Some of the more interesting problems in the cosmic-ray field relate to interplanetary observation outside of the geomagnetic field. A few of these have been made and have given very worthwhile results. For example, in PIONEER V a general decrease of cosmic ray intensity was observed which correlated with a decrease observed at the earth; it established that the mechanism for this decrease was an interplanetary and not a geocentric mechanism.[10]

Meteoric Particles

Satellites are measuring the flux of incoming meteor particles and time variations. These measurements have established so far that the flux is in rough accord with what would be expected from observation of the zodiacal light which gives indirectly a value for the concen-

tration of dust in interplanetary space. The time variations have established that meteor showers enhance the influx of particles, but there still remain many unsolved problems which can only be settled by further measurements, and in some cases by much more refined instrumentation. One problem relates to the spatial distribution of dust around the earth. There are competing theories all of which indicate that there should be a concentration of dust as one approaches the earth, but the expected concentration differs by a factor of 1000. One particular theory predicts a dust *shell* with a maximum at about 2000 km.[21] This could be established by satellites in eccentric orbits, as for example by the proposed EGO satellite.

More detailed problems relate to the size distribution and mass distribution of the dust particles, and their physical properties such as density, nature of the material, shape and so on. These studies are still in their beginning stage and will benefit greatly as satellites become more easily available and as the observations are extended into interplanetary space and into the vicinity of the planet Mars.

Astronomical Observations

It has been mentioned earlier that proper astronomical observations in the classical sense have not yet started, but promise to become one of the main applications of earth satellites. However, a new branch of astronomy, *ultraviolet astronomy*, was started years ago by a research group at the Naval Research Laboratory under H. Friedman. Most of their detailed results have been obtained in high altitude rockets. They have shown in detail that the ultraviolet spectrum of the sun plays an important part in the ionization and photochemistry of the upper atmosphere. They have studied in detail the spectrum as far down as 400 Å, and more roughly down to 1 Å. In pioneer investigations they have also established the incidence of ultraviolet radiation from sources outside of the solar system.[22]

It is in this area where future scientific applications of satellites may well be concentrated. They promise to be one of the most important tools for space exploration and the pre-eminent tool for the new science of ultraviolet astronomy.

The *astronomical satellite* is still in the stage of preparation; its impact will only be felt in the next few years. The planetary probes again will be coming into their own in the next few years, starting with unmanned RANGER and MARINER probes to the moon, Mars, and Venus, leading first to landings of instrument packages on the surface of the planets, and finally to full-scale automatic exploring equipment (SURVEYOR, VOYAGER), and eventually to manned expeditions.

NUCLEAR SCIENCE

Organized with the assistance of the IRE Professional Group on Nuclear Science

The Instrumentation and Control Circuits of Nuclear Reactors*

E. H. COOKE-YARBOROUGH†, MEMBER, IRE

Summary—**The chain reaction which takes place in a nuclear reactor is a regenerative process and can therefore be unstable, so the fission rate must be closely controlled in order that the nuclear reaction may proceed at a rate which is both useful and safe. Electronic circuits play a vital part in this, and their reliability must be exceedingly high, as many reactors are required to run for months without interruption and for years without an unscheduled shutdown.**

This paper considers in a very elementary way the dynamic behavior of a reactor and the circuit requirements associated with maintaining the power level constant. The additional problems associated with starting-up and the automatic shutting-down of a reactor are briefly surveyed and the use of automatic data-handling is considered. It is concluded that not all instrumentation and control problems presented by existing types of reactor have been satisfactorily solved and that more advanced reactors will present still more difficult problems.

Introduction

THE WORKING of a nuclear reactor depends on a chain reaction in which a neutron entering the nucleus of an atom of fissile material (such as plutonium or uranium 235) causes the fission of this nucleus into two or more fragments, with the release of energy and the emission of further neutrons, some of which in turn cause further fissions.

The chain reaction may be represented in the most elementary way by the idealized regenerative circuit shown in Fig. 1. By inspection we can write down,

$$\frac{dQ}{dt} = i_2(A-1) - i_1 + i_3. \tag{1}$$

If i_3 is small compared with i_2 and i_1, which is true except when the reactor is operating at very low level, then

$$\frac{dQ}{dt} = i_1\left[\frac{R_1}{R_2}(A-1) - 1\right]. \tag{2}$$

The term $R_1(A-1)/R_2$ represents the average number of neutrons which are produced by a fission and which cause further fissions. The symbol used to represent this number is k. To keep the reactor in equilibrium we must keep k very close to unity.

Since $i_1 = Q/CR_1$, we have

$$\frac{dQ}{dt} - \frac{Q}{CR}(k-1) = 0.$$

Solving this differential equation gives

$$Q = Q_0\epsilon^{t(k-1)/CR_1}. \tag{3}$$

If k differs from unity, the neutron flux in the reactor rises or falls exponentially with a period $CR_1/(k-1)$. In a slow-neutron reactor (one in which most neutrons are slowed down by a moderator before causing fissions) CR_1 may be of the order of hundreds of microseconds, but in a fast reactor, which needs no moderator, it is of

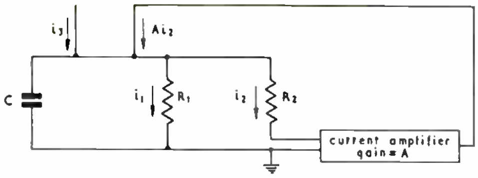

Fig. 1—Simplified equivalent circuit for a nuclear reactor.
Q (charge on capacitor C) represents the number of free neutrons in the reactor, and is thus proportional to the mean neutron flux.
i_1 represents the neutrons lost or captured without producing further neutrons.
i_2 represents the neutrons which cause fissions.
i_3 represents neutrons produced by processes other than neutron-induced fission (*e.g.*, from a neutron source introduced into the reactor or from spontaneous fission).
CR_1 represents the mean time which elapses before a neutron is lost or captured.
CR_2 represents the mean time which elapses before a neutron causes a fission.
A represents the average number of neutrons produced by a fission.

the order of 1 μsec. The expression shows that when k is close to unity the reactor period is much longer than these times.

There are many differences between the regenerative circuit in Fig. 1 and a real reactor, and the most important of these are indicated below:

1) In Fig. 1 it is assumed that there is no delay in the current amplifier, *i.e.*, all neutrons are emitted promptly when fission occurs. In more than 99 per cent of the cases this is true, but in less than 1 per cent of the cases the emission of a neutron is delayed for times ranging up to tens of seconds. When k is within 1 per cent of unity these delayed neutrons make the reactor period much longer than indicated by (3).
2) k may not be independent of fission rate, for it may vary with temperature, or fall as neutron-absorbing nuclei accumulate in the reactor. It is possible, in some types of reactor, for k to have a positive temperature coefficient.
3) The core of the reactor has finite volume, and conditions will not, in general, be uniform throughout this volume.

