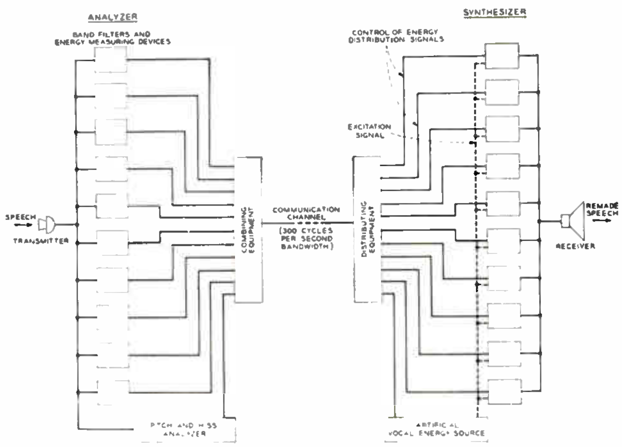

Fig. 8—The transmitting analyzer of the Dudley vocoders ends low-frequency signals over a narrow-band line to instruct the synthesizer on how to reconstruct the speech correctly.

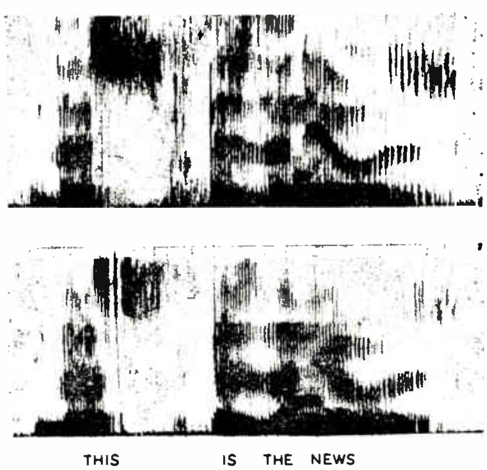

Fig. 9—Visible speech spectrograms of radio commentator Edward R. Murrow's words, "This is the news," show little difference between the original radio broadcast (top) and the synthetic vocoder version (bottom).

acquired by the analyzer can be transmitted over channels which are only 15 or 20 cycles wide. At the receiving end the synthesizer rebuilds the original speech from the information it receives, matching an artificial energy source (an electrical oscillator) in frequency content and pitch to the original speech. Factors of five or ten in bandwidth saving are possible. Early vocoders assigned equal bandwidth to the band filters in the analyzer and synthesizers. More recently R. L. Miller experimented with unequal bandwidth filters using narrower bands at the low-frequency end and wider bands at the high-frequency end of the speech spectrum. Using 16 analyzing filters he achieved vocoder speech of very high quality [26]. Fig. 9 illustrates the remarkable accuracy of speech reproduction obtained by this particular vocoder.

A somewhat allied type of vocoder developed from experiments at Bell Telephone Laboratories on the automatic recognition of speech sounds. In these experiments a recognition system designed to recognize any one of 10 speech sounds was used in an attempt to permit recognition of 10 complete words (the 10 digits). For this purpose, 10 electrical circuits were employed, each having frequency response characteristics which matched one of 10 selected phonemes (Fig. 10). Fig. 11 shows one speech sound (phoneme) being recognized in a word. This device (called Audrey) "recognized" individual sounds rather well and this suggested its use in a type of vocoder [27] as sketched in Fig. 12. Here only the information that a particular sound has been uttered is sent through the communication channel. At the receiving end the proper one of a series of spectrum modifiers is then activated to recreate the original sound. This type of vocoder may be promising where large amounts of bandwidth reduction (greater than 20 times) are desirable at some sacrifice of naturalness and perhaps intelligibility. The Audrey and "Audrey vocoder" experiments were conducted by K. H. Davis, R. Biddulph, S. Balashek [28] and the author [27], [29]. Earlier Dudley [30] had considered a vocoder related not only to the phonetic recognition vocoder but also, because of its use of variable resonant circuits, to the formant or resonance vocoder to be discussed shortly.

The acquiring of accurate fundamental frequency of the transmitted signal is one problem confronting all vocoder systems utilizing a synthetic energy source at the receiving end. In telephone circuits the fundamental component is usually missing and this aggravates the problem. One solution is to transmit the low-frequency end of the speech signal directly, coding only the higher frequency portion for bandwidth saving purposes [31]. Recently M. R. Schroeder and E. E. David sent a speech band of 10 kc in this way over a 3.5-kc channel [32].

The formant or resonance vocoder operates by transmitting information on the position in the frequency scale of the first three speech formants [33]–[36]. Fig. 13 portrays the motion of these formants in a section of

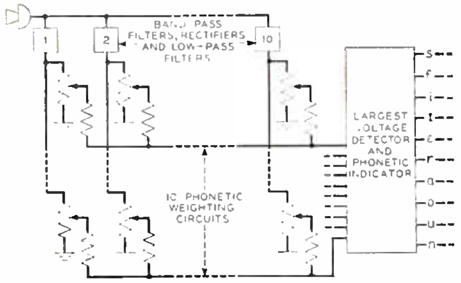

Fig. 10—The output of a filter whose frequency-amplitude characteristic matches that of a particular speech sound will be greatest when that sound enters the microphone. In this way, sounds can be "recognized" electronically.

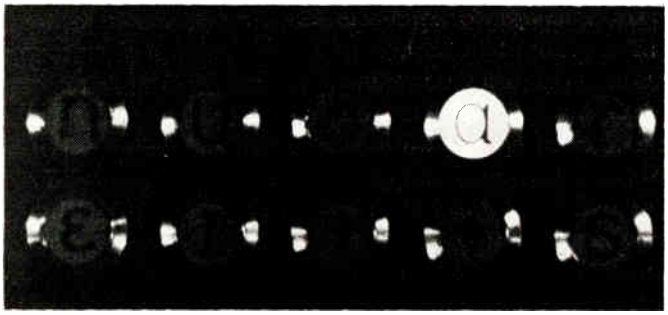

Fig. 11—The device of Fig. 10 has just "recognized" the sound *a* as in *father*, and caused a light to illuminate this symbol.

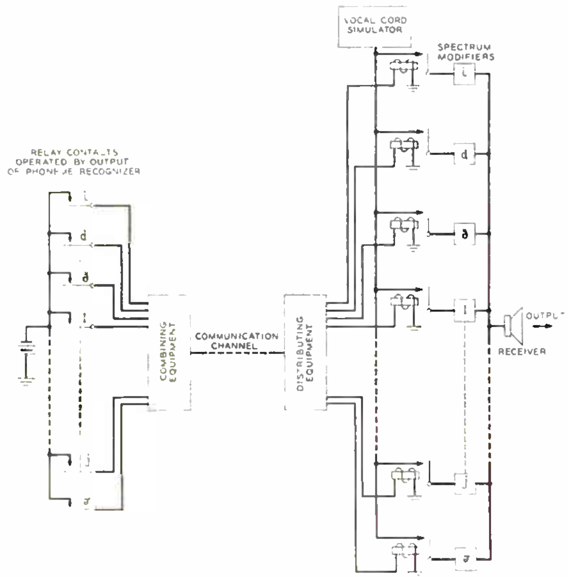

Fig. 12—An electronic analyzer (left) which recognizes successive speech sounds as categories in its memory can signal a speech synthesizer (right) for reconstructing the original speech. Since successive phonetic sounds in speech occur at rates less than 10 per second, the communication channel can be extremely narrow.

speech; the dotted lines suggest how the resonant filter circuits of a "formant tracker" at the transmitting end could control the position of similar filter circuits at the receiving end for reconstituting the speech sounds [37]. J. L. Flanagan applied to such a vocoder the technique mentioned earlier of transmitting a portion of the original speech in an uncoded way [38] (Fig. 14).

Recently a vocoder employing correlation techniques has been investigated. The "sound spectrogram" techniques of R. K. Potter (power spectra versus time) [39] were supplemented by W. R. Bennett's "correlatogram" techniques (auto-correlation functions vs time) [40]. This recognition of the possibility of representing the characteristics of speech sounds either by power spectrum or correlation function [41]–[43] led several to consider the correlation process in conjunction with vocoders. Inspired by a report [49] of R. M. Fano's "time domain vocoder" (which used a noise source as a signal for reconstituting the speech), B. P. Bogert and the author proposed in 1949 the correlation vocoder of Fig. 15 [44]. Here the speech signal is first distorted or "spectrum flattened" [45] so as to create a peak signal resembling the wave form at the top in Fig. 7. This is transmitted down a delay line and, at successive points in time, cross correlated with the original speech signal. Since the multiplication process of the cross-correlation procedure yields a signal only during the peak or pulse interval the cross correlation can be considered a sort of "gating" process. At the receiving end a similar periodic pulse (whose repetition frequency matches the fundamental frequency of the original speech signal) is multiplied, with proper delay, with the signals arriving over the various transmission channels. These signals are slowly varying signals, so narrow-band transmission can again be employed with bandwidth savings comparable to these achieved by the Dudley vocoder. The sampling intervals must be the Nyquist interval for the highest frequency of the signal involved, but because speech sounds die out during the course of a pitch period (Fig. 7), the sampling need only take place during the first portion of each period. Several forms of correlation vocoders including one employing auto-correlation have recently been designed and built by Schroeder [46], [47].

It is interesting to note that the same improvement obtained by Miller [26] through the use of nonuniform filter widths in a spectrum vocoder should also be available to correlation vocoders through the process of unequal spacing of the delay times. Formant bandwidths increase only slightly at the higher frequencies [48] and since decay time is inversely proportional to frequency *squared*, the decay time of the higher formants should be appreciably less than that of the lower-frequency ones. Maximum sampling rate thus need only be employed at the very start of the cycle and wider spacings can be employed between succeeding samples. This procedure (accomplished by increasing the values of the higher numbered τ's on the two delay lines of Fig. 15) was described in the original correlation vocoder patent [44].

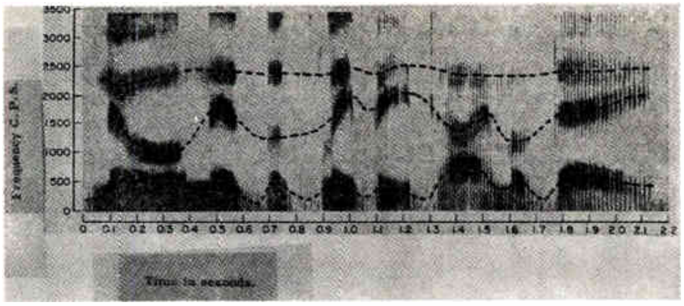

Fig. 13—A sound spectrogram of a section of speech portrays the varying motion of the resonances or formants. Formant "trackers," following the course of the important first three resonances can provide a speech synthesizer with the information needed to recreate the speech.

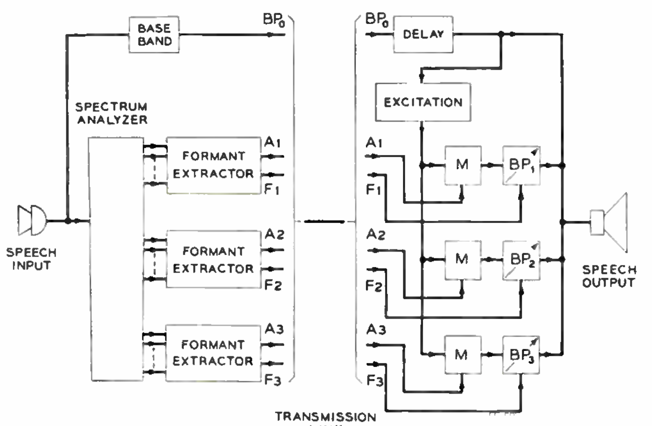

Fig. 14—The transmitting end (left) of a formant or resonance vocoder furnishes the receiving end (right) with information on the amplitude A and frequency F of the first three speech formants. At the receiver, modulators M and band-pass filters BP spectrum-modify the excitation signal to recreate the input speech. In this version some of the low-frequency portion of the original speech is transmitted in order to achieve better realism at some cost in bandwidth.

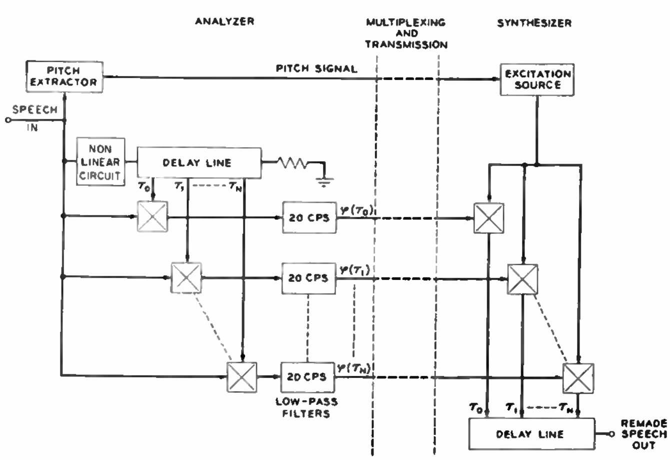

Fig. 15—Just as spectrum analysis has its counterpart in correlation or "time-domain" analysis, so spectrum vocoders have their counterparts in time-domain or correlation vocoders. This early version suggested by B. P. Bogert and the author, transmits signals in the time domain for reconstruction of the speech at the receiver.

Acknowledgment

The author wishes to express his deep appreciation to F. K. Harvey and M. R. Schroeder of the Bell Telephone Laboratories for assistance in securing reference material for this paper.

The History of Stereophonic Sound Reproduction*

JOHN K. HILLIARD†, FELLOW, IRE

Summary—**This paper reviews the history of stereophonic sound reproduction. It includes a comprehensive bibliography; the philosophical and psychological research on stereophony; methods used to make disc recordings and tape recordings on two channels; description of large auditorium motion picture systems for stereophonic effects; FM broadcasting of stereophonic programs on a multiplex basis and brief descriptions of pseudo-stereophonic reproduction systems for the home.**

INTRODUCTION

THE DEVELOPMENT of modern stereophonic sound reproduction in the home is generally represented as being recent. As shown by Offenhauser, (Reference Group A) however, it dates back to 1881, when two separate channels of telephone transmitters and earphones were used at the Paris Opera. G. W. Stewart spent years in research, and postulated in 1930, "The difference in phase is the important factor in determining the direction of sounds from 100 up to 1000 cps. Above this frequency, the intensity becomes a factor."

The reproduction of stereophonic sound thus had its foundations in the reproduction of "binaural" sound by telephone receivers worn on the head. The stereophonic reproduction of sound is preferably done on a high-fidelity basis. The groundwork for "hi-fi" reproduction may be found in the pioneering accomplishments of many scientists at the Bell Telephone Laboratories (Reference Group A), at the RCA Laboratories (Reference Group B) and elsewhere.

Stereophonic reproduction *per se* was pioneered almost simultaneously by Blumlein (Reference Group C) in Great Britain and at the Bell Telephone Laboratories (Reference Group D). Blumlein's contributions are presumed to be described in his patents. He showed a complete system applicable to sound-on-disc motion pictures, including microphone arrays utilizing bidirectional as well as omnidirectional microphones, transmission circuits, and disc recording systems utilizing simultaneous lateral and vertical recording. Economic difficulties are believed to have prevented completion and commercial exploitation of these systems.

The recognized early systems approach to large audience stereophonic reproduction was a public demonstration of Bell Telephone Laboratories equipment under the guidance of Dr. Harvey Fletcher on April 27, 1933. The Philadelphia Orchestra was in the Academy of Music in Philadelphia and it was reproduced in Constitution Hall, Washington, D. C. This was a three-channel system. The work was undertaken to evaluate a system which was capable of reproducing sound to a large audience and with a quality approaching "real performance." The basic equipment used is still at this

date a tribute to the knowledge and technique of that group.

Further improvements in the system were subsequently worked out, as illustrated, for instance, by a patent to Snow, (Reference Group D) showing a grouping of high-frequency loudspeakers in the middle and a separation of low-frequency speakers toward the sides; and a patent to Bogert, (Reference Group D) showing various refinements in two-channel film systems, including a phantom third channel having a loudspeaker positioned in the middle and having the audio signals transmitted to it through a time delay network.

Philosophical and Psychological Research on Stereophony

Various pseudo-stereophonic concepts have arisen. For instance, the frequency range has been divided into two parts, divided around 600 cps, and reproduced by laterally-spaced loudspeakers. This provides a novel effect, but cannot be depended upon for separating voices from music in a consistent manner. Another system is to divide the frequency range into two groups of alternate, narrow bands. This "comb filter" system is described by Schroeder, and relates to an earlier time-delay system by Lauridsen.

The early phase vs intensity concept stated by Stewart above has been highly refined. For instance, Hanson (Reference Group E) has demonstrated various relationships between the apparent position of a sound source reproduced by two laterally-spaced loudspeakers, including the effects of delaying the signal to one loudspeaker and of altering the intensity. Moushegian and Jeffress (Reference Group E) have presented data relating interaural time and intensity differences with laterality. The results indicate that time can be traded for intensity in the lateralization of low-frequency tones.

In general, it has been found that the direction from which a given sound appears to come is a function first, of the time of incidence and second, of the intensity. From this concept, Becker (Reference Group E) has developed a two-channel system in which all of the spectral information occurs in each channel, but in which the sound from selected sources, as on the left, is timed to occur first in Channel A, and after a slight delay of approximately 10 msec, occurs in Channel B; and the sound from other selected sources, as on the right, is timed to occur first in Channel B, and after a similar delay occurs in Channel A. Sources which are to be reproduced as occurring in the middle are timed equally in each channel. A stereophonic system is thus produced which is comparable with either of two monophonic systems, the latter being individually available for use through different reproduction channels such as AM and FM broadcasting.

The necessity for utilizing two separate low-frequency loudspeakers, rather than reproducing "lows" by a common loudspeaker located in the middle or at one side has been investigated by Beaubien and Moore (Reference Group F). It was found if the low-frequency reproduction were localized in one loudspeaker below, for instance, 300 cps, a considerable loss in stereophonic effect could be noticed; and that if it were localized below 100 cps, a significant loss could be detected. Their bibliography is exhaustive, containing 88 papers.

Optimum conditions for reproduction of stereophonic sound in the home have been thoroughly reviewed by Olson (References Group E). It was shown that listeners prefer full frequency range to limited frequency range under conditions of low distortion, similar to the case of monophonic reproduction. Other investigations, by Olson and Belar, include the application of "information theory" to a study of the "amount of information" which can be transmitted by a stereophonic record as compared to that for a monophonic record, with the conclusion that the amount of information is increased approximately 90 per cent (Reference Group E).

Disc Recording of Two Channels

The cutting of a disc record with both lateral and vertical undulations was described in the Blumlein patent, and other forms of such cutters and reproducers are shown, for instance, in patents to Harrison; Henning; and Keller and Rafuse (Reference Group G).

The original recording is generally made by the use of a considerable number of microphones, each with a separate tape sound track, without regard to the channel in which the information may ultimately be recorded. These tracks are subsequently edited and combined into two channels, which are finally recorded by a cutter such as that mentioned above.

The modern cutting of disc records has been engineered by Davis and Frayne, and their associates (Reference Group G). Two independent, highly-degenerated cutters are disposed at 45° to the surface of the record and controlled by the respective channels. The concept is to cut one side of the groove with the information of one channel and the other side with that of the other channel. The discs are usually released for $33\frac{1}{3}$-rpm reproduction.

For several years all of the master or original recording, both for tape and records, has been made with tape running at 30 inches per second to reduce the distortion and maintain a high signal-to-noise ratio. Under controlled conditions the noise level from the disc record base is lower than the noise from tape but after a few plays the impulse noise is greater than with tape.

Tape Recording Developments

Pre-recorded stereophonic tapes have been available in both two- and four-track types. At the present time, however, it appears that the four-track method will be universally used in the home field because of the economy in tape cost. When the linear speed of tape is maintained sufficiently high, the high-frequency response of tape can be maintained somewhat above that of the disc records.

SINGLE-UNIT LOUDSPEAKERS FOR HOME STEREOPHONIC

It would appear obviously desirable to reproduce stereophonic sound by a single-unit loudspeaker assembly. A compromise between two separate loudspeakers and a single assembly was patented by de Boer, in which two loudspeakers are mounted in front panels which are adapted to be slid laterally outwards from the main body of a cabinet (Reference Group H). In a later patent, de Boer shows two cone loudspeakers mounted in the side walls of a cabinet and having especially designed reflective doors, hinged at the rear corners of the cabinet, and being adapted to reflect at least the short wavelength sound from the respective cone loudspeakers. This can be made to operate with reasonable satisfaction, especially since the longer wavelength sound is reflected from the walls of a room and gives a diffused effect. The effective separation between the sound sources is, however, substantially limited to the distance between the midpoints of the doors.

A structure which gives wider apparent separation of the channels is disclosed in a patent to M. Camras. In this patent two cone loudspeakers are mounted in a cabinet and directed diagonally laterally outwards and towards a rear wall. Sound is reflected from the rear wall towards the side walls and from there towards the listening area. The effective separation of the loudspeakers is enhanced by the reduction in direct radiation toward the listening area due to their being directed somewhat rearward.

Another arrangement giving wide apparent separation has been described by Levy, Sioles and their associates. Two loudspeakers are mounted in the side wall of a cabinet, and doors are mounted on the front corners. When opened, the doors impede the propagation of sound from the cabinet directly to the listening area and thus increase the apparent separation of the sound sources. Sound is diffused toward the listening area by reflection from the side walls.

Still another arrangement providing wide apparent separation has been described by Bauer and Sioles. In this structure a labyrinth is located behind each of two laterally mounted loudspeakers by which the sound from each one is directed laterally outwards from the respective loudspeakers, and reaches the listening area by reflection from the side walls, as in the above systems. All of these systems are somewhat dependent upon the presence of walls at a reasonable distance from the cabinet, and are not adapted, for instance, to outdoor use.

The work of the Bell Telephone Laboratories ultimately was adopted for large motion picture theater production, beginning with Walt Disney's "Fantasia" in 1940, Cinerama in 1952, Cinemascope in 1953, and Todd-A-O systems in 1955.

These systems vary from the basic three-channel Bell system up to five basic and two derived channels for Cinerama. The derived channels are used for special "surround" or effects in other parts of the auditorium apart from the stage or channels directly associated with the picture on the screen.

On April 20, 1961, the Federal Communications Commission issued rules and regulations Docket #13506 to permit FM broadcasting stations to transmit stereophonic programs on a multiplex basis. The system is a composite of stereophonic standards proposed by the Zenith Radio Corporation and GE Company, respectively. Of the eight stereophonic systems submitted, the adopted system had standards capable of rendering as high a quality of service as the art can provide consistent with economic and other technical factors without significant degradation of the present monophonic FM service.

Many papers on pseudo-stereophonic reproduction indicated the stereo contribution can be restricted to less than the full frequency range normally required for high-quality transmission. However, the evaluation of the stereophonic FM broadcasting system clearly indicated contribution to the stereophonic beyond the 100 cycle to 8-kc band. The significance of the extreme frequencies to the stereophonic reproduction may increase in importance with the passage of time for two reasons:

1) Improvements in technologies may come about in the recording or reproducing processes to permit more of these high and low frequencies to contribute to the stereophonic effect.

2) Listeners may become more sophisticated relative to stereophony and require all available information.

Several proposals have been made for stereophonic broadcasting on an AM carrier but as of this date the FCC has not standardized this transmission.

ACKNOWLEDGMENT

The author wishes to acknowledge the generous work contributed by R. W. Carlisle in the preparation of this material.

AUTOMATIC CONTROL

Organized with the assistance of the IRE Professional Group on Automatic Control

Review of Control Developments *by John G. Truxal*

Automatic Control and Electronics *by Harold Chestnut*

Review of Control Developments*

JOHN G. TRUXAL†, FELLOW, IRE

Summary—**Control engineering, erected on the foundations of feedback theory and linear system analysis, brings together the fundamental concepts of communication theory, network theory, nonlinear mechanics, optimization theory, and statistical design theory. These various elements are combined in the modern research on adaptive control systems—research which provides the basis from which control theory contributes to system engineering and to the understanding of the behavioral, social, and biological sciences.**

ONE OF THE MORE significant technological developments during the first half century of the Institute of Radio Engineers has been the birth and explosive growth of the field of feedback control or automatic control. Providing the technical foundation for the development of both industrial automation and military guidance and control systems, the field of feedback control has produced such diverse accomplishments as the automatic control of the operation of a steel-rolling mill with the sheet steel produced at a rate of 30 mph, the automatic control of traffic lights in many of the major cities of the nation, the phenomenal terminal guidance characteristics associated with the modern infrared-homing antiaircraft missiles, and the guidance and control equipment permitting realization of both the desired orbit and the required attitude stabilization for the Tiros satellites.

From a technical standpoint, feedback control has built on the fundamental areas of network theory, communication theory, information theory, nonlinear mechanics, and finite mathematics. In the selection of basic analytical techniques from these various topics, feedback control has welded these diverse topics into a unified theory of lumped-parameter system analysis and design erected around the focal concepts of feedback theory and the properties associated with the existence of feedback. Thus, as control theory has developed over the past three decades and the control engineer has attacked more and more complex physical systems and more difficult phenomenological situations, he has drawn to an ever-increasing extent on the basic theoretical techniques developed by the applied mathematician and the electrical engineer.

Control engineering has also provided the strongest impetus to the accelerating cooperation and correlation among the different engineering disciplines. Control of a space vehicle can be achieved only through a joint effort of the aeronautical, chemical, mechanical, civil, and electrical engineers involved in the design of the vehicle structure, the design of the propulsion system, the packaging of the components and the realization of the electromechanical systems for construction of the required control operations. As a result of this strongly interdisciplinary character of feedback control, fundamental contributions to pneumatic and hydraulic control have been made by electronic engineers, to electronic system design by engineers of other specializations. The breadth of control engineering, represented by the strong interests of not only the IRE, but also such organizations as the AIEE, AIChE, ASME, ARS, ISA, and SAE, has been a primary influence in the gradual erosion of the barriers, academic and professional, which have so rigidly compartmented the various engineering fields.

The Birth of Feedback Control Technology

Although the basic principles of feedback control have been utilized in engineering equipment for many centuries, the modern intensive interest in control has

* Received by the IRE, October 11, 1961.
† Electrical Engineering Department, Polytechnic Institute of Brooklyn, N. Y.

evolved directly from the work on electronic feedback amplifiers by Black and Nyquist at the Bell Telephone Laboratories during the 1920's. In the development of repeater amplifiers for long-distance telephony, Black investigated[1] the relations between configuration and the sensitivity of the over-all transmission to changes in specific internal parameters. For example, the basic feedback configuration of Fig. 1 yields the following relations for T, the over-all transmission, and for S_x^T, the sensitivity of T to changes in a particular parameter x which is contained within the block G

$$T \equiv \frac{Y}{X} = \frac{G}{1 + GH} \qquad (1)$$

$$S_x^T \equiv \frac{dT/T}{dx/x} = \frac{1}{1 + GH} S_x^G. \qquad (2)$$

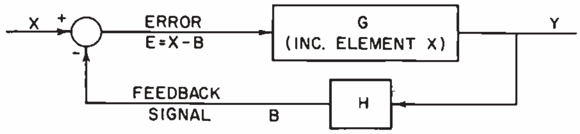

Fig. 1—Basic feedback configuration.

In the case of this simple, single-loop configuration, the sensitivity can be reduced to any extent desired if the designer is willing to accept a similar reduction in the over-all transmission; both functions are reduced by division by $(1+GH)$ as a result of the introduction of the feedback.

As soon as the essential property of sensitivity reduction is recognized as associated with the intentional insertion of feedback, the basic elements of feedback theory can be erected by consideration of other possible configurations in which similar results are achieved. For example, Fig. 2 displays two alternate configurations of slightly more complex structures in which sensitivity control is extended. System a) is designed to insert feedback around the feedback element H in order to reduce the sensitivity of T to changes in H. Configuration b) represents one realization of the advantages of a combination of the usual negative feedback (the G_cGH loop) and simultaneous positive feedback (the G_cG_mH loop). For this system

$$T = \frac{G_cG}{1 + G_cH(G - G_m)} \qquad (3)$$

$$S_G^T = \frac{1 - G_cG_mH}{1 + G_cH(G - G_m)} \cdot \qquad (4)$$

[1] Of particular interest as a retrospective view is the article by H. W. Bode, "Feedback—the history of an idea," *Proc. Symp. on Active Networks and Feedback Systems*, Polytechnic Inst. of Brooklyn, N. Y., 1961, pp. 1–18.

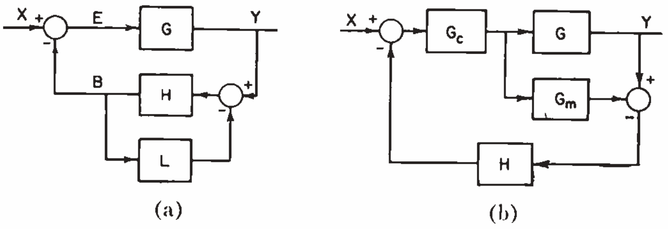

Fig. 2—Configurations for sensitivity control.

Hence, if G_m and H are selected so that $G_cG_mH=1$, the configuration realizes a zero sensitivity (or complete sensitivity control). Furthermore, if G_m is at least an approximate model of G, the over-all transmission is simply G_cG: the configuration is essentially an open-loop or nonfeedback system.

The effective removal of the feedback while still retaining sensitivity reduction is important because of the existence of the stability problem in the basic configuration of Fig. 1. As larger and larger values of the open-loop gain (GH) are utilized in order to realize smaller sensitivity functions, the system eventually exhibits uncontrolled oscillations (*i.e.*, instability). Following the presentation[2] of the Nyquist criterion (which establishes the relation between the transfer functions G and H and stability, and indicates experimental measurements on G and H to determine stability before the loop is closed), the highly developed techniques of equalizer design and network theory were applied to the development of methods for the design of compensation networks to stabilize feedback amplifiers[3] and then feedback control systems.[4]

In the same pattern characterizing so much of electronic engineering, the field of feedback control came of age during the rapid technical developments of World War II, particularly with the strong emphasis on the accelerated development of equipment for the control of radar antennas, antiaircraft turrets, and jet engines. During the early 1940's, the Nyquist-Bode-Hall techniques for design were fully developed, while at the same time a variety of new techniques were introduced which shaped the direction of control developments during the intervening 15 years and which provided the groundwork upon which modern control research was erected.

The awakening recognition of the importance of feedback control around 1940 is epitomized by the establishment of the Institute of Automatics and Telemechanics, in Moscow in 1939, the birth of the Servomechanisms Laboratory under G. S. Brown and the Instrumentation Laboratory under C. S. Draper at Massachusetts Institute of Technology, and the growth (during the

War) of control activity in such locations as the Naval Research Laboratory, the Bell Telephone Laboratories, and the M.I.T. Radiation Laboratory. The impact on engineering education was not particularly noteworthy until just after the war, when control suddenly emerged as a primary field of both undergraduate and graduate interest.[5]

The Bases of Modern Control Theory

Largely as a result of this emphasis on control engineering during the 1940's, control theory involved significant portions of a wide variety of basic theoretical disciplines. As a consequence, modern control theory combines viewpoints and analytical and scientific techniques from many different areas, with perhaps the most important being:

1) Network theory
2) Feedback theory
3) Sampled-data theory and computer science
4) Nonlinear mechanics
5) Statistical design theory
6) Communication theory
7) System engineering theory.

In all of these areas, the intensive control research efforts have yielded interrelated developments which, viewed together, constitute the current status of control theory.

The work on *network theory*, previously stimulated and guided by the activities of the IRE Professional Group on Circuit Theory, has provided the theoretical foundation for the design of compensation and stabilization networks for feedback systems. The extensive development of network synthesis techniques by E. A. Guillemin[6] and his colleagues and the subsequent work on the realization of active networks for specified transfer functions have provided the basis for the realization of open-loop dynamic characteristics (*e.g.*, the open-loop transfer function $G(s)H(s)$ in Fig. 1) which correspond to an over-all feedback system which simultaneously satisfies the stability and sensitivity requirements, or such subsidiary and equivalent requirements as the ability of the system to reject corrupting signals entering at points other than the primary input.

Closely coupled with the research on the design techniques for the transfer elements constituting the over-all system, has been the work on *feedback theory*, the relation between the feedback configuration and the properties of the system. This work has grown from the original contributions of Black and Bode to an extensive body of knowledge centered around the concept of signal flow graphs as originally introduced by Mason.[7] The modern, complex weapon or industrial control system often involves a multitude of feedback loops, each involving transfer functions of high order. Feedback theory is concerned with the properties which can be associated with such a configuration, first by virtue of the configuration alone, then as a consequence of the nature of the specific transfer functions within that configuration. For example, a fundamental problem[8] in feedback theory is the determination of the extent to which a given parameter can change without causing instability of the system. The solution is found in an appropriate manipulation of the sensitivity of the transmission with respect to that parameter: an algebraic manipulation which is determined by the form of the feedback configuration around the element. Once this analysis problem is solved, the same techniques can be utilized to design a system in which the sensitivity of the stability to a particular parameter is controlled both by the choice of an appropriate configuration and by the selection of suitable transfer functions within that configuration.

Sampled-data theory and digital techniques[9] provide a close correlation between control theory and both computer technology and communication theory. As, over the last two decades, the specifications on control problems have become more stringent concurrent with the development of small-size, high-speed digital computing equipment, more and more of the control systems for both military and industrial applications incorporate a digital computer as one element of the control system, as indicated by the block diagram of Fig. 3. Here the analog error signal is modified by the active network with the transfer function $G_c(s)$ in order to obtain the analog signal $m(t)$. This $m(t)$ is sampled, quantized, and coded in the analog-digital converter, then modified by

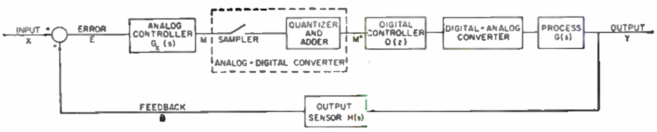

Fig. 3—Simplest computer-controlled feedback system.

[5] The full academic impact was not felt until after the publication of the first basic textbooks in the field: G. S. Brown and D. P. Campbell, "Principles of Servomechanisms," John Wiley and Sons, Inc., New York, N. Y., 1948; L. A. MacColl, "Fundamental Theory of Servomechanisms," D. Van Nostrand Co., Inc., New York, N. Y., 1945; H. Lauer, R. Lesnick, and L. E. Matson, "Servomechanism Fundamentals," McGraw-Hill Book Co., Inc., New York, N. Y.; 1947.

[9] H. M. James, N. B. Nichols, and R. S. Phillips, "Theory of Servomechanisms," MIT Radiation Laboratory Series, vol. 25, McGraw-Hill Book Co., Inc., New York, N. Y., 1947; J. R. Ragazzini and G. F. Franklin, "Sampled-data Control Systems," McGraw-Hill Book Co., Inc., New York, N. Y., 1958; C. T. Leondes, "Computer Control Systems Technology," McGraw-Hill Book Co., Inc., New York, N. Y., 1961.

the digital program $D(z)$ which yields an output number series related to the input number series $m^*(t)$. Following the digital-analog converter, the signal is utilized to actuate the output member or process being controlled. By insertion of the digital computer, the control system designer achieves the possibility of much greater flexibility in the transfer characteristics of the controller element, the potentiality of readily altering the controller program in order to automatically take into account changes in the environment or in the nature of the signals, and the possibility of programming entirely separate controller instructions for different operating conditions (*e.g.*, for start-up, shut-down, normal operation, and operation under temporary heavy overload). In addition, in many applications, the computer controller can be time shared for the simultaneous supervision of a variety of distinct control operations.

The field of *nonlinear mechanics* has provided the background for the development of nonlinear control theory,[10] a field in which the contributions of Russian control engineers have been particularly notable. By far the most important contribution in this area was the development of the describing-function approach for quasi-linearization,[11] in which a two-port nonlinear element is represented by an equivalent transfer function (or describing function) dependent upon the amplitude of the sinusoidal signal which is applied to the nonlinear device. In the analysis of the system described by the nonlinear differential equation

$$y'' + (3 + 2y^2)y' + 4y = x, \quad (5)$$

the equation is represented by the block diagram of Fig. 4. If the signal y at the input of the cubic element is assumed sinusoidal, the output contains the fundamental plus all odd-order harmonics. To an approximation sufficiently accurate for the majority of cases of control system design and evaluation, only the fundamental component of y^3 need be retained, and the system can be analyzed (for a single amplitude of the sinusoidal signal y) as a linear system only (the gain of the nonlinear block is the complex ratio of the amplitudes of the output and input sinusoids).

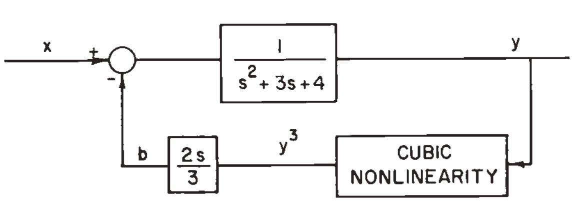

Fig. 4—Elementary nonlinear feedback system.

Perhaps the most significant work in control theory to evolve from the research efforts during the Second World War was the basic study on the design of optimum linear systems for the processing of *random signals.* In this work which was originally carried out by Wiener in studies of the antiaircraft fire-control problem,[12] several new concepts were introduced which have become of fundamental importance to the control engineer:

1) The utilization of correlation functions and numerical correlation techniques for the measurement of power density spectra of the signals which must actually be processed by the control system, rather than design on the basis of test signals such as the sinusoid or the step function.

2) The measurement of the transfer dynamics of a linear system by crosscorrelation of the input and output signals when the input is white noise (a measurement technique which provides the possibility of the measurement of industrial processes during operation and without disrupting the system for long periods of time).

3) The determination of optimum predictors and optimum filters as bases for the evaluation of the quality of performance of conventionally designed control systems.

Unquestionably, the primary result of this research was the entirely novel viewpoint which was introduced into control system design:-a viewpoint which encompassed recognition of the problems associated with the mathematical characterization of the actual signals upon which the system is to operate, and a viewpoint which represented a significant departure from the constraints imposed by the strong electronic engineering tradition of ac circuit analysis. Closely related to this work on the optimum design of linear systems is the more recent and as yet unapplied development by Wiener on the characterization of nonlinear processes through excitation by random signals.[13]

The aspects of *communication theory* which have been of particular interest to the control engineer are, in addition to statistical design theory, those which provide the bases for the evaluation of the ability of a system to transmit specified input waveforms with high fidelity, and those which are concerned with techniques for the identification problem, both signal identification (measuring the significant parameters such as the spectrum distribution of a given signal) and process identification (evaluation of an appropriate mathematical model for a physical system or subsystem). As an example of the former area of interest, the feedback control engineer is

involved with the design of the electronic feedback system for the control of the intermediate-frequency in a high-quality radar receiver: an operation which involves both frequency stabilization of the local oscillator and automatic compensation for Doppler frequency variations. The resulting feedback loop, involving frequency measurement equipment, limiter, and band-limited subsystems, poses a major feedback control problem which includes nonlinear theory, statistical design theory, electronic circuit theory, and the conventional control system evaluation and design theory.

The identification problem, one of the most important foci of modern control research, encompasses signal characterization in order to guide system design (*e.g.*, if the input signal can be represented as a finite sum of generalized exponentials, the sensitivity can be made zero at the corresponding natural frequencies without making the loop gain infinite over the sinusoidal frequency band of interest. Thus a zero-sensitivity characteristic can be achieved without the stability problem usually associated with systems involving both positive and negative feedback). Alternatively, signal characterization is required when the control system is to yield optimum performance in spite of specified power or saturation constraints or nonlinearities, in order that the controller characteristics may be changed automatically when the signals vary.

The second phase of identification is that of model evaluation: the determination of pertinent characteristics of the process which is to be controlled or other elements of the system. Successful design of a control system such as indicated in Fig. 3 requires that the engineer know at least approximately the dynamic transfer characteristics of the process G. For this purpose, extensive test procedures have been developed and extended by control engineers, including various techniques derived from impulse testing, crosscorrelation techniques requiring the addition to the process input of white noise uncorrelated with the primary input signal, and sinusoidal testing methods, based upon the measurement of the transfer function or describing function. The determination of the transfer function or the impulse response from normal operating records of the input and output signals is one of the key problems blocking the installation of automatic control equipment in industrial applications or the improvement of control equipment for military purposes. Past work by communication and control engineers in this area has centered on techniques for evaluating the amount of data required for a specified accuracy in the power density spectra,[14] investigation of the time required for measurements,[15] the utilization of matched filter techniques in such measurements,[16] and fundamental methods for the characterization of systems.[17]

Finally, control theory has built upon and utilized the applied mathematical work in the field of finite mathematics, in particular *statistical decision theory* and *dynamic programming* methods. The concept of dynamic programming provides an exceptionally powerful approach to a broad class of optimization methods,[18] when such problems can be visualized as multistage decision processes. Within the range of such problems fall the control engineering investigations of methods for the solution of terminal control problems (in which the only measure of the success of the control is the error at the end of the flight or the end of the control task), particularly when the control system is subject to constraints on quantities such as the total fuel consumed during the interval of control action. In more general terms, Kalman has made fundamental contributions[19] in the relation between the degree of controllability which can be achieved and the extent to which the state of the process can be accurately measured, as well as in the development of mathematical solutions to a broad class of optimization problems.

Concluding Comments

Thus, the control field is built upon the basic theoretical disciplines described briefly in the preceding paragraphs, with the different concepts and viewpoints focussed on the properties, design techniques, and evaluation methods of feedback control systems. Coupled with this theoretical foundation is the extensive development during the past two decades of continually improved control components, ranging from gryoscopic equipment for inertial navigation systems to hydraulic and pneumatic controllers for power amplification; from electronic circuits designed for improved reliability by the logical utilization of redundancy and self-checking techniques developed so extensively by the digital computer engineers to mechanical-electric transducers permitting the measurement of ever smaller displacements, pressures, velocities, accelerations, and temperatures in order to permit increasingly close control over the performance of physical equipment. Indeed, to a very considerable extent, major advances in control engineering are far more often associated with breakthroughs in component development than with the evolution of improved theories or design techniques. the component technology progresses toward greater accuracy, better resolution, improved reliability, and smaller weight and size, the theory which underlies the field draws on associated areas (such as network theory, communication theory, and applied mathematics) to expand continually the viewpoint of the control engineer and to encompass an ever wider range of fundamental problems.

The current status of control engineering is perhaps best exemplified by the extensive work throughout the world during the past three years in the development of adaptive control systems, systems in which the controller is automatically adjusted to compensate for changes in the signals, the environment, or the process which is being controlled. Fig. 5 shows one possible block diagram of a general adaptive control system,[20] in which measurement of the process and identification of the input signals are combined in a computer with information about the environment and knowledge of the performance criterion (the mathematical basis upon which performance is to be measured). The computer, which in the general case includes learning in order to improve system performance with usage, determines the optimum form for the controller, which is then realized by the adjustment elements. Thus, a system of this form maintains optimum performance in the presence of variations in the process, the environment, and the signals.

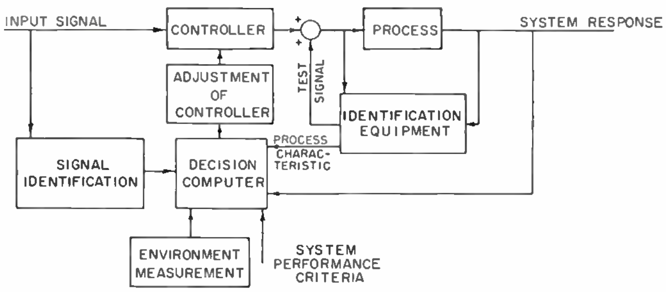

Fig. 5—Basic configuration for adaptive control.

Current research efforts are to a large measure centered on the various aspects of the design of a system such as that indicated in Fig. 5: the problems associated with identification; the problems related to the stability analysis of the nonlinear, adaptive loop involving the process, the controller, and the computer; the questions concerning the evaluation of various possible types of mathematical performance criteria; and the development of simple, feasible realizations of the concepts which are represented here.

Simultaneously, the control field is witnessing a major effort in the expansion of the fundamental concepts of feedback control to the study of related problems in the fields of physical science, social science, biological science and behavioral science. For example, feedback control theory and the related mathematics of systems engineering form a key element of the rapidly changing field of industrial engineering, with emphasis on the development of models for economic situations and the application of basic decision theory to such systems.[21] As a final example, the basic principles of feedback control are being utilized in the study of animal and human operations, as attempts are made to construct logical, feedback models representing the terminal characteristics of various biological organs.

Control engineering, in 1962 a middle-aged element of electronic engineering in the presence of the elderly discipline of communication engineering and the youthful field of solid-state devices, thus provides an essential element of technological developments which can be anticipated during the next half century of the IRE in both the industrial and the military fields.

Automatic Control and Electronics*

HAROLD CHESTNUT†, SENIOR MEMBER, IRE

Summary—**The past fifty years have seen the automatic control and electronic fields come close together and form an effective means for increasing man's productivity and his ability to control energy and materials. By extending automatic control concepts to new processes, by developing more flexible controls capable of changing their characteristics to optimize performance of the process being controlled, and by increasing the capability of the sensing means in difficult environments, man will be able to make even more effective his ability to control automatically in the years ahead.**

Electronics is increasingly able to provide physical means for providing the realization of automatic control principles and concepts. Increasing effort to achieve reliable electronic automatic control means must be continued in the years ahead to make possible the realization of the promised gains indicated by the automatic control theory. In addition, more use should be made of standardized design ranges of electrical and mechanical features so that all automatic control equipment can be made in less time and at a lower relative cost. The future appears bright for expanded use of automatic control and electronics as we look ahead for the next fifty years of the IRE.

IT IS SIGNIFICANT that on the occasion of the 50th Anniversary of the IRE, we think of Automatic Control and Electronics as being closely related. Today, automatic control has much of its technical structure firmly based on the same foundation of theory that was developed originally for electronic communications. A large proportion of automatic controls whether they be for the control of energy processes, materials processes, or information processes are electronic in nature. Further, the design, fabrication, and test of automatic controls are heavily dependent on the use of electronic computers both analog and digital.

In a somewhat parallel relationship, many of the applications of electronics are now considerably improved or enhanced by automatic control of such factors as voltage, frequency, or gain. Precision and high-speed fabrication methods for electronic devices and equipment are greatly facilitated by automatically controlled means of manufacture. In addition, many of the logic operations and other judgment criteria now being used more extensively for automatic control have served to make possible or increase the effectiveness of communication means such as automatic long-distance telephones and scatter transmission. Truly, the relationship between automatic control and electronics has developed into one that is most fruitful and mutually advantageous. Through use of some similar components these two fields have been able to capitalize to a certain extent on one another's practical developments, measurement equipment, and fabrication techniques.

* Received by the IRE, July 26, 1961.

† General Engineering Laboratory, General Electric Company, Schenectady, N. Y.

Developments During Past Fifty Years

At the same time of the inception of the IRE in 1912, however, neither electronics nor automatic control were terms that existed in the present sense of the words. It was essentially in the period of the 1920's and 1930's that these terms began to come into use, but the fields of engineering and science they represented tended to operate quite independently of each other.

Electronics in its early days was oriented largely in terms of its contribution to the higher frequencies of the communication and radio industries and operated in a physical environment that was in some respects more controlled and less rigorous than was that experienced by automatic control equipment used in heavy industry. However, as one reads the early IRE Proceedings in the 1913–1915 era, one has the feeling that environmental facts such as the vagaries of the transmission path for RF energy represented highly nonlinear and time-varying phenomena that are similar to those which challenge today's adaptive control.