Nevertheless, the model in Fig. 1 is a useful guide to understanding the problems of reactor control.

To control the reactor we require means of directly or indirectly measuring the fission rate, and of controlling the value of k. The reactor then becomes part of a degenerative feed-back loop.

Reactor Power Measurement

The actual quantity which is stabilized by the control system depends upon the purpose for which the reactor is to be used. A research or materials-testing reactor is required to give a known flux of neutrons, and here neutron-flux measurement is an essential part of the control system. In reactors used for power generation, the power output, and hence the financial return on invested capital, rises rapidly with the coolant outlet temperature. This must therefore be kept as high as possible without allowing the fuel elements or other important parts of the reactor to become too hot. Here thermal measurements are the ultimate factor in the control, though neutron-flux measurements usually also play an important part in the start-up and short-term control of the system.

In slow-neutron reactors the measurement of the fission rate is effected by measuring the flux of slow neutrons, usually by use of ionization chambers containing boron (which emits alpha particles when exposed to slow neutrons) or a fissile material (the ionization being produced by the actual fissions occurring in the chamber). Similar methods can be applied to fast reactors if the ionization chamber is enclosed in a moderator.

The temperature of coolant, moderator and fuel elements are usually measured with thermocouples. These can tolerate the temperatures and neutron fluxes encountered in existing reactors, but in future reactors using higher temperatures and fluxes other methods may have to be found. The use of thermocouples to measure fuel element temperatures presents serious practical difficulties, since the elements must be easily removable, so it is difficult to maintain proper thermal contact between the fuel element and the thermocouple and at the same time to maintain reliable electrical connections to the thermocouple. An over-all measurement of thermal power is usually also required, and is effected by measuring the inlet and outlet temperatures of the coolant and the coolant flow rate.

Control of Reactivity

While measurements of reactor power are almost invariably electrical in nature, the means of controlling reactor power are almost always mechanical. In slow-neutron reactors the usual method is to introduce a neutron-absorbing material, such as cadmium, into the reactor, either in the form of sliding rods or pivoted arms, which is equivalent to reducing the value of R_1 in Fig. 1. In reactors using a heavy-water moderator, control of the heavy-water level can be used to control the reactor power. Precautions in mechanical design must be taken to avoid the possibility of inadvertent or too-rapid withdrawal of absorbers or entry of heavy water. The mechanical design problems are quite difficult, especially as some parts of the control mechanism may be inaccessible after the reactor has first been put into operation.

The Control Loop

The control system of a reactor is essentially an electromechanical one, comprising the reactor itself, some electrical or electronic means of measuring the reactor power and some electromechanical means of controlling the power. In many cases a human operator is interposed between the measuring equipment and the control equipment. With many existing reactors manual control is not only possible but also easy, for the response of the reactor to a small change of reactivity is slow, since it is determined largely by the delayed neutrons. Moreover, these reactors usually have a negative temperature coefficient which, if the control rods are withdrawn slightly, tends to restabilize the power at a slightly higher level. Some more modern types of reactor can, however, show a positive temperature coefficient of reactivity, and this makes manual control much more difficult. Moreover, although the response to very small changes of reactivity is slow, it becomes much faster if the change of reactivity is rather larger, as has already been indicated. A large change in reactivity may therefore be difficult to correct by manual control.

Even if the operator is eliminated, the open-loop transfer function of the complete system is still quite complicated, since it is affected by mechanical lag (and possible lost motion) in the control system, lags in the reactor itself due to delayed fissions, temperature changes and delays in the cooling system, and possible further lags in the measuring system, especially if the measurement is of temperature rather than of neutron flux. To apply effective automatic control it is necessary to know the transfer function of the complete system under all conditions which might arise. Consequently in the design of new reactors, attention is being directed to factors which may affect the transfer function and to methods of calculating the transfer functions of particular reactor designs. Transfer-function measurements on existing reactors are also of considerable importance. They not only facilitate the design of a control system but also throw light on the nuclear behavior of the reactor itself.

Reactor Transfer Function Measurement

One method of measuring the transfer function is to oscillate a neutron absorber in the reactor at known rates and to observe the amplitude and phase of the resultant change in neutron flux at each rate. Each measurement has to be integrated over a period long enough to allow the noise component of the reactor neutron flux to be averaged out. Another approach is to analyze this noise by autocorrelation, but this depends upon the assumptions that the frequency spectrum of the agency causing the noise is known and that the reactor approximates to a minimum phase-shift network. These difficulties can be avoided by programming a control rod to move in a quasi-random manner and performing a cross-correlation between this movement and the resultant reactor flux changes. The first method is at present the most highly developed and accurate, but the noise methods may be more rapid.

The Control of Start-Up

So far we have considered only the problem of keeping the reactor operating at a constant power level. Starting it up and bringing it up to the desired power is often much more difficult, mainly because the range of fission power between shut-down and full power may be as large as 10^{12}. It is necessary to observe the rise of neutron flux continuously throughout the starting-up process to ensure that the reactor period does not become too short at any time. For this purpose logarithmic neutron-flux-indicating instruments have been developed which can cover five or six decades without the need for range switching. Nevertheless, it is difficult to cover the lower end of the range indicated above, and a solution is permanently to install a neutron source in the reactor. Referring again to Fig. 1, the neutron source increases i_3. We have

$$i_3 = i_1 + i_2 - A_{i_2} = \frac{Q}{CR_1} - \frac{Q}{CR_2}(A - 1).$$

Therefore

$$Q = \frac{i_3 CR_1}{(1 - k)}.$$

This increase of i_3 can bring the neutron flux within the range of measurement, and so allows k to be continuously monitored during shut-down. This is valuable, for more than one reactor incident has occurred when the reactor was thought to be shut down.

While the reactor is being started up, its period can be deduced from the rate of change of the logarithm of the neutron flux, but a direct indication of period is valuable and can be obtained by electrically differentiating the output of the logarithmic neutron-flux meter. The design of a satisfactory period meter is far from easy, because of the random fluctuations present in the power-level reading which are accentuated in differentiating the output of the power-level meter. These fluctuations vary with power level and, while they can be reduced by smoothing, smoothing-time constants large enough to deal with fluctuations at low-power level may lead to misleading period indications. This has been the subject of a good deal of theoretical and experimental work which is not yet complete.

Automatic start-up of a low-power reactor can be achieved by linking the period meter with the control system so that the power rises with a predetermined period until the desired power level is reached. In a high-power reactor many other factors, such as temperature gradients and thermal stresses, limit the rate at which power can be changed once the level has been reached at which fission heating is appreciable. In this range the need for automatic control of changes in power level does not seem yet to have been felt, but it may be needed in propulsion reactors or peak-load power stations, and will involve some sort of automatic computation.

Safety Circuits

Whether a reactor is under manual or automatic control there is always the possibility of some failure in the reactor or its associated apparatus which could cause damage or even danger. The function of the safety circuits is to detect a failure as early as possible so that the reactor can be shut down before serious damage occurs. Most important reactor failures result in a local rise in temperature, the detection of which depends on temperature measurements made at very many different parts in the reactor. The cause of the temperature rise is likely to be either a coolant-flow failure or a rise in fission rate, so coolant-flow measurements at every coolant channel together with neutron-flux measurements may prevent fuel element failure by causing a shut-down to be effected earlier than would temperature measurement alone. Fuel element failure may be detected by monitoring for radioactive particles in the exit coolant, though again the monitoring of every coolant channel may be necessary.

Indication of reactor failure may come from very many different sources and so it is difficult to decide whether or not a failure indication from any one source should be made to shut the reactor down automatically. Conservative design philosophy would indicate that any failure should cause a reactor shut-down, including a failure in any of the safety circuits. However, experience indicates that when a reactor has a very large number of such safety circuits the probability of one or more failing is so high that it is difficult to start the reactor or to keep it running for any length of time, even though the reactor itself may be without fault. This can lead to some safety circuits being deliberately put out of action temporarily.

The only real answer to this problem is to improve the reliability of the safety circuits and to make it possible to distinguish between a failure which really does demand a reactor shut-down and a local failure of part of the safety circuits. This can be done by making the circuits continuously self-checking and by introducing redundancy. A typical redundant arrangement will consist of three entirely separate systems monitoring the same point in the reactor. Logic circuits connected to the output of these three systems cause the reactor to shut down if a shut-down is demanded by a majority of the systems. The failure of a single system can be recognized as such, and dealt with, but the circuits must be so designed that while one system is out of action, a failure indication from only one of the remaining systems is able to demand a shut-down. The probability of a spurious shut-down is then increased, so from this point of view a higher order arrangement, say three out of five, is to be preferred. There is a temptation to group together systems covering associated but not identical parts of the reactor into a majority decision arrangement but this is generally bad practice since it might allow a genuine local failure in the reactor to go undetected. On the other hand, the use of majority decision arrangements everywhere in the reactor may involve introducing an inconveniently large number of detectors into the reactor. The difficulties are reduced if the problem is faced early in the design of the reactor.

Reliability can also be increased by using some form of self-checking system. A typical example is the superimposing of an ac signal on the high-voltage supply to an ionization chamber. This will be communicated to the collector electrode through the chamber capacitance and hence through the dc amplifier. The presence of this signal at the output of the dc amplifier is a fair assurance that everything is in working order and connected, though not a complete test of the system. Complete checking can only be effected in a majority decision arrangement, a simulated shut-down signal being applied to each system in turn. Since the system being tested is temporarily out of action, an arrangement of higher order than two out of three is preferable if testing occupies a significant part of the total time.

The mechanical parts of the shut-down system are also subject to failure. Common practice is to use safety rods which can fall into the reactor under gravity, but are normally held out by an electromagnet. It is not unknown for such arrangements to fail due to friction, and the use of multiple shut-down rods is advisable, though sometimes difficult to achieve.

Safety systems which make use of redundancy allow correct operation of the reactor despite failure in part of the shut-down system, but they become ineffective if there is delay in rectifying the faulty parts of the system. This is largely a problem of organization and psychology.

Reactor Poisoning

The fission process generates a large variety of fresh atomic nuclei, some of which, being strong neutron absorbers, reduce the reactivity of the reactor and are referred to as poisons. An important poison is xenon 135 which appears as a result of the beta-radioactive decay of iodine 135 which is in turn a decay product of the fission process. So long as the reactor is running, the xenon 135 is continually being removed, partly by radioactive decay but mainly because the captured neutrons convert it by conversion to xenon 136 which does not significantly absorb neutrons. When the reactor is shut down, the removal of xenon 135 by the conversion process ceases, while its generation by iodine 135 decay continues for some hours, so the xenon 135 concentration first rises and then decays. With high-flux reactors there may be a period after shut-down during which the xenon 135 concentration is so large that it is impossible to restart the reactor. In such cases it is essential to keep track of the xenon 135 concentration and to predict its future behavior. This can, in principle, be computed from a knowledge of the power level of the reactor as a function of time. If the neutron flux and composition of the reactor could be regarded as uniform throughout the reactor, a simple analog computation would suffice, but this is not always adequate, and a more accurate computation involves dealing with many different regions of the reactor concurrently.

Spatial Instabilities

In physically large reactors it is possible for an uneven distribution of reactivity to develop, so that the temperature may rise locally above the safe limit. A normal control system cannot prevent such spatial instabilities though, of course, a local excess of temperature would cause a shut-down. The instabilities can only be damped out by differential insertion and withdrawal of neutron absorbers in different regions of the reactor, but such differential movements can only be effected if differential information on neutron flux or temperature is available. Ionization chambers in the thermal shield of the reactor do not give a good indication of such instabilities and a better method is the monitoring of the temperature at the outlets of the various coolant channels. This, however, only deals with radial instabilities (*i.e.*, those in a plane perpendicular to the coolant ducts); if axial instabilities are likely to occur other means must be found for detecting them. One way is to insert fission chambers directly into the reactor core. This leads to serious problems with regard to depletion of fissile material in the chamber, radiation damage and insulation, but it has been shown that such chambers can be made which will last for more than a year in the core of a gas-cooled graphite power reactor.

Data Handling

It will be seen that the operation of a nuclear reactor involves the accumulation of a very large amount of data on neutron flux, temperature, coolant flow, coolant pressure, etc., at a very large number of points in and around the reactor. In addition, current data needs to be combined with previous data to give such information as the total irradiation of the various fuel elements since they were inserted, the state of poisoning of the reactor, the accumulation of Wigner energy in a graphite moderator and the appearance of spatial instabilities. The need for a small digital data-handling system to do such work is now widely accepted, but there may be a case for going further and making it participate directly in the control of the reactor. For example, instead of using the majority-decision safety circuits considered earlier, all temperature, coolant-flow and neutron-flux readings might be correlated, their space and time derivatives determined and the results used to apply appropriate confidence weighting to the information obtained from each sensing system. This would increase the reliability of decisions regarding control or shut-down and so should permit more economical operation. On the other hand, to rely entirely on a single data-handling system would call for a very high degree of reliability. A mistaken decision to shut down a power reactor might be acceptable if it occurred not more than once a year, but mistakes in the reverse direction would probably be unacceptable even if they occurred on average only once per reactor per thousand years. Whether such reliability can best be obtained from a single suitably designed data-handling system remains to be seen.