Automatic control had its background in the speed regulation of steam engines and other power devices. As such, it was initially concerned with the control of high-energy processes of relatively slow operating speeds operating in strenuous environments which might experience high vibration and shock. Because of the high value of the equipment or material over which it exerted its influence, automatic control from its early days was forced to face high reliability requirements. With its lower signal levels and energy implications, electronics reliability requirements were initially less demanding but have grown to be very demanding because of the high military importance of electronics. Gradually, over the years electronics and automatic control have blended their interests and now share many common problems.

Tying Together of Automatic Control and Electronics

The 1930's saw the development by Nyquist,[1] Black,[2] and Bode[3,8] of the frequency response concept of feedback amplifiers for use for communication purposes. By

[1] H. Nyquist, "Regeneration theory," *Bell Sys. Tech. J.*, vol. 11, pp. 126–147; January, 1932.

[2] H. S. Black, "Stabilized feedback amplifiers," *Bell Sys. Tech. J.*, vol. 13, pp. 1–18; January, 1934.

[3] H. W. Bode, "Amplifiers," U. S. Patent No. 2,123,178; 1938.

the early 1940's the automatic control engineers spearheaded by Brown,[4,5] Hall[4,6] and others, began to embrace this method of analysis and design for feedback control system design. Wiener,[7] Shannon and Blackman,[8] and others during World War II tackled prediction and control problems in terms of communication and signal concepts and the intrinsic similarity between communication and control problems began to be established.

It was during the 1920's that the initial emphasis took place on making the electronic tubes then in use rugged enough for the industrial and military environments that would be encountered in many automatic control applications. The possibilities of using electronic tubes as part of the automatic controls for industry were attempted in a limited fashion prior to 1940. However, it was the military requirements of the early 1940's with the increased need for speed and accuracy that provided the greatest impetus for the wedding together of automatic control and electronic ideas.

Post War Developments

The emphasis on servomechanisms[9] and linear control theory during and immediately after World War II was followed by an effort to analyze nonlinear and sampled-data controls. The work of Kochenburger[10] on the describing function has been most helpful in understanding and designing nonlinear systems. In the field of sampled-data controls, Ragazzini,[11,12] Zadeh,[11] Franklin,[12] and later Jury[13] and Tou[14] have done much to clarify the basic analytical appreciation of this phenomenon so important to time-shared controls that are required by electronic digital computers. Truxal's[15] work in bringing together these various analytical methods into a clear perspective has been most helpful.

The widespread use of practical electronic computers, first analog in the 1940's and later digital in the 1950's, has greatly extended the control-systems engineer's analytical ability to understand and design automatic control systems. At the same time, some control systems were being built in which electronic computations were performed as part of the actual control process. The internal logic and control needs, such as floating decimal point and time sharing within some digital computers, have pointed the way to control principles that have been used for automatic controls quite apart from their computer contexts. In similar fashion to the electronic automatic gain control used since the early days of radio, the concept of variable gain or other adaptive controls has in the 1950's found its way into increasing control usage.[16]

Electronics in the form of radar or sonar had been developed during World War II to provide input, detection, and tracking signals for automatic search, ranging and tracking systems. As time has gone on, more extensive use is being found for electronic means of sensing in instrumentation systems both for display purposes and for inputs to automatic control systems. The high-speed, noncontacting aspect of electronic sensing as well as its capability of measuring certain quantities, as for example by X-ray or nuclear magnetic resonance, provide control with capabilities that it might otherwise not be able to attain. The recent development of analytical instruments making extensive use of electronics is providing still further tools with which to increase the capability of automatic control in the chemical and petroleum fields.

Present Status

Gradually, from this evolutionary blending of control, communication, computation, and instrumentation through the common concept of information as influenced greatly by the common medium of electronics, there is taking shape a new grouping of ideas and equipment that is variously called automatic control, instrumentation, or information processing. The basic building blocks of this new automatic control include the functions of sensing, converting, programming, communicating, regulating, computing, storing, actuating, and display as described in Table I.[17]

In the past there has been a considerable effort on individual systems designed to perform the automatic control functions indicated in Table I, and there will continue to be emphasis to improve such equipments.

TABLE I

TABLE OF DEFINITIONS OF BASIC AUTOMATIC CONTROL OR INFORMATION CONVERSION FUNCTIONS

Function	Definition or Explanation
Sensing	Generates primary data which describe phenomena or things.
Converting	Changes data from one form to another to facilitate its transmission, storage or manipulation.
Storing	Memorizes for short or long periods of time data, instructions, or programs.
Communicating	Transmits and receives data from one place to another.
Computing	Performs basic and more involved mathematical processes of comparing, adding, subtracting, multiplying, dividing, integrating, etc.
Programming	Schedules and directs an operation in accord with an over-all plan.
Regulating	Operates on final control elements of a process to maintain its controlled variable in accord with a reference quantity.
Actuating	Initiates, interrupts, or varies the transmission of power for purposes of controlling "energy conversion" or "materials" conversion processes.
Presenting	Displays data in a form useful for human intelligence.

At present, however, there is increasing emphasis on the understanding, design, and installation of increasingly complex systems that are a combination of a number of such equipments. The stability, performance, cost, reliability and maintainability of such systems are facets of concern for present-day automatic control activities. Such efforts represent one of the important directions in which automatic control work is proceeding.

National and International Cooperation

A recent interesting development in the organization of people and technical societies interested in automatic control has been the closer association of such individuals and groups on a national and an international basis. Because automatic control embraces such varied equipment as pneumatic, hydraulic, mechanical, electrical, as well as electronic devices and includes instruments, computers, regulators, and many other control means, the American Auotomatic Control Council (AACC) was formed in 1957 to represent the five major American technical societies interested in automatic control in the International Federation of Automatic Control (IFAC) which was also founded in 1957. In addition to the IRE, represented by the Professional Group on Automatic Control, AACC includes the American Institute of Electrical Engineers, the American Society of Mechanical Engineers, the American Institute of Chemical Engineers, and the Instrument Society of America. Through AACC, American control engineers are able to broaden their areas of interests to include a great number of fields of application of automatic control as well as to consider alternate physical means for accomplishing any given desired result. The benefits to be gained by having access to information on the developments in automatic control from all over the world are significant. Such increased technical contacts can do much to accelerate the future development of automatic control in the years ahead.

NEW AREAS OF CONTROL DEVELOPMENT

As we look to other ways in which automatic control developments are progressing, there are a number of encouraging activites taking place. Included in these are:

1) More extensive use of automatic control concepts in new fields where they have not been used to any appreciable degree.
2) Use of more flexible controls through the application of adaptive control concepts and including such means as self-learning or automatic optimizing.
3) Development of new and better sensors capable of measuring more quickly and accurately quantities that will be helpful to new controls.

New Fields

Some of the new fields where automatic control principles have not been used extensively, but appear to hold considerable promise, include the business and economic fields, the social, biological and political fields. Forrester[18] and others working in the field of industrial management have been able to develop dynamic models of individual businesses or industries and have shown the effects of feedback and various strategies on the stability and speed of response of such economic systems. The recent formation of many new countries and the development and growth of many existing ones are being considered from their possibilities of control even though the degree of automatic control is perhaps quite minor at present.

The possibility of using information, sensing, and control concepts to study social, biological, and even political situations is being tried to a limited extent. Data obtained here should be of value to automatic-control people in developing new general control concepts such as self-learning as well as for their value in developing control ideas for specific processes of these types. Uses of automatic control in the form of heart-pacers, synthetic limb controls, and medical operating aids are indicative of some of the directions which automatic control may develop. The use of over-all hospital information systems is another application of automatic control into the biological-social area.

Fig. 1 shows how information conversion is being

[18] J. W. Forrester, "The Impact of Feedback Control Concepts on the Management Sciences," The FIER Distinguished Lecture 1960, FIER, N. Y.; 1960.

used in conjunction with energy and/or materials processes to an increasing degree. Recent activities in the chemical and petroleum industry have been directed at the determination of the dynamic characteristics of the processes themselves and the most effective methods of controlling them. Significant cost reductions appear to be possible by more automatic *control of systems of such variables rather than of fixed control of the individual variables themselves.*

Experiences in the steel and electric utility industries are beginning to supply actual data from advanced automatic control systems involving control of materials, energy, and information as indicated in Fig. 2. In addition to the conventional automatic control shown by the solid lines, programmed inputs are supplied by the programmer, information about the actual performance of the process are recorded by the data logger, and modified inputs to the reference are determined by the computer operating on- or off-line. The need for extensive automatic control in such advanced energy processes as nuclear fission, magneto-fluid dynamics and power generation in space also represent new challenges to the control field.

An important aid in the application of automatic control in new fields will be the development of appropriate models for representing in a space-time sense the phenomenon taking place in the "process." These models must be quantitative to be most effective but the application of automatic control principles may make it possible for somewhat inexact or approximate models to be employed.

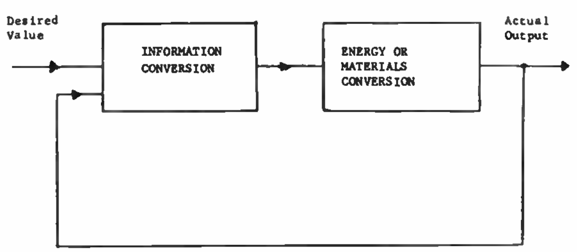

Fig. 1—Control system showing interrelationship of information, energy and materials conversion.

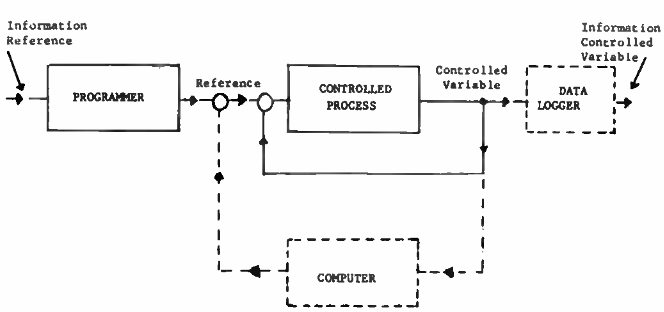

Fig. 2—Combined feedback control and information conversion system.

More Flexible Controls

The efforts at controlling such variable parameter processes as supersonic flight including that of space vehicles or combined materials and energy processes have highlighted the need for more flexible or adaptive controls. Fig. 3 serves to illustrate how changes in the character of the process being controlled can be used to provide an input to an adaptive control which in turn serves to modify the principal control of the process. Other forms of adaptive control use sensing and identification of the reference input or of the actuating error itself to provide a basis on which the adaptive control operates. Increasing sophistication, including extensive computation, is taking place in both the criteria being used as a basis for identifying the nature of the process as well as the nature of the changes that are made to take place in the principal control itself. Additional effort is required to provide a clear analytical understanding of the stability and performance phenomena of such highly nonlinear, time-varying, dynamic control systems.

Fig. 4 serves to illustrate the nature of the multivariable form of the adaptive control problem. By virtue of changing environments as well as the inherently nonlinear nature of the process itself, the control may be faced with the need for changing its logic and strategy in a fashion that can be only generally stated by the automatic control designer. Such controls need to possess a self-learning capability in which their characteristics are allowed fairly broad latitude if the process is so poorly known initially as to provide relatively little information to the designer. Based on quite general design criteria for acceptable performance, the control will use its memory as well as logic rules and endeavor to learn from its experience. By modifying its

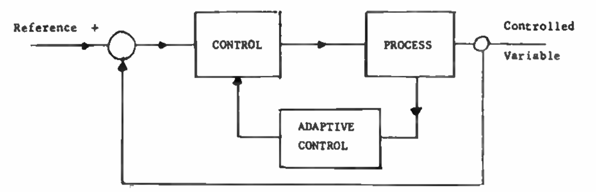

Fig. 3—Adaptive controls sought for processes which are not linear, constant, or fully known.

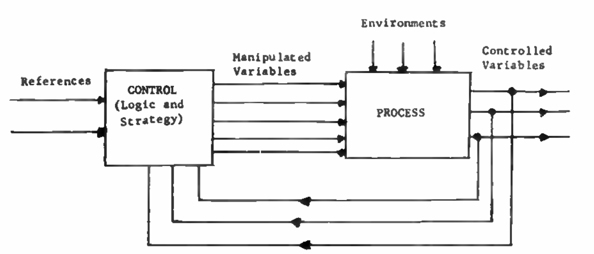

Fig. 4—More processes are multivariable with poorly controlled environments.

characteristics it will try to improve its performance in terms of some initially-agreed-upon objectives.

A variation of this problem is found in the information field itself where pattern or character recognition problems may possess a similar lack of definition for some information processes in their initial stages. Another form in which flexible adaptive control may prove increasingly effective is in the area of automatic design optimization. With engineering efforts representing a larger portion of the cost of producing new products and systems, more extensive computer methods for performing engineering evaluations are being employed. The expansion of control concepts of optimization more broadly to design[19] represents an attractive field for more flexible automatic-control concept application.

New Sensors

Paramount to the solution of any automatic control problem is the ability to sense the conditions that exist in the process. Although modern control theory is firmly based on the assumption that an adequate measure of the variables being controlled can be obtained, there are a number of materials and energy processes where sensors capable of making such measurements are not available. As Lord Kelvin has stated so well, it is necessary to measure things quantitatively in order to be able to understand and control them. Physical and chemical composition measurements in high and corrosive atmospheres are illustrative of specific problems in the sensor area. New analytical instruments capable of accurate and rapid measurements and suitable for on-line control applications will do much to further the usefulness of automatic control. Although creative thinking in conceiving new measurement concepts will be valuable, the development of new electronic components to operate in unfavorable environments such as these will also be very beneficial.

Associated Needs for Continued Control Progress

Accompanying the developments in the better understanding and broader application of automatic control, there exist associated needs for improved components and equipment to provide the means for accomplishing automatic control more reliably, quicker, and at lower relative cost. It is here that continued electronic development can be most effective.

Reliability[20]

The vast amount of work done in the past fifteen years on the reliability of electron tubes and their associated electronic components has resulted in marked electronic circuit improvement over the years and doubtless improvements will continue to be made. More extensive use of ceramic or relatively inert materials accompanied by strict observance of sound mechanical design principles have pointed the way to more reliable electronic and automatic control equipment. Conservative electrical designs in the sense of using components at operating conditions well below the design limits have likewise shown that improved reliability can be obtained.

The development of transistors and general solid-state electronics has provided smaller, lighter, and lower-power-consuming devices capable of high reliability that are finding increasing use in automatic control equipment. Certainly, the weight, size, and reliability needs in space vehicle control have emphasized the desirability of these miniature electronic devices. The possibility of micro-electronics for control in space appear to offer further advantages if the predicted reliability can be realized and adequate means for automatic controlled manufacture can be achieved at reasonable cost. Present thinking would seem to indicate however, that in the industrial area the need for extremely small size is not as important as high reliability and low cost.

Accompanying the efforts to improve the reliability of individual electronic elements or groups of elements, further emphasis is required in the judicious use of redundancy, fail-safe features, and/or other system means for providing over-all reliable operation. The large amount of electronic automatic control equipment currently being utilized in many industries and the large economic investment in processes being controlled automatically emphasize the present and future needs for automatic control of appreciably higher reliability.

Standardized Designs for Reduced Cost and Time

In many cases automatic control equipment has been designed from a custom-design point of view. Since the energy or materials portion of the system, *i.e.*, the controlled process, tended to be unique with each installation, the automatic control tended to be designed and tailored to the installation needs. This has resulted in the time required to produce automatic control being longer than if more standard control components were used. It is appropriate that increasing efforts be made to work toward a more standardized approach of automatic control system design in which appropriate voltage, frequency, impedance and power levels are established broadly across the control industry so that compatible components may be interconnected directly to a greater extent.

Compatible design should be directed toward achieving a greater measure of over-all electrical and mechanical uniformity for subassemblies and equipments so that shorter equipment delivery times can be realized and the cost for engineering and manufacturing per

[19] E. L. Harder, "Computers and automation," *Impact of Sci. on Soc.*, vol. 1, pp. 3–15; 1960.

[20] "Reliability of Military Electronic Equipment Report," Advisory Group on Reliability of Electronic Equipment (AGREE), U. S. Govt. Printing Office, Washington, D. C.; 1957.

individual equipment can be reduced. Automatic control and electronics are still changing at a sufficiently high rate that it does not appear appropriate that rigid standardization be introduced at this time. However, the rapid spread in the use of digital and logic control methods and the extensive use of transistor circuitry point up the desirability of having equipment with common characteristics for such electrical features as voltage level, impedances, and frequency in a number of ranges. By this means, fewer engineering designs and associated manufacturing fixtures will be required and more time and effort can be devoted to making sure the equipment is reliable and of suitable quality and performance. Industry efforts presently being undertaken in this direction should be strengthened and advanced more rapidly. With more compatible components the desirable objectives of reliable automatic control can be obtained more quickly and more cheaply.

Conclusions

The past 50 years have seen the automatic control and electronics fields come close together and form an effective means for increasing man's productivity and his ability to control energy and materials. By extending automatic control concepts to new processes, by developing more flexible controls capable of changing their characteristics to optimize the performance of the process being controlled, and by increasing the capability of the sensing means in difficult environments, man will be able to make even more effective his ability to control automatically in the years ahead.

Electronics is increasingly able to provide the physical means for the realization of automatic control principles and concepts. The increasing effort to achieve reliable electronic automatic control means must be continued in the years ahead to make possible the realization of the promised gains indicated by the automatic control theory. In addition, more use should be made of standardized design ranges of electrical and mechanical features so that automatic control equipment can be made in less time and at a lower relative cost. The future appears bright for expanded use of automatic control and electronics as we look ahead to the next 50 years of the IRE.

BROADCAST AND TELEVISION RECEIVERS

Organized with the assistance of the IRE Professional Group on Broadcast and Television Receivers

The Development of the Art of Radio Receiving from the Early 1920's to the Present*

WILLIAM O. SWINYARD†, FELLOW, IRE

***Summary*—A brief résumé of important scientific discoveries leading to radio broadcasting is given. There follows a discussion of the most important types of home broadcast radio-receiving circuits which came into use after the advent of entertainment broadcasting. These circuits include crystal receivers, regenerative receivers, neutrodynes and superheterodynes. Attention is also given to the development of automatic volume control, automobile radios and FM receivers.**

An effort has been made to present the developments chronologically with attention primarily being given to the work of leading pioneers.

In the final part of the paper some of the more important innovations in the radio-receiving art are mentioned and, in some cases, briefly discussed.

Introduction

THE radio-receiving art owes a great debt to early pioneers—Ampere, Henry, Faraday, and, more specifically, Maxwell and Hertz. Credit is due Maxwell for mathematical studies which led to his electromagnetic theory of light and his prediction of the existence of electromagnetic waves of relatively low frequency, and Hertz for being the first to produce them—in 1887, some 25 years later.

The first crystal detector was designed in 1906 by Pickard. It consisted of a silicon crystal and a cat whisker. At about the same time Dunwoody developed a detector using a carborundum crystal clamped between two brass holders. In 1883 Edison, in seeking the cause of blackening of lamps, discovered current flow inside a vacuum tube. This led to the invention of the vacuum diode, the "valve," by Fleming in 1904 and to the invention of the triode vacuum tube, the "audion," by de Forest in 1907.

However, the triode remained a rather unsatisfactory device until 1912 when H. D. Arnold recognized that its imperfections stemmed largely from its defective vacuum and the use of a tantalum, instead of an oxide-coated filament. He improved the vacuum and Wehnelt invented the oxide-coated filament. With the removal of these shortcomings the triode became the cornerstone of modern radio communications.

At the conclusion of World War I many former radio amateurs, "hams," returned to civilian life with a keen interest in radio. This interest was greatly sharpened by the awareness of these men of the radio developments of the day. They, along with an ever-increasing number of other hams, became an enthusiastic group of potential radio listeners.

In 1920 F. Conrad of Westinghouse converted his amateur wireless station, which he built in 1916, to radiotelephony and returned to the air. He announced regular two-hour broadcasts on Wednesday and Saturday nights and the response in the Pittsburgh area was very enthusiastic. A local department store bought a supply of crystal sets which were quickly sold to the "amateur" public. This response paved the way for a decision to put the station on a regular broadcasting basis, and on November 2, 1920, Westinghouse station KDKA in East Pittsburgh, Pa., was officially opened and the

* Received by the IRE, October 20, 1961.
† Hazeltine Research, Inc., Chicago, Ill.

era of radio broadcasting began. The station's initial broadcast of the Harding-Cox election returns was sensational.[1]

Since that time radio broadcasting has shown a spectacular growth. Many of the companies which had been manufacturing military equipment started to produce "amateur" sets. Newspapers, department stores and educational institutions opened their own broadcasting stations. By 1922 there were 30 licensed broadcasting stations in the United States, and by 1924 there were over 500.

Crystal Receivers

Before and during World War I crystal sets were in wide usage by radio hams. It was only natural, therefore, that this type of receiver should be the first employed after the beginning of radio broadcasting. Tuning in crystal receivers was effected by varying either the tuning capacitance or the inductance.

The most commonly used crystals were silicon, carborundum (silicon carbide) and galena (lead sulphide). The receiver was operated by tuning the circuit to the station and then assuming the use of a silicon detector, probing the crystal surface with the cat whisker to find a sensitive spot, retuning, reprobing, etc. The cat whisker was a sharp, firm metal wire and in the case of the widely-used silicon detector was sometimes made of antimony. With a good straight-wire outdoor antenna, the range of a crystal set for satisfactory response from a broadcasting station was limited to a radius of 5 to 50 miles. All crystal sets suffered from a lack of sensitivity and crystal instability. However, they were available and were relatively inexpensive and easy to produce.

Regenerative Receivers

Crystal sets were soon replaced by regenerative receivers.[2,3] The regenerative circuit (Fig. 1) was invented in 1912 by de Forest, Armstrong and Langmuir in the United States, and by Meissner in Germany. After 20 years of litigation, the United States Supreme Court finally decided in de Forest's favor. Meanwhile, in 1917 Armstrong received the first IRE Medal of Honor for his work on regeneration and the production of oscillations. After the Supreme Court decision, Armstrong returned the Medal of Honor to IRE, but the Board of Directors unanimously declined to accept it and reaffirmed the original award.

In the regenerative detector circuit RF energy is fed back from the anode circuit to the grid circuit to give positive feedback at the carrier frequency, thereby increasing the sensitivity of the circuit.

Regenerative receivers marked a big step forward in providing greatly increased sensitivity. Inherently they provided large amplification of small signals and small amplification of large signals. By 1922 they had reached the high point in their development and had almost entirely superseded crystal sets.

Three sets captured a large share of the market: 1) Westinghouse (RC) Radiola, 2) Clapp-Easthan, and 3) Grebe. Each of these receivers included a detector and two stages of audio amplification. In some cases the audio amplifier was sold separately. At that time only two frequencies were allocated to broadcasting: 300 and 360 meters. However, everyone wanted to receive ship signals on 600 meters (500 kc), and hams on the "short-wave" band, 200–250 meters (1200 to 1500 kc) and this demand determined the frequency coverage provided by these early sets.

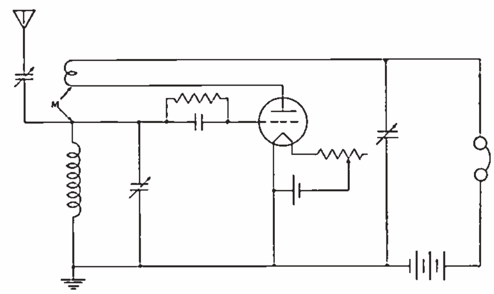

Fig. 1—Armstrong regenerative receiver.

Regenerative receivers, however, were subject to serious difficulties since they could easily be made to oscillate if the regeneration control were turned up too far. When the receiver was in an oscillating condition it produced heterodyne whistles in nearby receivers when it was tuned to, or through, stations to which they were tuned. This device soon became a public nuisance and threatened the development of the radio art. Regenerative receivers were also hard to adjust, and it was almost an impossibility to operate them so that they would always receive the same station at the same point on the dial. Logging stations was, therefore, impracticable.

Neutrodyne Receivers

The neutrodyne circuit was invented in 1918 by Hazeltine.[4–6] Basically this was a tuned radio-frequency (TRF) amplifier which employed a specific type of neutralization. A current obtained from the plate circuit was fed back into the grid circuit in the proper magnitude and phase to balance out, or neutralize, the effect of grid-to-plate capacitance inside the tube, and thus it achieved stability and prevented oscillation. The grid-to-plate capacitance of the tubes used in the early

sets was high, and in the case of the type 201A was between 8 and 12 pf. Hazeltine originally proposed this circuit to stop squealing in audio amplifiers, stating that it was no doubt also applicable to radio-frequency circuits. In 1922 Hazeltine designed a radio receiver on paper incorporating his neutralizing circuit. This receiver was a reflex neutrodyne employing three tubes and three tuned circuits, each tuned by a separate tuning dial. Magnetic coupling between the unshielded tuned RF transformers was eliminated by mounting them in line with their axes inclined 54.7° with respect to the line of centers. The circuit diagram is shown in Fig. 2. A modified version in which a separate audio amplifier was used was placed on the market by Freed-Eisemann in 1923. This was a five-tube set and was the first set having high RF amplification and high RF selectivity. By 1924 neutrodyne receivers were selling by the hundreds of thousands.

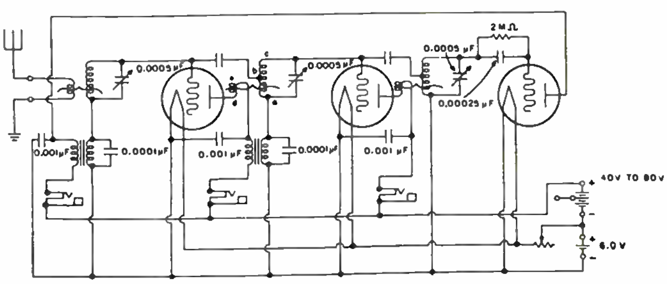

Fig. 2—Hazeltine reflex neutrodyne receiver.

Hazeltine developed the neutrodyne circuit to a complete solution from a mathematical point of view. For this work, along with his conception of vacuum-tube parameters, specifically mutual conductance,[7] he was awarded the Armstrong Medal by the Radio Club of America in 1937.

Neutrodyne receivers had stable characteristics; tuning dials could be logged when stations were tuned in and they were easy to operate.

In 1926 a neutrodyne receiver was designed which employed shielding between the coils, the shielded neutrodyne.[8] This receiver marked the first attempt at unicontrol. It had two dials (in addition to the volume control); one tuned the antenna circuit and the other tuned three stages of RF amplification. It was offered by Stromberg-Carlson and others.

For a number of years any set carrying the name neutrodyne was certain to sell. However, with the development of the screen-grid tube in 1928 with its low grid-to-plate capacitance, the necessity for neutralization disappeared and the demand for this receiver declined rapidly.

Many sets, neutrodynes and other types, having tuning capacitors ganged together so that they could be tuned by means of a single dial, were manufactured and sold in the late twenties. However, all fell short of true unicontrol operation since the volume control, or RF gain control, or both, had to be continuously readjusted as the set was tuned over the band in order to avoid inadequate volume or overload (blasting).

Automatic Volume Control

In 1925 the stage was set for the invention of a practical automatic volume-control circuit, and on January 2, 1926, Wheeler invented his diode AVC and linear diode-detector circuit.[9,10] This circuit was first incorporated in the Philco Model 95 receiver which he designed at the Hazeltine laboratory and which was announced about September, 1929.[11]

This receiver employed 9 tubes, two type-224 tuned RF amplifiers, one type-224 untuned RF amplifier, a type-227 connected as a diode detector, a type-227 resistance-coupled first AF stage, a type-227 transformer-coupled AF driver, and a push-pull audio output stage using type-245 tubes. The rectifier was a type 80.

Two coupled tuned circuits were employed preceding the first tube to prevent cross-talk from nearby local stations. The antenna circuit employed a high-inductance primary and was designed to provide tuning which was independent of antenna size, and uniform gain and selectivity over the band.

A type-227 tube with its grid and plate tied together served as a two-element (diode) detector which supplied both an AF signal to the audio amplifier and a dc bias voltage to the RF amplifiers. Since a two-element detector is linear over practically its entire rectification curve when a high dc impedance is used in its return circuit, as was the case here, it provided the greatly desired linear detection characteristic. In this receiver the useful range of linearity of the detector was from 1 to 10 volts, approximately.

Full AVC bias voltage was applied to the first two RF tubes, and, to prevent distortion in the third RF stage, half AVC bias voltage was applied to that stage. The automatic volume-control action was sufficiently gradual to permit accurate tuning by ear, and it was unnecessary to touch the volume control once it was adjusted. With all four tuning capacitors ganged to a common tuning dial, true single-knob operation was provided for the first time in any receiver. The sensitivity of the receiver was about 5 μv/m across the band,

[11] W. E. Holland and W. A. MacDonald, "The Philco '95' screen-grid plus," *Radio Broadcast*, vol. 16, pp. 111–112; December, 1929.

and the signal input ratio over which the automatic volume control was effective was 300 to 1. With a local-distance switch this was increased to 10,000 to 1.

By 1932 practically every receiver on the market used a diode AVC circuit employing a single-diode detector to supply both the audio signal and the AVC voltage. This situation remains unchanged today, insofar as electron-tube receivers are concerned.

The Superheterodyne

A number of engineers worked on the problem of the production of superaudible frequencies by means of heterodyning. Pioneers in this work were Levy in France, Round in England, and Armstrong in America.[12] The direct outcome of Armstrong's work was the development of the superheterodyne receiver.[13]

In the superheterodyne receiver the signal frequency is mixed with the locally-generated oscillator frequency in a nonlinear device to produce two new frequencies corresponding, respectively, to the sum of, and the difference between, the two frequencies. The difference frequency is fed to the IF amplifier where it is amplified and then rectified in the detector where the audio-frequency component is taken off and fed to the audio amplifier. In early receivers of this type the tube in which the signal and oscillator frequencies were combined was called the *first detector*, and the tube which separated the audio signal from the modulated IF signal was called the *second detector*. Later these terms were changed to *converter*, or *mixer*, and *detector*, respectively. More precisely, the term *converter* applies to the combined oscillator and mixer functions, which may be performed in the same tube.

The superheterodyne obtains only a relatively small part of its gain and selectivity in the antenna and RF amplifier circuits; by far the larger part is obtained at a lower frequency in the IF amplifier where gain is more manageable. Since tuning of the IF amplifier is fixed, a more desirable band-pass selectivity characteristic can readily be achieved. These factors combine to make it relatively easy to secure uniform gain, selectivity and fidelity over the band.

The first publicly sold superheterodyne receivers were made by the General Electric Company and placed on the market in March, 1924, by RCA.[14] These receivers were known as the Radiola Superheterodyne Second Harmonic, a table model, and the Radiola Super VIII, a console model. The table model employed a fixed built-in loop antenna, but did not include a loudspeaker. Batteries were located in side compartments of the cabinet. The console model included a built-in rotatable loop antenna and a horn loudspeaker. Both models employed the same chassis which utilized a circuit developed by H. Houck. This circuit employed six UV-199 tubes and included an untuned RF stage, second-harmonic converter stage, two IF stages, one of which was reflexed with the RF stage, an audio detector and two AF stages. Second-harmonic operation of the oscillator was employed to prevent tuning interaction between signal frequency and oscillator circuits. The circuit diagram is shown in Fig. 3.

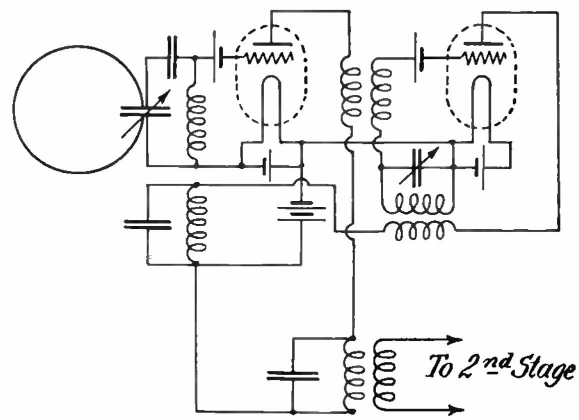

Fig. 3—Basic superheterodyne second harmonic circuit.

The chassis featured a component assembly called the *catacomb* which included the IF, RF and AF components and was potted in wax. The RF and IF transformers employed 3-mil silicon steel laminations, and two of the IF transformers had both primary and secondary tuned to 42 kc and were critically coupled to provide a band-pass selectivity characteristic. Regeneration was reduced by capacitive neutralization and by magnetic neutralization through the common silicon steel core.

Later superheterodynes were designed to operate on the fundamental of the oscillator, and the IF was raised to about 175 kc. By 1930 they began to take over, and by 1932 they were in universal use, as they are today. In 1938 the IF was set at 455 kc by the RMA Standards Committee.

Automobile Radios

Transitone began to produce automobile radios in about 1927 on a custom-made or low-production basis. In 1931 this company was bought by Philco, and the product was designated Philco-Transitone. However, Motorola claims to have turned out the first mass-produced commercial auto radio in 1929. This set employed a tuned RF circuit consisting of three gang-tuned stages, an antenna and two RF stages employing type-224 tubes, a type-224 detector, a type-201A audio driver, and push-pull type-112A's in the output stage. The 6-volt car battery supplied the filament current and "B" voltage was supplied by three 45-volt batteries. The receiver included a dynamic loudspeaker with a 6-volt field coil. Signal pickup was effected by means of a

[14] Prior to 1929, RCA was not a manufacturer. It was a patent licensing and sales organization owned by General Electric, Westinghouse and AT&T. See McLaurin, *op. cit.*, p. 147.

screen-type antenna mounted in the roof of the car. The three-section gang capacitor and the volume control were remotely operated by means of flexible shafts running from the metal box housing the receiver to a control box mounted on the steering column.

The superheterodyne circuit was first used in an auto set in 1931. This set also employed batteries to supply filament, plate and screen potentials. The intermediate frequency was 175 kc. It was replaced the same year by a set which utilized a wired-in vibrator power pack.

In 1932 Motorola marketed what is claimed to be the first auto set which employed a power supply with a plug-in vibrator to furnish plate and screen voltages. This receiver utilized a superheterodyne circuit and employed 8 tubes. The intermediate frequency was 175 kc. It incorporated circuits to filter the battery and plate-supply voltages to reduce ignition noise and vibrator hash.

After World War II, ganged capacitors were scarce, and permeability tuning came into wide usage in home receivers and in auto sets. Because of the improvement in SNR and freedom from microphonism provided by this type of tuning-in auto sets, the industry stayed with "perm" tuning in receivers of this type. The improvement in SNR came about because the "perm-tuned" antenna circuit could be more efficiently coupled to a low-capacitance automobile antenna, thus providing higher antenna gain.

The transistor, first publicly announced in 1948, is said to have been first applied in entertainment-type automobile receivers in a set made by Motorola and marketed in about 1956. In the audio-output stage this set incorporated a power transistor mounted on a heat sink outside the metal cabinet. All other functions requiring electron devices utilized tubes designed to operate with 12-volt plate, screen and filament potentials which were supplied directly by the car battery. Sets of this type are called *hybrid* sets because of the use of both tubes and transistors.

The main reason for the existence of the hybrid set is based on economic considerations, transistors being too high priced to make completely transistorized auto sets competitive for the commercial market. Additionally, a transistor was used in the power output stage because it delivered greater power output than could be secured with a 12-volt audio-output tube.

Some manufacturers made hybrid auto sets which employed conventional tubes whose plate and screen voltages were supplied by a transistorized power oscillator.[15]

Hybrid auto sets have been very popular from 1956 to the present. However, they are gradually giving way to all-transistor receivers as the price of transistors comes down. It is estimated that by 1963 almost all automobile sets will be fully transistorized.

The first all-transistor auto set is said to have been placed on the market by Philco in about 1956. It employed a conventional superheterodyne circuit and 12 transistors. The intermediate frequency was 262.5 kc, the power output 3.5 watts and the nominal battery current drain 0.4 ampere at 13.8 volts.

In connection with hybrid and fully-transistorized auto sets, it should be pointed out that the usual problems of vibrator hum and "hash" no longer exist.

Most early auto sets used antennas which were mounted in the car roof or under the car or running board. After "touring" cars were replaced by sedans having metal tops, present day whip-type antennas came into general use.

Frequency-Modulation Receivers

The credit for promoting FM as a broadcast service goes to E. H. Armstrong. For years he had been seeking a way to reduce static, and finally he turned his attention to FM. Toward the end of 1933 he had perfected a system of wide-band frequency modulation which seemed to overcome natural and many forms of man-made static.[16] In this system the carrier was frequency modulated ± 75 kc by audio components up to 15 kc.

In 1938 General Electric placed the first FM receiver on the market—their Model GM 125, a superheterodyne employing 11 tubes plus a rectifier.[17] It was tunable over a range of 41–44 Mc; the IF was about 3 Mc, and the bandwidth was sufficient to handle a frequency deviation of ± 100 kc. It employed a type-6SJ7, as a grid-current limiter to remove amplitude modulation, followed by a type-6H6 double diode in a Foster-Seeley discriminator circuit to provide FM detection. It is interesting to note that this discriminator circuit was originally proposed in 1936 for use as an automatic-frequency-control detector and came into rather wide usage in this application.[18]

In 1945 the ratio detector invented by Seeley came into use as an FM detector and was widely adopted, particularly in medium- and low-priced FM receivers, because it did not need to be preceded by a limiter stage.[19]

On January 1, 1941, the FM band of 42–50 Mc came into general use in accordance with the FCC decision of May, 1940, and in August, 1945, the FCC allocated the present band—88–108 Mc. In 1946 the Radio Manufacturers Association (now Electronic Industries Association, EIA) proposed 10.7 Mc as the standard FM intermediate frequency and proposed an antenna-to-set transmission-line impedance of 300 ohms.

Innovations

There have been many innovations introduced since radio-broadcast-receiver manufacturing began. Some were worthwhile and contributed to the development of the art, but many were only short-lived gimmicks.

All early radio receivers employed headphones. However, the need for greater sound output soon resulted in attaching horns to telephone-type receivers. These were followed in 1922–1924 by cone-type speakers such as those made by Western Electric and Farrand, which employed cones attached to moving armatures. In 1924 Magnavox designed and marketed a balanced armature magnetic-type horn loudspeaker.

In 1925 C. W. Rice and E. W. Kellogg of General Electric developed the electrodynamic loudspeaker, marketed by RCA, and in 1931 Jensen put on the market a dynamic loudspeaker with a permanent magnet made of chrome steel, the forerunner of the present Alnico V and ceramic magnets.

Some of the early radio receivers employed loop antennas. Later, in an effort to receive signals from greater distances, outdoor antennas of many types came into general use. As advances were made in tubes, circuit design and loop-antenna design, it became feasible to use loop antennas without too much loss of sensitivity. In 1939 loops came into general use, and some receivers appeared on the market with permeability-tuned loops. In 1950 the use of ferrite-rod antennas instead of loops was proposed, and gradually this type of antenna, the *loop-stick*, replaced conventional loops.

Early receivers all employed battery operation since tubes with ac-operated filaments were not available. Then, in 1924 the Philadelphia Storage Battery Company marketed "B" battery eliminators which came into wide usage. Shortly thereafter "A" battery eliminators were developed; these also gained wide public acceptance. In 1926 Zenith built a receiver with both "A" and "B" battery eliminators built in as an integral part of the receiver. The wide usage of the ac receiver followed the manufacture in 1926 of tubes with filaments which could be operated on alternating current. Since there were many areas in the country where only dc power was available, the present day ac-dc circuit was developed by R. Weurfel of International Radio to meet this need. This was first marketed by International Radio in 1931, and by 1935 about 20 per cent of the total sets made were ac-dc.

In 1939 portable receivers using battery tubes with 1.4-volt filaments became popular and ac-dc-battery sets appeared on the market. One of the outstanding developments of 1940 was the miniature receiver which weighed less than five pounds and which was powered by readily-replaceable batteries. Further attempts at miniaturization resulted in a pocket radio employing subminiature tubes and especially developed components. One of the first of such sets was produced by Belmont late in 1946.

In 1952 the use of printed circuits employing a dip-soldering process was extended to small radio receivers. These steps along with the use in the laboratory of transistors in radio receivers for the first time high-lighted developments in that year. In 1954 Regency marketed the first transistorized radio.

Over the years since the early twenties there have been many other innovations—all-wave receivers, including the "weather" band, "spread-band" receivers, AM-FM receivers and "Fremodynes."[20] Some of these receivers employed IF amplifiers with adjustable selectivity, automatic bass boost, noise limiters, tuning eyes and inverse feedback. There have been big tuning dials, little tuning dials, round dials, long dials, short dials, no dials, push buttons and automatic tuning.

These and many other innovations, together with the circuit developments previously described, have resulted in the sale of over 300,000,000 broadcast receivers at a factory price of about $8,000,000,000, in the United States to the end of 1960.[21]

A Half Century of Television Reception*

F. J. BINGLEY†, FELLOW, IRE

Summary—**The paper traces the development of television receiving, starting with a description of the earliest demonstrations of mechanical television. While the major emphasis is on reception, enough discussion of television system standards is included to support the development of the receiver story. The progression of events which led from the early mechanical systems, through the various phases of electronic television using cathode-ray picture tubes, up to the modern compatible color television receivers, is covered in some detail. The development of circuitry for IF, VF, and deflection is covered. A complete bibliography, containing some of the great historic as well as the most recent contributions, is included.**

Introduction

THE DEVELOPMENT of the art of television receiving is inextricably bound up with that of television transmission; there is a "lock-and-key" relationship between the transmitter and receiver. Thus, while the emphasis of this paper will properly be placed on receiving techniques, it will be necessary in many cases to supplement the discussion with sufficient explanation of the transmitter and over-all system philosophy.

The earliest development of television was directed towards generation of television signals, and their display as television pictures without the intervention of radio transmission and reception circuits. The earliest demonstrations of television used equipment comprising mechanical devices for scanning the image. It is fitting to begin with a discussion of them.

I. Early Mechanical TV History

So far as the author is aware, the first demonstrations of actual television images were made in the year 1925 by C. F. Jenkins in Washington [1] and by J. L. Baird in London. They worked independently of each other, but it appears not to be possible to state to whom should be given the credit of priority. The pictures shown by Baird were not transmitted and received by radio, but rather over a connecting wire. Similarly he avoided the synchronizing problem by using mechanical scanning with a common drive connecting the scanning devices at both "transmitter" and "receiver." Jenkins used radio transmission, and synchronous motors for synchronization.

By the fall of 1927, Baird had progressed to the point of making experimental broadcasts from a radio station near London. His scanning equipment included an 8 foot diameter lens disk carrying 30 lenses associated with a photocell. The monitor display was an 8 foot, Nipkow scanning disk with 30 apertures, scanning vertically. A neon lamp tube served as the light source. Synchronization at the studio end of the system was achieved by the solid shaft connecting the lens disk with the Nipkow disk. The broadcasts were received at White Plains, New York. History does not record how well the pictures were received, or how the synchronization was accomplished.

A great forward step was taken in 1927 by Bell Telephone Laboratories [2], who set up a system for transmitting television from Washington, D. C., to New York, a distance of 250 miles. The transmission could be carried alternatively by radio or by wire circuit. There were 50 scanning lines per frame and 16 frames per second. The receiver displays used were of two types; one produced a small image about $2 \times 2\frac{1}{2}$ inches, the other a large image $2 \times 2\frac{1}{2}$ ft. The smaller picture was produced by a scanning disk revolving in front of a special neon bulb having a flat cathode; the disk was driven by a synchronous motor fed and synchronized from a separately transmitted signal. The large display consisted of a set of 50 parallel tubes containing neon and a set of 2500 electrodes, arranged in a sequence of 50 along each neon tube. These electrodes were connected by 2500 wires to a 2500 segment commutator run by a synchronous motor similar to that used for the scanning disk. The video signal was used to modulate a 500 kc RF carrier, and this was distributed by the commutator which thus provided the scanning function. When the signal was received over wire facilities, the circuit was carefully corrected for amplitude and phase up to a maximum frequency of 20 kc. When it was received by radio, a special superheterodyne receiver was used for the TV signals (the transmitted carrier was 1575 kc); separate receivers were also used for speech (1450 kc) and synchronizing signals (185 kc).

Another early pioneer was E. F. W. Alexanderson who, working at General Electric, produced a projection display using a drum of mirrors associated with a modulated light source [3]. The image of the light source was formed at the screen after reflection by the mirrors of the drum; as the drum rotated the image was caused to move vertically on the screen. Because, in addition to their angular spacing around the drum, the mirrors were tilted progressively with respect to its axis of rotation, the images reflected by successive mirrors were displaced sideways on the screen as each successive mirror came into play. The result was that the receiving screen was scanned. In order to produce more scanning lines from a drum having a given number of mirrors (24 in the early experiments), he used seven light sources so that in effect each mirror scanned seven lines in parallel.

* Received by the IRE, September 21, 1961; revised manuscript received, November 16, 1961.
† Government and Industrial Division, Philco Corporation, Philadelphia, Pa.

Thus the total effective number of lines was 168. In later experiments the multispot scanning was abandoned and a simple sequential scanning of 48 lines at 15 frames per second was used; the picture was displayed on a screen about 3 ft square.

II. Early Electronic Television Receivers

The arrival of electronic television may be dated at approximately the year 1930. Much prior to this year Dieckmann in Germany (1906), Rosing in Russia (1907) and Campbell Swinton in England (1911) [3]–[5] discussed and described electronic television receivers employing cathode-ray tubes as display devices. Dieckmann actually had a crude unit in operation in 1906; however his system transmitted only silhouettes, so there is some reluctance to give him full credit for having produced the first electronic receiver. No further work on electronic television appears to have been done until the early 1920's, when the work of Philo Farnsworth and Dr. V. K. Zworykin became known. The importance of their work was not recognized until 1930 however, perhaps because some of the mechanical approaches to television were beginning to show real promise. It was only when the overriding limitations of mechanical TV were finally, if reluctantly, admitted that electronic television received the research and development effort it merited.

In about the year 1929 Farnsworth demonstrated an all electronic TV system in which the display device was a cathode-ray tube, magnetically deflected and focused [6]–[8]. In 1931 Farnsworth joined Philco Corporation, where he continued his work for about two years during which time early experiments in broadcast TV reception on frequencies in the order of 60 Mc were made. Transmissions from W3XE (the Philco experimental station) were received in Mt. Airy, Philadelphia, a distance of about 6 miles, in 1932.

The work of Dr. V. K. Zworykin was originally carried out at Westinghouse Research Laboratories. He is reported to have demonstrated an all-electronic system in 1924. The earliest published account of his experiments appeared in *Radio Engineering* in December, 1929 [9]. The display device at the receiver was a 7-inch cathode-ray tube with ES-EM deflection, and ES focusing. For beam modulation a control grid was used. When Dr. Zworykin joined RCA in 1930, this work was continued by him and his associates.

III. Television Standards

By about 1935 electronic television had progressed to the point where it became obvious that the most pressing requirement was for a set of standards, in order that the development of systems could proceed in an orderly fashion. By that year there already existed experimental transmitters in the VHF band, camera tubes such as iconoscope and dissector, and cathode-ray display tubes. The necessary ancillary circuits, such as for deflection and video amplification, were already well known. It was obvious that vitally important factors to be decided were those of how many scanning lines should be used, whether they should be interlaced, and what field and frame rates were required. These were basic factors, but they reflected their influence widely throughout the whole system design, affecting video bandwidth (and in turn transmitter and receiver bandwidth), picture flicker, and deflection circuit frequencies. Along a parallel track lay the problems concerned with transmission and reception of the video signal and the accompanying sound. Items needing consideration here were method of modulation, polarity of transmission, polarization, the applicability of single or double sideband or other band saving means, the channel layout (spacing and relation between video and sound carrier and their locations in the channel), allocation of broadcast frequencies, and many others. Standardization of these items was achieved in the fall of 1941, and the FCC issued commercial television standards at that time. Some of the more important standards will now be discussed.

Amplitude modulation was finally selected for picture transmission. Partial suppression of the lower sideband was used to save bandwidth. Frequency modulation for picture transmission was tested early in 1941, but found to produce bad effects in the receiver in the presence of multipath; it was abandoned for broadcast use for this reason. The polarity of modulation was selected as negative (that is, more light at the scene, less carrier amplitude). On the other hand, frequency modulation was selected for sound transmission, since a sufficiently high deviation ratio could be provided to take full advantage of the FM system.

The spacing between sound and picture carriers was standardized at 4.5 Mc, with the sound carrier 0.25 Mc below the upper edge of the channel, and the total channel width 6 Mc.

It was realized quite early (1933) that the transmission of 60 fields per second, interlaced two to one, was desirable from the standpoint of elimination of flicker. The matter was briefly reexamined in 1941, but the original decision was reaffirmed. The number of scanning lines progressed from 343 in 1935, to 441 in 1937, and was finally standardized at 525 in 1941. The video bandwidth increased correspondingly from about 2 Mc in 1933 to 4.25 Mc in 1941. The horizontal deflection frequencies increased from 10.29 kc to 15.75 kc during this period.

The work of standardization was carried out by a number of industry groups. The final coordination was done by the National Television System Committee. Their work has been described in detail by Fink [10].

IV. Development of Circuits for Electronic Television Receivers

The development of television standards briefly referred to above was concurrent with a progressive development of television receiving techniques. During the period up to about 1945, superheterodyne receivers were developed capable of handling the necessary bandwidth of 6 Mc [11]–[14] and video amplifiers capable of amplifying adequate bandwidth with acceptable frequency and phase characteristics were developed and design formulas were obtained [15]–[19]. Basic factors having to do with receiver and system optimization were studied during this period, and papers were written by Kell, Bedford and Fredendall [20], Wilson [21], Wheeler [22], [23], Loughren [22] and Baldwin [24].

The design of intermediate frequency amplifiers was considered by many workers in the field, including Butterworth [11], Landon [13], Sziklai and Schroeder [14] and more recently by Avins [25], Ruth [26], Bridges [27], and Bradley [77].

Prior to 1945 the accepted method of sound reception had been to use a separate IF amplifier for this purpose. It required great stability of the local oscillator in order to maintain the sound within the narrow sound IF channel. A new method, utilizing the 4.5-Mc beat between sound and picture carriers, was developed and is now used exclusively [28]. Since the 4.5 Mc beat frequency is determined at the transmitter, receiver tuning is now not critical.

Synchronizing and deflection circuits and yokes have shown progressive development. In the 1930's deflection angles of 50° were considered large. At the present time the figure has risen to 110°, with corresponding decrease in cabinet depth [29]–[33]. This has been accomplished by increased efficiency in circuits and yokes. At the same time synchronizing circuits have been improved, notably by the introduction of AFC synchronization.

Transistors are now being used in television receivers, particularly in portable models and in IF amplifiers. Much work has been reported in this field [34]–[44].

Considerable development has been applied to picture tubes since 1930. This development has covered screens, guns and geometry. Prior to about 1935 engineers had been satisfied to do what came naturally with respect to phosphors—namely, to use the readily obtainable green fluorescing willemite as a screen phosphor on the receiver display. However, about that year it became obvious that such a color would be unacceptable for monochrome TV receivers, and development of efficient white phosphors began. By 1938 the present two component white-balanced screens began to appear [45]–[47].

In about the year 1935 it became recognized that the central regions of picture tube screens were exhibiting dead areas in the phosphor—that is to say, the picture contained a dark spot in the center. It was established that this was due to bombardment of the screen by negative ions, presumably emitted from the heated cathode. The ionic mass was so great, compared to that of the electrons in the beam, that the ions were practically undeflected by the magnetic deflection fields. They could be focused by an electrostatic field, but not by a magnetic field. Magnetically focused tubes showed a sharp shadow of the tube neck as a boundary of the ion blemish. Electrostatically focused tubes showed a smaller more intense black spot due to the electrostatic focusing action. Research using the picture tube as a mass spectrograph identified the various ions involved.

By devising an electron gun having a bent section (the axis of the bend being normal to the tube axis) the ions became trapped in the gun. By adding an external auxiliary magnetic field the electron beam in the gun was bent so it could pass down the axis of the second section of the gun, which was coaxial with the tube neck. However, the ions, which were not deflected by the auxiliary magnetic field, remained trapped in the gun and thus could not reach the screen to damage it. The development of the aluminized tube provided protection for the phosphor from ion bombardment, and ion traps are not required with such tubes.

Phosphor screens emit light on both sides. That which is emitted on the side facing the electron gun is wasted so far as the observer is concerned, if it is permitted to be absorbed and reflected by the inside surface of the picture tube. More than this, it destroys the over-all contrast of the picture. The operation of the aluminized tube depends on the fact that an electron beam of velocity such as used in a picture tube can penetrate a film of aluminum which is at the same time thick enough to reflect essentially all the incident light. Thus, light emitted from the rear surface of the phosphor screen is reflected and appears as a useful image illumination to the viewer. It is prevented from destroying image contrast. The aluminum film also protects the phosphor screen from injury due to ion bombardment [48].

Deflection of the cathode-ray beam may be accomplished either by electrostatic or electromagnetic fields; and the same is true of focusing. During the period 1930 to 1950, ES and EM focusing were used, with the general predominance on EM focusing since it was easier to get fine bright spots and the focusing element was outside the tube, giving a freedom to adjust and experiment. In the period 1950–1955 the disadvantage of the current drain of the EM focuser was overcome by designing permanent magnet focusers with adjustable airgaps. Since 1955, with the increase in knowledge of electron optics, it has been possible to design good picture tubes with electrostatic focus, and these are now widely used in television receivers. Regarding deflection, some of the early experimenters used crossed ES-EM systems, using the ES for the high-frequency deflection. This was probably done because of the lack of knowledge at that time concerning the design of magnetic deflection circuits operating at high frequency. By about 1935 magnetic deflection circuitry was well understood and has been used almost exclusively since then. There are new developments in ES deflection cathode-ray tube which may affect the present monopoly of EM deflection [49]–[53].

V. Color Television Receivers

A. Early Devlopment

Within the period of this review, the earliest color television work appears to have been carried out in England by Baird in about June 1928. This was an all mechanical field sequential receiver display, with 15 red lines and 15 cyan lines. Naturally the results were quite crude, and only demonstrated principles [54].

The next demonstration of which the author is aware was one given by Bell Laboratories some time in June 1929, at their Laboratories in West Street, New York [55]. The system was devised by Dr. Ives, the well-known expert in optics and colorimetry. Three separate channels were used, one each for red, green and blue. The receiver display had 50 lines and 18 pictures per second, using a 20-kc band for each channel.

What may be called semi-electronic color television was first broadcast by Dr. P. C. Goldmark of CBS in 1940 [56]. The system used a field sequential receiver display, with a disk having successive red, green and blue filters revolving in front of a cathode-ray picture tube. The disk was synchronized so that red, green and blue separation images were displayed in succession. This system received much attention, particularly in the post-war years. It suffered from the compromise between resolution and flicker, and from its noncompatibility with the existing monochrome service. Since it was a sequential system, there was no way in which the bandwidths required to satisfactorily transmit red, green and blue separation images could be tailored to fit the lesser demands of red and blue as compared to those of green. It also suffered from the disadvantage of not being entirely electronic, requiring (at least at the time it was under consideration) a synchronized filter disk. In spite of these disadvantages the system was adopted as U. S. standard by FCC [57] in October 1950, the scanning specifications being 405 lines, 48 color fields, interlaced, leading to a flicker rate of 48 cps. In order to partially offset the lack of detail, ingenious "crispening" circuits were devised [58] and applied to the receiver. It was demonstrated that a receiver could be built with changeover switches to show either monochrome or color pictures, thus rendering the lack of compatibility somewhat less objectionable. The standard was rescinded in December 1953.

Most of the development of color television receivers since 1950 has centered about the development of the display device. The progress will therefore be discussed mainly in terms of the display.

B. Line Sequential Color Display

An early approach to color display was that called "line sequential," in which successive lines were scanned in red, green and blue. This was first demonstrated in 1949; but, since the display involved a triple interlace, objectionable traveling patterns intruded upon the picture. No solution being found, the system was abandoned.

C. The Chromatron Tube

This tube, developed by Dr. Lawrence, is characterized by having a screen structure in which the phosphors are laid down in horizontal stripes [59]–[61]. The phosphor lines are of three separate kinds of phosphor, fluorescing in red, green, and blue, respectively. Close to the screen is a set of deflection plates running parallel to the phosphor lines. The plates cause the electron beam to be selectively deflected according to the potential between them. In this fashion the scanned raster can be caused to fall only on the green phosphor, or only on the red or blue phosphor. The selection is made at the instants when the video signal amplitude is appropriate to control the luminance of selected phosphor. This is accomplished by signal processing at the receiver.

D. The Shadow Mask Tube

This tube is of the three gun type—that is to say, separate electron guns are assigned to exciting the red, green and blue phosphors, respectively [62]–[65]. This is achieved by the parallax existing between the three guns due to their slightly differing space positions, as they beam electrons through an apertured plate on to a phosphor screen placed parallel to it. The plate has about 300,000 holes and is of the same size as the phosphor screen. The phosphor screen has 900,000 phosphor dots, arranged in groups of three, each group consisting of a red dot, a green dot, and a blue dot (the color named refers to the fluorescent radiation). Each group of three is arranged at the corners of a very small equilateral triangle of such a size and so oriented that the electrons from one gun (call it the red gun) can only fall on the red dots; and similarly for the green gun and green dots, and the blue gun and blue dots. This relation must hold over the whole screen no matter where the three beams are deflected by a deflection yoke through which they all pass. Naturally the size of phosphor dots must be carefully controlled, as must the relation between the dots and the aperture mask, which requires great precision of alignment.

The signal processing circuits effectively feed red, green and blue separation signals between grid and cathode of each respective gun.

E. The Apple Receiving System

The name "Apple" was applied by Philco to a specific type of single gun color tube developed in its Research Laboratories [66]–[70]. Considerable signal processing is involved in utilizing the tube. Basically the tube consists of a striped phosphor screen, with the stripes running vertically. The stripes fluoresce in the additive primary colors red, green, and blue. They are arranged in the repetitive order red, green, blue, such a triplet of stripes occupying a width of about $\frac{1}{16}$ inch on a 21 inch picture tube, and there being some 320 triplets across the face of the tube. Adjacent phosphor strips are separated by an inert black material. The rear of the aluminized surface is imprinted with a set of index stripes in register with the red phosphor stripes. The index stripes provide a beam position reporting signal, which is used in the signal processing circuits to cause the video signal applied to the control grid of the gun to assume values representative of the required luminance of a given phosphor at the moment the scanning beam crosses it.

A major advantage of the Apple system is that the screen white balance is automatically determined by the screen structure itself. Absence of color carrier (whether caused by a white section of a color picture being transmitted, or by the fact that the transmitted picture is monochrome) causes the screen to fluoresce in its characteristic white. The quality of this white depends only upon the balance achieved in laying down the phosphor screen during manufacture.

VI. Miscellaneous Approaches to Television Reception

A. *Supersonic Light Valve*

The most sophisticated embodiment of mechanical scanning was the system employing the supersonic light valve described by J. H. Jeffrees and developed as a receiving system by Scophony Ltd. of England [71], [72]. The light valve consisted of a liquid cell about 2 cm wide by about 4.5 cm long; at one end was placed a piezoelectric crystal having a natural frequency of about 20 Mc, and at the other an acoustic absorber. The crystal was highly damped (mechanically speaking) by the liquid, so that if excited by a video modulated 10-Mc signal, its amplitude of mechanical vibration would accurately follow the modulation envelope. The crystal induced a traveling compression wave at a frequency of 10 Mc in the liquid; the wave traveled down the length of the cell to the absorbing barrier at the far end with a velocity of 10^4 cm/sec, and a corresponding wavelength of 10^{-2} cm. As the wave was formed at the sending end, it bore the instantaneous amplitude of the video signal, which it preserved throughout its journey to the end of the cell. The compression waves caused the liquid to act as a diffraction grating to light passing transversely through the cell. The energy in the zeroth order was blocked out, and that in the remaining orders was permitted to pass, by means of an optical system including a slit focused upon a complementary barrier. The greater the amplitude of the video signal modulating the carrier applied to the crystal, the greater the intensity of the compressional wave at the corresponding instant of generation; and the greater the light passed by the light valve. It took about 45 μsec for the modulated wave to travel the length of the cell.

An optical system was arranged to focus an image of the cell upon the receiver screen, with the long axis of the image (corresponding to the direction of travel of the compressional wave) horizontal. A high-speed mirror drum scanner suitably synchronized was used to immobilize the image of the compressional wave on the screen; and the light coming through the immobilized wave structure was, at any point, proportional to the corresponding video signal amplitude. Thus, the scanning lines of the image were reproduced in corresponding detail at the receiver screen. A second synchronized mirror drum was used to provide the vertical scanning component.

The system employed a 20-facet mirror drum running at 30,000 rpm for horizontal immobilization. Trouble was experienced with electronic sync generators, since their rate of change of frequency was greater than could be followed by the immobilizer. This trouble would probably not exist today when crystal masters are used for sync generators instead of 60-cycle power mains.

Using the above principles, a home television receiver giving a highlight brightness of up to 10 ft lamberts, and theater projection equipment giving 3 ft lamberts on a 12×15 foot screen, were designed.

B. *Skiatron Display*

The skiatron depends upon the discoloration of certain metallic salts (such as potassium chloride) by bombardment with cathode rays. It has been proposed to use this effect by causing a transparency to appear on the face of the cathode-ray tube coated with such material instead of the usual phosphor, but with a scanned and modulated beam otherwise exactly like a normal picture tube. The transparency is then projected or viewed with a light source.

Such a device was used during the war for a bright radar display. For television use it has, at the moment, the disadvantage that the effect decays slowly so that it is difficult to depict motion.

C. *Eidophor Display*

This is a unit primarily designed for theater projection. Its basic principle is the disturbance of the surface of a thin film of liquid brought about by electric charge. The electric charge is deposited by a cathode-ray beam scanned and modulated in the normal television fashion. The beam is focused on to the surface of the liquid, and causes a charge pattern representation of the TV picture to appear. The liquid film is formed on the surface of a mirror, and the reflection, resulting from its surface irregularities, causes the direction of the rays reflected by the mirror to be affected accordingly. A Schlieren type of optical system correspondingly varies the amount of emergent light. The surface of the liquid is focused on the screen by a projection lens. The unit was developed by Dr. Fischer at the Federal Institute of Technology in Zurich [78]. It has been adapted to field sequential color television.

Conclusion

The story of the development of television receiver techniques is a long one, characterized by contributions to its progress made by many scientists and engineers, Only the contributions made by the very earliest workers occurred long enough ago that they have acquired historic perspective so that just credit can be given them.

An appreciation of the amount of work and of the number of participating engineers and scientists involved in the recent development of color standards may be had by consulting some of the more recent texts [73]–[76]. The author does not presume to have the ability properly to weigh and apportion the credit for the more recent work.

The Impact of Receiving Tubes on Broadcast and TV Receivers*

E. W. HEROLD†, FELLOW, IRE

Summary—**The receiving electron tube has been primarily responsible for the modern superheterodyne, with its high sensitivity, high selectivity, automatic gain control, and ease of tuning. In examining the history, one finds an early period of triodes and diodes (1907 to 1927), a second period (1927 to 1936) of indirectly heated cathodes and multigrid tubes, and a third period (1936 to 1960) of close-spaced tubes and VHF operation. The most significant tube concepts are the triode, the multigrid tube, and the indirectly heated cathode, all of which started in the first period. The second and third periods were marked by tremendous advances in the technology of production, and in extensive application of the early inventions to new receiver designs. At present, solid-state devices are gradually supplanting vacuum tubes in some receiver applications, and this trend is expected to continue.**

Introduction

The history of the receiving electron tube, and the history of the Institute of Radio Engineers are almost coincident in time. It was only eight years after the invention of the Fleming valve, and six years after the invention of the DeForest triode, that the Institute was founded in 1912. In the present survey, the highlights of tube development, as they affected broadcast and television reception, will be outlined. The five decades which have elapsed saw the early and rapid rise, a peak period extending through the introduction of television, and a saturation point with a gradual decline, as solid-state devices became more and more prominent. For convenience, the discussion will be largely chronological and is divided into three historical periods.[1] A concluding section will give a brief view of the present period, and of future trends.

The first historical period was from roughly 1907 to 1927, when only filament-type triodes were widely used. This period included the invention and application to receivers of cascade amplification, regeneration and oscillation, heterodyning, and the superheterodyne. All these basic circuit principles are still with us today, and all were made possible by the electron tube. Some other developments of the period, superregeneration and reflex amplification have never been widely used in broadcast or television reception.

The second major period is the shortest in time, and is possibly the most outstanding, so far as rate of receiving-tube development goes. It started about 1927 with the delveopment of indirectly heated cathode tubes (and a few years later of multigrid tubes), and ended about 1936 with the octal base metal tube and beam power tube. The tube developments of this period were pri-

[1] The author wishes to apologize in advance for the many important and excellent contributions, particularly those of foreign origin, which he has been forced to omit in a discussion of this length.

marily responsible for the application in receivers of ac operation, high-level detection, very selective and single-knob tuning, the built-in loudspeaker, automatic-gain-control, tuning indicators, and multiband operation This was also the period in which the superheterodyne became the universal receiving circuit. Once again, every one of these receiver improvements remains with us thirty years later.

The third major period, from 1936 to about 1960, started with close-spaced (high gain-bandwidth) tubes and miniature glass envelope types, ending with the color picture tube and tubes for hybrid transistor-tube combination receivers. This is the period of VHF, *i.e.*, FM and television; the tube developments made these possible, together with their special circuits such as limiters, discriminators, automatic-frequency-control, saw-tooth deflection, synchronization, inverse feedback, wide-band amplification, and multiplexing.

It is unlikely that there will again be a period in which the device we know as a receiving tube will have as revolutionary an impact as in the three periods summarized above. The present and future of broadcast and television receivers appears to depend more and more strongly on solid-state methods, micro-electronics and other newer technologies. There will always be some exceptions, possibly in color picture tubes, or in tubes for higher-frequency operation of broadcast services.

The Years of the Diode and Triode, 1907–1927

The Fleming diode [1] of 1904, and the DeForest triode [2], invented in 1906, were used in radio receiver circuits shortly thereafter. Prior to 1912, the triode (Audion) was used exclusively as a detector, and showed marked superiority over other radio detection methods. The first Audions were highly nonuniform, and had a very poor vacuum. In fact, DeForest as late as 1915 said he could not predict whether the anode current would go up or go down when a signal was impressed; each tube was different [3]. However, starting in 1912, both General Electric Company and Western Electric Company scientists learned to make well evacuated and uniform tubes [4]. By 1915 Langmuir described high-vacuum tungsten-filament diodes and triodes [5], and the Western Electric telephone repeater tubes with oxide-coated filaments were already in use in cascade audio amplifiers.

These early triodes first made practical the cascade amplifier [6], the triode oscillator [7] and the regenerative feedback circuit [8]. In turn, the triode oscillator made possible application of the very important but unused principle of heterodyne reception, invented by Fessenden years before [9] when only arc generators were available. During World War I, both the General Electric and the Western Electric Companies manufactured substantial numbers of receiving tubes, of which the Western Electric VT-1 tube was perhaps best known.

The stimulus of the war led to the invention of the single most important receiver circuit to this day, the superheterodyne [10], [11]. Triode RF amplifiers had been rather unsuccessful except at very low frequencies. Major Armstrong tried to devise a more sensitive receiver, to detect enemy aircraft by their short-wave ignition noise. It then occurred to him [10] to use the heterodyne principle to lower the incoming frequency to a value which could readily be amplified, but which was still high enough to use selective circuits, at what we now call the intermediate frequency. In Germany, the same invention was made, and at about the same time [11]. Although it is obvious that the triode tube, used as an oscillator, as a heterodyne mixer, and as an amplifier, was essential to the superheterodyne, another important impact of the triode was to make possible multiple tuned circuits [12], separated by nonreciprocal active elements.[2]

World War I also stimulated the invention of the second most important electron-tube principle, the use of another grid interposed between control grid and anode, as made by Schottky [13]. Schottky saw the significance of the reverse-phase ac swing of the anode in reducing the cathode current excursion, and he devised the screen grid, at a fixed positive potential, to screen the cathode region from anode fluctuations. At the same time, he also saw that a fixed-potential positive grid between cathode and control grid (space-charge grid) could be used to greatly increase the tube current, if low voltages only were available [13a]. Two- and three-grid tubes were made in many laboratories, and went into modest production in Europe, but the tremendous advantages of the screen-grid principle for both RF amplification and for increased audio output were not widely appreciated at first. About 1926 Hull and Williams described their highly shielded two-grid RF amplifier tube [14] and research laboratories also began to experiment with pentode (*i.e.*, 3-grid) tubes for audio use, and the suppressor grid was invented [15]. A few years later, as we shall see, the screen-grid principle was used in almost every new tube type. However, in this first period of our history, tube manufacturing techniques were only just about reaching the point at which a multigrid tube could be considered; receiver designers had to make do with the triode.

An important help to the receiver designer who had to use triodes for RF amplification was the analysis by Miller [16] and others, of the feedback due to grid-anode capacitance. One proposed solution was the use of a neutralizing or cancelling type of feedback [17], a principle which was later extensively used in the Hazeltine Neutrodyne circuit [18]. Another invention of a completely different kind, was thought to eliminate entirely the need for extensive use of RF cascade amplification,

[2] Only after the perfection of the screen-grid tube was almost complete unilateral amplification achieved.

namely superregeneration [19]. However, many triode RF amplifiers used simple resistors in the grid circuit to prevent oscillation; in superheterodynes, very low IF was used. In all RF cascade triode amplifiers, stage gain was quite low, perhaps 10 to 15 db.

Up to 1920, there were no receivers in the hands of the general public, but by 1923 the broadcast receiver business was flourishing [20]. Among the available tubes were the type 200, a "soft" detector tube, and types 201 and 202 which were high-vacuum amplifier types, all with tungsten filaments. Because electron tubes were expensive, crystal receivers, or one-tube regenerative sets, with earphones, were the rule. About this time, the General Electric Company started manufacture of the '99 and the '01A triodes [21], with thoriated filaments, and the Westinghouse Company introduced the WD-11 oxide-coated filament triode [22]. The reduced filament power of these types was a great advantage to receiver designs, which were battery operated. The reflex type of circuit was devised to hold down the number of tubes, since a single tube was used as both RF and audio amplifier. Gradual reduction of tube prices over the next decade eliminated the economic need for either superregeneration or the reflex circuit, and they soon become obsolete. The Neutrodyne [18] type of tuned RF receiver with '01A tubes became very popular in the early days of broadcasting in spite of the use of a separate tuning knob for each stage. Superheterodyne receivers with six tubes were finally put on sale [23] in 1924 and this type of receiver rapidly developed a reputation for sensitivity and ease of tuning.

As the first period came to a close, elimination of "B" battery operation by means of gas-filled or high-vacuum double-diode rectifiers became common. The demand for higher audio output led to use of higher power or low-mu triodes (types '12, '20, '71, and 210) in the output stage; even so, outputs of under 500 mw were common. At this time, also, a large number of receiving tube companies began to compete strenuously for the increasing volume of business, which attained 67 million dollars per year (1927), for receiving tubes [25].

AC Operation and the Multigrid Tube, 1927 to 1936

Although complete ac operation was feasible with filament-type tubes, further advance in circuit design required the equipotential or indirectly heated oxide-coated cathode. Such a cathode had been invented many years before [24], but high manufacturing cost and great difficulty in controlling heater-cathode leakage prevented its commercial use. The first reasonably reliable indirectly heated triode was the 2.5-volt heater type '27 which was announced in 1927 and adopted by most receiver manufacturers [26]. For a year or two, a companion tube for triode RF amplification, the type '26, which had a low-hum oxide-coated filament, was also used [26]. However, it quickly became apparent to tube manufacturers that all but output tubes would soon require indirectly heated cathodes. The first screen-grid tube, the filament type '22, was also introduced late in 1927, but received almost no use. By early 1929, the 2.5-volt heater, type '24, screen-grid tube became available [27] and began to be used extensively.

Complete ac operation was the key to tremendous improvement in receiver performance from 1927 to 1930. It became practical to use many tubes in a receiver without impractical battery drain. RF amplification and high audio output led to very selective and sensitive receivers [27], [28] capable of operating the newly introduced electrodynamic loudspeakers. Along with the indirectly-heated screen grid and triode tubes, the low-mu, oxide-filament type 45 was commonly used for audio output [29]. The typical 1929 high-performance set used two or three stages of tuned radio-frequency, with screen-grid tubes and a single tuning knob, followed by a high-level linear detector and a triode audio stage with one or more type 45 output tubes, delivering from 1 to 3 w to the speaker. It was at this time that some earlier ideas, the self-bias resistor, and the automatic-volume control principle [30], began to be widely applied [31].

By 1930, superheterodynes with type 24 tubes for the RF and IF amplification began to greatly out-perform the tuned RF sets, particularly for selectivity above 1 Mc. Broadcast stations increased power enough so that cross-modulation became a serious problem and the variable-mu tube (remote cutoff) was invented [32] and appeared in receivers as the screen-grid 2.5-volt heater type 35. The output pentode [33], already in use in Europe, was introduced in the U. S. by one of the smaller tube manufacturers, Arcturus [34], and the similar type 47 soon superseded the old low-mu triode type 45 as the most popular output tube. In the meantime, automobile receivers were introduced and a 6-volt heater line, in a small glass envelope, became available as the types 36, 37, 38 and 39. The type 38 was the first indirectly heated output pentode. In a few years, the 6-volt heater took over, and 2.5-volt tubes were discontinued.

Tube developments came so rapidly in 1931 to 1933 that it is impossible to list more than a fraction. Class B amplification was used in the highest-output audio stages [35], [36] and the types 46, 79 and 53 were developed; the latter two types were double triodes, and were the forerunner of a very popular type of tube ten years later. The type 55 and 85 were combination diode-triodes. The 41, 42, 59 and 89 were all indirectly heated screen-grid output tubes. For 110-volt operation ac/dc receivers, with series string heaters, the types 43 and 48 screen-grid output tubes were developed. The year 1932 also saw the introduction of the dome-top bulb and a whole series of new screen-grid RF amplifier tubes [37] in which a separately connected suppressor was used for the first time. This series included the 56 and 76 triodes, and the 57, 58, 77 and 78 RF amplifiers.

About 1933, a considerably more revolutionary tube development took place, one which once and for all consolidated the superheterodyne as the one and only receiver circuit, even in the lowest-cost sets. This was the pentagrid converter, type 2A7 and 6A7, which used electron coupling between an oscillator inner section and an outer, remote cutoff screen-grid mixer section [38]. Thus, in a single tube, high conversion gain was achieved together with freedom from oscillator interaction with the signal circuit. Within a year or two, this converter tube was almost universally used in the U. S., although in Europe a combination triode-hexode was also used in the same general way. From this time on, it became possible to make a 4-tube-plus-rectifier superheterodyne, with performance not too far from 8- and 10-tube receivers of a few years before. For battery portable receivers, a corresponding low drain filament type, the 1A6 was introduced and was used with other 2-volt types in such applications.

In 1935 a change was made in the base and envelope of almost every basic type of receiving tube. The octal base, with up to eight pins, and with a convenient locating lug, became almost a standard from this point in time. A line of octal-base metal-envelope tubes included the 6J5, 6J7, 6K7, 6A8 and 6F6, which were the counterparts of the earlier dome-top bulb line [39]. The electron ray type of tuning indicator tube continued to use glass, of course, and in a year or two there were many straight-sided glass envelope equivalents to the metal types, designated by the suffix GT. Over the years to follow, metal tubes gradually disappeared from use, but the octal base remained.

For a year or two prior to the metal tube, receiver manufacturers had been including from one to three short-wave bands, with frequency ranges up to 20 Mc or even to 60 Mc. This presented problems for the pentagrid converter, and a 5-grid mixer tube, the 6L7, was developed for the metal line [38]. The 6L7 required a separate oscillator, but had much less oscillator-signal circuit interaction at the short wavelengths. A few years later, the 6K8 and 6SA7 converter tubes were devised for the same purpose [38].

During the development of the metal tube, extensive laboratory work had been undertaken to improve the audio output pentode. These endeavors led to an oval cathode, an aligned control-grid and screen-grid to reduce the screen-grid current, and a minimal suppressor consisting of two side "beam-forming plates"; the remaining suppression of secondary emission came from space charge [40]. The first tube using the new beam principles was the 6L6, and within a few years it was followed by a slightly smaller version, the 6V6. These "beam-power" types had higher output, higher efficiency, and lower distortion than the pentode tubes which they largely replaced; the same beam principles are still in use today.

The close of this period of rapid expansion saw receiving tube production rise to nearly 100 million units per year (1936) and price competition, plus mass production techniques, led to cost reductions which were among the most remarkable in the history of the industrial revolution. Whereas the type '01A triode of 1923 had a list price of about $9.00, the five-grid converter tube of 1936 had a list price of only around $1.25. In 1936, about 9 million radio receivers were sold, with a retail value of around 500 million dollars.

Close-Spaced Tubes and VHF, 1936 to 1960

Just as the first period was chacterized by the triode, and the second period by the indirect heater and multigrid tube, the third period is characterized by the use of close grid-cathode spacing. For many years it had been appreciated that closer spacing between control grid and cathode led to higher transconductance. However, tube manufacturers prior to 1936 held firmly to a conviction that 0.015-in (0.4 mm) spacing was about as small as practicable for a low-cost mass-production tube. The improved understanding of transit-time effects [41], fluctuation noise [42], and the principles of wide-band amplification [43] all led to only one conclusion: Practical television and FM at VHF frequencies required that tube spacings be very much smaller.

Fortunately, acorn tube [44] manufacturing experience showed that short lengths of cathode and grid *did* permit reasonable yields, even with 0.005-in spacing. The additional feature of dc inverse feedback, through a cathode bias resistor, turned out to make such spacings practicable even for longer length cathodes, and the first wide-band amplifier tubes, the 1853/6AB7 and the 1852/6AC7 were born [45]. From this point on, almost every subsequent tube development of importance used spacings substantially less than had previously been believed practicable and, most remarkable of all, this was eventually done with very little increase in manufacturing cost. At the same time as this progress was made in receiving tubes, television picture tubes with up to 12-in diameter white screens were developed and the 1939 World's Fair saw the introduction of the first television receivers designed for home use [46]. These operated up to 90 Mc and had IF and video bandwidth of 4 Mc. Just a year before, the first commercial FM receivers [47] were put on sale; they operated in the 50 Mc region.

By 1939, some other chacteristics of future receiving tubes were evident. Metal tubes were getting much competition from glass types, particularly from the GT and a glass base type known as the "loctal." Tube types, essentially the same in principle, but with very minor deviations in basing, or internal capacitances, proliferated almost without end (for this reason, specific tube types will no longer be mentioned in the remainder of this section). A line of miniature glass tubes for battery-operated portable receivers was successfully manufactured [48], and this small sized glass envelope with a new integral 7-pin glass base was destined to become the standard for all except the highest power receiving tubes of the future. The structure was small, inexpensive, and the short leads were ideally suited for

VHF type operation. During World War II, this trend to the miniature glass envelope became consolidated [49], and the tubes which are in use today (1962) in almost every broadcast and TV receiver are essentially World War II types modified for commercial production.

After the war, just about every tube which had been known before the war had a redesigned counterpart in either a miniature, $\frac{3}{4}$-in diameter envelope, a 9-pin $\frac{7}{8}$-in envelope, or in the GT octal-base glass construction. A major change, however, was a greatly increased use of double-triodes in receiver circuitry, particularly in TV receivers. In fact, this type of tube essentially halted the more extensive use of multigrid structures, since it was found that a double triode was a less expensive way to solve a circuit problem than use of two higher-performance multigrid structures [50]. In the case of low-noise TV input amplifiers, the cascode circuit [51] for the double triode actually provided better performance than any known multigrid tube circuit.

In their impact on receivers, the post-war tubes permitted excellent FM performance in the newly assigned 100-Mc band, and television reception up to 216 Mc was most satisfactory. In the television receiver, the special problems of magnetic deflection [52], [53] were solved by special beam type deflection tubes, and low-impedance damping diodes. Picture tube anode voltages were raised to high values permitted by pulse transformers operating filamentary high-voltage rectifiers. The picture tubes themselves were greatly improved, with greater size and aluminized backing for the phosphor [54]. By 1950 it was clear that electronic color television was entirely feasible, at least from a technical point of view, and color-television picture tubes had already been successfully demonstrated [55], [56]. Extensive use of inverse feedback in high-gain audio amplifiers led to greatly improved sound quality, both in receivers and in separate hi-fi equipment.

From 1953 on, tube developments played a diminishing role in broadcast receivers, because of the major impact of the solid-state art, *i.e.*, the transistor and the junction rectifier. The transistor quickly dominated the portable receiver, and the silicon rectifier is rapidly replacing the vacuum tube types in ac receivers. By 1956, tube developments were already altering to match the transistor. In the automobile receiver, an old principle, the space-charge grid (invented in 1913, but never used), was revived, so that 12-volt operation became feasible in the so-called "hybrid" receiver, with tubes for the RF and IF and a tube driver for a transistor audio output [57]. A radically new line of tubes, called Nuvistors, was developed [58]. These were very small in size, had extremely low power consumption, and had superior high-frequency performance over other low-cost tubes and transistors [59].

At the close of this period, receiving tube sales were still high[3] because the transistor had not yet entered the TV or FM receiver, and low-frequency broadcast receiver sales were chiefly confined to portable and auto receivers. However, the trend is clear and the amplifying type of receiving tube, as we knew it in the past, has clearly seen its zenith.

[3] In 1959, over 400 million receiving tubes were sold.

The Present and the Future

At the present time, the major advantages which the receiving tubes have over the competing solid-state devices are cost and performance. The tube has had forty years of improving technology, mass production, and cost reduction, while solid-state devices have had only about ten years. If size and power consumption are disregarded, there is almost no function in which the receiving tube is not superior in performance to the semiconductor device, except perhaps for the power rectifier. Nevertheless, it is also clear that the receiving tube is at a time of minor refinements, and no major new inventions are likely. The solid-state device, on the other hand, is only just beginning to achieve low-cost production, and major performance-improving inventions are being made each year.

Perhaps the real clue to the future lies in integrated and functional electronics, or microelectronics as it is also called. Future receivers will surely include functional subsystems, replacing the arrays of active and passive components we now use. By far the greatest research effort in micro-electronics is going on in the solid-state area. However, there are several groups of competent investigators who are convinced that a form of vacuum-tube technology may yet be the answer. The outcome will probably lie in both areas, *i.e.*, there will be microelectronic systems of both types. Nevertheless, in the writer's opinion, the broadcast and TV receivers of the future will slowly and inevitably tend toward predominant use of solid-state devices, with the exception of the picture tube.

BROADCASTING

Organized with the assistance of the IRE Professional Group on Broadcasting

AM and FM Broadcasting*

RAYMOND F. GUY†, FELLOW, IRE

Summary—**Interesting early experiments and significant technical milestones are described in radiotelephony preceding the birth of the broadcasting industry at KDKA in 1920. The technical problems and difficulties which faced the burgeoning early growth and subsequent development are outlined and the most significant advances in the technology are outlined as they occurred in both AM and FM broadcasting. The descriptions are accompanied by comments concerning the past, present and possible future status and trends in both services and the manner in which they may be influenced by factors which are unique to each.**

USEFUL COMMUNICATION by radio had its humble beginnings as the 19th century drew to a close. By 1920 it had attained stature as an important component in the world's economies, and had become a great boon to mankind. Yet throughout this period commercial radio operations were conducted by technically trained professional people at specially built commercial, governmental or military installations. In 1920 a profound change took place. Radio also moved into the home, to become a vital force to be enjoyed by all members of the family. A new service was born.

In retrospect it seems inevitable that such a development should have taken place because of the advances in the technology of transmission and reception of radiotelephony. In particular, the mass production of simple and inexpensive radio receivers, the "little black box," which could be installed and operated by any member of the family, represented the fruition of the dreams of pioneers such as Fessenden, de Forest, and Sarnoff.

* Received by the IRE, November 14, 1961.

Early Experiments in Broadcasting

The first documented successful broadcasting of speech and music was conducted by Dr. Reginald Fessenden at Brant Rock, Mass., on Christmas eve, 1906, utilizing a 50 kc radio-frequency alternator which produced about 1 kw of power and which was built by the General Electric Co. under the direction of Dr. E. F. W. Alexanderson. Modulation was accomplished by means of a microphone which is believed to have been water-cooled and which was connected in the antenna circuit. Clear reception was obtained at many locations including ships at sea [1].

Subsequently Dr. Lee de Forest conducted experimental broadcasting in 1907 from his laboratory in New York City, in 1908 from the Eiffel Tower in Paris, and in 1910 from the Metropolitan Opera House in New York City. These experiments, which were conducted with arc transmitters of about 500 watts power, modulated by microphones in the antenna-ground system, while successful, were handicapped by the high noise level inherent in arc transmitters. However, the Metropolitan broadcasts were particularly noteworthy in that they consisted of performances from the stage featuring Enrico Caruso and other great artists of the day.

The discovery that the de Forest triode could be made to produce continuous wave oscillations, and its adoption as a carrier generator, led to a succession of experimental transmissions of high-quality radiotelephony including those of de Forest in 1916 from High Bridge, N. Y., those at Tufts College in 1915–1916, and those of the ATT Co. in 1915 at the Naval Station, Arlington, Va. The ATT Co. equipment employed 500 tubes in parallel as Class A amplifiers and was heard in Paris and Honolulu.

Although it was demonstrated during this period that high-quality radiotelephony could be achieved with practical vacuum tubes and ancillary components, it was not until after World War I that it was shown that high plate operating efficiency could be obtained in combination with highly sophisticated and satisfactory methods of modulation. For the development of the class C radio-frequency amplifier and efficient methods of modulating it, including the constant current system, we are indebted to Dr. Raymond A. Heising. His work on modulating systems was described in the August, 1921, issue of the IRE PROCEEDINGS for which he was awarded the Morris Leibman prize [2], [3].

Experimental transmissions by Dr. Frank Conrad of the Westinghouse Electric and Manufacturing Co. in 1919 and 1920 from his amateur station 8 XK, in Pittsburgh, created such great interest that musical programs were transmitted at scheduled times. His rapidly growing audience led to the inescapable conclusion that the time was ripe for the creation of a public broadcasting service and a U. S. Government license was requested and received for the purpose. The world's first broadcasting station to be assigned special call letters and a special frequency for its purpose was KDKA, Pittsburgh, Pa., which inaugurated a public broadcasting service in November, 1920.

Early broadcasts from the studio soon were supplemented by broadcasts from churches and other remote points, using wire lines for conveying the program signals to the transmitter. Public acceptance and enthusiasm for this service was immediate and created a phenomenon which was not to be duplicated until many years later with the new television service after World War II. The tremendous rate of growth in broadcasting, particularly during the first few years, may be seen from the listing of station authorizations granted by the Department of Commerce as shown in Table I.

TABLE I

Year	New Authorizations Granted
1920	1
1921	30
1922	639
1923	239
1924	286

Allocation of Frequencies to AM Broadcasting

In 1920 and 1921, broadcasting stations were assigned the wavelength of 360 meters, or 833 kc. The creation of new stations quickly produced an allocations problem which in some areas led to the enforced sharing of time on the air. Recommendations of the First National Radio Conference in 1922 led to the recognition of the need for more adequate regulation of the new service. As a result the classification of "limited commercial" station was abandoned with respect to broadcasting stations, which became classified as such. In addition, the problem of crowding and time sharing was dealt with. More adequately to cope with the growing number of stations, the wavelength of 400 meters, or 750 kc, was also assigned to the broadcasting service, and the power limits of a minimum of 500 watts and a maximum of 1000 watts were established. But these regulations also quickly became inadequate as hundreds of new stations came into existence.

Based upon recommendations of the National Radio Conference of 1923 and 1924, the Department of Commerce allocated the whole band from 550 to 1500 kc to the rapidly growing service and authorized powers up to 5000 watts. This also quickly proved to be inadequate as the demands for frequencies and power increases grew inexorably. In 1925 a Fourth National Radio Conference requested that limits be established on power and broadcast time to relieve the severe and growing interference. However, the attempt to implement these limitations failed. While the Secretary of Commerce was empowered to grant authorizations, he found that he was unable to impose the desired limitations because court decisions held that under the Radio Act of 1912 he had no authority to do so. Thereafter, because of the recognized and admitted lack of regulatory authority, many broadcasters changed their operating frequencies and increased their powers at will. Bedlam resulted as Federal Regulation disintegrated.

In 1926 Congress was urgently requested by President Coolidge to take remedial action to restore control, which was accomplished under the Dill-White Act of 1927. The Federal Radio Commission was created with broad powers and one of its first tasks was to restore order and correct the chaotic conditions. It proved to be impossible to make satisfactory provisions for the 732 stations then in operation, as a result of which about 150 stations were required to surrender their licenses and cease operating, and many others to change frequencies and other operating conditions.

The final and most significant action in the regulatory field was the creation of the Federal Communications Commission under the Communications Act of 1934. This body was given broad authority and charged with responsibility for regulation of all interstate and foreign communications by radio and wire.

Under the FCC, growth has been orderly. New Rules and Regulations have taken advantage of technical developments through the years of its existence to increase the service to the public, and the number of stations which provide it. The broadcast band has been widened to encompass 540 to 1600 kc and the number of stations has grown to over 3500, with nearly 900 new applications currently awaiting processing.

International Interference Problems

The burgeoning broadcasting industry experienced other growing pains during its early years, as more stations were built and operating powers were increased in all of the countries of the North American Region. Each country has a sovereign right to use any part of the frequency spectrum at will. But the exercise of this right quickly led to interference between stations in the various countries in the North American Region, particularly during the night time hours when skywave propogation produced substantial interfering fields at distances of many hundreds of miles. International interference was becoming intolerable by 1935.

By mutual agreement the countries of the North American Region met in Havana in an effort to negotiate a satisfactory agreement on the sharing of the broadcast spectrum and the mutual protection of the services of the participants. An agreement was reached in 1937, signed by the United States, Canada, Cuba, Mexico, the Dominican Republic and Haiti. Unfortunately, this agreement was not made effective until 1941 and it expired in 1946. It was succeeded by an interim agreement, arrived at with some difficulty, which extended the original North American Regional Broadcasting Agreement for three years, until 1949, with concessions to some countries. Upon expiration, another difficult period of negotiations followed which led to a new agreement in 1950 among all of the countries except Mexico. This agreement was not ratified until about 8 years had elapsed, largely because, without the participation of Mexico, there was strong opposition on the grounds that protection to the participating countries was not assured. In 1957 a bilateral agreement between the United States and Mexico cleared the way for ratification which followed shortly thereafter.

Negotiation of such agreements was complicated by the conflict of interests among not only the countries which participated, but also by such conflicts between various interests in the individual countries. As an example, in the United States there were conflicts of interest between organized groups of stations limited to daytime operation, regional channel operation and clear channel operation. One of the most difficult issues was the demand for additional clear channel rights by Cuba and Mexico.

Insofar as technical performance was concerned, in all countries and to a large degree, these conflicts could have been relieved by the use of FM broadcasting by stations limited in power and service area by crowding in the standard broadcasting band. But the long established public habit of listening to AM stations, the cost of developing and building an FM audience, and the competitive dislocation and hardship involved left little choice for stations which would not have been able to survive a hazardous and uncertain transistion. The existence of a large, ready-made and established AM listening audience, compared with the far smaller FM audience, has been the incentive behind the very large increase in the number of new AM stations during the post-war period, despite the fact that for most small stations a larger area could be served, free of interference and with the other inherent advantages of the FM system.

Directional Antenna Systems

The very rapid growth of broadcasting during the period 1920–1926 required much sharing of carrier frequency assignments at what were deemed to be adequate geographical separations to maintain reasonable limits of mutual interference. The antennas employed at that time were omnidirectional. Under these conditions this technique for a time made it possible to find suitable frequency assignments for new applicants. But as the number of new applications continued to mount it was not long before difficulties arose. It became evident that if a technical solution were not found, either the interference standards would have to be relaxed or the granting of new applications would have to be increasingly limited until a static condition prevailed.

The technical solution which went far to relieve this problem was provided in 1927, early in broadcasting history, by two consulting engineers, Raymond Wilmotte and T. A. M. Craven, acting on behalf of a Florida applicant. Mr. Craven is now an FCC Commissioner.

Although directional antenna technology was not unknown, and a three-element medium frequency array had been described in a textbook around the turn of the century, none had been proposed for this service. Directional antennas used in other services were designed to increase the field intensity in a discrete direction. For the Florida application, Craven and Wilmotte proposed to utilize the directional properties to decrease it in the direction of a mid-western station, in order to protect it against interference.

Although directional antennas inevitably would have come into use at some time, the success of this project was particularly timely. It marked an important milestone in efficient use of the broadcast spectrum. The impact on the industry was substantial and beneficial, as evidenced by the hundreds of directional stations now operating which otherwise could not have been authorized.

Design Trends in AM Broadcasting Apparatus

Beginning with KDKA, the earliest broadcast transmitters generally consisted of self-excited oscillators modulated by class A constant-current Heising modulators. Because of the cost and design problems in developing large amounts of audio frequency power with class A modulators, most of the transmitters of that time were limited to 15 to 50 per cent modulation. One of the first 50 kw transmitters required 22 water-cooled modulator tubes to achieve 40 per cent modulation. The original KDKA transmitter produced 100 watts and others ranged from 5 to 500 watts. Lacking any special provisions for precise control of the carrier frequency, and a more precise measuring device than a wavemeter, stations operated on a rough approximation of the assigned frequency. It was not unusual in the earliest years to change the operating frequency 50,000 cycles to avoid, temporarily, interference from an unknown source.

Radiating systems consisted of *T* or *L* antennas with very poor ground systems and were characterized by radiation efficiencies which were very low by modern standards. Filament and plate supplies normally consisted of batteries or motor generators. One station, owned by a battery manufacturer, obtained plate power from a 10,000 volt battery. Safety devices were often crude or omitted entirely.

Improvements followed rapidly. The term "superpower" was loosely applied first to 5 kw in 1923, then to 50 kw in 1925, and finally to 500 kw in 1934 [4]. The one and only 500-kw transmitter licensed and used in the United States was at WLW, but this was destined to continue for only a limited time. A few years later the authorization was withdrawn and replaced with one for 50 kw, the highest power permitted since that time. In the absence of such a restriction, powers of 500 kw or more would have been used by many clear channel stations to provide new and improved service to millions of listeners. The wisdom of this restriction has been a highly controversial and debated question in the industry for over a quarter of a century.

It may be surprising to some that the achievement of satisfactory 100 per cent modulation in broadcast transmitters was, in general, delayed until new and improved techniques such as the class B modulator [5], [6], the Chireix outphasing system [7], and the Doherty high-efficiency system [8] were developed from 7 to 10 years after the birth of such a virile industry, but such was the case. All of these systems have been in use for about a quarter century. By far the most widely used is the class C radio frequency amplifier modulated by a class B modulator.