Electronic Circuit Design

In the space available little can be said about the details of circuit design. Solid-state devices play an increasingly important part in reactor control and safety circuits, but the dc ionization chamber followed by an electrometer valve amplifier remains widely used for reactor neutron flux measurement. A transistor dc amplifier can very usefully follow the electrometer valve. Replacement of this valve by a semiconductor diode capacity modulator is possible, but the spurious input currents are then higher and the circuits more complex. Modern electrometer valves are extremely reliable, provide an enormous current gain and use voltages and currents which match well with those of transistor circuit. Semiconductor devices are susceptible to damage by fast neutrons and this prevents their sustained use as amplifiers or radiation detectors inside a reactor.

The sensitive slow-neutron measurements required during the early stages of reactor start-up are performed with proportional counters containing boron, which deliver a pulse each time a neutron reacts with a boron atom. These pulses are amplified and their mean rate is measured by a counting ratemeter. The logarithmic characteristic required for period measurement may be obtained by summing the output currents of several diode pump circuits having different suitably chosen constants. With the dc ionization chambers used at higher power levels a nearly logarithmic characteristic may be obtained by exploiting the voltage/current relationship exhibited by an electrometer valve grid, a semiconductor diode, or a transistor emitter.

A disadvantage of pulse counters is that a good signal-to-noise ratio is difficult to achieve if the counter must be connected to the amplifier through a long cable, as may be necessary in a large reactor installation. Associating a head amplifier with the counter may call for high-temperature operation and resistance to radiation damage. A number of ways of dealing with the problem are currently under investigation.

The trend is increasingly towards reactors operating at higher temperatures and this raises severe difficulties in obtaining adequate insulation even in the ionization chamber and its connecting cable. Satisfactory operation of these components at 500°C is now obtainable and 800°C appears possible.

Majority-decision circuits make use of logical techniques not unfamiliar to the designers of digital computers. One method is to use multiple windings on a square-loop magnetic core, the state of magnetization of this core then being determined by the majority decision. Another way is to sample in turn the output of the various circuits and on each cycle to count the number which demand a shut-down. A shut-down is effected when this number exceeds a predetermined value.

Because so many thermocouples are used throughout a reactor it may be necessary to sample their outputs at a rate higher than can be satisfactorily achieved by mechanical contacts. Electronic commutation can be achieved by use of solid-state switches, but is quite difficult because of the small dc voltages which must be switched and the possibility of introducing spurious voltages.

Conclusions

In a short paper it has only been possible to touch on some of the major problems encountered in the control of modern reactors. Space does not allow even a very selective bibliography of the subject. It will be seen that current types of reactor pose control problems which have not all been satisfactorily solved. Future power reactors will be operating under still more stringent condition and, to obtain safe and economic operation, close control of the operating conditions will be needed. The success of these projects depends very largely on the success with which the control and instrumentation problems can be solved.

Nuclear Radiation Detectors*

G. A. MORTON†, FELLOW, IRE

***Summary*—Nuclear radiation detectors are required in all the major fields of nuclear science and technology. They fall into two principal categories, single element detectors and imaging detectors. Single element detectors can be classified into four types, based upon their physical mode of operation. These are**

1) Scintillation counters,
2) Gas ionization detectors,
   a) Ionization chambers
   b) Proportional counters
   c) Geiger-Mueller counters
3) Semiconductor detectors, and
4) Chemical detectors.

The limitations of these detectors are discussed in terms of sensitivity, energy resolution, speed, and ability to discriminate against background radiations. This gives some indication of the directions along which future developments must proceed.

Imaging detectors include both area imaging, such as radioautography and scintillation counter scanning, and track imaging. The various techniques of track imaging from the Wilson cloud chamber and bubble chamber through scintillation track imaging and spark chambers are discussed.

Introduction

THE FUNDAMENTAL principles of many of the nuclear radiation detectors used today date back to the beginning of the Twentieth Century. The discovery of radioactivity in 1896 by Henri Becquerel was through exposing a black paper-covered photographic plate to a uranium salt. The photographic process is today a very powerful means of detecting and measuring nuclear radiation. A few years after Becquerel's discovery, Rutherford and Geiger,[1] working on the problem of radioactivity and radiation from nuclear processes, used a detector consisting of a chamber filled with a rarified gas and having in it a central wire biased almost to breakdown which gave an electrical pulse each time a particle of radiation passed through the gas. This detector was later developed into what is now known as the Geiger-Mueller counter.[2] Rutherford also found that the arrival of individual particles of radiation could be detected by observing through a microscope the scintillations produced when they impinged upon a fluorescent screen. A logical extension of this principle was to detect these flashes of light with a photomultiplier as was described in 1947 in two nearly simultaneous papers, one by Kallmann working in Berlin, the other by Coltman and Marshall in the United States.[3] This device is now known as the scintillation counter and is one of the most effective radiation detectors in use at present. Other detectors which had their origin in the early years of this century were the ionization chamber,[1] the porportional counter,[1] the Wilson cloud chamber,[4] and the crystal counter.[5]

The development of radiation detectors proceeded rather slowly during the first four decades of the century. Beginning just before 1940, two sets of circumstances combined to greatly accelerate development in the field of nuclear radiation detectors. One was the discovery of nuclear fission and the successful operation of a fission reactor with its implication of practical nuclear power; the other was the great advances that were made in high-energy particle accelerators which expanded the detector requirements from the relatively simple ones for the few naturally radioactive elements to the very complex needs for the host of artificially induced nuclear processes. The stimulus given to the development has continued up to the present and shows every indication of continuing for the foreseeable future. The advances in nuclear radiation detectors and their associated electronics for processing and presenting the information are so rapid that to forecast what the situation will be five years hence is extremely difficult and, beyond that, virtually impossible.

Nuclear Radiation

Nuclear radiation is a generic term referring to the large variety of radiations resulting from nuclear processes. Table I summarizes the more important radiations falling in this category. Of these many types of radiation, gamma rays are the most important since they are produced as the result of almost all nuclear processes. Their accurate detection and measurement is essential in nuclear science and technology. Neutrons rank next in importance because of their role in nuclear power processes and the development of good neutron detectors is imperative.

Radiation Detector Applications

Before considering the detectors themselves, let us first examine the scientific and technological areas where nuclear radiation detectors are required. For convenience, these are classified into four domains, namely: 1) nuclear power, 2) radiation technology, 3) biological and medical, and 4) nuclear physics research.