In the early years of broadcasting, during which self-excited oscillators were used to generate the carrier power, precise control of the operating frequency was impossible. Carrier frequencies varied from hundreds to thousands of cycles from the assigned frequency. In co-channel operation, nighttime interference between stations was characterized by interchannel beat notes which were usually in the most responsive range of loudspeakers, and extremely destructive to reception. Fortunately, this aggravation could be and was solved following the evolution of the crystal controlled oscillator about 1926. A first step toward a solution was taken when, shortly thereafter, the Regularity Authority imposed a 500-cycle tolerance on carrier frequency deviation, representing a reasonable recognition of the technology. A few years later, as the technology advanced, this tolerance was reduced to 20 cycles. Since this limits the frequency of a beat note between two stations to a maximum of 40 cycles, and stations actually maintain their frequencies to within one or two cycles, audible beat notes ceased to be a problem.

The development of efficient broadcasting antenna systems lagged somewhat in the early years but gained impetus with the work of Brown, Gihring and Ballantine [9]–[12] in 1934–1936. These published works quickly were reflected in new designs and also new FCC minimum standards of performance which stations are required to meet.

Viewed in the light of improvements which have taken place in apparatus and techniques, technical progress in the broadcasting industry has been gratifying. However, these improvements in general had been accomplished 20 or more years ago. The technology of AM broadcasting at that time had attained substantial maturity and stability. Although the number of stations has tripled in the ensuing years, the growth has taken place largely within the technical framework and level of competence established then. Subsequently, changes have been marked principally by the growing application of automated operation, the terminal development and widespread use of audio tape, growing application of remote control of apparatus, including transmitters, and gradual refinements and improvements in moderate degree of apparatus units and components, of which solid-state power rectifiers is an example.

Were a listener able to compare the transmissions of today with those of 20 years ago, the technical difference would be unnoticeable. Program-wise the difference would be very noticeable because AM programming has had to be adjusted to meet the impact of television.

Stereophonic Transmission in AM Broadcasting

During the past few years there has been a growing interest in stereophonic reproduction of music. Several proposals have been made to the FCC that it be authorized in AM broadcasting. The methods proposed, in general, contemplated the use of amplitude modulation of $A+B$, and the use of velocity modulation of the same carrier for $A-B$. After studying these proposals, the FCC ruled that it would not be authorized because of the lack of public interest and the technical problems attendent upon its use in the Standard Broadcast band.

Compatible Single Sideband Transmission

Another proposal has been under consideration, the use of compatible single sideband transmission. This system, developed and advocated by Kahn [13], may be applied to a conventional Standard Broadcast transmitter by the addition of equipment mounted on standard telephone-type racks, and a few simple changes in the transmitter input circuitry. In the Kahn system only the low audio frequency components have sufficient amplitude to produce appreciable second-order sideband components. The bandwidth of the CSSB wave is essentially that of a conventional SSB wave, occupying about half of the bandwidth of a conventional AM double sideband wave. This reduction of transmitted sideband width may be employed effectively to reduce co-channel or adjacent channel interference. A desired-to-undesired sideband ratio of about 30 db is achieved with normal modulation. By tuning the receiver it is possible to utilize the full RF-IF pass band to obtain from the SSB system a wider range of audio frequency reproduction.

The Kahn system has merit and could be applied to Standard Broadcasting without cost to the public, obsoleting existing receivers, or other major complications. It is the first system of its kind to be proposed in the 41-year history of broadcasting and has the advantage that it could be authorized as an optional method of modulation. A technical description of the Kahn system is given in another paper in this issue by Reed [25].

Technical Status of AM Broadcasting

Although changes may take place in the continuing adjustment of the program format and the economics of AM broadcasting, it must be viewed as a relatively mature industry. Because of limitations of channel width and near-saturation of the broadcast band, the tremendous investment in publicly owned receivers, the cost, and the absence of public demand, any sweeping changes in frequency allocations or technical methods seem impractical. The Kahn system could be integrated with existing techniques without such sweeping changes.

The excellent national television service, and the growing FM service will not, in the foreseeable future, supplant AM broadcasting, which continues to expand. AM broadcasting provides service which cannot be duplicated by TV or FM with respect to daytime service range, and nighttime skywave service to relatively great distances.

Frequency Modulation Broadcasting

The development of commercial FM broadcasting, as was the case with commercial television, encountered some formidable obstacles. Both services were born in 1941; within a period of months the United States was at war. Production of apparatus was halted and expansion of these services came to a halt. After the war ended, both services were required to readjust to new changes in the portions of the frequency spectrum assigned to them.

Not the least of the problems facing the infant FM service was the competition from the well-established, prosperous and reasonably satisfactory AM service. In urban and suburban areas the vast majority of listeners received good service with a wide choice of programs, and could not receive FM transmissions without a substantial investment in receivers. The principal advantages of FM to the public were:

1) the availability of a system in which there were no inherent limitations on the fidelity of transmission and reception which could be achieved,
2) the inherent capacity to reduce noise and interference,
3) the availability of new channels on which more stations could operate to provide new or greater service.

FM broadcasting was authorized on January 1, 1941. For this service the FCC assigned the 42-50-Mc frequency band, which encompassed 40 channels. The 42–43-Mc bloc was for noncommercial operation and the 43–50 for commercial. About 350,000 receivers were sold for this allocation format. Then, in 1945, the entire FM allocation plan was changed, the 42–50-Mc bloc was abandoned and the service was moved up to 88–108-Mc to encompass 100 channels. 88–92 Mc are assigned for noncommercial use and 92–108 Mc for commercial.

For FM broadcasting, which produced little or no revenue, this was a difficult adjustment to make. Despite the fact that the increased number of channels was very desirable, this move was not made without spirited controversy based upon the financial hardship and dislocation involved, and doubts about the severity of the potential interference claimed to exist because of long-distance F-layer propagation at 40–50 Mc during periods of maximum sunspot activity. To a lesser degree there were some misgivings about the adequacy of 100 channels for a fully developed national competitive FM service, with particular reference to the heavily populated northeastern states.

Much of the impetus to the growth of FM broadcasting arose from the concern of AM station owners that if they did not have an FM station they might not be able to obtain a frequency assignment for one when, possibly, FM broadcasting would supplant AM. Most of the early stations, and many of those now operating, duplicated or duplicate their programs on AM and FM in the same area. Possibly 10 per cent of the early FM operations were abandoned as these fears diminished.

Subsidiary FM Services

In order to stimulate the growth of the struggling FM industry, the FCC, in May, 1945, authorized a subsidiary form of service upon the application for and granting of a Subsidiary Communications Authorization. Weather information, time signals, background music for restaurants, stores, homes, etc., special programs for merchandising establishments, religious, professional, educational, agricultural groups, etc., were permitted under the condition that the service on the main channel be conducted simultaneously, for general public reception, with conventional receivers, without interference. Within two years about 100 stations took advantage of this option.

The growth of FM broadcasting in recent years has been more solidly based upon a desire to provide high-fidelity transmission of good music, cultural and educational programs, or other forms of service which could not be provided in the almost saturated AM band. A lack of public understanding of high-fidelity reproduction, and rather widespread indifference to it in the early years of FM operation, have gradually diminished. Growing appreciation of high-fidelity reproduction and stereophony are creating a growing interest and appreciation of FM broadcasting and there is every reason to believe that this interest, and the FM broadcasting service, will continue to expand.

FM growth already has reached the milestone where FCC competitive hearings have been necessary to determine which of many applicants should be granted the only remaining unassigned channels in some of our large cities in the northeastern states and elsewhere. In the spring of 1961 over 800 FM stations were licensed, construction permits had been requested for about 300 more, and there were on file over 100 other new applications.

An Interesting Sidelight on FM Development

Any author writing about the history of FM would be remiss in omitting reference to two early patent applications 60 years ago by Cornelius D. Ehret, a Philadelphia patent attorney. On February 10, 1902, he filed with the U. S. Patent Office disclosures covering the transmission and reception of code signals or speech by varying the frequency of wireless waves. So far as is known these were the first disclosures to describe any system of modulation by name. His method of modulation consisted of varying the resistance or reactance in the circuitry of an oscillator. Inasmuch as the de Forest triode was not to be invented until four years later, and an additional period of several years was to lapse before it was discovered that it could be made to oscillate or amplify, Ehret showed the spark type of impulse oscillator of the day. He described a demodulator employing slope detection and specified that the method did not depend upon increasing or diminishing the amount of energy transmitted.

The amount of interest in FM in the very early years of the industry may be surprising in view of the fact that it was not used for telephony to any significant extent until 39 years after Ehret's disclosures. Table II shows year by year the number of patent applications applying to frequency or phase modulation, of which roughly 90 per cent cover FM.

It is evident that there have been many workers in the field of FM, and many contributors to the technology, but two certainly warrant special recognition, Edwin H. Armstrong and Murray Crosby.

TABLE II

Year	Applications or grants

An early and enthusiastic advocate of FM broadcasting, Armstrong, through his tireless dedication and efforts, his technical papers and his innumerable promotional activities, brought to public attention the merits of the system and provided the leadership which led to the adoption of frequency allocations and technical standards, and the authorization of commercial service by the FCC on January 1, 1941. His name has been inseparably linked with FM since his historic paper in 1936 [14].

Crosby, over a period of many years, enriched the technical literature with the results of his tireless investigation of phase and frequency modulation methods and systems [15]–[21]. His contributions were particularly timely and valuable during the years prior to 1941, when the system was being developed and field tested [24].

Stereophonic Transmission in FM Broadcasting

Since World War II there has been mounting public interest in high-quality reproduction of music. In the home instrument field the techniques for accomplishing it with audio tape and grooved recordings have improved a great deal, and the sale of such equipment has grown to hundreds of millions of dollars each year. There has been a parallel interest also in stereophonic reproduction in both home record players and FM broadcasting. In recognition of this interest the FCC invited industry proposals for national stereophonic standards for FM. With the assistance of a specially appointed National Stereophonic Radio Committee, under the chairmanship of A. Prose Walker, the several systems which were proposed were field tested [22], one was adopted, and the FCC on June 1, 1961 authorized commercial stereophonic transmission in the FM broadcasting service. This system is described by Reed [25].

The introduction of stereophonic and subsidiary subcarrier transmission requires more rigid tolerances in the transfer characteristics of the FM system to minimize crosstalk between carrier and subcarriers [23]. In this respect the achievement of a low voltage-standing-wave ratio in the transmission line and antenna system assumes increased importance. Multiplex crosstalk increases with increasing nonlinear phase shift, which usually accompanies a reactive component in the termination. Transient changes caused by ice deposits, rain or snow on some types of antennas may become so severe that continuity of operation may be acheived only by a reduction in power. In a multiplexed system the added vulnerability of crosstalk exists unless the VSWR is low and remians stable.

Trends in FM Transmitting Apparatus

Improvements in FM transmitting apparatus since 1941 have followed advances in the technology and consist principally of

1) the introduction of solid-state components in power supply rectifiers and other circuits,
2) improvements in over-all efficiency through the use of improved tube types and circuitry,
3) improvements in FM modulators to achieve more precise maintenance of average carrier frequency, simplicity, elimination of moving parts, and superior operational stability,
4) the introduction of stereophonic transmission,
5) the introduction of remote control of transmitters.

With the exception of the modulating systems, these new components or techniques are well known and require no recounting even though their application has substantially improved over-all operating efficiency and enabled economies to be achieved in the cost of construction and operation. With respect to the stereophonic FM modulating system which has been adopted as the industry standard, it is described in detail in this issue by Reed [25].

Television Broadcasting*

CLURE H. OWEN†, MEMBER, IRE

Summary—The story of television broadcasting may be divided into three periods of time, *i.e.*, the historical period—to about 1930, the developmental period—to the end of the Second World War, and the commercial period.

One of the first public demonstrations was given by C. Francis Jenkins in Washington, D. C. in 1925. During the 1930's the mechanical scanning equipment was replaced with all electronic equipment. The first "network" or long-distance pickup was the 1940 Republican National Convention in Philadelphia which was broadcast by the NBC station in New York and the General Electric station in Schenectady.

Commercial television was authorized by the Federal Communications Commission, effective July 1, 1941; however it was not until shortly after the end of the Second World War when the electronics industry returned to peace-time conditions that the public became aware of the magic of television in the home. In a relatively short period of time the television broadcasting industry developed from a few stations with very limited programming to a national industry with more than 600 television stations and over 50,000,000 receivers in use by the public. The impact of television has affected the lives of nearly every citizen of this country and its effects are being felt in most of the other countries of the world.

THE STORY OF television broadcasting, even when limited to the technical aspects, cannot be told by one person or contained in a single volume. Accordingly only the highlights can be touched upon in this brief article. Television broadcasting can roughly be divided into three periods of time, *i.e.*, the historical period up to about 1930, the developmental period from the early 1930's to the end of World War II, and the postwar commercial period.

Historical Period

For ages man has dreamed of transmitting sight and sound from one place to another. One of the milestones along the road to television was the isolation of selenium by the Swedish scientist Baron Berzelius in 1817. While the light-sensitive properties of selenium were known for some years, little application of this property was made until 1892 when Elster and Geitel devised a photoelectric cell [1]. This cell is the basic principal upon which television, as we know it today, is based. Another milestone, that of scanning and reproducing an image, was made by Paul Nipkow, a German experimenter, when he invented the scanning disc in 1884. It was Nipkow's concept of changing the picture into electrical bits at the transmission end of a circuit, the sequential transmission of these bits and the reassembly at the receiving end into a complete picture, which makes it possible to transmit a television picture over a single telephone or radio frequency circuit.

The invention of the triode vacuum tube by Dr. Lee deForest in 1906 was one of the greatest achievements in the advancement of communications including, of course, both radio and television. In the early 1920's J. L. Baird in England and C. F. Jenkins in the United States carried on separate experiments using mechanical scanning. The mechanical system of scanning had very definite limitations on the amount of information that could be transmitted (picture quality) and the size of the reproduced image. The appeal of an electronic system without the above limitations was evident by the work of several of the early experimenters. M. Dieckman and G. Glace received a German patent in 1906 and B. Rosing of St. Petersburg received a patent in 1907; both for systems of television using a cathode-ray tube receiver [2]. The first suggestion of an all electronic television system was made by A. A. Campbell-Swinton in 1908 [2]. His suggestion of the camera tube included a multiplicity of photoelectric cells in parallel so that each cell could store a charge until scanned and would deliver only one electric pulse for each picture period. In 1923, V. K. Zworykin filed a U. S. patent for an electronic camera tube known as an "Iconoscope." This tube differed from earlier electronic camera tubes in that it employed beam intensity modulation by an axially symmetric grid. One of the first public demonstrations of television or radio vision, as it was then called, was given by Jenkins on June 13, 1925 when a live picture was transmitted from the Naval Air Station at Anacosta, Maryland, to the Jenkins Laboratories in Washington, D. C., a distance of some miles. A mechanical system of scanning was used in this demonstration [3].

In 1929 Zworykin attained success with an electrostatic cathode-ray picture display known as a "Kinescope." By the early 1930's most work on systems of scanning had changed over to one of the electronic systems. In the United States Philo T. Farnsworth and Vladimir Zworykin headed parallel investigations which by 1933 proposed equipment to make electronic television possible. Other persons making contributions to television about this time were Ives of AT&T, Alexanderson of GE, Goldmark of CBS, Engstrom and Goldsmith of RCA and DuMont [4]. Experimental work was also being carried on in Germany using cathode-ray tubes in receivers [5].

Developmental Period

It is difficult to draw a line of demarcation between the experimental period and the developmental period as there was, during the 1930's, a gradual transition from an occasional equipment test to more frequent,

* Received by the IRE, June 29, 1961; revised manuscript received, November 20, 1961.
† American Broadcasting Company, New York, N. Y.

and in some cases more or less regular, program operations. One of the earliest and most important stations in the development of television was the RCA station W2XBS in New York which went on the air with mechanical scanning equipment in 1928.

During 1931 and 1932 field tests were made with the transmitter located at the Empire State Building [6]. The transmitter used 120-line, 24 frames/sec mechanical scanning. The receivers for these tests used cathode-ray tubes instead of mechanical scanning.

During 1933 a system was built in Camden, New Jersey which used the "Iconoscope" as a pickup device. The system operated on 240 lines, 24 frames/sec. The picture carrier was at 49Mc and the sound carrier was at 50Mc.

In 1934 the system operated with 343 scanning lines and used interlaced scanning. The frame frequency was 30/sec and the field frequency was 60/sec. The last mechanical element of the system was removed by the development of an electronic synchronizing generator.

In 1936 provisions were made for live and film studios at Radio City to be used with the Empire State Building transmitter. The picture carrier was operated at 49.75 Mc and the sound carrier at 52Mc. The two transmitter outputs were fed through coupling filters so that a common transmission line and antenna could be used. The receivers used in these tests were superheterodynes capable of receiving both the picture and sound simultaneously.

During the latter part of the 1930's regular studio programs were instituted (Figs. 1 and 2). At first most of the receivers were company-owned receivers in the homes of RCA-NBC employees; however, by 1940 it was estimated that there were about 3000 receivers in the New York area. On April 30, 1940 a regular public series of television programs was inaugurated with the opening of the New York World's Fair by President Roosevelt.

The Philco Radio and Television station W3XE-WPTZ [7] in Philadelphia carried on extensive broadcasts with remote pickups of outdoor events at Franklin Field. It used a high-frequency radio relay to transmit the programs from Franklin Field to the television station.

The General Electric Company's television station WRGB in Schenectady [7] was one of the early television stations carrying on both equipment and program development.

The Columbia Broadcasting System's station WCBW in New York had its transmitter located in the Chrysler Building and studios in the Grand Central Terminal Building. While this station carried on public interest programming its niche in history is on the basis of the equipment development and color television investigations under the capable leadership of Dr. Peter Goldmark.

The DuMont Laboratories' station WABD in New York [7] carried on both program and equipment development. The resourceful DuMont engineers, whose

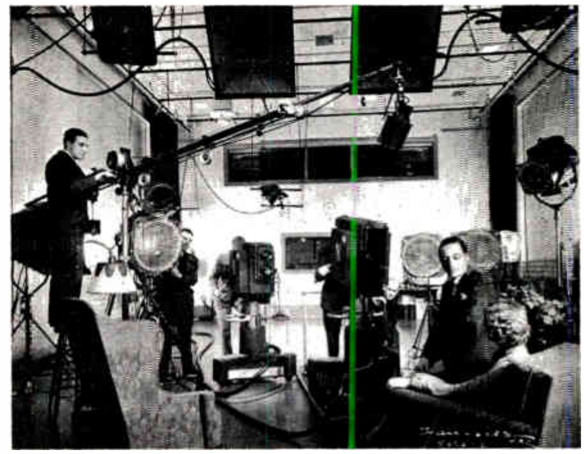

Fig. 1—NBC experimental television studio.

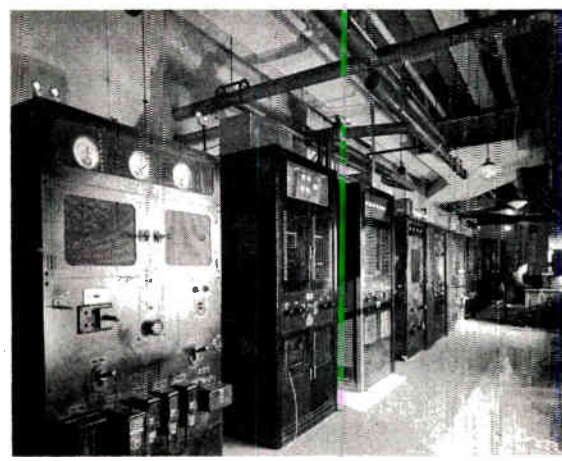

Fig. 2—NBC experimental television transmitter.

great experience in cathode-ray electronics made many contributions to television, produced some of the earliest large kinescope picture tubes.

The Don Lee Company's station W6XAO in Los Angeles [7] was instrumental in the development of interest in television on the West Coast. Station W6XAO carried on extensive tests of television reception in an airplane. Self-synchronized cathode-ray television receivers demonstrated that television reception was possible using power sources other than that common to the power source of the transmitter. A field strength contour map was prepared based upon reception of signals at 3000 feet [8].

The Paramount stations WBKB in Chicago and W6XYZ in Los Angeles [7] were more concerned with the development of programming methods and the production of entertainment than the development of equipment.

The Zenith station W9XZV-WTZR in Chicago [7] carried on small-scale but intensive development of equipment and field testing of television receivers.

The Farnsworth station W2XPF [7] originated on the West Coast but was later moved to Philadelphia. This organization under the guidance of the youthful electronics genius Philo T. Farnsworth made many contributions in the field of television, most noteworthy of which was the "image dissector" camera tube.

In 1936 the British Broadcasting Corporation opened a London transmitting station at Alexander Palace. Two systems were used for television transmission. The Baird system used 240 lines, 25 pictures/sec with sequential scanning. The Marconi-E.M.I. system used 405 lines, 25 pictures/sec, interlaced, to give 50 frames/sec. The Marconi-E.M.I. system used cathode-ray-type pickup for both direct and film transmission [9].

The first "network" or long-distance television pickup [10], [11] was the 1940 Republican National Convention held in Convention Hall in Philadelphia. It was broadcast by the NBC station W2XBS in New York and the GE station W2XB in Schenectady. The pickup was made by NBC field pickup equipment and transmitted by wire lines from the Convention Hall to the Bell System carrier terminal in Philadelphia, to the RCA Building in New York by coaxial cable, to the Empire State Building by wire lines and to the Helderberg mountain site of W2XB by an off-the-air pickup of W2XBS in New York. The wire lines used from the Convention Hall to the Bell System carrier terminal in Philadelphia and from the RCA Building to the Empire State Building in New York were carefully selected telephone circuits with wide-band repeaters and equalizers installed at the terminals, as well as at intervals along the circuits. The coaxial cable used was the experimental coaxial cable installed between New York and Philadelphia by the Bell System for the study of multiple carrier telephone transmission. The off-the-air pickup at the Helderberg mountain site near Schenectady was made possible by a specially constructed receiving antenna system.

Commercial Television

Commercial television was authorized by the Federal Communications Commission, effective July 1, 1941; however, the start of the Second World War shortly thereafter effectively curtailed any rapid development of commercial television. Following the conclusion of the war the television broadcasting industry developed at an unprecedented rate. With only a few low-power television broadcasting stations on the air and a small number of receivers in use the public suddenly became aware of the magic of television in the home. The television home in each neighborhood was a popular meeting place with neighbors, both adults and children, streaming in to watch the new medium of entertainment. Although the size of the television screens was small and the technical quality and program fare inferior by latter-day comparison, the public interest generated by this new medium far exceeded the most optimistic opinions of the "experts." The neighbors soon desired receivers in their own homes and the sale of receivers sky-rocketed. The popularity of television resulted in an increased number of stations until 1948 when the Federal Communications Commission stopped granting authority for additional stations pending a reallocation to minimize interference between stations. The television "freeze" imposed in 1948 was not lifted until 1952 when again new stations were permitted to start broadcasting and the total number of television stations rapidly increased. Table I shows the growth in the number of television stations authorized and the television receivers in use by the public from 1946 through 1960.

The impact of television upon the home, advertising, entertainment, etc., has been the subject of vast quantities of written material. For this article it is sufficient to say that the impact of television has affected the lives of nearly every citizen of this country and its effects are being felt in most of the other countries of the world.

TABLE I

	Commercial Television Stations Authorized* [12]	Television Receivers In Use [13]
1946	30	5,000
1947	66	150,000
1948	109	1,010,000
1949	117	3,660,000
1950	109	9,785,000
1951	109	15,590,000
1952	108	21,460,000
1953	483	26,920,000
1954	573	32,750,000
1955	582	37,360,000
1956	609	42,810,000
1957	651	46,690,000
1958	665	49,900,000
1959	667	53,290,000
1960	653	56,210,000

* At the close of each fiscal year, June 30.

Television Standards

The transmission and reception of television pictures require that the image be electronically disassembled at the transmitting end, transmitted bit-by-bit and reassembled in the correct order at the receiving end. For the receiver to correctly reassemble the picture it is necessary that the transmitter and receiver use the same set of transmission standards, *i.e.*, the same number of lines per picture, the same number of pictures per second, etc. To keep the received picture in step with the transmitted picture, synchronizing signals are transmitted.

During the experimental period of television various numbers of lines per picture and pictures per second were used, with as low as 30-line pictures scanned at a frequency of 5 pictures/sec. To obtain better definition of picture detail the number of lines per picture as well as the number of pictures per second were increased from time to time. During 1936 the RMA Television Committee recommended standards which included 441 lines, frame frequency of 30/sec and field frequency of 60/sec, interlaced. During 1941 the Federal Communications Commission adopted the 525-line standards proposed by the National Television Systems Committee.

Space does not permit the detailed discussion of all the standards of television transmission. The reader is referred to the Rules and Regulations of the Federal Communications Commission for details.

Unfortunately the various countries of the world have adopted different television standards. This, as might be expected, makes for some difficulty in transmitting television programs between countries. In transmitting live or taped television programs between countries where different television standards are used, various standards converters have been employed. In general these standards converters have been based upon the photographic principle, *i.e.*, the picture presentation on a kinescope monitor operating on one set of standards would be photographed by a television camera operating on a different set of standards. The resultant pictures suffered from loss of detail and often had some visible flicker. The American Broadcasting Company has developed an all electronic standards converter which has no optics in the system and has no perceptible picture degradation (Fig. 3). Table II gives the principal television systems of the world.

In 1953 the Federal Communications Commission adopted standards for color television. The standards adopted were the result of several years' work by the National Television Systems Committee. The color standards are compatible with the monochrome standards in that a monochrome receiver is able to receive a black and white picture when the picture is transmitted in color for color-equipped receivers. The color information is transmitted on an amplitude modulated subcarrier at about 3.58 Mc above the picture carrier.

TABLE II

PRINCIPAL TELEVISION SYSTEMS OF THE WORLD [14]

Description Used in Foreign Station Directory	British	World-Wide	Western Europe	Eastern Europe	French
Location of Principal Use	United Kingdom	Western Hemisphere, Far East	Western Europe	Soviet orbit	France and Possessions
Number of Lines Per Picture	405	525	625	625	819
Video Bandwidth (Mc)	3	4	5	6	10.4
Channel Width (Mc)	5	6	7	8	14
Sound Carrier Relative to Vision Carrier (Mc)	−3.5	+4.5	+5.5	+6.5	11.15*
Sound Carrier Relative to Edge of Channel (Mc)	+0.25	−0.25	−0.25	−0.25	0.10*
Interlace	2/1	2/1	2/1	2/1	2/1
Line Frequency (cps)	10,125	15,750	15,625	15,625	20,475
Field Frequency (cps)	50	60	50	50	50
Picture Frequency (cps)	25	30	25	25	25
Vision Modulation	+	−	−	−	+
Level of Black as Percentage of Peak Carrier	30	75	75	75	25
Sound Modulation	AM	FM	FM	FM	AM

* French standards invert the video and audio frequencies for certain channels.

Television Equipment

The experimental and developmental periods of television permitted a determination of the basic fundamentals of television equipment. However, commercial television resulted in demands for equipment which exceeded all expectations. These demands were not restricted to greater quantities of existing equipment but were also for specialized equipment to permit greater flexibility of operations, greater reliability, ease of maintenance, etc.

Competition between stations resulted in a necessity for technical quality control of broadcast signals which would permit the best possible pictures being received by the public. It is not the purpose of the paper to comment on all types of television equipment. However, comments follow on the basic types of equipment such as live cameras, projection, lighting, switching, video recording and transmitting equipment.

Live Television Camera

The live television camera, which can be considered the "eye" of television, is one of the most important single elements in the line-up of the equipment system. With the exception of film or tape reproduction of programs the live television camera serves as the "front door" for the entrance of all television signals into the broadcasting system.

The image orthicon camera is generally considered as the workhorse of the industry for studio use. Its ability to satisfactorily handle scenes with a wide range of light levels ranging from only a few foot-candles for mood scenes to some 300 foot-candles for high lights, is desirable for general studio use.

The vidicon camera has found universal use as a film camera, however, as a live camera its use has been limited. The target, being photoconductive rather than photoemissive as the image orthicon, has a higher sensitivity; as a result the size of the tube as well as the associated camera is much smaller.

Without the electron multiplier and shading control and with less critical beam current control, the operation of the vidicon camera is less critical than the image orthicon camera. The signal-to-noise ratio of the vidicon is more dependent upon light levels than the image orthicon. Accordingly, for general studio use, light levels above 200 foot-candles are required for satisfactory operation. The vidicon is being extensively used at present for unattended closed-circuit television, also for limited area scenes such as newscasts, flip-cards, etc. (Fig. 4).

Live color television cameras have three image orthicon cameras, one for each of the primary colors, red, green and blue. The light from the scene being televised is focused through a lens common to all of the tubes after which it is split three ways by means of dichroic mirrors and light filters. Each color channel has its own amplifiers and color correction circuitry.

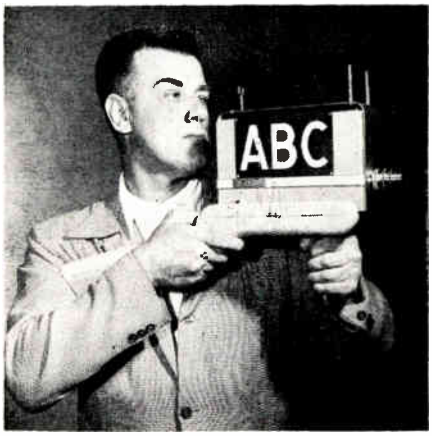

Fig. 4—Vidicon camera.

Film Projection Equipment

Film has always played a very important part in television programming. At first the film used was restricted to motion picture films. In later years more and more of the films used were made especially for television broadcasting. Commercial television started with the use of the iconoscope film cameras. Today the vidicon film cameras have almost completely replaced the old iconoscope cameras with a marked improvement in technical quality. Both 35-mm and 16-mm film projectors are used in the telecine rooms although many of the television stations in smaller markets use only 16-mm film projectors. The film projectors are sometimes used with an individual camera; however, most stations use multiplexers for selecting, by means of movable mirrors, any one of three or four light sources, *i.e.*, film or slide projectors, for use with one film camera chain.

Color television film projection requires the use of three vidicon cameras, one for each of the primary colors, red, green and blue. The light being projected through the color film is separated by appropriate dichroic mirrors and color filters. A separate lens is used for each vidicon film camera.

Lighting Equipment

Artificial lighting is necessary for practically all studio television program pickups. Outdoor scenes with adequate daylight can usually be picked up with an image orthicon camera without additional lighting.

In the early days of television the relatively insensitive iconoscope camera tube required very bright illumination of the subject to be photographed. To obtain adequate pictures light levels of 800 to 1200 foot-candles were needed. There were several disadvantages to these high light levels, such as actor discomfort, high power costs, the great number of lighting fixtures, and tremendous heat loads which made it essential to air-condition the studio.

With the greater sensitivity of the image orthicon camera tube the problem of studio lighting was greatly simplified. With the exception of mood scenes most studio illumination runs from 50 to 150 foot-candles. The lighting of television scenes is an art which involves not only the placement of the light fixtures but the regulation of the light output of the individual lights to obtain the desired artistic effect. The regulation of light output is accomplished by dimmers to control the voltage applied to the lamp filaments. The dimming circuits for the individual lamps vary from the old-fashioned series resistance, through the autotransformers, grid-controlled thyrathron rectifiers to the more modern solid-state silicon controlled rectifier dimmers with punch-card preset control (Fig. 5). The latter system permits almost instantaneous change from one lighting setup to the next.

Video Switching Equipment

In the early days of television the video switching requirements were relatively simple as it was only necessary to switch between cameras or from live to projection equipment. As great strides have been made in television programming great demands have been made upon the switching equipment. This has resulted in complex equipment for handling a large number of inputs and outputs as well as special effects and superimposition and montage of a portion of one scene as an insert within another scene.

Video Recording Equipment

The first type of video recording was accomplished by focusing a film camera on the face of a kinescope monitor. The film was then developed and the required number of prints made. This type of video recording has been used for network film distribution since the early days of commercial television. The principal users of kine recordings are stations which do not have live network connections or which desire to schedule the program at other than the time it is carried on the network.

Video tape recording equipment permits immediate playback of a program and is capable of higher technical quality than kine recordings. Video tape recording has added a third source of television programming to the previous live or filmed sources. The use of video tape equipment permits a more efficient use of studio space, as entire programs, selected scenes, or commercials can be prerecorded and inserted at the desired time.

Transmitting Equipment

Television transmitters are somewhat different from transmitters in other services as it is necessary to transmit both the aural and visual signals within the 6-Mc television channel. This is normally accomplished by two separate transmitters, one carrying the aural signals and the other carrying the visual signals. The outputs of both transmitters are generally fed into a diplexing circuit for exciting a single antenna with both aural and visual signals (Fig. 6).

The high-frequency propagation of television signals requires that the transmitting antennas be located as high as possible above the surrounding area to provide maximum service. Accordingly most transmitting antennas are located on mountain tops or tall buildings. Furthermore, due to the directional characteristics of television receiving antennas it is advantageous to have all of the television transmitters in the same area. Fig. 7 shows the transmitting antennas on the Empire State Building where all seven of the New York television stations are located.

Fig. 5—Solid-state silicon controlled rectifier dimmers with punch-card preset control.

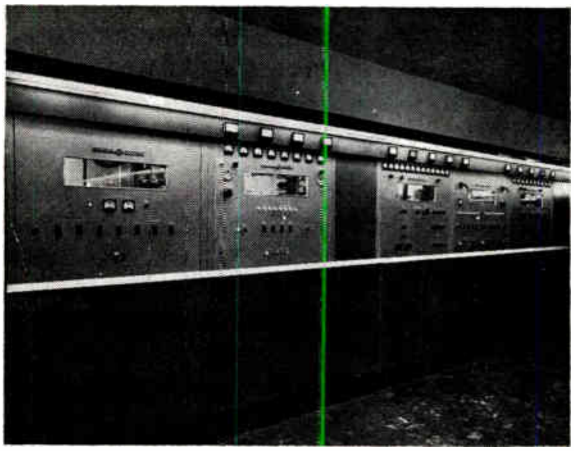

Fig. 6—50-kw television transmitter.

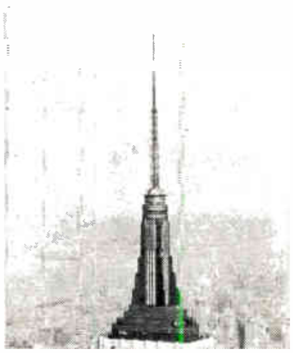

Fig. 7—The Empire State Building tower with seven television transmitting antennas.

Common Carrier Transmission of Television Programs

The common carrier facilities of the telephone companies are the arteries which carry the life-blood television programs from the network control centers to the affiliated stations across the country. The transmission of television programs, as distinguished from radio programs, involves the transmission of both the sound programs and the picture programs. Technically these could be transmitted together over the same circuits. In the United States, however, due to the existence of considerable audio facilities for more than two decades of radio network transmission, the aural and visual programs are transmitted over separate circuits.

Liaison between the television networks and the telephone companies is maintained by two special committees in addition to the normal operating contacts. The Video Transmission Engineering Advisory Committee (VITEAC) promotes a common understanding of the various factors of an engineering and policy nature as related to network service. The Network Transmission Committee (NTC) is the working subcommittee of the VITEAC.

It is the function of network facilities to deliver to numerous receiving locations a signal which is essentially unchanged from the signal which is applied at the originating point. To transmit audio signals satisfactorily, the facilities must transmit all frequencies with uniform loss and phase shift and must accommodate the complete range of loudness without distortion from overloading or interference from noise. For this reason they are gain and delay equalized, and maximum and minimum levels are established.

Similarly, video facilities are equalized for gain and delay and also for differential gain and phase, and operating levels are set. The frequency band required for video transmission extends from 0 to 4.5 Mc and the entire band is equalized essentially flat. Variations from flatness in the region from 0 to 250 kc result in streaking or smearing of the picture. In the high-frequency range different tolerances apply to color and monochrome transmission. For color television signals differential gain and phase require close control to avoid effects on the hue and saturation of the color signal. Color facilities in general are equipped with special equalizers which operate in the range of the color subcarrier and its sidebands. Circuits which are set up to handle color television transmission will also handle monochrome transmission.

In the early period of television network transmission coaxial cable was used for intercity circuits. New circuits are now using microwave radio facilities.

Community Antenna Systems

The location and service range of television stations in the United States and Canada were such that many of the people, particularly those residing in the mountainous areas, were unable to enjoy television reception. Due to the very great demand for television reception many community antenna systems were installed. In general these systems consisted of a high-gain television receiving system installed on a mountain top near the community, a radio frequency amplifier and a coaxial cable system for transmitting the television signals from the mountain-top location to the various homes in the community. Most of the installations have been able to receive and distribute the programs of several television stations. Some of the community antenna systems use a microwave circuit where off-the-air reception of television programs is not possible.

Television Booster and Translator Stations

Television booster and translator stations, in a manner comparable to the community antenna systems, are means of extending television service into underserved areas. In general these are low-power relay stations located on mountain tops or other areas of possible television reception. The signals are received and retransmitted, on the same television channel in the case of the booster stations, or on a different channel in the case of the translator stations, to the television receivers in the areas of desired reception.

Acknowledgment

The author wishes to express his appreciation to R. M. Morris of the American Broadcasting Company and to H. A. Ahnemann of the AT&T Long Lines Department for their assistance in the preparation of this manuscript.

Frequency Allocations for Broadcasting*

GEORGE R. TOWN†, FELLOW, IRE

Summary—**Any sound plan for frequency allocations for broadcasting must be based on engineering considerations. A broadcasting system—AM, FM or television—may be divided into its component elements, the characteristics of these elements pertinent to allocations may be analyzed, and a technically consistent allocation plan can be developed. The major components are the eye of the television viewer or the ear of the radio listener, the receiving installation, the existing electrical noise, the physical facts of wave propagation, and the transmitting installation. Historically, allocation plans were not developed solely through such engineering studies. AM broadcasting grew in a chaotic manner, and early attempts at governmental regulation were declared illegal by the courts. Remedial legislation resulted in the establishment of the Federal Radio Commission and its successor, the Federal Communications Commission (FCC) with legally delegated regulatory responsibilities and authority. Television and FM broadcasting, which came later, were always subject to governmental regulation. Television profited greatly from the high degree of cooperation at the engineering level which has existed between the FCC and the television industry. The practical administration of broadcast allocations depends upon other factors as well as engineering considerations. In analyzing the critical needs of the future, some of these non-engineering factors assume major importance.**

Introduction

THE Federal Communications Commission (FCC) has the responsibility for the allocation of radio frequencies in the radiated electromagnetic spectrum for all purposes except their use by the various agencies of the Federal government. Of the 762,886 stations authorized by the Commission on March 31, 1961, only 5699 were broadcasting stations—AM, FM and television. The allocation of frequencies for broadcasting is, however, one of the most troublesome of the many problems faced by the Commission.

The objectives of frequency allocation plans are "to maximize the service rendered, minimize interference, and ensure the fullest possible occupancy of the assigned channels."[1] To achieve these objectives, allocations must be based on sound engineering principles, which include both technological and economic factors. The first section of this paper is devoted to a statement of the general nature of the engineering factors which are basic to the development of a sound allocation plan. This is followed by a brief summary of the historical development of broadcasting allocations in this country. The third section of the paper will be concerned with some of the factors other than engineering which influence allocations for broadcasting. The paper will conclude with a brief discussion of the most critical problems now faced by those responsible for broadcasting allocations.

Engineering Basis for Allocations

Any sound allocation plan must be based on engineering considerations. Admittedly, factors other than engineering must also receive consideration; but unless adequate attention is paid to engineering factors, the plan will be far from optimum. The general engineering factors basic to allocations are the same for all types of broadcasting: AM, FM and television. These will now be discussed.

The ultimate purpose of a broadcasting system is to deliver a program to a viewer or listener. The final judge of the technical quality of the program is the eye or the ear of the consumer. Hence, any successful allocation plan must be based upon a study of the reaction of typical viewers and listeners to the controlled, varying technical quality of typical programs. In particular, it is necessary to determine on a sound statistical basis the minimum signal-to-interference level which is judged to provide satisfactory service. This determination must be made for all types of interference: thermal noise, impulse noise, and interfering carrier signals modulated in the same and in different manners as the desired signal. The interrelated nature of allocation studies and transmission standards is immediately evident, as the answers to the questions suggested above obviously depend upon the standards chosen, for example, the number of scanning lines per television picture, or the bandwidth of an AM channel.

The next step in an allocation study is to determine the critical characteristics of typical receiving installations, including antenna, lead-in and receiver. It is this equipment which serves to translate the signal at the receiving site into a picture or into sound. Here the most important factors include the gain of the antenna, the losses in the lead-in, the noise figure and sensitivity of the receiver, and the ability of the receiver to discriminate between desired and undesired signals. This latter factor includes such items as receiver selectivity, receiver rejection circuits (for example, adjacent channel traps and image rejection) and noise limiters. It also inherently includes a study of the noise-reducing effects permitted by the type of modulation employed. A major question is whether allocations should be based on the characteristics of new or of old receivers, or perhaps of hoped-for future designs; or on the characteristics of the best or of average receiving installations.

Information must next be obtained regarding typical electrical noise levels at the receiving antenna. Both

natural noise, such as static and galactic noise, and man-made noise, such as that from ignition systems and electric motors, must be considered. Typical noise levels are different in urban and rural areas, and these differences must be determined.

A knowledge of electromagnetic wave propagation phenomena is an essential ingredient in the development of an allocation plan. It is also the most complex of the technical factors basic to allocations. Until recently, there was not even general agreement as to how field strengths should be measured at VHF and UHF television frequencies and as to how the information regarding station coverage should be analyzed and portrayed.[2] Propagation studies must include a determination of the influence of such factors as transmitting- and receiving-antenna heights, terrain, climatic conditions, vegetation, time of day and of year and, of course, carrier frequency. Because of the many variables, results will usually be most useful when expressed in statistics which are probability functions both of location and of time. It is evident that two aspects of propagation must be considered. The first is propagation over the area served by a transmitter. The second is propagation over the greater distances at which a station provides a signal strength which is insufficient to give service but which is still sufficient to cause undesirably high levels of interference. Great differences exist between propagation at the medium frequencies used for AM broadcasting and at the VHF and UHF regions used for FM and television. The allocation objectives are, however, the same, namely, to provide an adequate ratio of desired to undesired field strength.

An allocation study must next consider the characteristics of practical transmitting installations, including transmitter, transmission line and antenna. It is here that economic, as well as technical, considerations become of real significance, although they are also of importance in studies of receiver performance.

There are, of course, many other engineering factors involved in addition to the major ones outlined above. These include such matters as the performance of directional transmitting antennas, the synchronization or the precise frequency offset of carriers, multipath interference (in television) and the manner of combining interferences from several sources. Finally, careful field studies, conducted in a statistically sound manner, must be made whenever possible to determine the over-all service provided by existing broadcasting facilities having known performance characteristics.

The synthesis of these various elements into a broadcasting system is easy to visualize in general terms. But the design of an allocation plan to maximize service and minimize interference is no simple matter. The basic engineering ingredients of such a design are, however, found in an analysis of the system components such as that which has been outlined, as the results obtained from this analysis permit the determination of such fundamental items as the minimum spacings of co-channel, adjacent channel and image-frequency stations of given power to produce a given statistical amount of interference in the customer's picture or sound program. Decisions on such basic matters as the quality of service which will be considered "normal" or "standard" are, however, not engineering in nature. They depend upon the judgment of the regulatory authorities. These, too, are essential ingredients in an allocation plan.

Historical Development of Broadcasting Allocations

The dependence of an allocation plan on the characteristics of the individual components of a broadcasting system and the evaluation of existing or proposed plans by means of a study of these characteristics seem obvious today. This is the line of attack now taken by the FCC and by industry groups in allocation studies. Historically, however, allocations for broadcasting were not always made in this manner. A detailed study of the historical development of broadcasting allocations is most fascinating. Space permits only a brief outline which summarizes authoritative information available elsewhere.[3–10]

AM Broadcasting

The early days of radio broadcasting were marked by confusion, not only with respect to allocations themselves but also with respect to the question of whether or not the Federal government had authority to make allocations. In 1910, Congress passed the Wireless Ship Act, the first legislation pertaining to wireless telegraphy. Under the provisions of this act, which became effective on July 1, 1911, and which had as its purpose the protection of life at sea, the Radio Service of the

Bureau of Navigation administered the laws pertaining to radio communication until 1927. An Act of Congress dated August 23, 1912, extended the authority of the Radio Service to regulate interstate radio communication and specified that such communication must take place at frequencies above 500 or below 187.5 kc. Broadcasting was first recognized by the Radio Service in a ruling dated December 1, 1921 (13 months after the broadcast of the Harding-Cox election returns by KDKA), in which the frequencies of 833 and 619 kc (wavelengths of 360 and 485 m respectively) were assigned to "limited commercial," or broadcasting, stations.

With the rapid increase in the number of broadcasting stations in 1921, it became evident that more effective governmental regulation was required to prevent intolerable interference. In 1922, Secretary of Commerce Herbert Hoover called the first of four annual industry-government conferences which "established the basic principles upon which our great American system of free (radio and television) broadcasting has been built."[4] This conference also set the pattern for the continuing cooperation which has since existed between governmental and nongovernmental organizations in developing allocation plans and transmission standards for broadcasting. As a result of these conferences, a third frequency, 750 kc, was allocated to broadcasting, and in 1923 the band of 550 to 1351 kc was established, with stations assigned to particular frequencies. Different classifications of stations were defined, based upon transmitter power, with different frequency bands allocated to the various classes. Rules were drawn up regulating the separation of stations according to geography and frequency, and a 10-kc channel was specified.

In the meantime, in 1923, the Court of Appeals of the District of Columbia had ruled that while the Secretary of Commerce had the right to assign an operating frequency to a station, he had no right to deny a license to any applicant. This was followed in 1926 by a ruling by the U. S. District Court for Northern Illinois that the Secretary of Commerce had no right "to establish regulations" for radio transmissions. This meant that, contrary to the previous ruling, the Secretary could not assign frequencies, and that a station could use any frequency it chose, within the limits established by the Act of 1912. This was confirmed on July 8, 1926, in a ruling by the Acting Attorney General, who recommended that remedial legislation be passed.

The effect of this chaotic situation was that Congress, which had failed to take action on a number of earlier pieces of remedial legislation, finally passed the Radio Act of 1927 which established the Federal Radio Commission (FRC). The act was signed by President Coolidge on February 23, 1927. Under the provisions of this act, and of subsequent extensions, the Commission was given authority to classify stations, to assign frequencies, to specify transmitter power and to make regulations to minimize interference. All types of interstate and foreign radio communication (except governmental) were placed under the purview of the Commission. The act stated that actions of the Commission should be taken in the interest of "public convenience, interest or necessity," a phrase which has been widely quoted in interpreting the powers of the FRC and its successor, the FCC. It should be noted that the act stated that it provided "for the use of channels, but not the ownership thereof," by station licensees.

One of the first actions of the FRC was a sweeping re-allocation of frequencies for broadcasting. In 1928, Congress passed the so-called Davis Amendment which directed the FRC to allocate broadcasting licenses, powers and frequencies equitably among the states, in proportion to population and area. This resulted in the development of a very complex allocation scheme which was doomed to ultimate failure by its very complexity. It did, however, permit the establishment of an orderly procedure for the growth of radio broadcasting and "by 1930, broadcasting had been brought to the level of functional public service."[5]

In 1934, after five years of discussion, Congress passed the Communications Act of 1934 establishing the Federal Communications Commission, which took over the functions of the FRC and other responsibilities relating to interstate and international wire and radio communications. With respect to broadcasting, the new act followed the general principles of the Act of 1927, particularly in its delegation to the FCC of complete authority over the licensing and allocation of frequencies.

In this account of the development of Federal authority over frequency allocation, only standard AM broadcasting has been considered. It was the only type of broadcasting of any significance at the time of the adoption of the Communications Act of 1934. From the standpoint of allocations, AM broadcasting has not changed greatly since that time, except for a slight extension of the broadcast band (now 535 to 1605 kc) and a trend toward an ever increasing number of stations with, as viewed by at least some engineers, an ever increasing amount of interference. The FCC, in contrast with the FRC, has been primarily concerned with FM and television broadcasting, rather than with AM broadcasting. These newer systems will also be the concern of the remainder of this paper.

It must be noted that during the first 13 years of government regulation (1921–1934), several basic principles were established which are now taken for granted. These include the private (as contrasted with public) ownership of our broadcasting system; government regulation through licensing, frequency allocation, and specified transmission standards; and the recognition of the frequency spectrum as a public resource, with portions allocated, but not given, to licensed stations. These principles, once established for AM broadcasting, have been extended to FM and television without question.

Television Broadcasting

Television was the second broadcast service to appear on the scene. The historical development of allocations for television has been traced so thoroughly, and at the same time succinctly, by Fink[7] and especially by Allen,[10] that repetition here is needless. It is sufficient to recall that experimental television broadcasting in the United States commenced in 1927; that the first stations had an almost unlimited choice of frequencies above 1500 kc; that in 1929, the FRC set aside for television five channels each 100-kc wide between 2000 and 2300 kc and between 2750 and 2950 kc; that licenses for experimental television in the region between 43 and 80 Mc were granted in 1931; that in 1936, permission for operation in the 2000-kc region was withdrawn; that in 1937, the FCC authorized 19 VHF channels each 6-Mc wide between 44 and 294 Mc; that in 1945, following World War II, the FCC revised the allocation plan to provide 13 (and later only 12) VHF channels plus an additional space 440-Mc wide for experimental operation in the UHF region; and that a comprehensive allocation plan providing the present 12 VHF channels (54–72, 76–88 and 174–216 Mc) and 70 UHF channels (470–890 Mc) was issued by the FCC in its Sixth Report and Order in 1952. Rather than discussing these developments in detail, it is more worthwhile to note one very significant aspect of the manner in which television allocation plans and transmission standards have been developed. This is the extensive participation, at the engineering level, of the television industry in this activity for which the Federal government has primary responsibility. The FCC and the industry have not always agreed. In fact, there have been several sharp disagreements. But the joint cooperative efforts have on the whole resulted in mutual understanding and the development of a reasonably satisfactory nation-wide television service.

In 1929, the Radio Manufacturers Association (now known as the Electronic Industries Association) formed its Television Standards Committee which in 1931 recommended the allocation of VHF channels to television broadcasting and which in 1936 and 1938 recommended transmission standards that form the basis for modern television broadcasting. Lack of complete unanimity in the industry led the FCC to refuse to give its expected approval to these standards. The Commission did, however, cooperate in the formation of the National Television System Committee (NTSC) composed of engineers representing all parts of the television industry. In a period of 12 months, this organization developed slightly modified standards which won the approval of the industry and the FCC.

In 1943, the electronics industry and the Institute of Radio Engineers, at the request of the FCC, formed the Radio Technical Planning Board (RTPB) to develop plans for post-war electronic activities. This Board included panels on AM, FM, and television broadcasting. One of the recommendations of the Television Panel in 1944 was that 30 channels be set aside in the VHF region for television broadcasting, starting at about 40 Mc and extending upward in a continuous band. The FCC actually allocated only 13 channels, because of the needs of other services. The RTPB recommendations were, however, realistic in terms of today's needs.

In June, 1948, the Joint Technical Advisory Committee (JTAC) was formed by the electronics industry and the IRE to make a study for the Commission of the use of UHF for television broadcasting. This was followed in 1952 by the publication of a comprehensive JTAC treatise on allocations.[11]

In the meantime, a second NTSC was formed in 1950 to develop acceptable standards for color television and an acceptable VHF-UHF allocation plan. A second group, known as the FCC Ad Hoc Committee on Propagation, composed of representatives of government and industry, advised the Commission on wave propagation problems. These groups played a large part in conducting the basic engineering studies leading to the Sixth Report and Order. This Order, however, disregarded an allocation plan of real merit, which minimized the intermixture of VHF and UHF stations, which had been submitted by the Allen B. DuMont Laboratories.

Finally, in 1956, the television industry, at the request of the FCC, established the Television Allocations Study Organization (TASO) to make a comprehensive study of the engineering factors underlying the allocation of frequencies for television broadcasting.[12] The two TASO reports[13,14] and a series of IRE papers[15] present the results of this contribution by the television industry to the work of the Commission.

This very incomplete summary of the cooperation between the television industry and the FCC on matters pertaining to television broadcasting indicates a most unusual and a most significant type of high-level joint activity between a governmental regulating agency and the industry which it regulates.

FM Broadcasting

Space does not permit a detailed discussion of FM allocations. Major Armstrong's pioneer FM station at Alpine, N. J., operated experimentally at a frequency of 42.8 Mc, although he also conducted experimentation at 110 Mc. As a result of hearings held in 1940, the FCC allocated channels 200-kc wide between 42 and 50 Mc to FM broadcasting. The RTPB recommended a mini-

mum of 80 to 100 channels (or a band of 16 to 20 Mc) in the vicinity of 40 Mc for FM broadcasting. The FCC, however, felt that space in this region was needed more urgently for television and other services and it developed a series of alternative FM allocation plans, finally choosing the present allocation of 100 channels extending from 88 to 108 Mc. This choice was made after lengthy discussions with the industry and in spite of vigorous opposition by a rather large segment of the FM industry.

Non-engineering Factors

It would be foolish to pretend that engineering factors are the only ones which influence the allocation of frequencies for broadcasting. For example, the practical economic fact that UHF television stations have difficulty in competing in an intermixed VHF-UHF area has led to a demand for more VHF television channels, while UHF channels are plentifully available but unwanted. Again, the increasing interest in educational television is expected by many to result, in the not far distant future, in a demand for more channels for this service, with a consequently greater scarcity of channels for commercial television. This demand may possibly, however, be met largely by UHF assignments.

The policy of the FCC of maintaining practically complete protection of the service area of an existing station from intrusion by an interfering signal from a new station can lead to a scarcity of channels. In some cases, a greater total population might be served under a different policy. Allied to this policy, is the practice of minimizing changes in frequency assignments to existing stations. The licensed stations do not legally have perpetual claim to a frequency assignment or to a license, but the FCC seldom makes major changes. In some instances, changes might be beneficial from an over-all point of view. These policy considerations are not mentioned as matters which necessarily should be changed, but merely as examples of non-engineering factors which definitely do affect allocations.

Finally, the Commission has a difficult task in maintaining close liaison with the industry which it regulates and still maintaining freedom from undue pressure from that industry. The Commission has a record of high integrity in dealing with this problem. It appears to an outsider that it must have an even more difficult task in maintaining its freedom from political pressures, especially from influential members of the government whose constituents wish to have favorable attention in allocation matters.

Critical Needs

If one were asked to name the most critical allocation need, the most common answer would be, more television channels, especially more VHF channels. The other broadcasting services have similar needs, but the question will be discussed in terms of television. And it may be that the above answer is not correct.

The first real need is to determine rather accurately just what service is being provided now. This cannot be determined in an office, but can be found only through extensive field work. The work of the TASO Field Test Panel[16] pointed the way toward the type of activity which is needed.

Second, there needs to be a serious study of just what type of service the public really needs. The purpose of broadcasting is to serve the public, not to serve the broadcaster. Should a broadcasting system serve the maximum area or the maximum number of people? Is it essential that every viewer receive television programs from all three (or more) networks? Does any viewer really need to receive as many as seven local television stations? What are the real needs of educational television? These, and similar, questions must be answered before a truly logical allocation plan can be developed.

Finally, after these first two studies have been made, an optimum allocation plan will need to be developed on a completely objective, and nonpolitical, basis. This would make use of all existing engineering techniques, such as directional transmitting antennas, to maximize service. With the use of modern computers, the development of an optimum plan, taking into account actual, existing geographic conditions, would not be an insurmountable task. This optimum plan, once developed, obviously would not be used, at least *in toto*. It would, however, serve as a standard against which other allocation plans could be compared and it would thus be of inestimable value. And it is only after the development of such an optimum plan that the extent of the real need for more channels can be determined.

The Technology of Television Program Production and Recording*

JOHN W. WENTWORTH†, MEMBER, IRE

Summary—**The basic concepts for television origination equipment are determined by operational requirements, which have remained relatively constant throughout the history of television broadcasting. In brief, television cameras and related studio equipment are designed to permit the assembly of a smooth flow of picture and audio signals from multiple sources, including both "live" scenes and prerecorded material. The photography of kinescope images on motion-picture film was an early approach to practical television recording which still offers enough advantages that major engineering efforts continue to be placed on the development of improved film recording equipment. A great deal of the current television recording activity, however, involves the use of magnetic tape. The most common types of television tape recorders employ 2-in. wide magnetic tape, on which picture information is recorded by rotating video heads which produce tracks extending across the width of the tape. Four separate heads are mounted on the rotating headwheel, but switching circuits are employed to deliver a single continuous signal during the playback process. Through the use of FM techniques and precise servomechanisms, it is possible to accomplish television tape recording with extremely high picture quality.**

Introduction

THIS PAPER is offered as one span of a "bridge of understanding" between the broadcast engineering fraternity and the larger circle of IRE members whose professional activities have nothing to do with broadcasting. One of the major benefits of IRE membership is the opportunity to keep in touch with major developments in all branches of electronic engineering, although the ever-increasing complexity of the electronic arts tends to make communication between dissimilar specialists increasingly difficult. The author has assumed that most IRE members have at least a mild *interest* in the technology of the broadcast industry. Most engineers maintain a healthy professional curiosity about all electronic systems with which they come in contact, and nearly all American families are influenced by the broadcast industry. The specific objective of this paper is to convey to non-television specialists a basic understanding of the technical concepts involved in the production and recording of television programs.

Picture Origination

In the typical studio scene shown in Fig. 1, only a small fraction of the electronic equipment required for the production of television programs is visible from the studio floor. Some of the equipment is usually mounted in a nearby control booth, like that shown in Fig. 2, but still more equipment is mounted in unattended racks. The equipment may be subdivided into six basic categories: 1) camera chains for live pickup, 2) television film equipment, 3) synchronizing equipment, 4) video distribution and switching equipment, 5) audio origination equipment, and 6) intercommunications equipment. While there have been major innovations and improvements in the circuit details of the equipment in all categories, the basic concepts involved have remained relatively constant throughout the history of television. Before discussing the equip-

* Received by the IRE, July 14, 1961.
† RCA, Camden, N. J.

ment itself, let us review briefly the production *objectives* and *problems* which influence the design of television studio equipment.

Basic Studio Operations

The technology of television program production has been greatly influenced by the "tyranny of the clock." Since *time* is the basic commodity broadcasters offer for sale, a major objective of television production facilities is the maintenance of a smooth, continuous flow of program material, usually accomplished by the *multiple-camera technique*. Except for the very simplest types of programs, television productions involve the use of two or more live pickup cameras, frequently supplemented by film cameras. The live cameras are so located that they command different views of the scene to be televised. While one camera is "on the air," another may be moved to a new position, or its objective lens may be changed (with the aid of a quick-change turret), to compose the next picture. Still shots from a slide projector or brief sections of motion-picture film can be used either to present pictorial information that cannot readily be set up in the studio, or to bridge the time intervals that may be required for more elaborate set or camera changes. The multiple-camera technique imposes special requirements on nonelectronic aspects of studio design, such as lighting and provision for rapid handling of sets.

The operator who stands behind a television camera has only two major responsibilities: 1) to compose the picture in accordance with instructions from the program director, and 2) to keep the picture in proper optical focus. (All other camera adjustments are of a setup nature only, or are made by remote control.) To aid the camerman, television cameras for live pickup are almost universally equipped with a viewfinder (a small television monitor displaying the camera's picture output), a lens turret with four lenses of different focal length (or a "zoom" lens), an optical focus knob, and a built-in intercom circuit permitting conversations with the program director. In addition, the camera is usually mounted on a dolly or pedestal which permits relatively free movement over the studio floor, as well as such basic movements as panning and tilting.

The Television Camera Chain

In addition to the camera proper on the studio floor, a complete television *camera chain* typically consists of a remote control panel, a signal processing amplifier, a "master monitor," and a regulated power supply. The remote control panel permits a video operator in a control booth to keep the circuits associated with the pickup tube in proper adjustment, to apply such electronic corrections to the signal as may be necessary, and to maintain a proper signal level at the output of the camera. The video operator is responsible for the technical quality of the picture in all respects except optical focus. The "master monitor" is an important tool for the video operator, providing both picture and waveform displays with special features for critical examination of picture quality. The *signal-processing amplifier* (sometimes called the *camera control unit*) serves two major functions: 1) it provides buffer amplification for the pulse signals which are transmitted outward along the camera cable to control the deflection circuits in the camera, and 2) it "cleans up" the camera output signal to make it conform to the desired signal specifications. In the special case of color television, the camera proper and the processing amplifier have *three* video channels for red, green, and blue signals, and the chain as a whole includes a *colorplexer* for encoding the three primary signals to form a single compatible signal.

Film Cameras

Television film cameras are specially designed to facilitate the generation of television signals from photographic materials. To preserve maximum quality, the photographic image is usually projected directly on the sensitive surface of the television pickup tube in the camera with no intermediate screen. Film cameras are frequently used with *optical multiplexers*, which employ movable mirrors or other means to combine the optical paths of several projectors. A very popular arrangement of television film equipment consists of a pair of 16-mm film projectors and a remotely-controlled slide projector mounted with an optical multiplexer as alternative inputs for a single film camera. Such a facility not only provides for film or slide inserts into live programs, but also permits smooth operation for prolonged periods with exclusively photographic material.

Synchronizing Equipment

All of the cameras, monitors, and other apparatus in a television studio system are kept in proper synchronism by pulses from a *sync generator*. One of the waveforms provided by the sync generator is known as *blanking*, and serves to define the retrace intervals during which no picture information is transmitted. The waveform commonly designated *sync* is a complex train of pulses with both horizontal-frequency and vertical-frequency components, timed to occur during the blanking intervals. This sync waveform is added to picture signals prior to transmission to provide timing control for the deflection circuits in distant television receivers. To assure continuity of service, sync generators are frequently installed in pairs with automatic changeover facilities.

Electronic Editing

The final assembly or editing of television programs involves the use of *video switching equipment*, controlled through pushbutton panels like those shown in Fig. 2. In very small-scale switchers, the push buttons actuate switches connected directly to video circuits, but in larger systems the push buttons are merely remote controls for relays or transistorized switching elements.

The switching operations are usually performed by the program director or his assistant with the aid of a bank of monitors displaying all the picture sources available.

A typical arrangmenet of switching equipment is shown in Fig. 3. Each vertical row of buttons corresponds to a single picture source, and each horizontal row corresponds to an output bus. One such output bus feeds the outgoing line directly, and is designated the "program bus." The other buses provide signals for several types of effects equipment or for preview monitors. All output buses are *interlocked*, so that only one picture signal can appear at a time, although a given input signal may be connected simultaneously to several output buses.

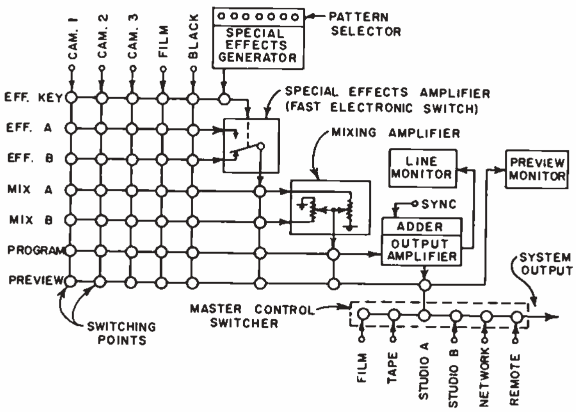

Fig. 3—Simplified sketch of a typical television switching panel and associated amplifiers.

Basic Editing Operations

The most basic electronic editing process is the direct "cut," achieved by simply pushing a button on the program bus to switch cleanly from one signal to another. The preview bus and the associated preview monitor permit the program director to check an upcoming picture before he actually switches to it.

The addition of two more buses plus a mixing amplifier provides facilities for fades, lap-dissolves, and superimpositions. In principle, a mixing amplifier is nothing more than a pair of remotely-controlled, variable-gain amplifiers. For a lap dissolve, the two picture signals involved are "punched up" on Bus A and Bus B, and the control levers for the two variable-gain stages are locked together in such a way that as the level of one signal decreases, the level of the other increases a corresponding amount. For a "fade to black," one may either punch up the "black" input on one of the two "mix" buses, or one may separate the two control levers and reduce the level of one signal to zero before advancing the gain control for the subsequent picture. For a superimposition, one may also separate the control levers to adjust the relative levels of the two picture signals to be combined. Because the sync pulses must always be transmitted at a standard level, they are normally added after the mixing amplifier at the output of the program bus. Remote signals which enter the studio with sync pulses already present are made available in a secondary portion of the program bus beyond the sync addition point, or in an entirely separate "master control" switcher, as indicated in Fig. 3.

Special Effects

Still more elaborate editing effects are possible with a *special effects amplifier* and a *special effects generator.* The special effects amplifier is essentially a very fast electronic switch (operating in the order of 0.1 μsec) carefully designed to minimize switching transients. The fast switching between the A and B picture inputs is controlled by a *keying signal*, which may be any camera signal or the output of a special effects generator. Typical camera signals used for keying purposes might consist of letters to be inserted in a background picture, or special shapes such as keyholes or trademarks. With a special effects generator, a wide range of transitional effects, including horizontal wipes, vertical wipes, diagonal wipes, and iris effects may be obtained. The desired transitional pattern is selected by means of a switch associated with the generator, and the actual movement of the pattern may be controlled by a pair of levers comparable to those used for a mixing amplifier. The two levers, normally locked together, may be separated to provide independent control of horizontal and vertical movement. Many of the transitional patterns may be held stationary for extended periods for interesting "split screen" effects. With careful control of lighting and signal levels, it is even possible to obtain "traveling mattes" or self-keyed insets with special effects equipment.

Audio Origination

Many electronic engineers are surprised to learn that audio problems are frequently more difficult in television program production than video problems. The capital investment in audio facilities is normally much less than for video equipment, but the number of input channels required and the complexity of operations during actual program time is usually much greater. It is not at all uncommon to employ ten or more microphones plus several turntables and tape recorders in conjunction with only two or three cameras. Even the acoustic environment is normally unfavorable. There is usually considerable ambient noise in a television studio resulting from "off-camera" activity, so directional microphones are used frequently and studio walls and ceilings are lined with sound-absorbing materials to make them as "dead" as possible. It is often necessary to employ artificial reverberation to achieve proper audio quality.

A second type of audio system in a television studio is the intercom facility which plays a vital role in coordinating the complex activity on the studio floor and in the control rooms. During rehearsals, the program director frequently employs a public-address system to give instructions to people on the studio floor, but during actual programs it is necessary to rely on headsets connected by wires or low-power radio links. While the investment in intercom facilities is usually even less than for program audio, and while the requirements for audio quality are not very high, the importance of such facilities as major production tools should not be minimized.

Since the problems in audio origination are primarily nonelectronic in nature, we shall not review them in greater detail here, but the writer hopes that he has aroused some sympathy for the often-neglected audio engineer.

Television Film Recording

One of the earliest and most obvious approaches to television recording involves the use of a motion-picture camera to photograph the image on a kinescope. Superficially, this approach seems to offer great advantages. Once a film negative is recorded, it is possible to produce, at reasonable cost, a large number of prints which can be "played back" either through a television film chain or on low-cost, direct-view projectors. In practice, however, the photography of television pictures involves so many practical problems that the phrase "kinescope recording" became, at one time, almost a synonym for "poor picture quality."

Some of the practical problems in television film recording are rather self-evident. Because of the required chemical processing, the final result of a film recording process cannot be monitored instantaneously to check the need for either major or touch-up adjustments. The intermediate picture on the kinescope necessarily introduces some image degradation, especially with respect to graininess and sharpness. Proper reproduction of the gray scale requires extremely good stability in the kinescope picture, precise adjustment of the camera exposure, and close control of the chemical developing process. Added to the other difficulties is the fact that kinescope phosphors with substantial ultraviolet output are commonly employed to gain maximum sensitivity with fine-grain emulsions, so even optical focus cannot be checked properly by simple visual means.

A special problem in television film recording is the "shutter bar" effect resulting primarily from the need to convert the 30-frame-per-second television signal to 24-frame-per-second motion pictures. The nature of this problem is illustrated in Fig. 4. Because of the difference in frame rates, the time interval corresponding to two motion-picture frames is equal to 2.5 television frame periods or 5 television *field* periods. In one sense, the presence of the extra television field period is an advantage, because it provides time for the film shutter to close while the film is "pulled down" from one frame to the next. Unfortunately, however, it is very difficult to assure identical exposure conditions for each motion-picture frame, because at least some of the film shutter operations must occur during active scanning time. In the case illustrated in Fig. 4, for example, film frame 1 (and all subsequent odd-numbered frames) has been made to coincide with a complete television frame period (two successive fields), so a proper exposure of all TV lines in the image can be obtained without much difficulty. The even-numbered film frames, however, must begin and end during the active scanning periods of two different fields. Unless the shutter timing is very precise, the exposure for lines near the center of the image is not quite correct, and a prominent 12-c flicker appears in the final pictures. Even with perfect shutter timing, the photographic effect known as "reciprocity law failure" prevents uniform exposure unless elaborate means of precompensation are employed.

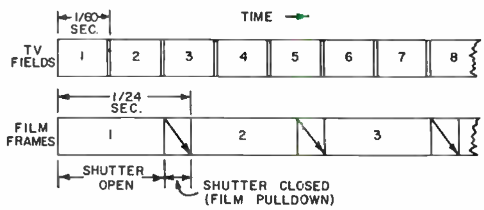

Fig. 4—Sketch illustrating the frame rate and shutter bar problems in television film recording.

In spite of these problems, the case for television film recording is far from hopeless. Interestingly enough, the advent of television tape recording has resulted in a strong rebirth of interest in television film recording, since a combination of the two techniques offers distinct advantages. At the time of this writing, serious development and design work on improved television film recording equipment is in progress in a number of laboratories, and it is quite possible that the term "kinescope recording" will become fully respectable within the next few years.

Television Tape Recording

The recent history of the television industry has been profoundly influenced by the development of practical equipment for recording television programs on magnetic tape. Signals recorded on tape can be played back immediately after recording, and costs are held within reasonable limits by the fact that tape can be erased and re-used a number of times. The lack of any intermediate image-forming process permits very high-quality picture reproduction.

The television tape recorders in most widespread use at the time of this writing employ a *lateral scanning technique* to obtain the very high writing speeds required to record wide-band video signals. Machines operating on this principle are manufactured in the U. S. by the Ampex Corporation and the Radio Corporation of America. The recorders produced by these two companies differ considerably in appearance and design details, but they involve similar basic concepts and produce recordings that can be played back readily on other machines of either make. A typical RCA television tape recorder is shown in Fig. 5.

The magnetic tape employed for television recording is 2-in wide, and information is recorded in the pattern of tracks shown in Fig. 6. The tape moves through the machine at 15 in/sec, but the picture signals are recorded by heads which move across the tape at a speed of nominally 1561 in/sec. Four such heads are spaced around the circumference of an approximately 2-in-diameter wheel, revolving at 240 revolutions per second (or 14,400 rpm). Each track contains approximately 16 lines of the television picture, with an overlap of slightly more than one line period in the information at the end of one track and the beginning of the next.

In addition to the transverse video tracks, the recording also contains three longitudinal tracks. One of these is used for the program audio signal, recorded by techniques equivalent to those in normal audio practice. A second, much narrower, audio track near the opposite edge of the tape is provided for cue information or special-purpose tone signals. The third track contains control information needed by the servo system which controls the capstan speed during playback.

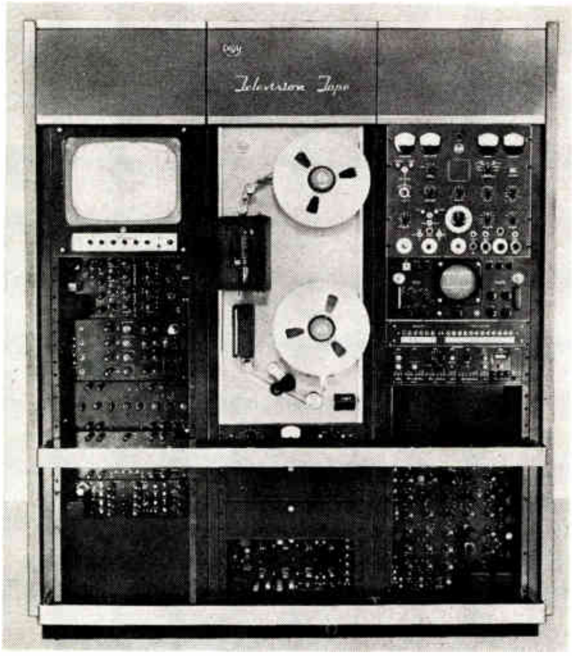

Fig. 5—Photograph of a typical television tape recorder.

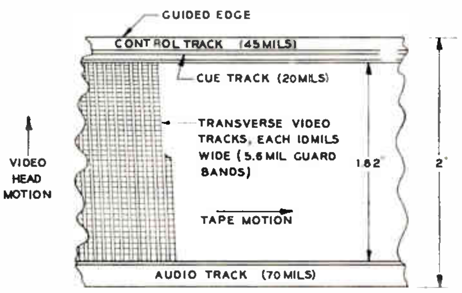

Fig. 6—Pattern of tracks on magnetic tape for television recording (not to scale).

Tape Transport Panel

A typical television tape transport panel is shown in Fig. 7. The driving force which pulls tape through the machine is imparted by a rotating capstan in association with a solenoid-operated pinch roller. In passing through the video head-wheel panel assembly, where the picture recording takes place, the tape is cupped to conform to the circumference of the rotating video head wheel by means of a guide shoe, which employs a vacuum to hold the tape firmly in place. Signal currents to and from the video heads are conducted through brushes and slip rings at one end of the motor shaft, and a tone wheel at the other end provides a feedback signal for the servo system which controls the speed and phase of the head-wheel motor. The control track is recorded by a small head mounted near the base of the guide shoe.

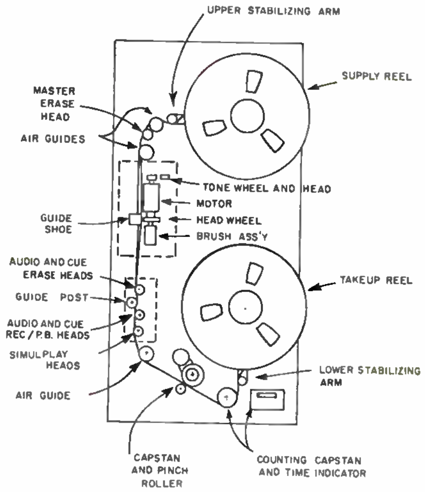

Fig. 7—A typical transport panel for a television tape recorder.

Three heads are used in sequence for the program audio track along the outer edge of the tape: 1) a narrow erase head, which removes the transverse video information previously recorded in the audio area, 2) the main record/playback head, and 3) a simultaneous playback head, which may be used while recording to give complete assurance that a proper audio signal has been recorded. For actual program playback, it is necessary to use the same head that made the recording (or one in the same relative position on a different machine) in order to preserve proper picture-sound synchronization. The cue channel employs similar (though somewhat narrower) heads mounted near the opposite edge of the tape path.

Video Recording and Playback Circuits

The circuits involved in handling the picture signals are shown in greatly simplified form in Fig. 8. To overcome the poor linearity of the tape medium, the video signal is converted to an FM wave before it is applied to the tape. The FM technique also provides a better SNR than would direct recording, and eliminates the need for extreme degrees of LF equalization by translating the entire signal upward to a somewhat higher frequency band. For monochrome recording, the normal deviation characteristic extends from 4.3 Mc for sync tips to 6.8 Mc for reference white. The band actually recovered from the playback of the tape extends from approximately 0.5 to 7.0 Mc, a range great enough to embrace the actual carrier deviation plus the first-order lower sideband only. Fortunately, the missing upper sideband can be restored by a limiting process, and the low deviation index serves to keep the significant signal energy within the first-order sideband spectrum.

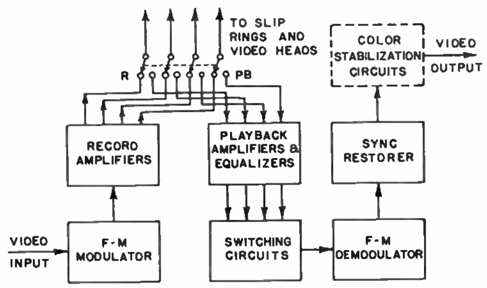

Fig. 8—Block diagram of video record and playback facilities.

Upon leaving the frequency modulator, the signal is passed through the record amplifiers, where the signal is split into four channels which are separately adjustable for optimum recording levels in the four heads. In some machines, the record amplifiers also include means for adjusting the relative *delays* of the four channels to compensate for minor dimensional variations in the physical spacing of the heads around the circumference of the video head wheel. The signals from the record amplifiers are conducted to the heads via a transfer relay, brushes, and slip rings.

In the playback process, the signals recovered from the heads are passed through a set of four-channel amplifiers and equalizers. These amplifiers not only raise the signal levels, but also provide adjustments for the frequency-response characteristics of the four channels and electronic quadrature adjustments in the form of variable delay lines. The signals are then passed through switching circuits which transform the original four head channels to a single channel. As noted earlier, there is a slight overlap in the information delivered by any two successive heads, so smooth switching is possible. To permit complete removal of switching transients, the transition from one head to the next is made to occur during a horizontal blanking interval. The FM signal delivered by the switching circuits is converted to a video signal by a frequency demodulator. This video signal may be somewhat distorted in the sync and blanking regions by switching transients and other imperfections in the many signal-handling operations, so a *sync restorer* or *processing amplifier* is employed to regenerate the sync and blanking portions of the signal. Finally, if the machine is to be used for color television signals, the output is passed through a set of *color stabilization circuits* which utilize the information in the color synchronizing bursts to remove the effects of jitter resulting from small-order imperfections in the servo systems.

Guide Servo System

Three different servo systems are employed in most television tape recorders. One of these is used during the playback mode to control the precise positioning of the vacuum guide shoe which pushes the tape against the rotating video head wheel.

As shown in exaggerated form in Fig. 9(a), the inner diameter of the guide shoe is deliberately made slightly smaller than the outer diameter of the video head wheel at the pole tips. Thus the pole pieces are forced to deflect the tape, placing it under rather severe local tension as the heads pass by. The *degree* of this tension may be adjusted by movement of the guide shoe to compensate for minor dimensional variations between different machines or in the same machine as a result of wear. If the center of curvature of the guide shoe is too high or too low relative to the center of the video head wheel, the tape tension varies across each track, yielding a characteristic "scalloping" effect along all vertical lines in the picture, as illustrated in Fig. 9(c). Fortunately, this effect can be avoided by careful mechanical positioning of the guide shoe. If the guide shoe is too close or too far away from the head wheel, the tension is not correct and the signals are not truly coincident at the instant a switch is made from one head to the next. Under these conditions, vertical lines in the picture break up into "venetian blinds," as shown in Fig. 9(b). To prevent this effect, the servo system shown in Fig. 10 is employed.

A servo system is, of course, an application of the negative feedback principle. In the case at hand, the feedback path comprises the entire video playback system which includes, among other things, a sync separator to recover the sync pulses from the composite video signal. These sync pulses are passed through an error detection circuit designed to sense the presence of timing variations at 960 cps, which is the head-to-head switching rate. If such timing errors are found, their polarity or direction is also sensed, and the error information is amplified and processed in suitable fashion to actuate a motor which moves the guide shoe to the proper operating position.

Head-Wheel Servo System

A second servo system is employed to control the speed and phase of the head-wheel motor. A simplified block diagram of a typical circuit arrangement is shown in Fig. 11. During the "record" mode of operation, the major objective of the head-wheel servo system is to assure the formation of a standardized pattern of tracks on the tape, in which each television field occupies exactly 16 tracks. (Such a standardized track pattern permits both interchanging and *intersplicing* of tapes.) The feedback signal employed in the head-wheel servo system consists of a pulse signal derived from the tone generator on the motor shaft. This pulse signal is compared in a phase detector circuit with a 60-cps pulse signal derived from the vertical synchronizing portion of the signal to be recorded. By means of this error detector and the subsequent motor drive circuits, the 240-cps output of the motor is kept "locked" to the fourth harmonic of the 60-c reference pulse.

In the playback mode, the 60-c reference pulse for the head-wheel servo system is derived from an external source, such as a local sync generator or a 60-c power line. In some more recent television tape recorder designs, the head-wheel servo operates with sufficient precision when locked to a sync generator that the tape output signal may be handled through electronic editing equipment as freely as a local camera signal.

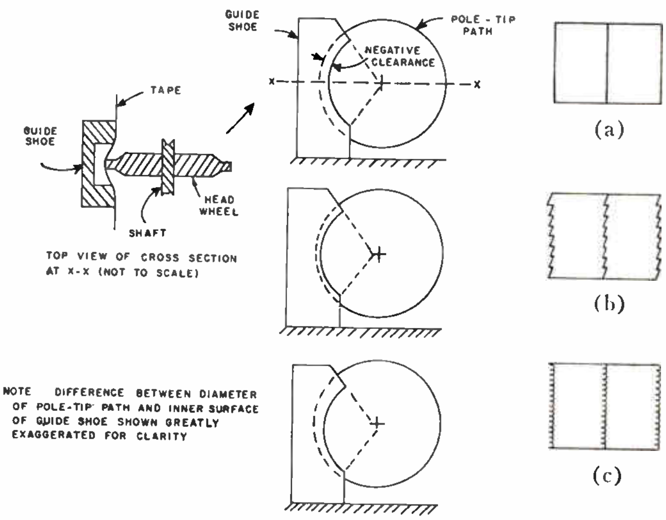

Fig. 9—Sketch illustrating the significance of guide shoe position adjustments. (a) Guide shoe in correct position. (b) Guide shoe displaced to left. (c) Guide shoe too low.

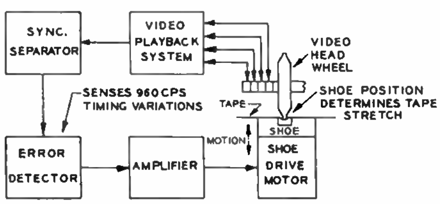

Fig. 10—Block diagram of guide shoe servo system.

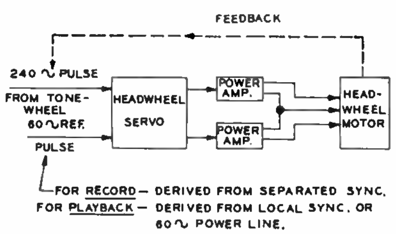

Fig. 11—Simplified block diagram of a typical head-wheel servo system.

Capstan Servo System

The third and final servo system controls the speed of the capstan through an arrangement like that shown in Fig. 12. When a recording is made, the capstan motor is driven synchronously by 60-c power derived from an oscillator kept locked to the 4th subharmonic of the 240-cps tone-wheel signal. Information about the relative speed of the capstan is recorded on the tape in the form of a 240-cps tone on the control track. Since this 240-cps tone is derived from the tone wheel on the head-wheel motor shaft, each cycle corresponds to exactly four video tracks. In the playback process, the error detectors in the capstan servo system compare the 240-cps tone from the control track with the 240-cps output of the tone wheel. Any error signal that may be present varies the speed of the capstan just enough to assure that exactly four video tracks are moved past the head wheel during each revolution. The phasing adjustment required to center each video head over a track on the tape is usually provided in manual form.

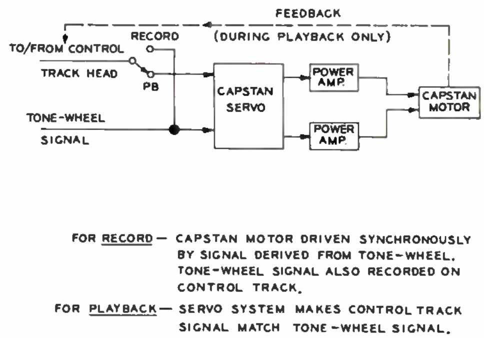

Fig. 12—Simplified block diagram of a typical capstan servo system.

Control and Monitoring Facilities

The operating controls for a television tape recorder are grouped for maximum operational convenience, and built-in monitoring instruments are provided to check significant aspects of the machine's performance during operation. Routine operation of a television tape recorder is surprisingly easy, and most basic operations can even be performed from a remote location.

Conclusion

In the brief space of this "overview" paper, it has been possible to review only the highlights of the technology of television program production and recording, but it is hoped that IRE members have found here a little insight into the problems that have already been solved and those still under exploration by their colleagues in the broadcast industry. During the 50 years of the IRE's history, broadcast engineers have provided for the American people the world's best facility for mass communications. There is every reason to assume that major creative contributions will continue to flow from this branch of the engineering profession throughout the next half-century.

Broadcasting Developments Now Taking Place*

OSCAR REED, JR.†, SENIOR MEMBER, IRE

Summary—**New developments in broadcasting in the past 20 years are treated from the general allocations development viewpoints including regulatory aspects and the evolution in the broadcast standard, frequency modulation, and television station industry. The prospects for compatible single sideband modulation techniques in standard broadcasting, developments in FM stereo regulations and experimental techniques in the color television field are explored. Brief treatment is accorded the horizon subject of extra terrestrial satellite relay usage in broadcasting as well as the currently developed backbone of international broadcasting.**

References are included to fundamental explorations of several government-industry engineering committees including the Television Allocations Study Organization, technical study papers issued under the auspices of the Chief Engineer of the Federal Communications Commission, and studies carried on by broadcasters, network organizations, and manufacturers.

NEW DEVELOPMENTS in broadcasting now taking place may be scanned from several points of view. The broadcasting industry is regulated by a government agency, the Federal Communications Commission. The interaction between technological progress and the official Rules and Regulations of this Commission, including engineering Standards, is continuous. Broadcast industry engineers and government agency engineers work toward the common goal of "public interest, convenience and necessity" set forth as a guideline in the Communications Act of 1934. The following general groupings will be used for consideration:

I. Regulatory Aspects—General Allocations Developments.

II. Developments in Systems and Techniques.

In each of these general groups it is pertinent to consider specific items in three major types of broadcasting. These are standard amplitude modulation (AM) broadcasting, frequency modulation (FM) broadcasting, and television (TV) broadcasting. These types of broadcasting are all comprehended in Part 3 of the Rules and Regulations of the Federal Communications Commission. In addition, Part 4 of the Rules and Regulations sets forth provisions relating to experimental, auxiliary, and special broadcast services.[1] Developments in this area will be outlined in some instances under the general groups breakdown. International broadcasting, also provided for in Part 3 of the Rules and Regulations will be treated from an over-all point of view without regard to the general categories. Satellite relays for broadcasting also will be considered.

* Received by the IRE, July 5, 1961; revised manuscript received, August 16, 1961.

I. Regulatory Aspects—General Allocations Developments

A. Standard (AM) Broadcasting

At present there are 3543 licensed standard broadcast stations and construction permits have been issued for an additional 205 stations. Presently pending before the Federal Communications Commission are 711 applications for new AM facilities some of which are mutually exclusive. An additional number of 578 applications pend for changed facilities on the part of existing stations wishing to improve their operations. This picture represents a growth from 882 operating stations in 1941. Standard broadcast stations operate on frequencies ranging from 540 kc to 1600 kc inclusive, representing 107 ten kc channels.

1) Class IV "local" type stations are designed to render service to cities or towns and the rural area contiguous thereto. They formerly were authorized powers not to exceed 250 watts day and night. Under an Order adopted in Docket No. 12064, effective July 7, 1958, many stations have been able to increase their daytime power to 1000 watts. This trend still continues. Of the approximately 1100 stations of this class, approximately 300 have now increased their daytime operating power, in some cases installing daytime directional antennas to do so. No changes in night operating powers have been allowed on the six channels of this class.

2) With the entry into effect of the new United States-Mexican Broadcast Agreement on June 9, 1961, United States daytime Class II stations operating daytime only on the Mexican clear channels 730, 800, 900, 1050, 1220, and 1570 kc had their power ceiling lifted from 1000 watts to 5000 watts. With 22 applications on file for increased power as of that date the Federal Communications Commission began processing these requests. About 20 per cent of the approximately 1500 stations in the United States which operate daytime only utilize these channels.

3) The Commission on June 12, 1961 instructed its staff to prepare a report and order concluding the clear channel proceeding in Docket No. 6741 initiated in February, 1945. Rules amendments look toward opening the way to the assignment of one unlimited time Class II station on each of 13 selected Class I-A clear channels under controlled conditions to provide service to underserved regions of the country. The proposed action does not affect the present use of the remaining 12 Class I-A frequencies. Class I and II stations employing up to 50 kw power continue to provide secondary sky-wave coverage to much of the United States.

4) In June, 1960, the Commission instituted a Notice of Inquiry in Docket No. 13596 looking toward a possible amendment of its Rules to permit standard broadcast stations to operate with a "compatible single-sideband system of modulation" known as CSSB. The petitioner claimed that the proposed mode of operation would result in improved high frequency audio response, increased signal-to-noise ratio, reduction in cochannel and adjacent channel interference, reduction in television receiver radiation interference, and reduction of certain types of fading distortion. Several standard broadcast stations including KDKA, Pittsburgh, WSM, Nashville, WGBB, Freeport, New York, WABC, New York, N. Y. and WMGM, New York, N. Y. were authorized to conduct experiments to test the CSSB system and to gather data regarding this type of operation in the standard broadcast band. The record was closed on this proceeding in the Spring of 1961 with a number of proponents including Westinghouse Broadcasting Company supporting favorable action.

B. Frequency Modulation (FM) Broadcasting

There are presently 812 licensed FM broadcast stations. Construction permits have been granted for 274 more. Pending applications total 107. Since the authorization of Subsidiary Communications Authorizations in May, 1955, the number of FM stations has been on the increase, approximately doubling in number since that year. The Subsidiary Communications Authorizations (SCA) services are provided on a multiplex subchannel basis by the licensee of an FM broadcast station supplying the conventional type of programming on the main channel. Transmission of programs which are of a broadcast nature, but which are of interest primarily to limited segments of the public wishing to subscribe thereto is carried on under the (SCA) authority. Illustrative services include background music, storecasting, detailed weather forecasting, special time signals and other material of a broadcast nature expressly designed and intended for business, professional, educational, religious, trade, labor, agricultural or other groups engaged in any lawful activity. Such operations may be conducted without restriction as to time so long as the main channel is programmed simultaneously. Supersonic tones or other similar means may be employed in conjunction with the material transmitted during the SCA operation in order to promote or maintain its commercial marketability, with the station using appropriate actuating devices with the subscriber's receivers. Subchannel frequencies in common use include 67 and 41 kc frequency modulated subcarriers.

FM broadcasting has been assigned 100 channels each 200 kc wide between 88 and 108 Mc. The lower four megacycles of this band have been reserved exclusively for noncommercial educational broadcasting. Stations in the educational service may employ powers as low as 10 watts while stations in the commercial service employ effective radiated powers (transmitter power times antenna gain) up to several hundred kilowatts. Use of the higher effective radiated powers is quite common in the educational service also. Antenna heights utilized range from below 100 feet effective height up to 1000 feet and above in some instances.

1) Stereophonic FM broadcasting was authorized to commence June 1, 1961, by Order adopted April 19, 1961, in Docket No. 13506. FM stations operated by Zenith Radio Corporation in Chicago and the General Electric Company in Schenectady, New York, initiated operations on that date. After an extensive study of several proposed systems of FM stereocasting including field testing,[2] conducted with the help of the National Stereophonic Radio Committee (NSRC), the Commission adopted a system akin in all major respects with those techniques proposed by Zenith and GE. FM was given first priority of consideration with the indication that standards for stereo in the standard broadcast and television services would be the subject of further determinations.

Stereophonic FM broadcasting is defined as the transmission of a stereophonic program by a single FM broadcast station utilizing the main channel and a stereophonic subchannel. The stereophonic subchannel is that band of frequencies from 23 to 53 kc containing the stereophonic subcarrier (38 kc, suppressed), and its associated sidebands.

2) FM technical standards first established in 1941 were last extensively revised upon the adoption of a new frequency band for FM in 1945. Currently deliberations are under way in government-industry groups looking toward a revision and modernization of these standards. The Technical Standards specify engineering standards of allocation which relate to FM station coverage, determination of interference between stations, the location of transmitters, and other technical factors. Considerable incentive to revision of the FM Technical Standards has been occasioned by the availability of new field strength measurements made in connection with the program of the Television Allocations Study Organization. The results of this measurements program probably will yield new field strength vs distance curves for FM broadcasting.

On June 29, 1961 the Commission issued a Notice of Inquiry, Notice of Proposed Rule-Making and Memorandum Opinion and Order dealing with the following matters:

> Proposed an over-all plan of new FM station assignments based on minimum mileage separations with respect to existing stations, and also to some extent based on maximum separations.
>
> Proposed three classes of commercial FM stations instead of the present two classifications, and two classes of educational stations.
>
> Proposed particular channels for operation of the different classes of FM stations with protection to existing FM stations if they conform to at least the new minimum operating requirements; and

[2] A. P. Walker, "Engineering performance of six proposed stereo systems," *Electronics*, vol. 33, pp. 85–89; November, 1960.

Instituted an inquiry into numerous technical subjects related to FM broadcast, such as signal ratios, polarization, directionalizing, receiver characteristics, etc.

In substance, the proposals contemplated FM broadcast operation on the following basic pattern, giving each station a certain protected service area with respect to cochannel and adjacent-channel interference, and a somewhat smaller protected service area as to second and third adjacent-channel interference. This is achieved by providing for minimum cochannel and adjacent-channel mileage separations. The proposed maximum facilities, cochannel protected service radius, and minimum cochannel separation, are as follows:

Class	Maximum facilities (or equivalent)	Protected service area radius	Minimum co-channel spacing
Class A (low power)	1 kw ERP, 250 ft*	25 miles	115 miles
Class B (intermediate power)	20 kw ERP, 500 ft*	50 miles	190 miles
Class C (high power)	100 kw ERP, 2000 ft*	100 miles	300 miles
Class D (low power educational)	10 watts (transmitter power), 100 ft*	6 miles	25 miles
Class E (high power educational)	Same as for maximum commercial station at the same location		

* Above average terrain.

Provisions with respect to FM antenna systems also will be of importance. In recent years a proposal was filed with the Federal Communications Commission requesting that FM broadcast stations be allowed to operate with either horizontal or vertical polarization. This petition was subsequently denied. However, the present Standards indicate that while horizontal polarization shall be the standard for FM, circular or elliptical polarization may be employed if desired. Thus, within these present Standards a signal having some vertical component may be provided and certain experiments have been carried out along this line. Results indicate that this can be beneficial in consideration of the problem of providing adequate field strength to automobile receivers which conventionally operate using a vertical antenna. The present provision of the Standards in this respect requires merely that the supplemental vertically polarized effective radiated power shall in no event exceed the effective radiated horizontal power authorized to the licensee.

C. Television (TV) Broadcasting

Television stations operate on VHF and UHF frequencies and are assigned three bands of frequencies which are divided into six Mc channels. The frequency ranges are 54–88 Mc (except 72–76 Mc), 174–216 Mc, both VHF ranges and 470–890 Mc in the UHF range. A total of 585 stations is now operating of which 494 utilize VHF channels and 91 occupy UHF channels. This number includes 56 noncommercial educational stations of which 16 operate in the UHF portion of the range. Availability of channels is determined by a Table of Assignments contained in the Rules of the Federal Communications Commission listing the various cities and towns. The table lists approximately 2200 channels of which 270 are presently reserved for noncommercial educational television use.