Nuclear Power

It is expected in the future that the most important contribution of nuclear processes to human society will be in the form of nuclear power generation. Therefore, nuclear detectors for use in this domain must rank high in the general consideration of the problem. At present and in the near future, nuclear power will be obtained from fission reactors. The role of neutrons in the chain of events occurring in a fission reactor has been described in another article in this Journal. It is clear from this discussion that for an efficient control of reactor performance, detectors must be provided which will measure low-level neutron flux and rate of change of flux during reactor start-up and also monitor the high-level neutron flux during operation. In other words, detectors must be provided which will cover a range of ten or twelve orders of magnitude of flux density. As yet, detectors having the requisite sensitivity at low-flux level and at the same time the large capacity, stability, and long life required at the high-level operating flux

TABLE I

Nuclear Radiation

Type	Symbol	Constitution	Occurrence	Remarks
Gamma rays	γ	Electromagnetic waves	Almost all nuclear processes	Corpuscular (photon) behavior when interacting with matter to give up energy
Beta rays	β^-	Electrons	Natural radioactivity Artificial radioactivity High-energy machines	
	β^+	Positrons	Artificial radioactivity High-energy machines Pair production, etc.	
Alpha rays	α	Helium nuclei	Natural and artificial radioactivity	All fission fuels are α-ray emitters
Neutron beam	n	Neutrons (neutral particles of mass of hydrogen nuclei)	Fission reactions Transmutation processes	Important in all nuclear power processes
Proton beam	p	Hydrogen nuclei	High-energy machines Cosmic rays	These radiations are of interest to nuclear physics in the study of elementary particles, high-energy processes, and the basic constitution of matter
Meson beam	$\mu^+\mu^-$ $\pi^+\pi^0\pi^-$ $K^+K^0K^-$	Muons, Pions, Kaons: particles of mass 250 to 1000 that of electrons	↓	↓
Hyperon beam	Λ $\Sigma^+\Sigma^0\Sigma^-$ Ξ ?	Λ hyperons, Σ hyperons, Ξ hyperons: particles of mass greater than proton	↓	↓
Neutrinos	ν	Neutrinos	β-decay, etc.	Of considerable theoretical interest, but of no practical importance

have not been developed. The expedient of several detectors, some of which may be removable, must be resorted to at present.

While the problem of controlled fusion has not yet been solved, it is virtually certain that neutron monitoring will be required in the operation of this type of power source. Thus, it can be expected that neutron detectors will be essential instruments for all nuclear power sources.

In addition to the neutron detectors, the housekeeping of a reactor installation requires gamma-ray detectors and monitors to ensure freedom from radioactive contamination. Finally, alpha-particle detectors will also be required by the health physicist responsible for reactor safety to monitor the air for possible alpha emitter contamination.

Many of the technological processes for preparing reactor fuel whether from the virgin ore or the depleted and poisoned fuel which has spent a period in the reactor will require a number of radiation detectors. These, for the main, will be alpha-particle detectors, since all fission fuels are alpha-particle emitters, and gamma-ray detectors to appriase the amount of radioactive contamination remaining in fuel to be recycled.

Radiation Technology

Under the category of radiation technology is included tracer and activation analysis, food processing, and chemical processing. Tracer and activation analysis is most demanding of the nuclear radiation detector. In general, as has already been mentioned, a gamma-ray spectrum (particularly when supplemented with a knowledge of the half-life of the elements involved) can serve to identify radioactive elements. Therefore, radioactive tracer work is dependent upon gamma ray energy spectrometers. The principle of these detectors will be discussed below. Activation analysis where elements in a specimen being studied are transmuted into radioactive isotopes by neutron bombardment requires the same study of gamma ray energy spectra as does tracer analysis. It should also be mentioned that a very important and fruitful branch of tracer analysis is concerned with organic chemistry. Radioactive carbon and tritium can be used to tag organic molecules so that their chemical reactions can be studied. Both tritium and radioactive carbon emit very low energy nuclear radiation which is quite difficult to detect. Special techniques have been developed for this purpose.

Active experiments are in progress in the use of nuclear radiation for sterilizing food. Many of these experiments have been successful and it may be expected in the future that this technique will be widely used in food processing. The detector problem here is one of monitoring the radiation to ensure that it is of the level required for sterilization but not so high that it will damage the food. Food thus processed must be examined to ensure freedom from residual radioactive contamination. Also, health physicists will be responsible for safe operating conditions in these radio-processing plants. This will require radiation detecting and monitoring equipment similar to that needed for good housekeeping in nuclear power plants.

The use of nuclear radiation to promote chemical reactions which would otherwise not take place or occur too slowly to be of practical use is proving very promising. Chemical plants employing these techniques will need monitoring equipment very similar to that required in food processing plants. Both will demand reliable, long-lived equipment for monitoring the radiation used in the various processes and sensitive, reliable instruments for use by the health physicists.

Medicine and Biology

The application of nuclear radiation and radioactive elements to medicine and biology appears to be giving very promising results. Nuclear processes can not only be used as a tool in research but appear also to be important in therapy. In discussing detector requirements in this field of science, it is necessary to subdivide it into three categories, namely, therapy, medical diagnosis and biological research.

Encouraging results have been obtained from the use of nuclear radiation in the treatment of a number of diseases, particularly the class represented by tumorsand cancers. Successful treatment has been accomplished by using beams of nuclear radiation which include gamma-ray beams, neutron beams, and, less frequently, proton and alpha particle radiation. By properly focusing the radiation beam and orienting the patient, it is possible to make the radiation exposure a maximum in the diseased tissue and to minimize the exposure to the more sensitive portions of the healthy tissue. In order to do this, detection means must be provided which can serve to indicate the intensity and focus of the radiation. In general, high sensitivity is not required for the detectors, but they frequently must have accurate directional properties. In addition, detectors are required to monitor the environment of the radiation equipment for the protection of the physicians and technicians operating the equipment. Therapeutic results have also been obtained by introducing into the patient radioactive elements which are selectively absorbed by the diseased tissue. For example, favorable results have been obtained with thyroid cancer even after metastasis has occurred. Elaborate detecting equipment may be required in order to map the location of the radioactive material in the patient as the treatment progresses.

Techniques similar to radioactive tracer techniques are frequently very valuable in medical diagnosis. The rate at which the patient absorbs and eliminates specific radioactive atoms or tagged molecules will, in many instances, give the physician valuable information as to the state of a patient's health. By employing detectors in mapping systems, the regions where these specific chemicals accumulate can be determined. This application requires rather special detectors. They must be extremely small in size, must be constructed in such a way as to eliminate the possibility of electrical shock to the patient, and must be both sensitive and reliable. Detectors small enough to make internal measurements are sometimes required. Finally, gamma rays, like X rays, may be used to locate and investigate structural damage within the patient; for example, broken bones, malignant growths, and other lesions.

The detector requirements for biological and medical research are extremely varied. They range from simple gamma-ray detectors to the most elaborate gamma-ray spectrometers and from single element detectors to imaging devices capable of giving high definition pictures of the distribution of radioactive material in a specimen. The breadth of detector requirements is second only to the detector requirements for nuclear physics.

Nuclear Physics

Nuclear physics requires by far the broadest diversity of detector types. This area of science employs a large number of conventional detectors in energy spectrometers and radiation monitoring equipment. In addition, detectors are needed which have the maximum possible energy resolution capabilities, the best time resolution that can be achieved, and, in many instances, the very maximum sensitivity. Detectors must be made to respond to a wide variety of radiation including all of those mentioned in Table I. Frequently, the detector or detector system is asked to identify the type of radiation particles passing through it. Extensive use is being made in this field of detectors which present a two- or three-dimensional display of the path of the particle through various media. These imaging detectors are a field in their own right and will be discussed in some detail below.

Radiation Detectors

Nuclear radiation detectors can be divided into two distinct domains, namely, single element detectors and imaging detectors. The former, as is evident from the discussion above, has wide application in all of the fields discussed. Imaging detectors, on the other hand, are primarily of use in the fields of nuclear physics and of medicine and biology. Even in these two fields, single element detectors dominate both numerically and in importance. Because of this, imaging detectors will be discussed only in sufficient detail to bring out the salient features of the principal types.

Single element detectors may be divided into four major classes. These are listed in Table II. The classification here is by the physical mechanism of detection rather than by the type of radiation to which it is sensitive or by its field of application.

Scintillation Counters

The scintillation counter is named first in the table because it is the most sensitive and versatile detector for many types of radiation and, in particular, for gamma rays, that has yet been devised. Furthermore, its speed of response and time resolution capability exceeds that of any other detector.

The scintillation counter consists of a transparent scintillator optically coupled to a photomultiplier whose

TABLE II

Nuclear Radiation Detectors

Type		Application, Remarks
Scintillation Counter		
Scintillator	Example	
Inorganic crystal	NaI:Tl	General survey, energy spectrometry (with photomultiplier having high quantum efficiency, good statistics)
Inorganic powder screen	ZnS:Ag	α-ray detection (with large area photomultiplier)
Organic single crystal	Anthracene	For combined high speed and energy discrimination
Liquid solution	Diphenyl in Xylene	Good time resolution, coincidence measurements
Plastic	Polystyrene+tetraphenyl-butadiene	Large volume, good time resolution
Neutron sensitized phosphor	ZnS:Ag with Li^6	Neutron detection
Cerenkov scintillator	Non-fluorescent plastic	High-energy physics, good time resolution
Gas Ionization Detectors		
Ionization Chambers		Quantitative radiation measurements, personnel monitoring, area monitoring
Proportional Counter		α-particles (with air or inert gas filling), neutrons (with $B^{10}F_3$, etc. filling)
Geiger-Mueller Counter		Survey work, health physics
Semiconductor Detectors		
p-type silicon with diffused surface junction (phosphorus)		α-particles, high-energy particles, low-energy β-rays
n-type silicon with Au barrier layer		α-particles, high-energy particles, low-energy β-rays
Single crystal (diamond, AgCl)		Experimental
Chemical Detectors		
Photographic		Film badge
Glass or crystal radiation darkening (F-centers, etc.)		High-level radiation monitoring, personnel hazard monitoring
Dye reactions		High-level monitoring
Fluorescent activation of glasses		High-level monitoring

output is connected to electronic circuitry for analyzing and presenting the information obtained from the detected radiation.[6] A schematic diagram of the basic arrangement is shown in Fig. 1. When a particle or photon of nuclear radiation gives up its energy in the scintillator, it produces an excitation which generates a flash of light or scintillation. The optical photons thus generated strike the photocathode of the multiplier causing the release of photoelectrons. These photoelectrons are directed into the electrode structure of the multiplier where their number is increased by a very large factor through the cascaded secondary emission process occurring at the successive dynodes. The amplified space current is collected by an anode or collector electrode as a pulse whose amplitude is proportional to the absorbed energy from the particle or photon of nuclear radiation.

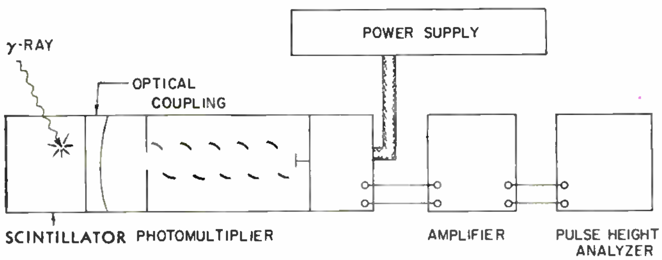

Fig. 1—Scintillation counter.

As indicated in the table, there are a variety of scintillators. The selection depends upon the application for which the counter is designed. For high sensitivity and good energy resolution, thallium activated sodium iodide gives excellent results. For speed and time resolution, a Cerenkov scintillator or a short decay time organic phosphor is employed. Neutron-sensitive scintillation counters are a special problem and will be discussed later. There is also a variety of photomultipliers available designed for different scintillation counter applications.[7]

Gas Ionization Detectors

A large class of nuclear radiation detectors depends for their operation upon the ionization of a gas as a result of the passage of a high-energy charged particle through it. This class may be divided into three types, namely, the ionization chamber, the proportional counter, and the Geiger-Mueller counter.

Basically, the members of this class consist of a chamber filled with an appropriate gas and two electrodes across which voltage is applied. Frequently, the outer wall of the chamber forms one electrode while a small diameter wire through the center serves as the other. The arrangement is shown schematically in Fig. 2(a). The essential difference between the three types in the voltage applied between the two electrodes and the field strength in the filling gas.

The detector functions as an *ionization chamber* if the applied voltage is low.[8] The ions produced by a charged particle are collected on the electrodes and the accumulated charge, measured with an electrometer or other electrical measuring instrument, is a measure of the radiation passing through the chamber.

With an intermediate value of applied voltage, it will be found that the ions released by the passage of the energetic charged particle will be multiplied by secondary ionization. Thus, the collected charge will be proportional to the particle energy, but will be greater than that from an ionization chamber by a factor which may be as large as 100 or even 1000. A detector operating in this mode is called a *proportional counter*.[8,9] The voltage range over which gas amplification occurs is indicated on Fig. 2(b).