There are about 140 construction permits outstanding which represent uncompleted construction or stations which have been on and gone off the air reverting to construction permit (CP) status for economic problem reasons. Many of the latter represent UHF facilities whose coverage has not measured up to that available to VHF facilities, which in many cases are assigned in the same market area. Thus with only 12 channels available for assignement in the VHF portion of the spectrum and 70 channels, many of which are unused in the UHF region, the Commission has been faced for some years with an allocation problem by reason of coverage and other technical inequities.

1) In January, 1960, a new Notice of Proposed Rule-Making was issued by the Federal Communications Commission identified as Docket No. 13340. The Commission therein invited comment on its proposal to:

a) Consider applications for waivers of minimum television station separation in exceptional, individual cases meeting certain criteria; and

b) Adopt revised rules and standards governing calculations of the service areas of television broadcast stations.

In April of 1959 the Commission indicated to the Senate Committee on Interstate and Foreign Commerce that it was pursuing studies and negotiations needed to ascertain the practicability of four alternative approaches to basic revision of the television allocations structure. These alternatives included further exploration of de-intermixture of VHF and UHF channels in the same market area, the possible ability to secure a continuous block of VHF channels in the VHF portion of the spectrum by trading with UHF channels, or the move of all television broadcast services to the UHF portion of the spectrum. In the interim period, developed in the Docket 13340 proceeding notice, the Federal Communications Commission proposed to consider "interim" courses of action utilizing short spaced channel separations under the following conditions:

c) The assignment would make possible a second or a third VHF television station in an important market.

d) The need for the additional service outweighs the need for any service lost as a result of additional interference to existing stations.

e) The new VHF service would not have substantial adverse effect on established UHF television services.

f) A new assignment would not require an excessive number of channel changes of existing stations.

It was proposed as a corollary to these provisions to require any new station assigned at a substandard cochannel separation to suppress radiation (presumably through the use of a directional antenna) in the direction of the existing station. Directionalization would be employed to the extent necessary to insure that such a new station created no more interference to the existing one than that which would be caused if the two stations were to be operating at the standard minimum mileage separations of 170, 190, and 220 miles, depending upon the locality of the United States involved. For this purpose tentative methods for calculating television broadcast interference also were proposed. The existing rules and regulations lack any such provision.

Revisions of the Television Engineering Standards also were set down in proposed form in this Notice. These revisions included new VHF propagation curves and definitions of signal strength required to provide various Grades of Service using in part recommendations of the Television Allocations Study Organization (TASO) which had been submitted in March, 1959.[3] The work of this organization made up of industry and government engineers and scientists previously had covered a period of two and one-half years. A supplementary TASO report was also issued on June 13, 1960, relating to television directional antenna tests, further propagation studies, and certain minority report matters.[4] In this effort extensive comparisons were made of VHF versus UHF capabilities to provide television services through the work of six major panels. The primary areas involved were transmitting equipment, receiving equipment, field tests, propagation data, analysis and theory, and levels of picture quality.

After the issuance of two supplementary FCC notices in May and July of 1960, comments in this proceeding were closed at the end of the year.

2) In mid 1960 the Federal Communications Commission received an authorization from the United States Congress to undertake a $2,000,000 study of the feasibility of providing UHF television service to the City of New York, admittedly one of the most difficult areas to provide with VHF and UHF service in the nation. This investigation is currently going forward. A UHF transmitter and high gain antenna capable of an effective radiated power of 1,000,000 watts is being installed at the same location as the seven VHF stations atop the Empire State Building in New York City. Measurements of field strength and observations of picture quality are to be made at 5000 statistically selected locations within a 25-mile radius of the transmitter. Comparisons will be made with existing VHF signals and prototype UHF receiver installations will be made at 1000 of the locations selected above for more intensive study. One hundred UHF receivers, 10 of them for color reception, representing the best the state of the art can provide, would be used for these investigations. Furthermore, RF preamplifier use would be investigated in those cases where very difficult reception conditions were encountered and where special receiving antennas still proved incapable of securing a satisfactory picture.

A second UHF transmitter had been planned for installation in the New Jersey area to test the possible advantages of multicasting.[5] This technique has been proposed to overcome the problems of shadowing and multipath transmission difficulties which are much more pronounced on the UHF portion of the spectrum than the VHF. In effect several transmitters would be used within a given market area to provide a signal source dispersion and facilitate reception of at least one good quality broadcast signal.

3) In June, 1961 the Federal Communications Commission through the Office of the Chief Engineer and the Associated UHF-TV project issued a UHF-TV Report TRR-5.2.2 containing a possible approach to a UHF assignment plan.[6] Based on studies conducted in Europe of the most efficient means of assigning channels, when a number of criteria must be met in addition to simple cochannel and adjacent channel spacings, a way was pointed theoretically which would permit the assignment of over 8000 stations in the UHF television band. The practical limits imposed by UHF receivers and their susceptibility to picture and sound image interference, oscillator radiation and intermodulation would still be a factor in any such utilization. These "taboos" which dictate certain mileage separation criteria would still impose severe restrictions on the flexibility of assignment if such an assignment efficiency is to be approached. Under the present Table of Assignments, however, which was based on a triangular lattice approach, the required cochannel separation factor is the major inhibiting consideration as more channels are sought in a given region. The rhombus configuration suggested in the report, while requiring a more arbitrary assignment grid, does offer considerable hope of increased channel availability for the UHF television broadcast service.

D. Experimental, Auxiliary, and Special Broadcast Services

This category of services includes the following types of operation, many of which are tied in with the day-to-day operations of AM, FM, and TV stations:

Conelrad provisions,
Experimental television broadcast stations,
Experimental facsimile broadcast stations,
Developmental broadcast stations,
Remote pickup broadcast stations,

Standard and FM broadcast STL and FM intercity relay stations,
Television auxiliary broadcast stations,
Television broadcast translator stations, and
Television broadcast booster stations.

Several years ago the Federal Communications Commission authorized the use of UHF translators. A translator generally is used to extend the service area of an existing station. A station in this service is operated for the purpose of retransmitting the signals of a television broadcast station or other television broadcast translator stations. Direct frequency conversion and amplification of the rebroadcast signals without significantly altering any characteristic of the incoming signal other than its frequency and amplitude are used to provide an extended area of television reception to the general public. UHF translators may operate on UHF Channels 70 through 83. Such translators have been authorized for some time and there are now 248 in operation and applications are pending for an additional 34 stations.

More recently VHF translators have been authorized and there are currently five of these on the air. However, construction permits have been granted for an additional 194 such operations and the backlog of pending applications currently totals 706. Present UHF translators can employ a maximum peak visual power output of 100 watts and there is no limitation on the effective radiated power which may be used within the limits of practical antenna gain. VHF translators are limited to a maximum peak visual power output of one watt and similarly there is no limitation as to effective radiated power.

UHF translator signal boosters are also provided for in the Rules. The transmitting apparatus consists of a simple RF amplifier, with one or more amplifying stages, which is capable of receiving, amplifying and transmitting the signals of the parent translator without significantly altering its electrical characteristics other than amplitude. The purpose of this type of operation is to fill a coverage gap in the nominal service area of the translator station. The maximum power input to the final radio frequency amplifier is not to exceed five watts. Generally, television broadcast translator and booster stations may be operated as remote controlled and unattended operations. The equipment is generally so arranged as to come on the air when the main transmitter comes on and goes off when the main station operation ceases.

An additional class of television booster station exists which may be employed to fill the gaps within the intended service area of a main UHF television broadcast station which may not be getting service directly from the main station. Whereas the translator type of station frequently extends the nominal service area of the main station, this latter class of booster station is intended to fill "holes" in the licensed service area. This type of booster station may employ any power needed to fill the gap in the main service area providing that it does not operate with an effective radiated power of more than 5000 watts peak visual power.

Several years ago in the mountainous regions of the west, in areas inaccessible to signals from the main commercial or educational stations, the enterprising public began to put in low power "boosters" which served to relay signals from the main station back into the hills and valleys. These were not licensed or regulated by the Federal Communications Commission and were generally condemned as potential sources of interference having been placed in operation illegally. More recently, however, under the impact of public and congressional pressure the Federal Communications Commission has taken steps to legitimatize these operations and they are currently referred to as repeaters. These repeater stations operate on the VHF channels, rebroadcasting programs on a different channel to avoid interference to the received signal being used as a program source. Several hundred of these stations in Arizona, Colorado, Idaho, Montana, Nebraska, Nevada, New Mexico, Oregon, South Dakota, Utah, Washington, and Wyoming as well as several other states have been afforded recognition by the Commission. For example, there are now over 150 such operations listed for the State of Colorado alone. Such stations provide service to the public by means of direct home reception in contrast to the many homes in such areas which may obtain their signal by direct cable means through the medium of a remote master receiving antenna and signal distribution amplifiers. This latter type of system is not regulated under the present Rules of the Commission and is generally known as a community antenna television system.

The Rules governing the class of stations known as television auxiliary stations now provide that a licensee of a television broadcast station may secure authority for television intercity relay stations. This provision is in contrast to an earlier period in the development of the television broadcast service when this intercity relay prerogative was the exclusive right of the common carrier operator. While television remote pickup facilities and television studio to transmitter links had long been authorized directly to the licensee of the broadcast facility, the intercity provision is a relatively new one. The license may be issued in any case where the relay will operate between television broadcast stations either by means of "off the air" pickup and relay or involve location of the initial relay station at the studio or transmitter of a television broadcast station. Such stations may be operated by remote control and be unattended provided that certain precautions are met.

II. Developments in Systems and Techniques

A. Standard (AM) Broadcasting

Remote control of standard broadcast stations has been allowed for the past several years. Stations utilizing directional antennas have been the most recent ones to come under such an allowance with new provisions in the Engineering Standards. In the spring of 1961 the industry put forward a proposal to the Federal Communications Commission to allow automatic logging of station operation.

In the realm of new modulation techniques the compatible single sideband system has been advanced for use by the AM broadcaster. In the programming field the industry has begun to make extensive use of cartridge tape systems with automatic cuing provisions. Various types of automation are being applied to studio operations utilizing punched tapes and cards geared to program department requirements.

1) Applications to operate a station by remote control may be made as a part of the application for construction permit for a new station provided that the proposal is for nondirectional operation with a power of 10 kw or less. If a station operates with a directional antenna, or higher powers, certain further evidences of stability of operation and suitability for remote control must be given over a period of time prior to application for such operation. Control and monitoring equipment has to be so installed at the remote control point to allow the licensed operator at such a distance to perform all the functions in a manner required by the Commission's rules.

The dc control system using two wire pairs is most commonly in use. Indications at the remote control point of the antenna current meter, or for directional antennas the common point current meter and remote base current meters, are read and entered in the operating log each half hour. If a directional antenna is used, the tower base currents, phase monitor sample loop currents and phase indications must also be read and entered in the operating log once each day for each pattern. These readings must be made by personal inspection at the transmitter within two hours after the commencement of operation for each pattern.

Several hundred AM and FM stations now operate employing remote control. Approximately 100 of these involve directional antenna operations. The Columbia Broadcasting System now handles six of its seven owned and operated AM radio stations by remote control. Five of these are 50 kw stations and one a 5 kw plant. One of the 50 kw operations at KCBS uses a directional antenna with different patterns for day and night operation. The stations involved operate on 24-hour daily schedules with a minimum time off for maintenance. In general experience with remote control has been good.[7] The two major problems encountered were personnel training to handle remote type operation and reliability of control lines. Training in handling failure procedures and instructions in correct logging helped overcome the former. Telephone lines providing dc paths are the lowest grade of circuit available and apparently are given only minimum consideration by the phone companies. Disruption from telephone company tampering has been given as the main difficulty.

2) On January 13, 1961, the National Association of Broadcasters filed a proposal with the Federal Communications Commission to amend its rules to permit the use of automatic logging devices for broadcast transmitter logs. Logs currently require entries every 30 minutes of the operating parameters of the transmitter including final plate current, final plate voltage and RF power output. The proposal filed contained extensive experimental material obtained from prototype operations using such techniques, while continuing manual logging, at several stations including WIP, Philadelphia, Pa.; KFI, Los Angeles, California; and WTOP, Washington, D. C.

The equipment at WTOP was designed and built by the Brown Instrument Industrial Division of the Minneapolis-Honeywell Company in Philadelphia, Pennsylvania.[8,9] Automatic logging is accomplished by means of a recording device driving a strip chart on which 15 different parameters are recorded in a continuous cycle. On a remote system this information may be transmitted by a telemetering servo via a leased metallic telephone line. The line need not be equalized nor are amplifiers required. Its maximum resistance may be as high as 10,000 loop ohms. For remote sampling a measuring unit and a telemetering unit must be placed at the transmitter, the equipment filling about 20 vertical inches of standard relay rack space. Where the transmitter and logging equipment are to be at the same location, a combination arrangement may be made incorporating the measuring system and the recording device in a single rack.

The recorder strip chart is provided with a scale of 0–100 units which can be expanded to any convenient value in multiples of 10. The chart is marked by a dot representing the exact value of measurement. The chart speed is two inches per hour and is calibrated in 10 minute segments. There is sufficient paper on one chart roll for one month's operation. All sampling of the various parameters is transduced to direct current or voltage of low level and close to ground reference. These are fed through a selector switch into the measuring servo.

3) A form of AM modulation developed for use in the standard broadcast band by Leonard R. Kahn of Kahn Research Laboratories has been termed compatible single sideband (CSSB). The system is said to be compatible in the sense that it may be received on existing broadcast receivers. Field tests have been made to determine its capabilities.

CSSB is generated through the use of an adaptor that

[9] G. Ehrenberg, "Automatic logging of AM, FM, and TV transmitting station parameters," *Elec. Engrg.*, vol. 79, pp. 304–308; April, 1960.

can be used with an existing broadcast transmitter.[10] The adaptor provides two outputs for connection to the transmitter. One output is a phase modulated RF signal at the transmitter's normal operating frequency. The phase modulation is in accordance with the audio information to be transmitted. This same audio is provided at the second output. The unique characteristic of the audio at the second output is that it has been subjected to the same delay as the audio used for the phase modulated output. The adaptor's RF output is applied to the transmitter's regular first RF amplifier stage. The second output (audio) is applied to the transmitter as a modulation source in the normal manner. When modulation takes place the phase modulated source causes the transmitter carrier to change frequency and at the same time output No. 2 amplitude modulates the moving carrier. The effect is a redistribution of the radiated energy from the usual symmetrical fashion to an asymmetrical one.

Measurements undertaken of the performance of the KDKA transmitter when using the CSSB adaptor have been reported.[11] Frequency response runs and distortion checks at all levels of modulation were made. The transmitter performance was very nearly the same as with the normal double sideband system. Wide band receivers respond about the same to the conventional modulation process and the CSSB system. On the other hand, narrow band receivers will have to be shifted 1 to 2 kc in the direction of the favored sideband. Generally such tuning will make the CSSB signal sound more treble and if the transmitter is not modulating heavily on either double or CSSB, make it sound louder. With CSSB and "off resonance" tuning the amplitude of the favored side frequencies is enhanced and the carrier somewhat attenuated giving the effect of increasing the depth of modulation. Results in noisy low signal areas favor the CSSB signal, especially if a narrow band receiver is used and the transmission is predominantly voice modulation. The chief gain of using CSSB to KDKA has been the reduction of adjacent channel interference between KDKA on 1020 kc in Pittsburgh and WBZ in Boston on 1030 kc. The suppression of KDKA's upper side frequencies has relieved interference to WBZ reception and the ability of receivers tuned to KDKA to tune slightly off resonance away from WBZ and toward the radiated lower sideband of KDKA has also given KDKA some additional immunity from WBZ.

4) Automatic tape control record and playback machines have been designed to accept tape packaged in hand size plastic cartridges in which the magnetic tape is both contained and recorded or played.[12] The plastic cartridges are loaded with an endless tape, generally supplied in any length required from a 30 second announcement to a 30 minute program. To play the tape, the cartridge is inserted in the playback machine, a button is pushed to activate the tape and the announcement goes on the air, on cue, with no manual threading or cuing. In addition to the basic tape playback and recording equipment, remote control panels and automatic master switchers are available. Automatic transfer can be arranged between two playback machines with one unit supplying the program material and the other machine the announcements or introductions. Magnetic disc units also have been introduced by one manufacturer which combine the advantages of magnetic recording and the conventional disc handling approach.

5) Present Federal Communications Commission rules and regulations require that program logs be kept showing the starting and ending time of each program and announcement as broadcast. One system of handling such record keeping has been suggested using a Productograph P131 unit manufactured by the Simplex Time Recorder Company. This time stamping device, when actuated, prints on a standard adding machine tape the month, day of the month, hour, minute, second, and an identifying letter code.[13] Systems also have been developed utilizing IBM punched cards to provide a combination program logging and billing record.

B. *Frequency Modulation (FM) Broadcasting*

The action of the Federal Communications Commission of April 20, 1961, concluded a proceeding initiated in March, 1959, looking toward the adoption of rules for FM stereophonic broadcasting. Eight proposed systems were put forward for study during this period and six were finally field tested. The Commission's decision in favor of the Zenith-GE system hinged in part on the desire to maintain an element of compatibility with existing multiplex SCA operations. As of January 31, 1961, more than 250 FM stations held SCA multiplex authorizations. Such stations would be able to utilize the stereophonic system adopted while retaining at least one SCA channel capability.

The instantaneous frequency of SCA subcarriers is required to be within the range of 20 to 75 kc at all times. When an FM station is engaged in stereophonic broadcasting the SCA subcarriers must lie within the range of 53 to 75 kc. The stereophonic components would require use of the range from 23 to 53 kc. Stereophonic transmission standards put forth in new Rule 3.322 are as follows:

a) The modulating signal for the main channel shall consist of the sum of the left and right signals.
b) A pilot subcarrier at 19,000 cycles plus or minus 2 cycles shall be transmitted that shall frequency modulate the main carrier between the limits of 8 and 10 per cent.

[13] R. W. Flanders and R. M. Brockway, "An automatic program logging system," IRE Trans. on Broadcasting, vol. BC-7, pp. 11–14; January, 1961.

c) The stereophonic subcarrier shall be the second harmonic of the pilot subcarrier and shall cross the time axis with a positive slope simultaneously with each crossing of the time axis by the pilot subcarrier.
d) Amplitude modulation of the stereophonic subcarrier shall be used.
e) The stereophonic subcarrier shall be suppressed to a level less than one per cent modulation of the main carrier.
f) The stereophonic subcarrier shall be capable of accepting audio frequencies from 50 to 15,000 cycles.
g) The modulating signal for the stereophonic subcarrier shall be equal to the difference of the left and right signals.
h) The pre-emphasis characteristics of the stereophonic subchannel shall be identical with those of the main channel with respect to phase and amplitude at all frequencies.
i) The sum of the sidebands resulting from amplitude modulation of the stereophonic subcarrier shall not cause a peak deviation of the main carrier in excess of 45 per cent of total modulation (excluding SCA subcarriers) when only a left (or right) signal exists; simultaneously in the main channel, the deviation when only a left (or right) signal exists shall not exceed 45 per cent of total modulation (excluding SCA subcarriers).
j) Total modulation of the main carrier including pilot subcarrier and SCA subcarriers shall meet the requirements of Section 3.268 with maximum modulation of the main carrier by all SCA subcarriers limited to 10 per cent.
k) At the instant when only a positive left signal is applied the main channel modulation shall cause an upward deviation of the main carrier frequency; and the stereophonic subcarrier and its sidebands signal shall cross the time axis simultaneously and in the same direction.
l) The ratio of peak main channel deviation to peak stereophonic subchannel deviation when only a steady state left (or right) signal exists shall be within plus or minus 3.5 per cent of unity for all levels of this signal and all frequencies from 50 to 15,000 cycles.
m) The phase difference between the zero points of the main channel signal and the stereophonic subcarrier sidebands envelope, when only a steady state left (or right) signal exists, shall not exceed plus or minus 3 degrees for audio modulating frequencies from 50 to 15,000 cycles.
Note: If the stereophonic separation between left and right stereophonic channels is better than 29.7 db at audio modulating frequencies between 50 and 15,000 cycles, it will be assumed that paragraphs l) and m) of this section have been complied with.
n) Cross-talk into the main channel caused by a signal in the stereophonic subchannel shall be attenuated at least 40 db below 90 per cent modulation.
o) Cross-talk into the stereophonic subchannel caused by a signal in the main channel shall be attenuated at least 40 db below 90 per cent modulation.
p) For required transmitter performance, all of the requirements of Section 3.254 shall apply with the exception that the maximum modulation to be employed is 90 per cent (excluding pilot subcarrier) rather than 100 per cent.
q) For electrical performance standards of the transmitter and associated equipment, the requirements of Section 3.317 a) 2), 3), 4), and 5) shall apply to the main channel and stereophonic subchannel alike, except that where 100 per cent modulation is referred to, this figure shall include the pilot subcarrier.

When the main carrier is modulated by the sum of the left and right stereo signals a conventional FM receiver accepts the radiation as a full monophonic signal. The addition of a stereophonic multiplex adaptor to the conventional FM receiver allows reception of other information if stereophonic transmission is being employed. Another signal which is the difference of the left and right stereo signals amplitude modulates a supersonic 38 kc subcarrier. This subcarrier is suppressed and the resulting sidebands are used to frequency modulate the FM transmitter in accordance with the foregoing Standards. The transmitter also is modulated by a 19 kc pilot subcarrier. At the multiplex stereo adaptor attached to the receiver the second harmonic of this pilot subcarrier is used to synchronize the suppressed 38 kc reference with the sidebands received.[14] Several means are possible in the FM receiver stereo adaptors for recovering the multiplexed signals.[15] Adaptors may be devised that are relatively simple in circuitry and more complex units approaching the price of the conventional receiver itself have reached the market.[16]

C. *Television (TV) Broadcasting*

In the area of television broadcasting there are several potential developments of major importance and a number of existing ones. The use of directional antennas has been proposed by the industry and explored by TASO. Very precise frequency control of television carriers to reduce cochannel interference has been extensively studied. A system of color field redundancy for the simplification and cost reduction of color television relaying has been proposed and operated experimentally. A system involving airborne television is in use for educational television broadcasting purposes.

1) In the field of television broadcasting directional antennas have long been employed to achieve antenna gain through the concentration of horizontally polarized radiation into a narrow vertical plane in order to achieve relatively high effective radiated powers. Very little use, however, has been made of directivity in the horizontal plane. However, a few directional antennas have been employed to suppress radiation toward ocean areas or mountain regions and achieve the utmost efficiency in the desired service directions. As has been noted, the Federal Communications Commission in its considerations in Docket No. 13340 has now given some indication that directional antennas for allocation purposes may be authorized. The general advantage would be to secure additional VHF stations in an already fully occupied portion of this frequency spectrum.

During the latter phases of the TASO program, tests of directional antennas were undertaken at WBZ-TV in Boston, Massachusetts, and at WKY-TV in Oklahoma City. The installation at WBZ consisted of two three-section superturnstile antennas mounted one above the other on the 1100-foot tower at WBZ-TV. For the purpose of the test the upper antenna was used as an experimental directional antenna. Transmission lines were so arranged that north-south or east-west pairs of superturnstile elements could be used for directive operation.[17] During the period of field measurements a power divid-

[17] F. G. Kear and S. W. Kershner, "Determining the operational patterns of directional TV antennas," PROC. IRE, vol. 48, pp. 1088–1097; June, 1960.

ing network was switched to provide alternate 15 minute periods of nondirectional and directional operation with the same power input from the aural transmitter.

Three types of field measurements were made in the evaluation program. The first of these involved measurements along four radial routes from the transmitter, at distances ranging from about 9 to 50 miles. At each measuring location a continuous mobile recording over a distance of approximately 100 feet was made using a half-wave dipole receiving antenna mounted 30 feet above the road. At each location recordings were obtained over the same path for both directional and nondirectional operation during the adjacent 15 minute periods. The second type of measurements consisted of similar field strength determination at locations traversing a "cross minimum" route at distances ranging from about 18 to 22 miles. A third type of measurement involved recordings made at a distance of about 120 miles at a fixed location. All types of measurements served to indicate that the expected directivity was obtained and that there was reasonably good correlation between close and far fields.

The measurements at WKY-TV in Oklahoma City again utilized a modified three-section superturnstile antenna for directional purposes. In this case a special reference antenna mounted about 20 feet above the upper superturnstile elements was used. Both the superturnstile antenna and the reference antenna were equipped with motor driven mechanisms so that the antennas could be independently positioned to give desired orientations. The antennas were installed on a 263-foot supporting tower located some distance from the main antenna in use at WKY-TV. In these tests also the measurements indicated the expected directivity within a fair degree of approximation. On the basis of these tests, recommendations were made concerning the preferred methods for proving the performance of television directional antennas and establishing the validity of suppression which might be expected.

The observations at Oklahoma City showed that for a theoretical indicated suppression of 20 db in the directional pattern, measured suppressions of 16 or 17 db could be counted upon at considerable distances from the transmitter. Furthermore, the field strength averages over a long period of time approximated the calculated 20 db value. The tests at WKY-TV also indicated that with suppressions of the order of 20 db reflections of the main beam from nearby objects could reach a magnitude equal to or greater than the direct signal. Caution was therefore indicated in siting a television station requiring a directional antenna with a high degree of directivity so that the suppressed direction is toward the area of lowest population density. In summary, TASO recommended that until further observations and experience were gained with directional antennas they should not be used to provide greater than 15 db suppression and that a 2 db "fill-in factor" should be used as a safety margin for required suppressions of this order of magnitude.

Various other types of directional VHF antennas have been suggested, some employing the slot radiator techniques similar to current UHF practices. Multiple slots around the surface of a cylindrical antenna structure may be used to provide a variety of patterns.[18]

2) About five years ago it was suggested that very precise control of television carrier frequencies could be employed to reduce cochannel interference between television broadcast stations.[19] In the early 1950's "offset carrier" operation was incorporated into the television Table of Channel Assignments to take advantage of the fact that when carriers were offset by about 10 kc the visibility of the carrier beat pattern from television stations on the same channel was at a minimum. If picture carriers are not offset, as was the case in the early years of operation, the visible beat pattern took the form of large horizontal bars moving across the picture. With 10 or 20 kc offset operation (to take care of a triad of stations) the beat pattern was reduced to a relatively fine horizontal line structure. The work of Behrend of RCA showed that if the optimum offset frequency values could be held within a few cycles a further and finer grain arrangement of the beat pattern would obtain resulting in a further reduction of interference. While it had been possible with the offset carrier technique to achieve an improvement from a required desired-to-undesired signal to ratio of 43 db for non-offset conditions to 28 db for the offset condition, studies showed that for very precise offset techniques this ratio might be reduced to the order of 20 db.[20,21]

Tests made between the NBC stations in Washington and New York City and between New York City and the Westinghouse station in Boston, all involving Channel 4 facilities, have indicated the validity of the demonstrated interference reduction previously explored in laboratory experiments and controlled subjective tests. The tests of this technique by the Federal Communications Commission at its Laurel, Maryland, Laboratory has given promise of utilizing this new scheme to improve television service in fringe areas. Conversely, this tool might be used for allocation purposes and implemented together with directional transmitting antennas to allow greater occupancy of the presently restricted VHF portion of the spectrum.

3) In an extensive research program at the Iowa State University Engineering Experimental station,

[21] E. W. Chapin, "FCC laboratory observations of precision frequency control of TV stations," 1961 IRE International Convention Record, pt. 7, pp. 36–37.

Dr. William L. Hughes developed a system of color television using redundancy for simplification of the color television system.[22] The technique appears to give promise of cost reduction in color television transmission by network means and certain simplifications in color television pickup equipment including live camera, film camera, film and video tape systems. This description of one feature of the Iowa System has been given:

> A special color television camera is required for the modified system. In this camera the image is focused on the Y pickup and the chroma pickup through the use of a lens and beamsplitter arrangement. The Y filter, together with the Y pickup, has a total light spectral response of the luminosity function y. This luminance signal goes to the NTSC encoder without modification except for amplification and gamma correction. This signal carries full video band width. The image on the chroma pickup is modified by the color filters in the color filter wheel. The chroma pickup is really a field sequential pickup, except that the field sequency is simply red, blue, red, blue, and so on. The color filter wheel is driven by a motor which is controlled by the vertical synchronizing pulse. Thus, at any one time, a luminance signal and one piece of color information, either red or blue, results. (Now comes the part which one has to see if he is to believe that it works, and it does work very nicely.) Each color field is delayed approximately 1/60 of a second. Then the result of any one time is a luminance signal, a red (or blue) signal, and a blue (or red) signal that is 1/60 of a second old. The three signals are sufficient to make a full three-color picture in the standard manner and they can be fed to an NTSC encoder as from three camera tubes.

4) Plans to transmit educational television from airplanes have developed to the operational phase. As an outgrowth of the Stratovision program engaged in by Westinghouse and the Glenn L. Martin Company both of Baltimore, Maryland, in 1948, DC-6 aircraft carrying UHF TV transmitters are broadcasting over Montpelier, Indiana. Flying at 23,000 feet, present indications are that service is being provided to participating schools within a radius of about 200 miles. Operation is on UHF Channels 72 and 76. Ultimately plans call for the use of special spectrum conservation techniques to have each transmitter broadcast two programs simultaneously. Special narrow band receivers under development by CBS Laboratories will be a factor in providing increased channel efficiency.[23]

Video tape recorders are used to provide the program material involved. Operations are under the auspicies of the Mid-West Council on Airborne Television Instruction. The Purdue Research Foundation and Purdue University are assisting in the project. The special antenna system, which is retractable for take-off and landing is maintained in a vertical plane gyroscopically. Initially programs were transmitted three hours a day for four days a week. It is anticipated that this schedule will be increased to six hours a day Monday through Friday after preliminary operational experiments are completed.

D. Experimental, Auxiliary, and Special Broadcast Services

FM transmitters are often located at remote points where high ground elevations are available and good effective antenna heights can be obtained. In many such locations wire line facilities are not available for either program material or remote control provisions. Arrangements may be made under Part 4 of the Rules to use radio relay for program or remote control purposes. There is also some networking between FM stations in adjacent areas on a direct pickup and rebroadcast basis. In the educational FM area of operation there is a system in operation utilizing radio relay frequencies which provide for talk back from receiving locations to the program source. Such facilities result in the ability to provide a "radio classroom."

1) FM transmitter sites which are beyond wire service may now be utilized employing radio facilities for interconnection with program sources. Radio remote control can also be accomplished in the 942–952 Mc band. Such an interconnection can provide for positive transmitter control circuits, a means of relaying monitoring information from the transmitter to the control point, program relaying and provision of means of communication between the studio and transmitter.[24] The use of simplex supersonic tones provides a reliable and relatively simple means of establishing transmitter control. Fail safe operation of the remote FM transmitter can be accomplished by a carrier operated relay in the link receiver so that in the event of link failure the transmitter would be removed from the air. Transmitter metering information also may be returned to the control point by multiplexing this information on the main transmitter FM carrier.

2) FM radio relay techniques have been demonstrated in the past and are currently being used in the WQXR-New York Times network. A suggestion has been put forward for an educational FM network to use this technique plus a multiplex adjunct to provide both radio remote control of isolated FM transmitters and a program relaying circuit.[25] Thus in addition to relaying the main channel program, a second audio program channel would be relayed via a multiplexed subcarrier at about 67 kc. The second audio program channel would be independent of the main program and would permit simultaneous two-way program relaying. Remote control is proposed by means of an audio channel multiplexed on each of the stations at about 41 kc. This subcarrier would carry coded tones to convey the control information to the remote stations. Other coded tone combinations would be used for the return of the remote transmitter monitoring information using this same subcarrier frequency multiplexed on the remote station.

The remote control of the transmitters and the network switching would be broken down into four general functions. These would be audio switching control, transmitter function control, transmitter indicators, and supervisory indicators.

3) Considerable experience has been gained with two-way radio talk back for medical education in the Eastern New York and New England area.[26] WAMC located atop Mount Greylock, Massachusetts, utilizes an effective radiated power of 10 kw at 90.3 Mc. The effective antenna height is almost 2000 feet. Programs are sent to the transmitter site on a 940 Mc link from the Albany Medical College studios 40 miles away. Remote pickup transmitters in the 153 Mc band are used at the participating hospitals (some 30 in number) to transmit questions back to the Mount Greylock site which is on the highest mountain in Massachusetts. Thus, anything transmitted from either a remote hospital or from the originating studio at Albany may be heard by anyone with an FM receiver capable of receiving the broadcast signal. Specifically, this includes any medical men who can take time from their office duties to listen to these mid-day "round tables" from their homes.

A tone alerting system has been installed throughout the main conference network. This consists of tone sources at the remote participating locations and tone responsive circuits at the originating studio control room. When a participating hospital has a question they may use their tone device to actuate a signal which flashes a light to the medical program moderator in the main studio. Through a suitable control board function, the identity of the remote participating hospital may be recognized, and time cleared for the question. This technique need not be limited to medical education and it appears to afford greater flexibility than similar arrangements for talk back which have been made using wire circuits.

International Broadcasting

International broadcasting, a service of the United States Information Agency, is known as the Voice of America. Studios are located in the Health, Education and Welfare Building in Washington, D. C. The master control board is reputed to be the largest and most versatile in the world. Especially designed and built for the Voice of America facilities, it can select programs from 100 different sources and originate 26 programs simultaneously. Preset control is utilized to permit a 15 minute lead time set up and checkout in advance of program change. Thirty-five different languages are used plus a large number of dialects to reach a world-wide audience.[27]

Presently 30 short-wave transmitters at seven locations in the United States utilize powers ranging between 25 and 200 kw. Overseas the Voice of America has provided nine relay stations with 47 transmitters ranging in power from 35 to 1000 kw. Taken as a whole, the operation is on a 24-hour a day basis. Direct radio propagation from the United States to many important target areas of Eastern Europe and Asia is prevented by the shielding effect of the auroral zone. This necessitates the use of relay stations to overcome the vast distances involved and enable the "Voice" to reach the desired listener with strong signals competitive to local stations in the areas involved. The problems of overcoming Communist jamming are severe and the multiplicity of additional sources and flexibility in frequency utilization helps combat this problem.

Satellite relays for communication and broadcast relaying have been proposed.[28] To accomplish relaying by satellites wide band modulation must be used to secure the required information through noise. The expectancy is that a frequency channel of 250 Mc bandwidth would be required for each channel served. A channel could consist of 600 voice circuits or one television circuit. Some studies indicate that as many as 20 such channels might be needed requiring a spectrum of some 5000 Mc in width. In all probability because of this tremendous demand for frequency spectrum, many different satellites would be required so that many pairs of ground stations could reuse the same frequencies by orienting highly directive antennas at different satellites. The Federal Communications Commission is currently studying several proposals put forward for such purposes by common carrier and manufacturing interests. A satellite broadcasting station theoretically could put out a signal that could be received on home receivers. A synchronous satellite operating at about 22,000 miles height and having the same period of rotation as the earth could conceivably provide service to an area the size of the United States. The power requirements to provide such a system, however, would seem to be beyond the reach of immediately foreseeable techniques to solve. It does appear, however, that intercontinental television and communication by means of relaying by satellites will be feasible within the next few years.

CIRCUIT THEORY

Organized with the assistance of the IRE Professional Group on Circuit Theory

Summary of the History of Circuit Theory*

V. BELEVITCH†, FELLOW, IRE

Summary—**After a brief survey of the state of circuit theory before World War I, the various directions of its development in the last 50 years are discussed, mainly in relation with applications to communication engineering. The early period of network design (1920–1925) was followed by the beginning of synthesis (1926–1935). The next steps were the development of feedback amplifier theory and insertion loss filter theory. The numerous new directions of research started during and after the second war are briefly mentioned. Finally recent progress is reported in formal realizability theory and in topological synthesis. A last section deals with nonlinear and linear variable circuits.**

Introduction

Although circuit theory is more than 100 years old (Ohm's law, 1827; Kirchoff's laws, 1845), it seems that no systematic account of its historical development has ever been written. The present essay attempts to cover the last 50 years, the fiftieth anniversary of the IRE being taken as an excuse to exclude the more distant past. This limitation is also justified by the development of circuit theory itself, which shifted from a steady to an accelerated progress a few years before World War I, simultaneously with the expansion of communication technology following the invention of the vacuum tube (de Forest's audion, 1906). This growth of circuit theory is directly testified by the number of articles published per year, which remained below unity till 1910 and increased from 5 to 25 in the period 1920–1940; after a drop during World War II, the increase continued, and a figure of 100 was exceeded in 1954.

We start with a brief survey of the state of the theory just before World War I and discuss in separate sections the various directions of its development up to the present days, mainly in relation with applications to communication engineering. Due to space restrictions, bibliographic references are omitted altogether: at least 200 important contributions out of a total of some 2000 would deserve mention. Important authors and dates are simply quoted in the main text; the dates generally refer to publications in regular scientific journals, for it was materially impossible to search through patents, theses and reports.

Circuit Analysis Before 1914

Long before 1914 circuit theory had emerged, from general electromagnetic theory, as an independent discipline with original concepts and methods. The conception of a circuit as a system of idealized lumped elements is already firmly established—drawings of Leyden jars and rheostats have gradually disappeared in favor of the now familiar graphical symbols. This assumes, at least implicitly, that a resistor is considered as a 2-terminal *black box* defined by the relation $v = Ri$, rather than as a physical device made of metal or carbon. This abstract point of view becomes

* Received by the IRE, May 22, 1961.
† Comité d'Etude des Calculateurs Electroniques, Brussels, Belgium.

more prominent in the modern developments, where the laws defining the elements, and the interconnection constraints (Kirchoff's laws) are explicitly taken as postulates. With this approach, *network theory*[1] only studies the properties of systems of elements and becomes a purely mathematical discipline dealing with abstract structures generated by various sets of postulates. Another consequence of this point of view is that the physical devices themselves are no longer studied by network theory but by what is sometimes called *device theory;* complicated physical devices are then naturally described by their *equivalent circuits.*

Conventional network elements are linear and time-independent; moreover, the stored electric and magnetic energies, and the dissipated power, are positive definite quadratic forms, and the constraints are instantaneously workless. This reduces the problem of network analysis to the classical theory of small vibrations in dissipative mechanical systems. The use of complex variables to combine the amplitudes and phases of harmonic steady states, and the separation of transients into normal modes, all familiar in analytical dynamics, were naturally taken over by circuit analysts. In particular, Steinmetz (1894) vulgarized the use of complex quantities in electrical engineering. Some specifically electric properties were, however, also established; we mention Kirchoff's topological rules (1847) and their extension by Feussner (1902–1904), the so-called Thévenin's theorem (Helmholtz, 1853), the star-delta transformation (Kennelly, 1899) and the concept of duality (Russel, 1904).

The impedance concept was fluently used by Heaviside, with p treated both as a differential operator and as an algebraic variable. The use of complex values for p is physically justified by Campbell in 1911. Although the relation between Heaviside's operational calculus and integration in the complex plane was only clarified after 1916, the mathematical tools allowing to derive transient behavior from harmonic response were available, since all is needed for lumped circuits is Heaviside's formula based on a partial fraction expansion. It took, however, 20 more years to introduce the terminology of poles and zeros into common engineering practice.

Although network analysis is, in principle, already separated from line theory, both branches remain in close contact in their later evolution, so that a few words about the latter are not out of place. Classical line theory has been worked out in detail by Heaviside, and such concepts as matching, reflection, iterative impedance, etc. began to be transferred from continuous to discrete structures, probably through the intermediary of artificial lines, a subject to which Kennelly devoted a book in 1917. Although the general concept of quadripole, or 2 port, as a black box characterized by its voltage equations, does not explicitly appear before 1921 (Breisig), attenuators and artificial lines calibrated in "equivalent length of standard line" were used earlier for telephone transmission measurements (the decibel was only introduced in 1924). Finally, Heaviside's invention of inductive loading successfully applied by Pupin led Campbell, through the theory of iterative structures (1903), to the invention of the electric filter to be discussed in the next section.

[1] Our restriction of the term *network* (as opposed to *circuit*) to situations where reference is made to an idealized model conforms with the IRE Standards ("IRE Standards on Circuits: Definitions of Terms for Linear Passive Reciprocal Time Invariant Networks, 1960" (60 IRE 4.S2), Proc. IRE, vol. 48, p. 1609; September, 1960). Both terms are in fact synonymous in common usage. Another distinction has sometimes been made which reserves *network* for systems with free terminals or terminal-pairs (Campbell and Foster, 1920); in this terminology, an n-port becomes a circuit when terminations are specified at all ports.

Network Design, 1920–1925

The progress in circuit theory during this period is connected with the development of long distance telephony in more than one respect. First, the theory of loaded lines is closely related with the invention of the electric filter, which found an immediate application in carrier telephony (first realiztion in 1918, Pittsburgh-Baltimore). Secondly, the design of bidirectional amplifiers (two-wire repeaters) immediately raised several problems of network synthesis (hybrid coils, balancing networks, filters, equalizers), not to mention the question of over-all stability. Although satisfactory engineering solutions were rapidly found to all these problems, their theoretical foundation was insufficiently systematic—the art of design, with its cut and try procedures had not yet matured into modern synthesis.

The electric filter was invented during World War I, independently by Campbell and Wagner. The first filters were iterative ladder stuctures, although lattice sections (in particular all-pass sections) are discussed by Campbell (1920–1922). After Zobel's invention of m-derivation (1923–1924), the catalogue of elementary sections was sufficiently extended to cover most practical requirements. In the spirit of line theory, a filter was designed as a cascade connection of sections with matched image-impedances, but the difference between image attenuation and insertion loss was thoroughly estimated by Zobel.

To Zobel are also due the understanding of the ideal transmission conditions (frequency independent attenuation and linear phase), the design of constant impedance equalizers (1928) including a method of approximation to prescribed frequency characteristics, the discovery of bandwidth conservation in the low-pass /band-pass transformation, and the first correction for mutual bridging effects in a parallel connection of two filters (x-derivation).

Simultaneously with the development of filter theory, the general concept of a quadripole, with its impedance, admittance and chain (ABCD) matrices was introduced in Germany and France, and the rules for computing the matrices of series, parallel and tandem combinations of quadripoles were discovered. One distinguished between 2-terminal pair networks and 3-terminal networks (grounded quadripoles), and the combination rules were correctly restricted to cases where no "longitudinal voltage" appears. Here again, the separation of a general disturbance into a transversal and a longitudinal wave (using both conductors as "go circuit" and the earth as "return") was familiar in line theory, and effectively used in long distance telephony (phantom circuits) since 1903. A similar separation into three modes (symmetrical components) for three-phase power circuits was introduced by Fortescue in 1918.

The concept of n-terminal-pair network, or n-port, does not seem to have appeared during this period. It occurs, however, implicitly in a 1920 paper by Campbell and Foster, which is probably the first publication on network synthesis in the true sense—the energy relations in matched nondissipative 4 ports are discussed, the biconjugacy of the networks is proved, and a complete enumeration of all realizations is given; moreover, the circuits (which include the familiar hybrid coil) are explicitly treated as composed of ideal transformers, a new network element whose theory is established.

Acoustical telephone repeaters (telephone+microphone) were used before the invention of the vacuum tube, and difficulties due to singing were experienced. It is not easy to trace the evolution during the first war, and the post war publications already show a well-established technique. This is testified by the Campbell-Foster paper of 1920, by the design formulas for balancing networks (Hoyt, 1923–1924), and by the recognition of the fact that singing is essentially limited by line irregularities (Crisson, 1925).

The Beginning of Synthesis, 1926–1935

Although Foster's proof of his reactance theorem (1924) is already a transition from the methods of analytical dynamics to those of modern network synthesis, the first paper dealing explicitly with the realization of a one-port whose impedance is a prescribed function of frequency is Cauer's 1926 contribution, based on continuous fraction expansions (also studied by Fry, 1926). With Cauer's and Foster's theorems, the synthesis problem for one ports containing two kinds of elements only was solved. The analogous problem for general one ports was solved by Brune (1931) and led to the concept of positive real function. Pomey (1928) proved that the real part of the impedance matrix of a general passive 2-port was positive definite at real frequencies. The remaining developments of this period deal mainly with nondissipative n-ports; although Gewertz (1933) found a synthesis method for general 2-ports (containing all three kinds of elements), the general problem for n-ports was only solved after World War II and will be discussed in another section. The concentration on LC networks is closely connected with filter theory and its engineering interest. Another aspect of network synthesis, the approximation problem, made also its appearance during this period; the maximally flat approximation was used by Butterworth (1930) in the design of multistage amplifiers; simultaneously and independently, Cauer realized the optimal character of the Chebyshev approximation and solved the approximation problem for an important class of image-parameter filters. Finally, it should be remarked that the canonical structures obtained as solutions of the various synthesis problems made a free use of ideal transformers; the much more difficult problem of synthesis without transformers was not of paramount interest for communication applications and has only been treated recently.

The simplest network after the one port is the symmetric 2-port, which involves two frequency functions only. Geometrically symmetric 2-ports were treated by Bartlett (1927) and Brune (1932), whereas Cauer (1927) and Jaumann (1932) found a number of canonical circuits for all symmetric 2-ports. Dissymetric, and, in particular, antimetric 2-ports were studied by Cauer, who also extended Foster's theorem to LC n-ports (1931) and showed (1932–1934) that all equivalent LC networks could be derived from each other by the linear transformations considered by Howitt (1931). Certain classes of symmetric n-ports were studied by Baerwald (1931–1932).

Cauer's first book on filter design (1931) contains tables and curves for the Chebyshev approximation to a constant attenuation in the stop-band of an image parameter low-pass filter, as well as frequency transformations for other filter classes. The solution of the approximation problem involved rational functions whose extremal properties were established by Zolotareff in 1877 and which reduce to ordinary Chebyshev polynomials when elliptic functions are replaced by trigonometric functions. Cauer's presentation of his design data was based on canonic structures, practically less convenient than ladder structures, and was not accepted in engineering circles before it was realized that the statement and the solution of the approximation problem were of interest in themselves, for most of Cauer's results could easily be transferred to the ladder structure. The systematic theory of image parameter filters was further developed by Bode (1934) and Piloty (1937–1938), thus placing Zobel's earlier results in a clearer perspective. The particular problems raised by crystal filters were studied by W. P. Mason (1934–1937).

Feedback Amplifiers, 1932–1945

The construction of oscillators was one of the first applications of vacuum tubes, and the amplification increase due to a positive feedback below the threshold of oscillation is mentioned in several early publications on radio-engineering. The elementary, but erroneous, physical reasoning based on the round and round circulation of the signal in the feedback loop yielded the geometric series $\mu(1+\mu\beta+\mu^2\beta^2+\cdots)$ for the effective amplification. This gave the impression that instability must occur for all $|\mu\beta|>1$, for the series then diverges.

Stable behavior with a negative feedback exceeding 6 db was thus apparently forbidden, and such low values have little practical interest. It was soon recognized that the theory based on the geometric series was contradicted by experience, and the expression $\mu/(1-\mu\beta)$ was used even for $|\mu\beta| > 1$ without theoretical justification until Nyquist (1932) proved his famous stability criterion and showed the error in the older theory—the physical reasoning based on the loop circulation is only correct when transients are taken into account, the terms in the geometric series then becoming convolution products; the steady-state formula is obtained as the limit after infinite time; the transient series is convergent, but not always uniformly, so that the limit operation and the summation cannot be interchanged. The case of conditional stability, predicted by Nyquist's theory, was experimentally confirmed (Peterson, *et al.* 1934) and the advantages of negative feedback were systematically discussed by Black (1934).