If a still higher voltage is applied between the electrodes, the passage of a high-energy charged particle produces a saturated discharge. Provision must be made to quench the discharge either by external circuit means or by the use of a quenching agent (*e.g.*, a higher alcohol or a halogen gas) added to the filling gas. The voltage range over which this type of triggered discharge occurs is known as the Geiger region and a detector operating in this region is termed a *Geiger-Mueller counter*.[9]

The filling gas of a gas ionization detector is, in general, very transparent to gamma radiation. Where these detectors are used for gamma radiation measurements, the detector is designed so that the radiation is

absorbed in the walls, causing the release of high-energy electrons into the filling gas of the chamber. Frequently, for example, the wall material will have absorption characteristics resembling that of organic tissue so that the response of the detector is a measure of the biological effect of the radiation. Where high sensitivity to gamma rays is desired in a Geiger-Mueller counter, the walls of the tube are coated with a thin layer of a heavy metal to enhance the useful absorption of radiation.

Ionization chambers are employed for accurate quantitative measurements of radiation. They are also extensively used as monitoring devices to determine the exposure of personnel to radiation. The most frequent application of the proportional counter is for alpha particle detection and for measurement of neutron flux. For this latter, the filling gas is boron trifluoride which has a large capture cross section for low-energy neutrons. The Geiger-Mueller counter is a high sensitivity, simple, easily operated radiation detector. It has been very widely used as a radiation survey instrument to indicate the presence of small amounts of nuclear radiation such as would indicate the presence of radioactive contamination.

Semiconductor Detectors

The operation of a semiconductor detector can best be explained in terms of the solid-state energy diagram given in Fig. 3.[10] The illustration represents a lightly p-type silicon semiconductor with a thin p-n junction close to one surface. The junction is back biased to a point just below that at which appreciable reverse current occurs. An ionizing particle enters the material through the junction and gives up its energy throughout the depletion layer exciting hole-electron pairs. Experimentally, it is found that a hole-electron pair will be excited for each 3.5 ev loss of energy by the particle. The minority carriers (electrons) are drawn through the junction and are collected on the positive electrode. Therefore, a current pulse will be observed every time a particle passes through the material. The amplitude of this pulse (total charge) is proportional to the energy absorbed.

In a practical semiconductor detector, the junction will be a fraction of a micron in thickness while the depletion layer may be a hundred or more microns thick. Semiconductor detectors have been very effective for the detection of heavy charged particles such as alpha particles and are also useful for low-energy beta rays. However, the transparency of the depletion layer is too great for them to be effective as gamma ray detectors. The semiconductor approach to radiation detectors is one of the newest and most promising avenues of development.

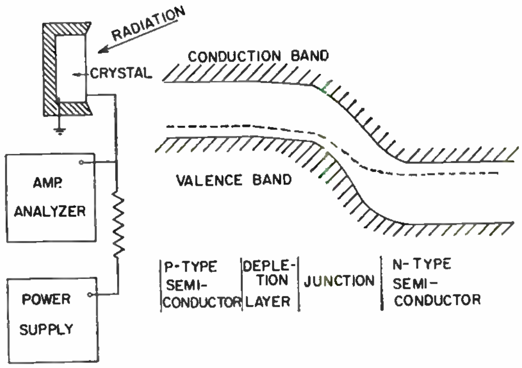

Fig. 3—Semiconductor detector.

Chemical Detectors

As indicated in Table II, there are a variety of chemical detectors. The only one to be mentioned here is the photographic film. Emulsions have been developed which are quite sensitive to gamma rays and whose blackening is proportional to the integrated exposure. Photographic film, in the form of film badges, is universally used as a safety measurement in almost all areas of nuclear work.[11]

Radiation Detector Requirements

A large amount of very important detail is involved in each of the detectors mentioned in Table II. In spite of the fact that this detail is so important that it may determine the operational success or failure of a given detector, it is not the purpose here to discuss this detail, much of which can be found directly or indirectly in the references cited. Instead, the group of radiation detectors as a whole will be considered from the standpoint of some of the more important attributes which they must possess. These are 1) high sensitivity, 2) energy resolution capability, 3) high speed, 4) radiation discrimination, and 5) ability to detect neutrons. The inclusion of neutron detection is, without doubt, a logical misdemeanor; however, the subject is of great importance and should be singled out for emphasis.

Sensitivity

Detectors should be available which will detect every particle or photon of nuclear radiation. The scintillation counter satisfies this requirement for most radiation, including gamma rays, provided that the area over which detection must be accomplished is not too great and that the particle energy is not less than a few kev. With an efficient scintillator, (*e.g.*, NaI:Tl), a good photomultiplier and good optical coupling between the two, each photoelectron released from the multiplier cathode requires 300 ev energy from the nuclear particle. Since this is a statistical quantity, the nuclear particle

[11] G. M. Corney, "Photographic monitoring of radiation," in "Radiation Hygiene Handbook," McGraw-Hill Book Co., Inc., New York, N. Y., pp. 10-53 to 10-75; 1959.

must have several times this energy in order to ensure a reasonable certainty that at least one photoelectron will be released. Therefore, if the photomultiplier generated no spurious "dark" pulses, a scintillation counter could detect each particle of nuclear radiation if the energy were above 1000 to 1500 ev. However, a photomultiplier does generate "dark" pulses due to thermionic emission from the photocathode and other nonfundamental processes. The thermionic emission from a CsSb (S11) photocathode at room temperature is about 1000 electrons/sec/cm². The gain process in a multiplier is, in itself, statistical and the pulse output from single electrons has an exponential pulse height distribution. Because of this spurious pulse background, reasonable certainty of single particle detection requires that the particle energy be 10 to 20 kev. The "dark" pulse rate corresponding to single electrons can be reduced two orders of magnitude by cooling the multiplier to the point where thermionic emission is negligible and the limit is set by other nonfundamental sources of "dark" pulses. As the development of photomultipliers proceeds, it is expected that the nonfundamental "dark" pulses can be materially reduced. However, even if this improvement is made, it is clear that the scintillation counter principle probably can never yield a detector approaching the ideal. The solution more probably lies in the direction of semiconductor detectors, and it may eventually be possible to develop a sensitive element which has a large thermal excitation energy and a nuclear particle excitation energy more nearly equal to the thermal excitation energy.

Alpha-particle detection, because of the low penetrating power of the radiation, presents the problem of an optically opaque window which is not easily solved for a scintillation counter. Here, proportional counters have been very effective. Recent developments in solid-state counters have resulted in outstandingly successful alpha-particle detectors.