The domestication of negative feedback made it possible to design the wide-band highly linear amplifiers required for multichannel carrier telephony. Although various designs for interstage networks were proposed, for instance by Wheeler and Percival, the limitations due to parasitic capacities, and the way of overcoming them by an optimum over-all design, were only clarified by Bode in 1940, with the help of the integral relations between attenuation and phase.

The fact that the real and imaginary parts of physical network functions could not be specified independently from each other was first stated in connection with the ideal filter paradox. Küpfmüller's treatment (1926) of the transient response to a unit-step led to the well-known sine-integral embodying a response preceding the stimulus. Restrictions imposed by causality to physical response functions are mentioned by Y. W. Lee (1932) in connection with a method of synthesis for arbitrary transfer functions based on Fourier transforms, a method patented by Lee and Wiener (1938). Physical approximations to the ideal filter response, both in amplitude and phase, are discussed by Bode and Dietzold (1935). Explicit integral relations between real and imaginary parts of various network functions were studied independently by Cauer (1932–1940), Bayard (1935) and Leroy (1935–1937), but similar relations were known earlier in the theory of optical dispersion (Kramers-Kronig, 1926).

Bode extended the relations to the case where either component is specified in a partial frequency range, and worked out their consequences for input, output and interstage networks with prescribed parasitic capacities. He also computed the maximum obtainable over-all feedback in terms of band width and asymptotic loop transmission. The stability criterion for multi-loop amplifiers was obtained by Llewellyn, and the effect of feedback on impedances was discussed by Blackman (1943). Bode introduced the concepts of return reference and sensitivity in his classical book (1945).

Insertion Loss Filters and Related Problems

The limitations of image-parameter theory first appeared in connection with the design of filter groups, a problem frequently encountered in carrier telephony. Zobel's procedure of x-derivation, already mentioned, was first replaced by a more systematic method of impedance correction (Bode, 1930). An image-parameter theory of constant impedance filter pairs was developed by Brandt (1934–1936), Cauer (1934–1937) and Piloty (1937–1939), and it was recognized that this also yielded a solution to the equivalent problem of open-circuit filter design.

A completely new approach to the whole problem is contained in Norton's paper (1937) on constant impedance filter pairs, where the method of design starting from a prescribed insertion loss is established. The general synthesis problem for a reactance 2-port with prescribed insertion loss was solved independently by Cocci (1938–1940), Darlington (1939), Cauer (1939–1941) and Piloty (1939–1941). These contributions establish the canonic realization of a reactance 2-port as a ladder structure with mutual inductances restricted to adjacent or nearly adjacent arms and, as a consequence, the possibility of realizing an arbitrary passive one port by a network containing one resistance only. The approximation problem for insertion loss filters was reduced to the similar problem for image-parameter filters. Finally, Darlington also devised a method for precompensating the dissipative distortion.

As already mentioned, the prewar evolution of network theory was closely related with the development of wire communication, and the perfection reached by filter and feedback amplifier theory around 1940 made possible the design to strict tolerances which is required in long distance telephone equipment. On the contrary, the easier narrow-band problems of radio-engineering were treated by elementary circuit analysis, and it is only with the advent of video and pulse techniques that the theory of wide-band multi-stage amplifiers (without over-all feedback) underwent a systematic development, mainly during World War II. Another direction of war-time evolution was the extension of filter techniques to higher frequencies, leading to transmission line filters and microwave networks. Both directions have influenced classical filter theory and, as a consequence, common mathematical methods are now used in an extended field.

In microwave applications, the classical description of network performance in terms of voltages, currents, impedance and admittance matrices, was naturally replaced by a description based on transmitted and reflected wave amplitudes, leading to the concept of scattering matrix (Montgomery, Dicke and Purcell, 1948) taken over from general physics. This concept is also of interest in the field of lumped networks, where it was introduced independently and simultaneously by Belevitch. The scattering formalism allowed an easier presentation of insertion loss filter theory, and has been of great help in other applications to be discussed later.

The war-time progress in amplifier design is described in the book of Valley and Wallmann (1943), but similar work has been done independently in Germany, namely by Cauer (posthumous publications). Most input and inter-stage circuits are actually ladder filters, terminated or open-circuited, so that filter and amplifier problems are closely related. Explicit formulas for the element values of various important classes of ladder filters have been investigated by many workers, but it was recently realized that most results had been anticipated by Takahasi (paper in Japanese, 1951; English adaptation, 1960). The design of input and output circuits is also related with the broad-band matching problem, which consists in constructing a 2-port which transforms a given frequency-dependent output load (for instance a resistance shunted by a parasitic capacitance) into a pure input resistance. A rigorously constant resistance can be obtained by a lossy 2-port, but it is practically important to know the approximation to matching in a given frequency range obtainable from a lossless 2-port, and to see how the transmission loss varies with the degree of impedance equalization for lossy 2-ports. The broad-band matching problem with lossless 2-ports was solved by Fano (1950) for important classes of load impedances. The relations for lossy 2-ports were obtained by Carlin and La Rosa (1952–1955) with the help of the scattering formalism.

Distributed amplifiers, which overcame the limitations imposed by parasitic capacities to stagger-tuned circuits, had been invented by Percival in 1937, but were only practically exploited after 1948; the problem of their optimum design is still unsolved, although some progress has been recently achieved.

The scattering formalism proved useful in the design of various classes of n-ports of interest in telephone applications. Belevitch (1950–1955) discussed matched n-ports with equal losses between any couple of ports, and biconjugate n-ports for $n>4$. Dosoer (1958) and Oswald (1958) established design methods for a class of filter 4-ports (invented by Darlington in 1938) used in submerged repeaters.

The methods of best approximation used in filter and amplifier design were applied to other problems, namely to the design of various classes of delay networks. The maximally flat approximation for the group delay was obtained by Thomson (1949), and the Chebyshev approximation by Ulbricht and Piloty (1960). The Chebyshev approximation to a constant phase difference between two all-pass 2-ports (of interest for polyphase modulation) was obtained independently by Darlington, Orchard and Saraga (1950), and a mathematically equivalent problem on the phase angle of an impedance (of interest in feedback amplifier design) was solved by Baumann (1950). For problems having no exact analytic solution, Darlington (1952) described a procedure based on a series expansion in Chebyshev polynomials, whereas the potential analogy and the related electrolytic tank technique were practically applied at least since 1945 (Hansen and Lundstrom).

New Trends in Post-War Evolution

The field of application of circuit theory extended in so many new directions during and after World War II that only the major tendencies can be outlined. Several new developments lie on the borderline between circuit theory and other disciplines (information theory and noisy systems, electronic computers, automatic control), and will not be discussed. The present section attempts a brief classification of the new ideas, concepts and methods, in relation with their engineering applications; the next two sections review in detail the postwar developments of network theory *stricto sensu*. Nonlinear and linear variable circuits are treated separately in the last section.

Pulse techniques, already mentioned, raised various synthesis problems in the time domain. Although every problem stated in the time domain is, in principle, equivalent to a problem in the complex frequency domain, the approximation requirements are often difficult to translate from one domain into the other, and the convergence properties in the two domains may be quite different. Various mathematical methods, such as Laguerre functions (Lee, 1932), time series expansions (Lewis, 1952), complex integration (Guillemin and Cerillo, 1952), have been used, but there seems to have been little fundamental progress; for instance, the problem of the steepest monotonic response in presence of a given parasitic capacity is not completely solved, although important contributions have been published, namely by Zemanian (1954) and Papoulis (1958).

Microwave circuits have also been previously mentioned. The realization of a microwave gyrator (Hogan, 1952), based on the Faraday effect in ferrites, justified the interest of the ideal gyrator concept (Tellegen, 1948) and promoted theoretical research on nonreciprocal networks initiated by Tellegen (1948–1949). Theoretical work on the synthesis of passive n-ports (both reciprocal or not) is discussed in the next section. Its practical importance is due to the fact that, without the limitations of reciprocity, better performances can be obtained (interstage networks; Tellegen, 1951) or otherwise impossible behavior can be achieved (design of circulators: Carlin, 1955).

Progress has been slower in the theory of active networks because it was more difficult to represent the real physical devices by simple ideal elements; needless to say, even greater difficulties await the circuit theorists of the future, with the advent of integrated microelectronic devices. Classical amplifier theory dealt in fact with passive networks separated by ideal unilateral buffer stages, and amplifiers with large negative feedback were used to realize the active transfer function $-1/\beta$ involving only the transfer ratio β of the passive feedback network. With the advent of the transistor

(Bardeen and Brattain, 1948), practical design problems became much more difficult due to the internal feedback of the device. The fundamental limitations of active non-unilateral devices, at a fixed frequency, were progressively understood; for instance, the conditions for intrinsic stability were established by Llewellyn (1952), power invariants were found by S. J. Mason (1954), and noise invariants by Haus and Adler (1956–1959). The analysis of complex feedback structures was clarified by the use of the flow-graph notation (S. J. Mason, 1953). After the introduction of gyrators, it appeared more convenient to represent active devices by an equivalent circuit containing gyrators and (positive and negative) resistors, so that negative resistance remained the only new element in the theory of active networks. Although various negative resistance effects (arc discharge, dynatron, etc.) had been known for many years, practical and economic devices simulating linear negative resistors became available only with solid-state components (negative impedance converter: Linvill, 1953; tunnel diode: Esaki, 1958), and this favored the adoption of negative resistance as the basic element in theoretical work. Recent results in the theoretical field are summarized at the end of the next section.

Returning now to the synthesis of passive reciprocal networks, we briefly comment on the progressive separation between formal realizability theory (where ideal transformers are freely accepted) and topological synthesis (where even mutual inductances are excluded). The recent interest in topological methods originated from several distinct fields. First, mutual inductances, and even self-inductances, are difficult to realize at very low frequencies; this stimulated research on RC circuits, mainly for servomechanism applications, although similar problems arose earlier in the design of RC-oscillators (invented by van der Pol and van der Mark in 1934). Secondly, even at higher frequencies, it may be economical to replace inductances by capacitances combined with positive and negative resistances; this possibility was known theoretically before 1930, but became only practical with the availability of solid-state devices. Topological problems also arose in the design of contact networks, and some recent developments in the theory of switching are related with various fundamental problems of conventional network theory. Finally, the treatment of network problems on electronic computers asked for a more complete and detailed algebraization of all topological notions and raised various enumeration problems. Topological analysis was recently discussed by many workers, such as Bryant, Okada, Percival, Seshu and Watanabe; for combinatorial and enumeration problems, we refer to the book of Riordan (1958).

Formal Realizability

The synthesis of passive reciprocal n-ports has been achieved by three methods. The first one extended Gewertz's procedure for 2-ports and consisted in the successive extraction of reduced impedance matrices; the process is heavy and laborious, and only of historical interest; it enabled, however, Oono (1946) and Bayard (1949) independently to prove that any positive real impedance or admittance matrix is realizable, thus showing that RLC elements and the ideal transformer constitute a *complete* system of passive reciprocal elements. After a discussion of the 2-port case by Leroy and Belevitch (1949), it appeared that the first method was actually a disguised extension of Darlington's process for one ports, *i.e.*, the realization of an n-port as a reactive $2n$-port closed on n resistors. The second method consists in a direct application of this idea; it was used by Bayard (1950) and with the scattering formalism by Belevitch (1951). The third method extends Brune's process for one ports and arrives to a structure containing the minimum number of reactive elements; synthesis by this method was achieved independently by Oono (1948), Mac Millan (1948–1952) and Tellegen (1953) and contributed to a satisfactory definition of the degree of a rational matrix. In an important paper (1954), Oono and Yasuura rediscuss the synthesis by the second method, using the scattering matrix both for reciprocal and nonreciprocal n-ports and solve completely the equivalence problem.

In connection with the design of narrow-band unsymmetrical band-pass filters, Baum (1957–58) introduced a new fictitious passive element, the imaginary resistance (or frequency-independent reactance), and showed its interest in various synthesis problems. Using this concept, Belevitch obtained a simple derivation of Brune's for one-ports (1959) and extended Tellegen's process to nonreciprocal n-ports (1960).

Extensions to active networks were delayed due to difficulties arising with certain pathological n-ports admitting none of the conventional matrix descriptions (Tellegen, 1954; Carlin, 1955). These difficulties were circumscribed by Oono (1960), and by Carlin and Youla (1960). The latter showed that any active n-port is realizable as a passive nondissipative $3n$-port closed on n positive and n negative resistors. In a companion paper, Youla and Smilen (1960) establish the gain-bandwidth limitations due to parasitic capacitances in negative-resistance amplifiers and derive design formulas for optimum amplifiers.

Topological Synthesis

Logically, but not historically, the first problem arising in this field is the one of discriminating between constraints which are realizable without ideal transformers and general workless reciprocal constraints. In synthesis problems, constraints generally appear under the form of prescribed incidence relations between loops and branches, and the problem is to determine the necessary and sufficient conditions under which a prescribed incidence matrix corresponds to a graph. A necessary condition is well known (the matrix must be totally unimodular, *i.e.*, have all its minors of all orders equal to 0 or ±1), but is certainly not sufficient, a classical counter-example being the dual of the constraints in a nonplanar graph (Foster, 1952). Sufficient conditions were found by Tutte (1958–1959). Various algorithms have recently been devised which either prove a given matrix to be unrealizable, or lead to a unique realization, within trivial isomorphisms. The first such algorithm is due to Gould (1958) and was applied to the synthesis of contact networks.

The next problem is the synthesis of resistance n-ports, and of resistance networks having $n+1$ terminals (grounded n-ports). It was known for some time that dominancy (any diagonal element not smaller than the sum of the moduli of all elements in the same row) was sufficient, but not necessary, for the admittance matrix of an n-port. Necessary and sufficient conditions for a 3-port with prescribed impedance or admittance matrix were obtained by Tellegen (1952) by expressing that the network cannot yield current nor voltage gain under any set of open- or short-circuit conditions. A nontrivial extension of Tellegen's approach led Cederbaum (1958) to the condition of paramountcy (any principal minor not smaller than the modulus of every minor based on the same rows), which is weaker than dominancy. Paramountcy is necessary for admittance and impedance matrices, but its sufficiency is not established for impedance matrices with $n>3$. For $(n+1)$-terminal networks, the synthesis is equivalent to to a congruence transformation into a positive diagonal matrix by means of a realizable constraint matrix. An algorithm yielding a unique (except for trivial variants) transformation, if possible at all, has been found by Cederbaum, but this algorithm accepts totally unimodular transformation matrices, which are not necessarily realizable. Related synthesis procedures were described by Guillemin (1960) and Biorci (1961).

For two-element kind one ports, the canonical structures of Foster and Cauer contain no transformers. It has long been thought that the transformers appearing in Brune's process are unavoidable in the synthesis of general three-element kind one ports; a canonical realization without mutual inductance was, however, published by Bott and Duffin (1949). In spite of various small improvements (Pantell, 1954; Reza, 1954), the method is quite wasteful in elements; no further general improvement has been obtained, but procedures due to Miyata (1952) and Guillemin (1955) sometimes yield more economical realizations.

The synthesis of RC 2-ports was first treated by Guillemin (1949), who showed that the class of grounded RC 2-ports was practically not narrower than the class of general reciprocal 2-ports, in the sense that the modulus of the input-output voltage ratio of any 2-port of the second class can be arbitrarily approximated within the first class, except for a constant multiplier. Guillemin's synthesis was in terms of parallel ladders; Orchard (1951) established a synthesis by RC lattices and discussed the extraction of terminal resistances in order to realize prescribed insertion loss functions. The approximation problem was treated by Ozaki and Fujisawa (1953). Miscellaneous synthesis procedures were discussed by a number of authors, but the most general and complete results are due to Fialkow and Gerst in a half-dozen papers published between 1951 and 1955. These authors found the necessary and sufficient conditions for voltage ratios of grounded and nongrounded RC and RLC 2-ports, as well as for various restricted structures (ladder, lattice); they indicated canonic realizations and discussed the value of the constant multiplier which fixes the maximum available voltage gain. Articles by Cederbaum (1956) and Kuh and Paige (1959) bring certain additional precisions.

The synthesis of RC grounded 2-ports with prescribed admittance or impedance matrices is still an unsolved problem. A series-parallel synthesis procedure was described by Ozaki (1953), and sufficient conditions under which it succeeds are known, but have not been proved necessary. The problem progressed through contributions of Lucal (1955), Slepian and Weinberg (1958) and Adams (1958), but Darlington's conjecture (1955), stating that any RC grounded 2-port admits an equivalent series-parallel realization, is still unproved.

The problem of ladder synthesis of two-element kind 2-ports arose earlier in filter theory, and the important method of zero-shifting in cascade synthesis was introduced by Bader (1942). Necessary and sufficient conditions for ladder realizability, in the case of a prescribed impedance matrix, or prescribed insertion loss, are unknown in general, but have been established for important classes of networks (Fujisawa, 1955; Watanabe, 1958) and applied to filter design (Meinguet, 1958).

Active grounded RC networks have recently been discussed by Kinariwala (1959–1960) and Sandberg (1960).

Nonlinear and Linear Variable Circuits

In contrast with the maturity of linear network theory, it is often considered that the theory of nonlinear and of linear variable networks is still in its infancy: it is not yet completely separated from nonlinear mechanics and has not reached the stage of synthesis. The present brief review limited to purely electrical problems is intended to show, however, that there has been some systematic progress and that the theory in its present state is no longer a collection of odd results.

First, it is important to separate the problems raised by the unavoidable nonlinearities appearing in nominally linear systems, and the intentional nonlinear effects allowing performances unobtainable with linear systems. The calculation of nonlinear distortion is relatively elementary in the case of slightly nonlinear characteristics (vacuum tube amplifiers, carbon microphone, etc). A more difficult problem arose in connection with the cross-modulation due to hysteresis in loading coils (Kalb and Bennett, 1935). The computation of the modulation products generated by two harmonic signals turned out to be mathematically equivalent to the similar problem in an ideal rectifier, and the amplitudes were obtained as hypergeometric functions. Further progress is reported in later publications by Bennett and others, and the results proved useful in a number of problems involving sharp nonlinearities, such as overload effects in rectifier modulators and feedback amplifiers.

The typically useful properties of nonlinear, or linear variable systems are related with frequency conversion in a wide sense, including harmonic or subharmonic generation, and even simple oscillation, for an oscillator transforms dc power into power at its own frequency. The theory of the triode oscillator was developed by Appleton and van der Pol (1920–1926), and explained such effects as synchronization, amplitude hysteresis, etc. Subharmonic generations in the triode oscillator were analyzed by Mandelstam and Papalexi (1931). Although van der Pol had shown the continuity between quasi-harmonic and relaxation oscillations, these extreme types of behavior actually occur in different technical applications and continued to be treated in separated contexts. Starting from relaxation oscillators and multivibrators (Abraham and Block, 1919) a particular branch of electronic circuit technology developed in the direction of such applications as time bases, counters, logical circuits, wave form generators, etc. On the other hand, the main concern in the design of harmonic oscillators was frequency stability; the way it is affected by nonlinearities was deduced from the principle of harmonic balance (Groszkowski, 1933) and the analysis of linear effects led to the development of the numerous oscillator circuits bearing the names of their inventors. All the above problems are, however, treated by elementary circuit analysis and are more related with device technology than with circuit theory.

Frequency conversion by amplitude modulation raised only elementary problems as long as tubes were used. With the introduction of rectifier modulators, such as the Cowan and ring modulators, in the early thirties, more difficult problems appeared, due to the interaction of all products whose amplitudes thus finally depend on the load impedances at all frequences. In carrier systems, modulators normally operate between highly selective filters, and a corresponding small signal theory for rectifier modulators between selective terminations was developed after 1939 by such workers as Caruthers, Kruse, Stieltjes, Tucker and Belevitch. The conception of a linear variable network as a linear network with an infinite number of ports (treating the impedance presented to each modulation product as a separate termination) did not yield tractable solutions in the case of nonselective terminations, and the case of RC loads (Belevitch, 1950) was treated by a direct method. The general problem became recently of major importance for the optimum design of filters for pulse-time modulated systems; after contributions by Cattermole (1958) and Desoer (1958), an analysis leading to a finite set of linear equations was obtained by Fettweis (1959). Another application of rectifier modulators was treated by Miller (1959) who showed that better frequency dividers could be designed by separating the various nonlinear effects which occur simultaneously in the tube of ordinary oscillators—in the circuits of Miller, the tube is a linear amplifier and the necessary nonlinear effects are produced by rectifier circuits separated by selective filters.

Harmonic generation by rectifier circuits does not seem to have been treated until quite recently—Page (1956) published a theorem on the maximum harmonic efficiency, and Belevitch and Neirynck (1957) described optimal circuits. On the contrary, harmonic production by non-linear reactance is not subject to the same restrictions, and magnetic harmonic generators (Peterson, Manley and Wrathall, 1937) are widely used. The theory of frequency conversion in magnetic modulators is more recent—power relations in nonlinear reactances were discussed by Manley and Rowe (1956), Page (1957), Duinker (1957) and many others. The possibility of amplification and the related negative resistance effects (Hartley) were known however, around 1920 and applied quite early to frequency dividers (transformation of a 60 cps supply into a 20 cps telephone ringing current) and to magnetic amplifiers. The recent revival of interest in parametric amplification is due to the availability of solid-state nonlinear capacitances. On the other hand, resonant circuits with nonlinear inductances, and the phenomenon of ferroresonance were also discussed before World War I, and led to Duffing's equation (1918). New interest in related phenomena was raised by the invention of the parametron (Goto, 1955).

The analysis of complicated nonlinear oscillator circuits by the classical methods of nonlinear mechanics is practically impossible and various approximate engineering methods have been developed, the first one being the so-called equivalent linearization of Krylov and Bogoliubov (1937). During the Second World War, a method based on the describing function has been introduced separately in the U.S.A., the U.S.S.R. and in France. In this method, one derives, from the instantaneous response of the nonlinear element to a harmonic excitation or to a combination of such excitations, an amplitude response or a set of amplitude responses, which are functions of the incident amplitudes; the linear part of the circuit is characterized by its transfer function or matrix. With the additional hypothesis that the linear circuits are highly selective, a finite set of algebraic equations is obtained for the steady-state amplitudes, and it is no longer necessary to consider explicitly any differential equations. This also holds true for the stability analysis of the steady-states, which is performed by linear perturbation methods, thus using only the standard criteria of linear network theory (Hurwitz, Nyquist). This "filter method" (as it is called in Russia) allowed a much simpler derivation of the classical results of van der Pol and others, and is now being successfully applied to new problems.

From Circuit Theory to System Theory*

L. A. ZADEH†, FELLOW, IRE

Summary—**The past two decades have witnessed profound changes in the composition, functions and the level of complexity of electrical as well as electronic systems which are employed in modern technology. As a result, classical RLC network theory, which was the mainstay of electrical engineering at a time when RLC networks were the bread and butter of the electrical engineer, has been and is being increasingly relegated to the status of a specialized branch of a much broader discipline—system theory—which is concerned with systems of all types regardless of their physical identity and purpose.**

This paper presents a brief survey of the evolution of system theory, together with an exposition of some of its main concepts, techniques and problems. The discussion is centered on the notion of state and emphasizes the role played by state-space techniques. The paper concludes with a brief statement of some of the key problems of system theory.

I. Introduction

THE past two decades have witnessed an evolution of classical circuit theory into a field of science whose domain of application far transcends the analysis and synthesis of RLC networks. The invention of the transistor, followed by the development of a variety of other solid-state devices, the trend toward microminiaturization and integrated electronics, the problems arising out of the analysis and design of large-scale communication networks, the increasingly important role played by time-varying, nonlinear and probabilistic circuits, the development of theories of neuroelectric networks, automata and finite state machines, the progress in our understanding of the processes of learning and adaptation, the advent of information theory, game theory and dynamic programming, and the formulation of the maximum principle by Pontryagin, have all combined to relegate classical circuit theory to the status of a specialized branch of a much broader scientific discipline—system theory—which, as the name implies, is concerned with all types of systems and not just electrical networks.

What is system theory? What are its principal problems and areas? What is its relationship to such relatively well-established fields as circuit theory, control theory, information theory, and operations research and systems engineering? These are some of the questions which are discussed in this paper, with no claim that the answers presented are in any way definitive. Technological and scientific progress is so rapid these days that hardly any assertion concerning the boundaries, content and directions of such a new field as system theory can be expected to have long-term validity.

The obvious inference that system theory deals with systems does not shed much light on it, since all branches of science are concerned with systems of one kind or another. The distinguishing characteristic of system theory is its generality and abstractness, its concern with the mathematical properties of systems and not their physical form. Thus, whether a system is electrical, mechanical or chemical in nature does not matter to a system theorist. What matters are the mathematical relations between the variables in terms of which the behavior of the system is described.[1]

To understand this point clearly, we have to examine more closely the concept of a system. According to Webster's dictionary, a system is "... an aggregation or assemblage of objects united by some form of interaction or interdependence." In this sense, a set of particles exerting attraction on one another is a system; so is a group of human beings forming a society or an organization; so is a complex of interrelated industries; so is an electrical network; so is a large-scale digital computer, which represents the most advanced and sophisticated system devised by man; and so is practically any conceivable collection of interrelated entities of any nature. Indeed, there are few concepts in the domain of human knowledge that are as broad and all-pervasive as that of a system.

It has long been known that systems of widely different physical forms may in fact be governed by identical differential equations. For example, an electrical network may be characterized by the same equations as a mechanical system, in which case the two constitute analogs of one another. This, of course, is the principle behind analog computation.

While the analogies between certain types of systems have been exploited quite extensively in the past, the recognition that the same abstract "systems" notions are operating in various guises in many unrelated fields of science is a relatively recent development. It has been brought about, largely within the past two decades, by the great progress in our understanding of the behavior of both inanimate and animate systems—progress which resulted on the one hand from a vast expansion in the scientific and technological activities directed toward the development of highly complex systems for such purposes as automatic control, pattern recognition, data-processing, communication, and machine computation, and, on the other hand, by the attempts at

quantitative analyses of the extremely complex animate and man-machine systems which are encountered in biology, neurophysiology, econometrics, operations research and other fields.

It is these converging developments that have led to the conception of system theory—a scientific discipline devoted to the study of general properties of systems, regardless of their physical nature. It is to its abstractness that system theory owes its wide applicability, for it is by the process of abstraction that we progress from the special to the general, from mere collections of data to general theories.[2]

If one were asked to name a single individual who above anyone else is responsible for the conception of system theory, the answer would undoubtedly be "Norbert Wiener," even though Wiener has not concerned himself with system theory as such, nor has he been using the term "system theory" in the sense employed in this paper. For it was Wiener who, starting in the twenties and thirties, has introduced a number of concepts, ideas and theories which collectively constitute a core of present-day system theory. Among these, to mention a few, are his representation of nonlinear systems in terms of a series of Laguerre polynomials and Hermite functions, his theory of prediction and filtering, his generalized harmonic analysis, his cinema-integraph, the Paley-Wiener criterion, and the Wiener process. It was Wiener who, in the late forties, laid the foundation for cybernetics—the science of communication and control in the animal and the machine—of which system theory is a part dealing specifically with systems and their properties. It should be noted, however, that some of the more important recent developments in system theory no longer bear Wiener's imprint. This is particularly true of the theory of discrete-state systems, the state-space techniques for continuous systems, and the theory of optimal control, which is associated mainly with the names of Bellman and Pontryagin. We shall touch upon these developments later on in the paper.

Among the scientists dealing with animate systems, it was a biologist—Ludwig von Bertalanffy—who long ago perceived the essential unity of systems concepts and techniques in various fields of science and who in writings and lectures sought to attain recognition for "general systems theory" as a distinct scientific discipline.[3] It is pertinent to note, however, that the work of Bertalanffy and his school, being motivated primarily by problems arising in the study of biological systems, is much more empirical and qualitative in spirit than the work of those system theorists who received their training in the exact sciences. In fact, there is a fairly wide gap between what might be regarded as "animate" system theorists and "inanimate" system theorists at the present time, and it is not at all certain that this gap will be narrowed, much less closed, in the near future. There are some who feel that this gap reflects the fundamental inadequacy of the conventional mathematics—the mathematics of precisely-defined points, functions, sets, probability measures, etc.—for coping with the analysis of biological systems, and that to deal effectively with such systems, which are generally orders of magnitude more complex than man-made systems, we need a radically different kind of mathematics, the mathematics of fuzzy or cloudy quantities which are not describable in terms of probability distributions. Indeed, the need for such mathematics is becoming increasingly apparent even in the realm of inanimate systems, for in most practical cases the *a priori* data as well as the criteria by which the performance of a man-made system is judged are far from being precisely specified or having accurately-known probability distributions.

System theory is not as yet a well-crystallized body of concepts and techniques which set it sharply apart from other better established fields of science. Indeed, there is considerable overlap and interrelation between system theory on the one hand and circuit theory, information theory, control theory, signal theory, operations research and systems engineering on the other. Yet, system theory has a distinct identity of its own which perhaps can be more clearly defined by listing its principal problems and areas. Such a list is presented below, without claims that it is definitive, complete and non-controversial. (To avoid misunderstanding, brief explanations of the meaning of various terms are given in parentheses.)

Principal Problems of System Theory

1) System characterization (representation of input-output relationships in mathematical form; transition from one mode of representation to another).
2) System classification (determination, on the basis of observation of input and output, of one among a specified class of systems to which the system under test belongs).
3) System identification (determination, on the basis of observation of input and output, of a system within a specified class of systems to which the system under test is equivalent; determination of the initial or terminal state of the system under test).
4) Signal representation (mathematical representation of a signal as a combination of elementary signals; mathematical description of signals).
5) Signal classification (determination of one among a specified set of classes of signals or patterns to which an observed signal belongs).

[2] To quote A. N. Whitehead, "To see what is general in what is particular, and what is permanent in what is transitory is the aim of modern science."

[3] Dr. Bertalanffy is a founder of the Society for General Systems Research, which publishes a yearbook and has headquarters at the Menninger Foundation, Topeka, Kans.

6) System analysis (determination of input-output relationships of a system from the knowledge of input-output relationships of each of its components).
7) System synthesis (specification of a system which has prescribed input-output relationships).
8) System control and programming (determination of an input to a given system which results in a specified or optimal performance).
9) System optimization (determination of a system within a prescribed class of systems which is best in terms of a specified performance criterion).
10) Learning and adaptation (problem of designing systems which can adapt to changes in environment and learn from experience).
11) Reliability (problem of synthesizing reliable systems out of less reliable components).
12) Stability and controllability (determination of whether a given system is stable or unstable, controllable—subject to specified constraints—or not controllable).

Principal Types of Systems

1) Linear, nonlinear.
2) Time-varying, time-invariant.
3) Discrete-time (sampled-data), continuous-time.
4) Finite-state, discrete-state, continuous-state.
5) Deterministic (nonrandom), probabilistic (stochastic).
6) Differential (characterized by integro-differential equations), nondifferential.
7) Small-scale, large-scale (large number of components).

Some Well-Established Fields Which May Be Regarded as Branches of System Theory

1) Circuit theory (linear and nonlinear).
2) Control theory.
3) Signal theory.
4) Theory of finite-state machines and automata.

Comment 1: Note that *approximation* is not listed as a separate problem, as it is usually regarded in classical circuit theory. Rather, it is regarded as something that permeates all the other problems.

Comment 2: Note that *information theory* and *communication theory* are not regarded as branches of system theory. System theory makes extensive use of the concepts and results of information theory, but this does not imply that information theory is a branch of system theory, or vice versa. The same comment applies to such theories as *decision theory* (in statistics), *dynamic programming*, *reliability theory*, etc.

Comment 3: Note that there is no mention in the list of *systems engineering* and *operations research.* We regard these fields as being concerned specifically with the operation and management of large-scale man-machine systems, whereas system theory deals on an abstract level with general properties of systems, regardless of their physical form or the domain of application. In this sense, system theory contributes an important source of concepts and mathematical techniques to systems engineering and operations research, but is not a part of these fields, nor does it have them as its own branches.

It would be futile to attempt to say something (of necessity brief and superficial) about each item in the above list. Instead, we shall confine our attention to just a few concepts and problems which play particularly important roles in system theory and, in a way, account for its distinct identity. Chiefly because of limitations of space, we shall not even touch upon a number of important topics such as the design of learning and adaptive systems, the analysis of large-scale and probabilistic systems, the notion of feedback and signal flow graph techniques, etc. In effect, the remainder of this paper is devoted to a discussion of the concept of state and state-space techniques, along with a brief exposition of systems characterization, classification and identification. We have singled out the concept of state for special emphasis largely because one can hardly acquire any sort of understanding of system theory without having a clear understanding of the notion of state and some of its main implications.

II. State and State-Space Techniques

It is beyond the scope of this presentation to trace the long history of the evolution of the concept of state in the physical sciences. For our purposes, it will suffice to observe that the notion of state in essentially the same form it is used today was employed by Turing [1] in his classical paper, "On computable numbers, with an application to the Entscheidungs problem," in which he introduced what is known today as the Turing machine.[4]

Roughly speaking, a Turing machine is a discrete-time ($t=0, 1, 2, \cdots$) system with a finite number of states or internal configurations, which is subjected to an input having the form of a sequence of symbols (drawn from a finite alphabet) printed on a tape which can move in both directions along its length. The output of the machine at time t is an instruction to print a particular symbol in the square scanned by the machine at time t and to move in one or the other direction by one square. A key feature of the machine is that the output at time t and the state at time $t+1$ are determined by the state and the input at time t. Thus, if the state, the input and the output at time t are denoted by s_t, u_t

[4] A thorough discussion of the Turing machine can be found in M. Davis, "Computability and Unsolvability," McGraw-Hill Book Co., Inc., New York, N. Y.; 1958. For a discussion of a variant of the Turing machine, see C. Y. Lee, "Automata and finite automata," *Bell Sys. Tech. J.*, vol. 39, pp. 1267–1296; September, 1960.

and y_t, respectively, then the operation of the machine is characterized by:

$$s_{t+1} = f(s_t, u_t), \qquad t = 0, 1, 2, \cdots, \tag{1}$$

$$y_t = g(s_t, u_t) \tag{2}$$

where f and g are functions defined on pairs of values of s_t and u_t. Note that (1) and (2) imply that the output symbols from any initial time t_0 on are determined by the state at time t_0 and the input symbols from time t_0 on.

An important point about this representation, which was not pointed out by Turing, is that it is applicable not only to the Turing machine, but more generally to any discrete-time system. Furthermore, we shall presently see that it is a simple matter to extend (1) and (2) to systems having a continuum of states (*i.e.*, continuous-state systems).

The characterization of a system by means of equations of the form (1) and (2) (to which we will refer as the *Turing representation* or, alternatively, as the *state equations* of a system) was subsequently employed by Shannon [2] in his epoch-making paper on the mathematical theory of communication. Specifically, Shannon used (1) and (2) to characterize finite-state noisy channels, which are probabilistic systems in the sense that s_t and u_t determine not s_{t+1} and y_t, but their joint probability distribution. This implies that the system is characterized by (1) and (2), with f and g being random functions, or, equivalently ,by the conditional distribution function $p(s_{t+1}, y_t | s_t, u_t)$, where for simplicity of notation the same letter is used to denote both a random variable and a particular value of the random variable (*e.g.*, instead of writing S_t for the random variable and s_t for its value, we use the same symbol, s_t, for both).

It was primarily Shannon's use of the Turing representation that triggered its wide application in the analysis and synthesis of discrete-state systems. Worthy of note in this connection is the important work of von Neumann [3] on probabilistic logics, which demonstrated that it is possible, at least in principle, to build systems of arbitrarily high degree of reliability from unrealiable (probabilistic) components. Also worthy of note is the not-too-well-known work of Singleton [4] on the theory of nonlinear transducers, in which techniques for optimizing the performance of a system with quantized state space are developed. It should be remarked that the problem of approximating to a system having a continuum of states with a system having a finite or countable number of states is a basic and as yet unsolved problem in system theory. Among the few papers which touch upon this problem, those by Kaplan [5], [6] contain significant results for the special case of a differential[5] system subjected to zero input. A qualitative discussion of the related problem of ϵ-approximation may be found in a paper by Stebakov [7].

There are two important notions that are missing or play minor roles in the papers cited above. These are the notions of equivalent states and equivalent machines which were introduced by Moore [8] and, independently and in a somewhat restricted form, by Huffman [9]. The theory developed by Moore constitutes a contribution of basic importance to the theory of discrete-state systems and, more particularly, the identification problem.

So far, our discussion of the notion of state has been conducted in the context of discrete-state systems. In the case of a differential system, the state equations (1) and (2) assume the form

$$\dot{\mathbf{s}}(t) = \mathbf{f}(\mathbf{s}(t), \mathbf{u}(t)) \tag{3}$$

$$\mathbf{y}(t) = \mathbf{g}(\mathbf{s}(t), \mathbf{u}(t)) \tag{4}$$

where $\dot{\mathbf{s}}(t) = d/dt\ \mathbf{s}(t)$, and $\mathbf{s}(t)$, $\mathbf{y}(t)$ and $\mathbf{u}(t)$ are vectors representing the *state*, the *input* and *output* of the system at time t. Under various guises, such equations [particularly for the case where $\mathbf{u}(t) \equiv 0$] have long been used in the theory of ordinary differential equations, analytical dynamics, celestial mechanics, quantum mechanics, econometrics, and other fields. Their wide use in the field of automatic control was initiated largely in the late forties and early fifties by Soviet control theorists, notably A. I. Lur'e,[6] M. A. Aizerman, Ya. Z. Tsypkin, A. A. Fel'dbaum, A. Ya. Lerner, A. M. Letov, N. N. Krasovskii, I. G. Malkin, L. S. Pontryagin, and others. In the United States, the introduction of the notion of state and related techniques into the theory of optimization of linear as well as nonlinear systems is due primarily to Bellman, whose invention of dynamic programming [10] has contributed by far the most powerful tool since the inception of the variational calculus to the solution of a whole gamut of maximization and minimization problems. Effective use of and or important contributions to the state-space techniques in the field of automatic control have also been made by Kalman [11], Kalman and Bertram [12], LaSalle [13], Laning and Battin [14] (in connection with analog simulation), Friedland [15], and others. It is of interest to note, however, that it was not until 1957 that a general method for setting up the state equations of an RLC network was described by Bashkow [16]. An extension of Bashkow's technique to time-varying networks was recently presented by Kinarawala [17].

Despite the extensive use of the notion of state in the current literature, one would be hard put to find a satisfactory definition of it in textbooks or papers. A reason for this is that the notion of state is essentially a primitive concept, and as such is not susceptible to exact

[5] By a differential system, we mean a system which is characterized by one or more ordinary differential equations.

[6] We are not citing specific references to the work of Lur'e and others on state-space techniques, since their contributions are spread over such a large number of papers that it is difficult to isolate the most relevant ones.

definition. However, it is possible, as sketched below, to define it indirectly by starting with the notion of *complete characterization* of a system. Specifically, consider a black box B[7] and some initial time t_0. We assume that B is associated with three types of time-functions:

1) a controllable variable u [*i.e.*, a time-function whose values can be chosen at will from a specified set (input space) for all $t \geq t_0$];
2) an initially controllable variable s [*i.e.*, a time-function whose value can be chosen at will at $t=t_0$ from a specified set (*state space*), but not thereafter]; and
3) an observable variable y (*i.e.*, a time-function whose values can be observed for $t \geq t_0$, but over which no direct control can be exercised for $t \geq t_0$).

Furthermore, we assume that this holds for all values of t_0.

If these assumptions are satisfied, then we shall say that B is *completely characterized* if for every $t \geq t_0$ the value of the output at time t, $y(t)$, is uniquely determined by the value of s at time t_0 and the values of u over the closed interval $[t_0, t]$. Symbolically, this is expressed by

$$y(t) = B(\mathbf{s}(t_0); \mathbf{u}_{[t_0,t]}) \tag{5}$$

where $u_{[t_0,t]}$ denotes the segment of the time-function u extending between and including the end points t_0 and t; $\mathbf{s}(t_0)$ is the value assumed by $\mathbf{s}(t)$ at time t_0; and $B(\cdot\ ;\ \cdot)$ is a single-valued function of its arguments. [Note that B is a functional of $\mathbf{u}_{[t_0,t]}$ and an ordinary function of $\mathbf{s}(t_0)$; $\mathbf{s}(t)$ is usually a vector with a finite number of components.] It is understood that (5) must hold for all possible values of $\mathbf{s}(t_0)$ and $\mathbf{u}_{[t_0,t]}$ and that to every possible input-output pair $\mathbf{u}_{(t_0,t)}$, $\mathbf{y}_{(t_0,t)}$ there should correspond a state $\mathbf{s}(t_0)$ in the state space of B.

If B is completely characterized in the sense defined above, then $\mathbf{u}(t)$, $\mathbf{y}(t)$ and $\mathbf{s}(t)$ are, respectively, the values of the *input*, the *output* and the *state* of B at time t. [The range of values of $\mathbf{s}(t)$ constitutes the *state-space* of B. A particular value of $\mathbf{s}(t)$, *i.e.*, a particular state of B, will be denoted by $\mathbf{q}$.] In this way, the input, the output and the state of B are defined simultaneously as by-products of the definition of complete characterization of B.

The intuitive significance of the concept of state is hardly made clear by the somewhat artificial definition sketched above. Essentially, $\mathbf{s}(t)$ constitutes a description of the internal condition in B at time t. Eq. (5), then, signifies that, given the initial conditions at time t_0, and given the values of the input between and including t_0 and t, we should be able to find the output of B at time t if the system is completely characterized.

With (5) as the starting point, it is a simple matter to demonstrate that (5) can be replaced by an equivalent pair of equations:

$$\mathbf{s}(t) = \mathbf{f}(\mathbf{s}(t_0); \mathbf{u}_{[t_0,t]}), \qquad t \geq t_0 \tag{6}$$

$$\mathbf{y}(t) = \mathbf{g}(\mathbf{s}(t); \mathbf{u}(t)), \tag{7}$$

the first of which expresses the state at time t in terms of the state at time t_0 and the values of the input between and including t_0 and t, while the second gives the output at time t in terms of the state at time t and the input at time t. Note that these relations are in effect continuous analogs of the Turing representation

$$s_{t+k} = f(s_t, u_t, \cdots, u_{t+k-1}) \tag{8}$$

$$y_t = g(s_t, u_t). \tag{9}$$

It will be helpful at this point to consider a simple illustrative example. Let B be the network shown in Fig. 1, in which u is the input voltage and y is the output voltage.

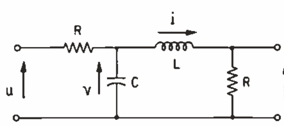

Fig. 1—Network for illustrative example.

It can easily be shown that the state of this network is a 2-vector, $\mathbf{s}(t)$, whose components can be taken to be $v(t)$ (voltage across C) and $i(t)$ (current through L). With this choice of $\mathbf{s}(t)$, the state equations can readily be set up by inspection. In matrix form, they read:

$$\dot{\mathbf{s}} = A\mathbf{s} + Bu \tag{10}$$

$$y = \alpha \mathbf{s} \tag{11}$$

where

$$A = \begin{bmatrix} -\frac{1}{CR} & -\frac{1}{C} \\ \frac{1}{L} & -\frac{R}{L} \end{bmatrix}, \quad B = \begin{bmatrix} \frac{1}{RC} \\ 0 \end{bmatrix}, \quad \alpha = [0 \quad R].$$

On integrating (10), we obtain

$$s(t) = \mathbf{G}(t - t_0)s(t_0) + \int_{t_0}^{t} \mathbf{G}(t - \xi)Bu(\xi)d\xi \tag{12}$$

$$y(t) = \alpha s \tag{13}$$

where the matrix G, called the *transition matrix* of B, is given by the inverse Laplace transform of the matrix $(sI - A)^{-1}$. Specifically,

$$G(t) = \mathcal{L}^{-1}\{(sI - A)^{-1}\}$$

$$= \mathcal{L}^{-1} \begin{bmatrix} \dfrac{s + \frac{R}{L}}{\det A} & \dfrac{-\frac{1}{C}}{\det A} \\ \dfrac{\frac{1}{L}}{\det A} & \dfrac{s + \frac{1}{RC}}{\det A} \end{bmatrix} \tag{14}$$

[7] For simplicity, it is assumed that B is (1) deterministic (*i.e.*, nonrandom), (2) time-invariant, (3) nonanticipative (not acting on the future values of the input), and (4) continuous-time (*i.e.*, with t ranging over the real time-axis).

where

$$\det A = \left(s + \frac{1}{RC}\right)\left(s + \frac{R}{L}\right) + \frac{1}{LC}.$$

Note that (12) expresses $s(t)$ as a function of $s(t_0)$ and $u_{[t_0,t]}$. Thus, (12) and (13) represent, respectively, the state equations (6) and (7) for B.

III. State and System Equivalence

One cannot proceed much further with the discussion of state-space techniques without introducing the twin notions of equivalent states and equivalent systems.

Suppose that we have two systems B_1 and B_2, with q_1 being a state of B_1 and q_2 being a state of B_2. As the term implies, q_1 and q_2 are *equivalent states* if, for all possible input time-functions u, the response of B_1 to u starting in state q_1 is the same as the response of B_2 to u starting in state q_2. Following Moore, B_1 and B_2 are said to be *equivalent systems* if, and only if, to every state in B_1 there is an equivalent state in B_2, and vice versa. What is the significance of this definition? Roughly speaking, it means that if B_1 and B_2 are equivalent, then it is impossible to distinguish B_1 from B_2 by observing the responses of B_1 and B_2 to all possible inputs u, if the initial states of B_1 and B_2 are not known to the experimenter.

To illustrate, let us consider the two simple networks shown in Fig. 2.

The state of B_1 is a vector with two components (which may be identified with the currents flowing through the two inductances); the state of B_2 is a scalar (the current through $2L$). Nevertheless, by writing the state equations for B_1 and B_2, it is easy to verify that B_1 and B_2 are equivalent in the sense defined above, as well as in the more conventional sense of circuit theory.

On the other hand, consider the constant-resistance network shown in Fig. 3. Its input impedance is equal to unity at all frequencies. Does this mean that B_1 is equivalent to a unit resistor?

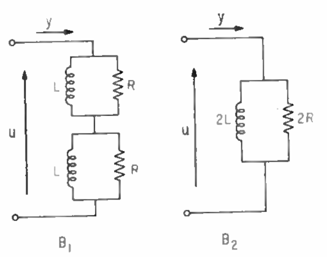

Fig. 2—Equivalent networks.

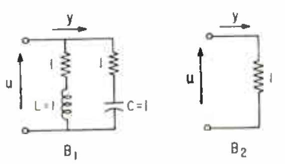

Fig. 3—Ground-state equivalent networks.

The circuit theorist's answer to this question would be "yes," since in circuit theory two networks are defined to be equivalent if their respective terminal impedances (or admittances) have the same values at all frequencies. By contrast, the system theorist would say "no," since there are states in B_1, say the state (0, 1) (where the first component is the voltage across C and the second component is the current through L), to which no equivalent state in the unit resistor can be found.[8] However, we note that the unexcited state (ground state) of B_1, which is (0,0), is equivalent to the ground state of the resistor. Thus, we can assert that, although B_1 is not equivalent to the unit resistor, it is ground-state equivalent to the unit resistor. In plain words, this means that if B is initially unexcited, then it will behave like a unit resistor. On the other hand, if B is initially excited, then it may not behave like a unit resistor.

This simple example shows that the notion of equivalence in circuit theory has a narrower meaning than it does in system theory. More specifically, the equivalence of two networks in the sense of system theory implies, but is not implied by, their equivalence in the sense of circuit theory. In effect, the notion of equivalence in circuit theory corresponds to the notion of ground-state equivalence in system theory.

IV. The Notion of Policy

Another important difference between circuit theory and system theory manifests itself in the way in which the input to a system (circuit) is represented. Thus, in circuit theory it is customary to specify the desired input to a network as a function of time. By contrast, in system theory it is a common practice—particularly in dealing with control problems—to express the input as a function of the state of the system rather than as a function of time.[9] In many ways, this is a more effective representation, since it is natural to base the decision on what input to apply at time t on the knowledge of the state of the system at time t. Furthermore, in the latter representation (input in terms of state) we have feedback, whereas in the former (input in terms of time) we have not.

To say that the input depends on the state of the system means, more precisely, that the input at time t is a function of the state at time t, *i.e.*,

$$u(t) = \pi(s(t)) \tag{15}$$

where π is a function defined on the state space with values in the input space. This function is referred to as a *policy function*, or simply a *policy*. In effect, a policy is

[8] The resistor represents a degenerate case in which the output (say voltage) depends only on the input (say current) and not on the state of the system. In such cases, the choice of state is immaterial. For example, it may be taken to be the current through R.

[9] For simplicity, it is tacitly assumed here that the system as well as its performance criteria are time-invariant; otherwise, the input would be expressed as a function of both the state of the system and time.

a function which associates a particular input with each state of the system.

The notion of policy plays a key role in system theory and, especially, in control theory. Thus, a typical problem in control theory involves the determination of a policy for a given system B which is optimal in terms of a specified performance criterion for B. More specifically, the performance criterion associates with each policy π a number $Q(\pi)$, which is a measure of the "goodness" of π.[10] The problem, then, is to find a policy π which maximizes $Q(\pi)$. Such a policy is said to be *optimal*.

As was stated previously, the most effective general technique for solving problems of this nature is provided by Bellman's dynamic programming. The basis for dynamic programming is the so-called *principle of optimality* which in Bellman's words reads: "An optimal policy has the property that whatever the initial state and the initial decision are, the remaining decisions must constitute an optimal policy with regard to the state resulting from the first decision."

Needless to say, one can always resort to brute force methods to find a policy π which maximizes $Q(\pi)$. The great advantage of dynamic programming over direct methods is that it reduces the determination of optimal π to the solution of a succession of relatively simple maximization or minimization problems. In mathematical terms, if the payoff resulting from the use of an optimal policy when the system is initially (say at $t=0$) in state $s(0)$ is denoted by $R(s(0))$, then by employing the principle of optimality one can derive a functional equation satisfied by R. In general, such equations cannot be solved in closed form. However, if the dimension of the state vector is fairly small, say less than four or five, then it is usually feasible to obtain the solution through the use of a moderately-sized digital computer. The main limitation on the applicability of dynamic programming is imposed by the inability of even large-scale computers to handle problems in which the dimensionality of the state vector is fairly high, say of the order of 20. A number of special techniques for getting around the problem of dimensionality have recently been described by Bellman [18].

A very basic problem in system theory which has been attacked both by the techniques of dynamic programming [19], [20] and by extensions of classical methods of the calculus of variations [21] is the so-called *minimal-time* or *optimal-time* problem. This problem has attracted a great deal of attention since the formulation of the so-called maximum principle by Pontryagin [20] in 1956, and at present is the object of numerous investigations both in the United States and the Soviet Union. Stated in general terms (for a time-invariant, single-input, continuous-time system) the problem reads as follows.

[10] It is tacitly assumed that B is a deterministic system. Otherwise, $Q(\pi)$ would be a random variable, and the performance of B would generally be measured by the expected value of $Q(\pi)$.

Given: 1) A system B characterized by the vector differential equation

$$\dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t), u(t)) \tag{16}$$

where $\mathbf{x}(t)$ and $u(t)$ represent, respectively, the state and the input of B at time t. ($\mathbf{x}$ is a vector; u is a scalar, and $\mathbf{f}$ is a function satisfying certain smoothness conditions.)

2) A set of constraints on u,[11] *e.g.*, $|u(t)| \leq 1$ for all t or $|u(t)| \leq 1$ and $|\dot{u}(t)| \leq 1$ for all t.

3) A specified intial state $\mathbf{x}(0) = \mathbf{q}_0$ and a specified terminal state $\mathbf{q}_1$.

Find an input u (satisfying the prescribed constraints) which would take B from $\mathbf{q}_1$ to $\mathbf{q}_2$ in the shortest possible time. This, in essence, is the minimal-time problem.

In a slightly more general formulation of the problem, the quantity to be minimized is taken to be the cost of taking the system from $\mathbf{q}_0$ to $\mathbf{q}_1$, where the cost is expressed by an integral of the form

$$C(u; \mathbf{q}_0, \mathbf{q}_1) = \int_0^{t_1} f_0(\mathbf{x}(t), u(t))dt. \tag{17}$$

In this expression, f_0 is a prescribed function, t_1 is the time at which B reaches the state $\mathbf{q}_1$, and $C(u, \mathbf{q}_0, \mathbf{q}_1)$ denotes the cost of taking B from $\mathbf{q}_0$ to $\mathbf{q}_1$, when the input u is used.

It is not hard to see why the minimal-time (or, more generally, the minimal-cost) problem plays such an important role in system and, more particularly, control theory. Almost every control problem encountered in practice involves taking a given system from one specified state to another. The minimal time-problem merely poses the question of how this can be done in an optimal fashion.

Various special cases of the minimal time problem were considered by many investigators in the late forties and early fifties. What was lacking was a general theory. Such a theory was developed in a series of papers by Pontryagin, Boltyanskii, and Gamkrelidze [21], [22].

The maximum principle of Pontryagin is essentially a set of necessary conditions satisfied by an optimal input u. Briefly stated, let ψ be a solution of the variational system

$$\dot{\psi} = -\left(\frac{\partial \mathbf{f}}{\partial \mathbf{x}}\right)' \psi \tag{18}$$

where $[\partial \mathbf{f}/\partial \mathbf{x}]'$ is the transpose of the matrix $[\partial f_i/\partial x_j]$, in which f_i and x_j are, respectively, the ith and jth components of $\mathbf{f}$ and $\mathbf{x}$ in the equation $\dot{x} = \mathbf{f}(\mathbf{x}, u)$. Construct a Hamiltonian function $H(\mathbf{x}, \psi, u) = \psi \cdot \dot{x}$ (dot product of ψ and $\dot{x}$), with the initial values of ψ in (18) constrained by the inequality $H(\mathbf{x}(0), \psi(0), u(0)) \geq 0$. The

[11] More generally, there might be additional constraints imposed on $\mathbf{x}$. This case is not considered here.

maximum principle asserts that if $\hat{u}(t)$ is an optimal input, then $\hat{u}(t)$ maximizes the Hamiltonian $H(\mathbf{x}, \psi, u)$, with x and ψ held fixed for exact t.

An application of the maximum principle to a linear system characterized by the vector equation

$$\dot{\mathbf{x}} = \boldsymbol{A}\mathbf{x} + \boldsymbol{B}u, \tag{19}$$

where $\boldsymbol{A}$ is a constant matrix and $\boldsymbol{B}$ is a constant vector, leads to the result that an optimal input is "bang-bang," that is, at all times the input is as large amplitude-wise as the limits permit. More specifically, an optimal input is of the form

$$\hat{u}(t) = \text{sgn}\ (\psi(t) \cdot \boldsymbol{B}) \tag{20}$$

where sgn stands for the function sgn $x=1$ if $x>0$, sgn $x=-1$ if $x<0$, and sgn $x=0$ if $x=0$, and ψ is a solution of the adjoint equation

$$\dot{\psi} = -\boldsymbol{A}'\psi \tag{21}$$

satisfying the inequality

$$\psi(0) \cdot [\boldsymbol{A}\mathbf{x}(0) + \boldsymbol{B}u(0)] \geq 0. \tag{22}$$

This and other general results for the linear case were first obtained by Pontryagin and his co-workers. Somewhat more specialized results had been derived independently by Bellman, Glicksberg, and Gross [25].

The main trouble with the maximum principle is that it yields only necessary conditions. The expression for $\hat{u}(t)$ given by (20) is deceptively simple; in fact, in order to determine $\hat{u}(t)$, one must first find a $\psi(t)$ which satisfies the differential equation (21), the inequality (22), and, furthermore, is such that $\boldsymbol{B}$ reaches q_1 when subjected to the $\hat{u}$ given by (20). Even then, there is no guarantee that $\hat{u}$ is optimal, except when either the initial state or the terminal state coincides with the origin. Still another shortcoming of the method is that the optimal input is obtained as a function of time rather than the state of the system.

One could hardly expect the maximum or any other principle to yield complete and simple solutions to a problem as difficult as the minimal-time problem for nonlinear, continuous-state, continuous-time systems. Actually, complete solutions can be and have been obtained for simpler types of systems. Particularly worthy of note is the solution for the case of a linear discrete-time system which was recently obtained by Desoer and Wing [26]. Quite promising for linear continuous-time systems is the successive approximation technique of Bryson and Ho [27]. In the case of systems having a finite number of states, the minimal-time problem can be solved quite easily even when the system is probabilistic and the terminal state changes in a random (Markovian) fashion [28].

Closely related to the minimal-time problem are the problems of reachability and controllability, which involve the existence and construction of inputs which take a given system for one specified state to another, not necessarily in minimum time. Important contributions to the formulation and solution of these problems for unconstrained linear systems were made by Kalman [29]. It appears difficult, however, to obtain explicit necessary and sufficient conditions for reachability in the case of constrained, linear, much less nonlinear, systems.

V. Characterization, Classification and Identification

Our placement of system characterization, classification and identification at the top of the list of principal problems of system theory (see Section I) reflects their intrinsic importance rather than the extent of the research effort that has been or is being devoted to their solution. Indeed, it is only within the past decade that significant contributions to the formulation as well as the solution of these problems, particularly in the context of finite-state systems, have been made. Nevertheless, it is certain that problems centering on the characterization, classification and, especially, identification of systems as well as signals and patterns, will play an increasingly important role in system theory in the years to come.

The problem of characterization is concerned primarily with the representation of input-output relationships. More specifically, it is concerned both with the alternative ways in which the input-output relationship of a particular system can be represented (*e.g.*, in terms of differential equations, integral operators, frequency response functions, characteristic functions, state equations, etc.), and the forms which these representations assume for various types of systems (*e.g.*, continuous-time, discrete-time, finite-state, probabilistic, finite-memory,[12] nonanticipative,[13] etc.). Generally, the input-output relationship is expressed in terms of a finite or at most countable set of linear operations (both with and without memory) and nonlinear operations (without memory). For example, Cameron and Martin [30] and Wiener [31] have shown that a broad class of nonlinear systems can be characterized by (ground-state) input-output relationships of the form

$$y(t) = \sum_{n=0}^{\infty} A_n X_n(t) \tag{23}$$

where the $X_n(t)$ represent products of Hermite functions of various orders in the variables $z_1, z_2, \cdots$, which in turn are linearly related to u (input) through Laguerre functions. Note that the operations involved in this representation are 1) linear with memory, *viz.*, the rela-

[12] A system has finite memory of length T if its output at time t is determined by $u_{[t-T, t]}$.

[13] A system is nonanticipative if, roughly speaking, its output depends only on the past and present, but not future, values of the input.

tions between the z's and u; 2) memoryless nonlinear, *viz.*, the relations between the X_n and $z_1, z_2, \cdots$; and 3) linear with no memory, *viz.*, the summations. In this connection, it should be pointed out that the basic idea of representing a nonlinear input-output relationship as a composition of an infinite number of 1) memoryless nonlinear operations and 2) linear operations with memory, is by no means a new one. It had been employed quite extensively by Volterra [32] and Frechet [33] near the turn of the century.[14]

A key feature of the Wiener representation is its orthogonality [meaning uncorrelatedness of distinct terms in (23)] for white noise inputs. This implies that a coefficient A_n in (23) can be equated to the average (expected) value of the product of $X_n(t)$ and the response of the system to white noise. In this way, a nonlinear system can be identified by subjecting it to a white noise input, generating the $X_n(t)$ functions, and measuring the average values of the products $y(t)X_n(t)$. However, for a variety of technical reasons this method of identification is not of much practical value.

The problem of system classification may be stated as follows. Given a black box B and a family (not necessarily discrete) of classes of systems $C_1, C_2 \cdots$, such that B belongs to one of these classes, say C_λ, the problem is to determine C_λ by observing the responses of B to various inputs. Generally, the inputs in question are assumed to be controllable by the experimenter. Needless to say, it is more difficult to classify a system when this is not the case.

A rather important special problem in classification is the following. Suppose it is known that B is characterized by a differential equation, and the question is: What is its order? Here, C can be taken to represent the class of systems characterized by a single differential equation of order n. An interesting solution to this problem was described by Bellman [34].

Another practical problem arises in the experimental study of propagation media. Suppose that B is a randomly-varying stationary channel, and the problem is to determine if B is linear or nonlinear. Here, we have but two classes: C_1 = class of linear systems, and C_2 = class of nonlinear systems. No systematic procedures for the solution of problems of this type have been developed so far.

Finally, *the problem of system identification* is one of the most basic and, paradoxically, least-studied problems in system theory. Broadly speaking, the identification of a system B involves the determination of its characteristics through the observation of responses of B to test inputs. More precisely, given a class of systems C (with each member of C completely characterized), the problem is to determine a system in C which is equivalent to B. Clearly, the identification problem may be regarded as a special case of the classification problem in which each of the classes $C_1, C_2, \cdots$, has just one member. This, however, is not a very useful viewpoint.

It is obvious that such commonplace problems as the measurement of a transfer function, impulsive response, the A_n coefficients in the Wiener representation (23), etc., may be regarded as special instances of the identification problem. So is the problem of location of malfunctioning components in a given system B, in which case C is the class of all malfunctioning versions of B.

A complicating feature of many identification problems is the lack of knowledge of the initial state of the system under test. Another source of difficulties is the presence of noise in observations of the input and output. For obvious reasons, the identification of continuous-state continuous-time systems is a far less tractable problem than the identification of finite-state discrete-time systems. For the latter, the basic theory developed by Moore [8] provides very effective algorithms in the case of small-scale systems, that is, systems in which the number of states as well as the number of input and output levels is fairly small. The identification of large-scale systems calls for, among other things, the development of algorithms which minimize the duration of (or the number of steps in) the identifying input sequence. With the exception of an interesting method suggested by Bellman [35], which combines dynamic programming with the minimax principle, little work along these lines has been done so far.

Another important area which is beginning to draw increasing attention is that of the identification of randomly-varying systems. Of particular interest in this connection is the work of Kailath [36] on randomly-varying linear systems, the work of Hofstetter [37] on finite-state channels, the work of Gilbert [38] on functions of a Markov process, and the generalization by Carlyle [39] of some aspects of Moore's theory to probabilistic machines. All in all, however, the sum total of what we know about the identification problem is far from constituting a body of effective techniques for the solution of realistic identification problems for deterministic, much less probabilistic, systems.

VI. Concluding Remarks

It is difficult to do justice to a subject as complex as system theory in a compass of a few printed pages. It should be emphasized that our discussion was concerned with just a few of the many facets of this rapidly-developing scientific discipline. Will it grow and acquire a distinct identity, or will it fragment and become submerged in other better-established branches of science? This writer believes that system theory is here to stay, and that the coming years will witness its evolution into a respectable and active area of scientific endeavor.

[14] A more detailed expository account of the representation of nonlinear operators may be found in a paper by the author, "On the representation of nonlinear operators," 1957 IRE WESCON Convention Record, pt. 2, pp. 105–113. A thorough mathematical treatment of related problems is available in the books by M. M. Weinberg, "Variational Methods of Investigation of Nonlinear Operators," Moscow, USSR, 1956; and M. A. Krasnoselski, "Topological Methods in the Theory of Nonlinear Integral Equations," Moscow, USSR, 1956.

Academic and Theoretical Aspects of Circuit Theory*

RONALD M. FOSTER,† FELLOW, IRE

Summary—**This paper discusses various types of realizability problems in electric circuit theory, with particular attention to the role of necessary and sufficient conditions. The first example is the general realization of an arbitrary driving-point impedance function discovered by Brune, together with his introduction of the use of the positive real function. Next comes the remarkable synthesis of the same problem by Bott and Duffin, with their complete elimination of all transformers. A brief survey is then given of subsequent efforts to simplify the original networks prescribed by Bott and Duffin, together with various alternative conditions which are sufficient but not necessary. All of this is then illustrated by application to the relatively simple case of the biquadratic impedance function.**

The other chief example discussed is the current work on the realization of a given real matrix as the open-circuit impedance matrix, or closed-circuit admittance matrix, of a network composed entirely of ordinary resistors. Particular attention is given to the work of Cederbaum in this field. It would seem that, although complete necessary and sufficient conditions have not yet been obtained, this problem is almost at the point of being solved.

IN this fiftieth year of the Institute, it may well be said that circuit theory has come of age. Perhaps this is best indicated by the fact that circuit theory by now has become almost a mathematical discipline. This is true, not so much because it is founded upon a generally accepted and well-understood system of assumptions or postulates, nor because various abstruse branches of mathematics have been brought to bear upon its problems, but rather because of the mathematical point of view now in vogue.

The principal question now in almost any branch of circuit theory relates to the possibilities of physical performance, and the essential limitations on what can be done with given means—in other words, the determination of necessary and sufficient conditions for a given type of network performance. Furthermore, we now demand that these conditions be stated in precise form, with no exceptions, or if one prefers, that the exceptions to our statements be listed explicitly, with a statement of the modified conditions holding for each such exception. Exact and precise statements are now demanded.

Perhaps we should note that what are sometimes called "exceptions" to the stated rule may ultimately prove to be among the most useful cases. The familiar constant-resistance network (two resistors with one inductor and one capacitor suitably adjusted) is just the equivalent of a single resistor; therefore, it would tend to be ignored in any census of biquadratic driving-point impedances as a highly degenerate or pathological exception. Nevertheless, this exceptional network was the starting point for a whole series of networks [42] designed for groups of filters quite a number of years ago.

In asking for a set of necessary and sufficient conditions for a given type of network, we are now perhaps even more demanding than is usual in mathematics. We ask not only that a set of conditions be sufficient, but also that it be operational, in that the conditions actually prescribe a means of synthesis for the network in question; this synthesis includes both the determination of the particular structure involved and the determination of the element values. Furthermore, we ask that the sufficient conditions be stated in a form readily tested before proceeding to the actual synthesis of the network.

In any specified problem the answer will depend on the variety of network envisaged, that is, both on the structural form and on the kinds of elements permitted.

So far as structural form is concerned, there are two broad classes of networks: 1) the n-terminal network, and 2) the n-port network (that is, a $2n$-terminal network, but with the terminals always paired in a designated way—in other words, a n-terminal-pair network). In this category of structure, we may also encounter specifications of particular types of linear graphs such as series-parallel or bridge structures, planar or nonplanar, or other special forms.

Perhaps the most important type of structure is the 2-terminal, or 1-port, network, largely because it is a principal building block in all other types of structure. The problem here is often thought of as the synthesis of a prescribed driving-point impedance (or admittance).

Possibly next in importance is the 2-port network (2-terminal pair, quadripole, transducer). Certain special requirements may be added: ladder, lattice, bridged-T, or some other similar specialized structure; they may be possibly balanced or unbalanced, grounded or not grounded.

Recently, another structural form has received a considerable amount of attention, namely, the true 3-terminal network. This has proved to be of some interest in its own right, instead of being regarded as a grounded 2-port network.

The other question concerns the kinds of elements allowed. In the present discussion we are limiting ourselves to ordinary lumped, passive elements, finite in number, with certain specified additional types of ele-

* Received by the IRE, June 30, 1961.
† Dept. of Mathematics, Polytechnic Institute of Brooklyn, Brooklyn, N. Y.

ment, to be considered presently. Thus, in the main we are concerned with resistors, inductors, and capacitors.

The first general class of networks to be considered is that made up of a single kind of element. Usually, the language used implies that resistors are being used. Actually, however, this is without any loss of generality. Indeed, we may go further and say the network is made up of possible multiples of any physically realizable building block of impedance Z_1.

From this class, we naturally go to the class of networks composed of two kinds of elements, usually taken to be inductors and capacitors, or resistors and capacitors, again without any loss in generality. Here again, we may say we are really dealing with the case of networks made up of positive multiples of any two physically realizable building blocks, Z_1 and Z_2.

Finally, we have the class of networks composed of all three kinds of fundamental elements: resistors, inductors, and capacitors. Here, however, we do not have an immediate extension of the theory to three arbitrary kinds of elements: Z_1, Z_2, and Z_3. Very little seems to have been done in this particular field of three perfectly arbitrary kinds of elements. The extension of the theory from all three ordinary kinds of elements to three arbitrary kinds of elements would appear to hold only for the case when

$$Z_1 Z_3 = Z_2^2 \tag{1}$$

[assuming that the units of measurement have been so adjusted as to eliminate a positive multiplier in (1)].

The first extension to the above categories occurs with the addition of mutual inductance in those cases when inductors are included among the kinds of elements.

Then we come to the possible inclusion of various sorts of ideal elements, perhaps the best known being the ideal transformer. This has been discussed in the circuit literature [8], [14] since as early as 1920. Next, we have the gyrator [56], [57], discussed since 1948. Quite recently, we have had two new such ideal elements [9]: the "nullator," a 2-terminal device which acts simultaneously like a short-circuit and an open-circuit, that is, it imposes the requirement that the current through it and the potential drop across it are both equal to zero; and its companion, the "norator," which permits a perfectly arbitrary choice of current and potential drop.

Current interest today seems to be directed in two quite diverse directions: 1) toward a complete investigation into what can be accomplished with no more than the three ordinary kinds of elements (resistors, inductors, and capacitors) without the presence of any transformers, ideal or ordinary, and with no other ideal elements; and 2) toward developing a complete theory of the perfectly general finite, linear network.

To some extent, the present paper is a summary and an extension of four survey articles [20], [29], [30], [63] which have appeared in the last decade, and to which the reader is referred for further details.

With the above two-fold classification in mind, the first problem to be dealt with in some detail is that of the 2-terminal network, or 1-port—in other words, the physical realization of a specified driving-point impedance.

For a single kind of element, there is no problem. For two kinds of elements, the problem was given a virtually complete solution [10], [11], [12], [28] in the 1920's, that is, necessary and sufficient conditions given on the impedance function for it to be realizable by networks made up of the specified two kinds of elements, including a detailed set of rules for synthesis in various prescribed structural forms.

It might be noted in passing that the addition of mutual inductance adds nothing to the problem if inductors comprise one of the two kinds of elements. Networks composed of inductors and capacitors, for example, with mutual inductance linking any set of inductors, yield impedances which can be realized by inductors and capacitors alone.

It might be of some slight historical interest to note that the case of networks composed of resistors and capacitors was the first for which the general solution was obtained, in the very early 1920's, in connection with the design of balancing networks for submarine telephone cables. But, when written up for publication in 1924, it was presented in terms of inductors and capacitors.

It might also be noted that, before 1930, it was known that the most general driving-point impedance obtainable with the three ordinary kinds of elements (together with mutual inductance) could be realized in a certain canonical form [10], [13] by means of ideal transformers and the three kinds of elements. However, no conditions on the nature of the impedance itself were apparently known.

For the realization of the general driving-point impedance, the modern era may be said to have started in 1931 with the publication by Brune [6] of his celebrated theorem. The importance of this step rests essentially in the giving of necessary and sufficient conditions on the impedance function in order that it could be realized by means of the three kinds of ordinary elements, together with mutual impedances. Thus, we were given the general concept of a positive real function. Any driving-point impedance of the sort of network in question was a positive real rational function; any positive real rational function could be realized by that sort of network. In brief, a positive real rational function is a rational function of a complex variable with the following two properties: 1) if the real part of the variable is positive, the real part of the value of the function is positive; and 2) if the variable is real, the value of the function is real.

Brune's work covered a variety of cases, showing that in certain instances mutual inductances were not needed, but that in general his method of synthesis called for mutual inductance, introduced through the medium of perfectly coupled coils.

Thus the matter rested until 1949. I dare say that in the intervening years, many specialists in the subject may have ventured the opinion that mutual inductance could not be entirely eliminated. But in that year, Bott and Duffin [4] showed that any positive real rational function could be realized as the impedance of a network composed of just the three kinds of ordinary elements. This was really an amazing result; and it was presented to the public, proof and all, as a letter-to-the-editor that took only one-half a printed page!

This synthesis was accomplished at a price—the price of many superfluous elements, superfluous in the sense that they far exceeded in number the number of independent coefficients in the rational impedance function.

It was natural that there should be attempts to simplify the original structure as called for by the Bott and Duffin synthesis. Within a half-dozen years, several different papers [26], [44], [46]–[49], [55] presented the same essential simplification, reducing the number of reactive elements called for in each step of the synthesis from six to five. For a biquadratic impedance function, this simplification has recently been shown [51] to be the best possible, that is, so far as the number of elements is concerned. However, the general question still remains unanswered as to further possible simplifications in the case of impedances of higher order.

In the meantime, other methods of synthesis [2], [35], [37], [41] have been developed, which, though without the complete generality of the simplified Bott and Duffin method, nevertheless provide methods for realizing certain restricted classes of positive real rational functions with considerably fewer elements. Much remains to be done in this direction. The answer to the following question has not yet been given in all completeness: For a given numerical positive real function, what is the least number of elements with which this particular impedance function can be synthesized? And, having answered that question, what is the complete set of equivalent structures, each composed of this minimum number of elements, realizing the given impedance function?

Even in the comparatively simple case of the biquadratic impedance function, these questions have not been completely answered, although some attempts have been partially successful [37], and considerable progress has been made to date. Perhaps it may be worthwhile to consider this case of the biquadratic impedance function in some detail, in order to illustrate many of the matters mentioned above.

The general biquadratic impedance function is

$$Z(s) = \frac{As^2 + Bs + C}{Ds^2 + Es + F}. \tag{2}$$

There is no loss in generality in assuming that the six coefficients A, B, C, D, E, F are all non-negative real numbers. Furthermore, in the interest of complete generality, it is advantageous to retain all six coefficients, although there are just five parameters involved (the ratios of the six coefficients). It is perhaps a temptation to reduce some one of them to unity, but then a degree of generality would be sacrifice (the possibility of reducing that particular coefficient to zero).

A necessary and sufficient condition that this function $Z(s)$, with the assumptions as to its coefficients, be a positive real function is that

$$(\sqrt{AF} - \sqrt{CD})^2 \leqq BE. \tag{3}$$

Furthermore, we will assume that the biquadratic function (2) is a true biquadratic in the sense that at least one of the two polynomials (numerator and denominator) is of the second degree, with no common factors which might cancel out. Accordingly, the discriminant

$$\begin{aligned} K &= (AF - CD)^2 - (AE - BD)(BF - CE) \\ &= A^2F^2 - ABEF - 2ACDF + ACE^2 + B^2DF \\ &\quad - BCDE + C^2D^2 \end{aligned} \tag{4}$$

cannot vanish. For, if $K=0$, there is a linear factor common to both numerator and denominator, and so the function would reduce immediately to no more than a bilinear function.

If, however, $K<0$, then the roots of both the numerator and the denominator are real and separate each other. Under these circumstances, the impedance function is realizable with two kinds of elements: resistors and inductors if, in addition, $AF-CD>0$; resistors and capacitors if $AF-CD<0$. Note in passing that $AF-CD$ cannot equal zero if K is less than zero

In the case of most interest, therefore, we may assume that the discriminant K is actually positive, and so all three kinds of elements are required. The problem is therefore the synthesis of a positive real biquadratic function meeting this condition on K.

Now the modified Bott-Duffin synthesis in the case of the biquadratic function calls for no more than eight elements. We would expect that, in general, five elements would be needed in view of the five independent parameters in the function specified. We realize, of course, that for special choices of the coefficients, four, three, or even two elements may be sufficient.

The major questions to be answered are these: What additional restrictions must be imposed upon A, B, C, D, E, F in order that the impedance fucntion be realizable by a five-element network? By a six-element network? By a seven-element network? Then, those questions having been answered, it will be desirable, in the case of any specified impedance function meeting the requirements for an n-element network, to know the totality of equivalent n-element structures realizing this particular function.

Partial answers have been given to some of these questions, for example, in the extreme case when the equality sign holds in condition (3) for a positive real function—that is, when

$$\sqrt{AF} - \sqrt{CD} = \sqrt{BE}, \tag{5}$$

or

$$\sqrt{CD} - \sqrt{AF} = \sqrt{BE}. \tag{6}$$

In the first of these cases (5), the modified Bott-Duffin method calls for seven elements: two resistors, three inductors, and two capacitors. There are two different structures each using the same number of elements. In the second of these cases (6), the numbers of inductors and capacitors required are simply interchanged.

This seems to be a complete answer for these extreme cases, except for the obvious 2- and 3-element special cases, and for the rather unusual pair of 5-element bridge networks [35], [51], [59] corresponding to the extreme cases

$$AF = 4BE = 4CD, \tag{7}$$

and

$$4AF = 4BE = CD. \tag{8}$$

These bridge cases illustrate one of the few theorems dealing with three arbitrary kinds of elements. If one pair of opposite bridge arms consists of Z_1 elements, the other pair of Z_2 elements, and the cross arm of Z_3 element (a Z_1, Z_2 lattice terminated in Z_3), the driving-point impedance across the terminals of the bridge is

$$Z = \frac{2Z_1^2Z_2 + Z_1^2Z_3 + 2Z_1Z_2^2 + 2Z_1Z_2Z_3 + Z_2^2Z_3}{Z_1^2 + 2Z_1Z_2 + 2Z_1Z_3 + Z_2^2 + 2Z_2Z_3}. \tag{9}$$

Upon eliminating the common factor (Z_1+Z_2) from numerator and denominator, we obtain

$$Z = \frac{2Z_1Z_2 + Z_1Z_3 + Z_2Z_3}{Z_1 + Z_2 + 2Z_3}. \tag{10}$$

This can be made to yield a biquadratic in a variety of ways.

A somewhat different approach [36], [41] yields a synthesis in the biquadratic case when

$$|AF - CD| \leqq BE. \tag{11}$$

This yields a seven-element network, with a six-element network in the extreme case when the equality sign holds, once again with the exception of obvious special cases.

Still another approach [38] is to make a census of all five-element networks consisting of three resistors, one inductor, and one capacitor, covering all such structures realizing a biquadratic impedance (provided the particular impedance cannot be realized with even fewer elements). The result of such a census yields 25 distinct networks, arranged in 11 groups, the networks in any one group being completely equivalent, one to the other. Thus, there are 11 sets of special conditions on the coefficients, one set for each group.

A further elaboration of the above study includes a census of four-element structures (two resistors), leading to 18 networks in 12 groups, each group again with a special set of conditions on the coefficients. To complete this study we find eight networks in the three-element class, each with its own special set of conditions, and finally the two extreme two-element structures (inductor and capacitor in series, and in parallel).

Thus, we find a total of 53 distinct networks, arranged in 33 groups each irreducible in the sense that there exists no equivalent network containing fewer elements; each group has its own distinctive set of conditions on the coefficients A, B, C, D, E, F.

In addition, it may be pointed out that nothing is gained by adding resistors in excess of the three called for in the original census. Thus, in one sense, the problem has been completely solved for a biquadratic function which does not essentially have common factors added to both numerator and denominator, a case that perhaps might be termed the strict biquadratic.

An obvious extension would then be to consider, in much the same exhaustive way, the case of the biquadratic with one added linear factor in both numerator and denominator, thus in general entailing three reactive elements. Then consider the case with two added linear factors, calling in general for four reactive elements, and so on.

Another avenue of investigation might involve a comprehensive study of cases involving more than the minimum number of elements, especially those cases where the function form is simplified, somewhat similar to the case of the constant-resistance network mentioned above.

Let us now turn to a consideration of networks composed of just one kind of element, and since no loss in generality is involved, let us deal specifically with resistance networks.

With regard to the true n-terminal network, not much seems to have been done since the days of Campbell [7]. He showed that the network consisting of $n(n-1)/2$ elements, directly connecting the n terminals in pairs, was the most general possible n-terminal network. Furthermore, he gave formulas for obtaining the values of the elements in this directly connected network from the set of $n(n-1)/2$ impedance measurements—the impedance measured across each pair of terminals with all other terminals left free. Quite recently, a somewhat different line of attack [52] on this problem transformed the problem into an n-port problem, but an n-port problem of a very special type, where special methods can be used.

However, when we consider the n-port resistance network, we find a problem under active investigation. Here, the problem is usually stated as follows: Given a symmetric square matrix of order n composed of real numbers, what are necessary and sufficient conditions that this matrix be realizable as the open-circuit impedance matrix (or closed-circuit admittance matrix) of a resistance network?

It has long been known that, if ideal transformers are allowed, a necessary and sufficient condition for realizability is simply that the matrix correspond to a positive definite quadratic form, either singular or nonsingular (often referred to as semi-definite).

At present, efforts are being directed toward obtaining necessary and sufficient conditions for realizability by means of a network composed entirely of ordinary resistors, with no ideal transformers whatsoever. Important advances in this attempt have been made by Cederbaum [15]–[19] in the last few years, and by other investigators [53], [64]. One of the major points made is the discovery of a new necessary condition on such a matrix, namely, that it must be a paramount matrix. A paramount matrix, by definition, is a symmetric real matrix with the property that the determinant of any principal minor (of any order from 1 to n) is not less than the absolute value of the determinant of any other minor selected from the same rows of the matrix as the principal minor involved.

For several years, it had been known [58] that paramountcy was also a sufficient condition for realizability provided n did not exceed 3. Cederbaum [19], however, has shown quite recently that paramountcy is not sufficient, in general.

On the other hand, Guillemin [31], [32] has developed some sufficient conditions for realizability; but it has not been shown that these are necessary.

Thus, this general question is still open. It seems to present a very puzzling state of affairs: a seemingly simple question, easily stated, but so far defying a complete solution. Also, it represents a peculiar situation, where the necessary and sufficient conditions for realizability as an open-circuit impedance matrix must differ (in the light of Cederbaum's examples) from the conditions for realizability as a closed-circuit admittance matrix. This seems to present an extraordinary state of affairs when viewed in the light of the usual concepts of the principle of duality. Nevertheless, this problem would appear to be on the verge of being solved; all indications point that way.

When we come to networks composed of two kinds of elements, that is, beyond the 2-terminal (or 1-port) stage, we find much less progress. Perhaps the best progress has been made with the 3-terminal network composed of two kinds of elements.

One way of handling the 3-terminal network is to introduce the equivalent delta composed of three admittance-type elements (usually not all physically realizable), or, alternatively, the star composed of three impedance-type elements (usually not all physically realizable). Then, by passing alternately from the one representation to the other, extracting a suitably selected physically realizable portion at each step before proceeding to the next step, and also by a possible splitting of the delta representation into deltas in parallel, a 3-terminal series-parallel synthesis is obtained.

Adams [1] has given necessary and sufficient conditions for such a series-parallel synthesis for reactance networks, valid when the equivalent delta admittances (or star impedances) are of no higher than the sixth degree. These conditions are necessary for synthesis in the prescribed series-parallel form; but it is not known whether they are necessary for synthesis in arbitrary form.

Another approach has centered around the number of interior nodes involved in the network employed to connect the three terminals [20], [63]. Other authors have developed special sufficient conditions [39], [43].

Much the same state of affairs prevails with respect to the 2-port network composed of two kinds of elements, that is, with respect to a complete specification of the network. If only one network function is to be realized (usually a transfer function), then the problem has been almost completely solved [21]–[25]—but that is not the question under consideration here.

A somewhat similar situation holds with respect to the realization of a single transfer function, with all three kinds of elements allowed [27], [34], [45], [54], [60]–[63].

In addition to the search for necessary and sufficient conditions for specific kinds of network performance, there has developed, in recent years, a great deal of interest in the study of the abstract linear graphs corresponding to the physical electrical circuits. Witness the interest in circuit topology, so-called, as evidenced by at least two special issues of the IRE TRANSACTIONS ON CIRCUIT THEORY [65], [66], and elsewhere. The state of linear graph theory, especially in its applications to electric circuit theory, has been well summarized in a recent paper [33], to which the reader is referred for further details. Enumerative problems concerning graphs have also received comprehensive treatment in a recent book [50].

Teaching of Circuit Theory and Its Impact on Other Disciplines*

E. A. GUILLEMIN†, FELLOW, IRE

Summary—**In order to place the teaching of circuit theory in proper perspective, it is necessary first to formulate rather explicitly the principles and the philosophy of educational methods and objectives in an engineering curriculum. Subject content and subject order, as well as difficulties experienced because of existing academic policies, provide the central theme which is concerned with developments throughout the past 35 years in which circuit theory experienced its major growth.**

Introduction

THE TWO things that have interested me most throughout my professional career are teaching and circuit theory. I look with considerable pride and satisfaction upon the fact that many of the attitudes and principles that emerged out of these years of activity are now being ably carried on by some of my former students who, in their own teaching careers, are scattered throughout engineering schools both here and abroad. While I am tempted to dwell and elaborate upon this pleasant theme, my conscience and my deep-rooted interest in engineering motivates me rather to make comments and criticisms that may be helpful in guiding the future teaching of circuit theory.

I have been very fortunate in having lived through and taken part in an era during which circuit theory experienced its major growth and development. I have seen the effect of this growth upon all of the electrical engineering curriculum in which circuit theory, in reality linear system theory, has always played a dominant role. I have had an opportunity to compare the peculiarities of this evolutionary process in the conservative years preceding World War II with its strikingly accelerated character in the post-war years. I have seen many schemes tried; I have seen many successes and many failures.

Throughout these years I have consistently clung to defending and promoting those methods and procedures that provide the basic values in an engineering education. Strange as it may seem, the struggle to achieve these goals is never ending. One cannot rest upon one's laurels, for memories, unfortunately, are short and new recruits, eager to try their own wings and unwilling to pay heed to lessons of the past, are constantly changing the attitudes of engineering faculties.

So, once again, I feel compelled to make a speech that I have made many times before, but never to so wide an audience as the entire membership of the Institute of Radio Engineers. I can only hope that my message will fall upon a sufficient number of sympathetic ears to make this effort worth while.

* Received by the IRE, July 31, 1961; revised manuscript received, October 27, 1961.

Objectives and Basic Philosophy

Before any topic can be discussed intelligently, one must clearly understand what is meant by its title, which brings us to the question: what is circuit theory? Unlike other topics in electrical engineering, almost everyone in the profession is confident not only that he knows what circuit theory is, but also that he knows how to solve problems in circuit theory. Since this attitude is largely motivated by practical problems involving circuits of one sort or another, and since the variety of such circuit problems and their pertinent aspects is almost endless, there is a corresponding divergence of opinion as to what constitutes the essentials of circuit theory or what should be taught in a subject bearing that title.

It is not difficult to see that one of the first things a teacher must do here is to bring some order into this rambling situation through appropriate classification, and try, if possible, to find a "common denominator" or theoretical basis that he can regard as the "fundamentals" of circuit theory. On these he can, then, at first concentrate all of his attention and later expand logically by broadening his horizon so as to encompass as much more of the total picture as his available time permits, always stressing the basic character of fundamental principles in providing the essential means for constructing whatever partial or total solution is achievable.

While simple in principle, this statement of objectives is not simple in its implementation; neither is there a widespread agreement on its appropriateness for the training of the engineer who, unlike the pure science student, must be taught to cope with practical as well as the purely theoretical aspects of problems in his field. Can or should these practical aspects be taught in the classroom, and if so, what apportionment of time to such things is proper? This and a host of similar questions enter the picture and confuse the real issues. Industrial leaders are divided on the answers and so are those in the teaching profession. Attitudes today are even more divided than they were 35 years ago, in spite of the fact that experiences during World War II had a tremendous effect in pointing up the value of basic science in the engineering curriculum.

This is an era of gadgets and gadgetry; it is also an era in which the mania for changing things is rampant. Everything must be changed, whether for better or worse; and anyone who resists this trend, be it for stubbornness or sound reason, becomes an obstructionist. An idiotic idea is retitled a bold innovation and is seized upon by those who have little originality or sound judgement of their own but are ever eager to be found among that group enjoying the popular spotlight. This trend of the times penetrates even the academic environment of our learned institutions and causes confusion in the minds of those whose primary responsibility it is to distinguish clearly between the relevant and the irrelevant from a basic point of view.

It is a common inconsistency for educators, on the one hand, to cast aspersions upon the electrical engineering curriculum of yesteryear because it gave significant time and attention to rotating machine devices such as the synchronous converter instead of emphasizing basic energy conversion principles; while on the other hand, they find it quite appropriate and in keeping with the modern trend to spend half the available time in a fundamental circuits subject upon such gadgets as the transistor and the tunnel diode. Thirty years hence, these devices will be as obsolete as the rotary converter is today; and to give prominence to their discussion in the electrical engineering curriculum now is as proper or improper as it was to give similar prominence to rotating machines in days gone by.

Today's devices, like those of past decades, are merely current examples of the application of basic scientific principles. The devices live only long enough to be superseded by better ones, while the principles upon which their discovery rests endure and give birth to new devices in a never-ending sequence. It should be rather clear, therefore, that the emphasis should be placed upon basic principles and that devices should enter only by way of illustrative examples, except insofar as methods for their utilization involve techniques that, in themselves, are basic in character. In that case an appropriate degree of emphasis should be placed upon the techniques and their usefulness in dealing with a broad class of devices having certain common characteristics.

Since most of what has been said here is rather self evident, one may wonder why it needs to be said at all. That fundamental principles are important and enduring while their applications are essential only because it is through a discussion of them that the fundamental principles become thoroughly understood, has been said so often that it begins to sound like a platitude. In spite of this fact, and particularly in today's complex pattern of activity where relative values are often badly distorted, it is ever more important not to lose sight of our objectives, for it is only through a clear understanding of what we wish to accomplish that we can decide between a proper and an improper course of action.

Science and its pursuit have suddenly become glamorous; and in the minds of the general public, science and its achievements are measured solely by the performance of the gadgets that it produces. We should not be tempted to use the same yardstick in measuring the appropriateness of an engineering curriculum. To teach engineers how to build moon rockets would be a pedagogical blunder, even if we knew how to do it.

I know that many of my colleagues will disagree with this view. They will say: "What better way is there to teach engineers than to pick some comprehensive practical problem whose solution requires a combination of theoretical disciplines as well as engineering judgement and knowhow, and apply these in the proper manner? This really motivates and gets ideas across. In one package the student learns about theoretical dynamics, circuit theory, automatic control, celestial mechanics, radio transmission and reception, ballistics, etc. etc.!" The fallacy in this viewpoint is that the student gets only a smattering of each of these disciplines; and, even if many such problems are discussed, he still gets only a random collection of smatterings which add up to nothing but confusion. The discussion of such comprehensive problems is appropriate only *after* the separate disciplines have been adequately presented. Then such discussion serves as a useful integration and orientation medium, which is all that it can be expected to do. The disciplines themselves cannot properly be taught in this way.

Some argue that the comprehensive discussion should come *before* not *after* the introduction of separate disciplines, that it motivates interest in them and makes their subsequent separate consideration more meaningful to the student. This sounds like a good argument, but it doesn't work out that way, as those of us who have taught long enough and have tried this method know very well. Instead of becoming eager for a thorough understanding of the separate disciplines, the student becomes misled into thinking that he already knows all that he needs to know about them. Each subject is regarded as "old hat" and its further study as a waste of time and effort which could preferably be devoted to other specialized applications. Instead of being motivated, his attitude is one of intolerance and disinterest toward any systematic consideration of the topic in question.

Except for a few exceptional individuals, any attempt to fill in a proper background at this stage falls very flat. The students will not listen to it. Their attitude is apathetic. Trying to arouse them or reawaken their interest is like trying to stir an animal out of its state of hibernation. Their minds are already focused upon other things, and they refuse to become excited about what they believe to be unessential. They are wrong, of course, and will find this out when it is too late—when they have left behind those of us who were ready and eager to help them.

In the teaching of circuit theory we run into the same situation on a smaller scale; the conflict between those who would start with a discussion that includes literally everything but the kitchen stove, and those of us who would limit our introductory discussion to a minimum of essential topics and make thoroughness, scholarliness and depth rather than breadth our guiding theme.

The contention that we must acquaint the student with many different kinds of circuit elements that he will be expected to be familiar with when he assumes a post in industry, is in most cases a palliative with which the instructor tries to satisfy his conscience and rationalize his procedure. Students in electrical engineering, for the most part, have played with these gadgets in their spare time and in the associated laboratory. What they do not already know about them when they arrive at their jobs, they can readily acquire, especially in an environment that abounds in practical things. What they cannot acquire in such an environment is a habit of thoroughness and the ability to apply fundamental principles to create solutions to new problems.

A collateral argument put forth to justify the survey-type and gadget-filled presentation in an introductory circuits subject is that it provides its own motivation by keeping students amused with the manifold functions of devices, much as one would amuse a child by turning the pages in a picture book. This attitude literally degrades the dignity and scholarliness of a college atmosphere to the kindergarten level. Students who need this kind of motivation are misplaced in an academic environment; they are either too immature or too poorly prepared for it. To "nurse them through," so to speak, is a serious mistake. What the entering college student needs more than anything else is to be exposed to the discipline of a scholarly approach. If he cannot survive this, then he is not collegiate material, at least not in the best tradition of university standards. He must find another environment more suitable to his intellectual capacity.

All of these thoughts have a direct bearing upon the initial question raised here, for we cannot define the fundamentals of circuit theory without first clarifying what we mean by the term "fundamental" in connection with educational principles and methods. Whether or not a presentation is fundamental depends not only upon the material dealt with, but even more importantly, it depends upon the scholarliness with which it is considered, and the thoroughness with which its study is pursued. Unless the attitude is one in which thoroughness and depth of understanding are paramount, no claim regarding the fundamental nature of topics presented is justified. This point is of utmost importance, since it clearly establishes the fact that a syllabus or outline alone is nothing more than a collection of words; no criticism or discussion of its possible fundamental character can be based solely upon it. The all important factor concerns the manner in which the topics contained in such a syllabus are presented. Thoroughness and scholarliness are the indispensable attributes by which the fundamental character of a classroom presentation can be measured.

In this kind of a presentation we do not introduce a topic unless we are prepared to follow it to its ultimate conclusion, or at least to a point where the breadth of its implications, its limitations, and the subtleties of its detailed character reveal themselves. A quick look at many things, as is done in a survey type of presentation, can hardly be regarded as hitting at fundamentals regardless of content, since the student never learns what being fundamental means. Subject matter is important, of course, but primarily the question of being fundamental in an approach to a problem has to do with one's attitude or state of mind. This is why it is not a clear-cut matter to set down or define the fundamental principles pertinent to a subject whether it be circuit theory or anything else.

We touch here upon an old and much debated question regarding methods and objectives in engineering education. In view of the fact that the practice of engineering is largely practical rather than theoretical in nature, should not the practical aspects of the subjects taught receive major emphasis? Unless we regard engineering as limited to the practice of well established procedures and exclude creativeness and originality, the answer should be definitely negative. This does not mean that practical matters be excluded from our discussions. We need these to serve as illustrations and applications of basic theory and principles. But we should encourage, rather than discourage, students to consider the purely academic aspects of their studies. Once they leave the college campus behind them, they will have to be practical all the rest of their lives. We should not deny them the privilege and the luxury of being impractical during their few student years. The leaders in our profession are almost without exception those who spend at least some of their time in the role of an impractical dreamer.

Being thorough and teaching students how to think through a topic to its logical conclusion has collateral value also, in that it provides the basis upon which one exercises that elusive and much talked of quality called "engineering judgement" which, after all, is a decision making process. One cannot teach students how to make decisions, but one can teach them how to think straight, be thorough, and weigh carefully all the factors relevant to a given situation. Whether the pertinent problem acting as a vehicle for this process is practical or theoretical in nature is immaterial.