Energy Resolution

The ability to measure particle or photon energy is, for many detectors, an important requirement. This is particularly true for gamma-ray detection since the gamma-ray energy spectrum (wavelength spectrum) of radioactive nuclei is quite analogous to the visible light spectrum of excited atoms and is very useful for element identification. Scintillation counters are, at present, the most effective detectors for measuring gamma ray energies. The gamma ray is absorbed in the scintillator by one of three processes, namely, photoelectric absorption, pair production, or Compton collision. This gives rise to one or more charged particles having the energy absorbed from the radiation. These charged particles, in turn, excite fluorescence in the scintillator. Assuming total absorption of the gamma-ray photon, the number of visible light photons and the photoelectrons in the multiplier will, on the average, be proportional to the gamma-ray photon energy. However, the processes involved are statistical and it can be shown that there will be a root-mean-square error ΔE_{rms} in the measured value of gamma-ray energy E given by

$$\Delta E_{rms} = \beta\sqrt{E\epsilon},$$

where ϵ is the energy required to excite the photoelectron and β is the statistical loss in the scintillator crystal and photomultiplier ($\epsilon = 300$ ev, $\beta = 2$ for a scintillation counter using NaI:Tl). With a 1-Mev gamma ray, the rms error will be about 3 per cent.

In order to improve the energy resolution, it would be necessary to devise an excitation process requiring much less energy. Solid-state detectors meet this requirement. It has been found for electrons and alpha particles that a hole-electron pair is excited for each 3.5 ev energy loss of the incident particle. However, the present solid-state detectors are too transparent to be useful for gamma-ray detection. They are very effective for energy measurements of alpha particles and root-mean-square deviations of 0.2 to 0.3 per cent have been observed for alpha particles in the 5- to 7-Mev energy range. The resolution limit is not, in this case, set by the statistics of the excitation process but rather by amplifier noise.

Further work with semiconductor detectors may overcome the two problems indicated, namely, obtaining sufficient absorption to make them effective for gamma-ray energy measurements and the incorporation of a gain process so that the energy resolution limit is set by the fundamental statistics of the conversion process rather than by amplifier noise.

Speed

High-speed capabilities are required of many radiation detectors. Speed here is used in two connotations; one is that the detector be capable of extracting the information (*e.g.*, energy) from nuclear particles when their rate of arrival is very high, the second is that it be capable of resolving the arrival of two nuclear particles separated by a small time interval. Technically, the two place very similar requirements on the detector. At present, scintillation counters with appropriately selected scintillators and photomultipliers have the best time resolution capabilities and speed of any detector known.

The time resolution depends primarily upon the fluorescent decay characteristics of the scintillator and upon the interdynode transit time spread in the early stages of the photomultiplier. With a fast organic scintillator and a commercially obtainable high-speed multiplier, time resolutions of a fraction of a nanosecond can be achieved. Special experimental multipliers have been built with a transit time spread reduced by almost an order of magnitude.

A great deal of effort has been spent on developing electronic circuitry for time measurements. The application of tunnel diodes now plays a major role in these fast circuits. The circuit development includes coincidence, delayed coincidence, and anticoincidence circuits as well as other special circuits designed for time interval determination.

Up to the present, solid-state detectors are not competitive with the scintillation counter for speed and time measurements. However, these detectors are in their infancy and ways may be devised to make them competitive or superior as time measuring detectors.

Radiation Discrimination

A frequent requirement for nuclear radiation detectors is that they be capable of detecting a small amount of radiation of a particular type in a background of other nuclear radiation. One way of achieving discrimination is by making the sensitive elements of the detector responsive to the wanted radiation and relatively insensitive to the background. The second is for the detector to respond to both wanted radiation and background and to obtain sufficient information from each so that the wanted radiation may be selected on the basis of this information. An example of the former is the boron trifluoride proportional counter for neutron detection. The filling gas is insensitive to γ rays and by properly selecting the geometry and materials of the walls, the γ ray response of the detector can be made small. However, the boron (B^{10}) of the filling gas is very neutron sensitive. As an example of the second method, it might be required to detect a high-energy γ ray in a background of low-energy γ rays. A scintillation counter would be employed and its energy resolution capability would be used to separate the wanted radiation from the background. However, the speed of the detector must be sufficient so that the probability of arrival of two photons or more of background radiation during the interval required for the detector to measure particle energy is small. Both of these methods are used either singly or in combination in the problem of discrimination.

The present type of semiconductor detectors with relatively small depletion layers exhibits good selectivity for heavy charged particles against a gamma-ray background. This is because the absorption of the latter in the depletion layer is quite small.

In addition to the two methods mentioned above, coincidence and anticoincidence detectors can frequently be used to aid radiation selectivity. While these and other methods are at present applied with good results, a general solution to the problem has not been achieved as yet and much research remains to be done in this direction.

Neutron Detection

As has been pointed out earlier, neutron detection is fundamental to the development of practical nuclear power. Fairly sensitive neutron detectors have been developed both for fast neutrons and slow or thermal neutrons.[12] The former are based on the impact exchange of energy between a fast neutron and the protons in hydrogenous material. The high-energy protons can excite luminescence if the hydrogenous material is the phosphor of a scintillation counter. Slow neutron detection is efected by using certain isotopes such as B^{10}, Li^6, or U^{235} which transmute after absorbing a neutron with the release of considerable energy. This energy is in the form of kinetic energy of the charged nuclear fragments and can produce ionization or excitation in the medium through which they pass. A europium or samarium activated lithium iodide crystal, for example, makes a fairly satisfactory scintillator for a neutron detector. Similarly, boron trifluoride in a proportional counter is a very effective neutron detector. Finally, Li^6 sandwiched between two semiconductor counters has also given good results.

The principal problem, however, is not that of obtaining sensitivity to neutrons but is due to the fact that most practical neutron detectors must be used in the presence of a very large gamma-ray background. This is particularly true of neutron detectors used in reactor technology. Therefore, the ability of the detector to discriminate against gamma rays is vital. A good deal of progress has been made in achieving adequate discrimination. However, the problem cannot be considered completely solved.

A second problem encountered in the application of neutron detectors to reactor technology is due to the extreme range of flux levels over which the detector must operate. At reactor start-up the neutron flux and rate of change of flux must be measured rapidly and precisely to determine the reactor period. Under these conditions, the flux may be less than 10^5 n/sec/cm². Under full operation, on the other hand, the flux may rise to a value of 10^{14} or more n/sec/cm². An ideal detector must be sensitive enough to make the low level determination but yet be stable and long-lived under the high flux condition. This problem has not been solved and, at present, retractable detectors, multiple detectors and similar expedients are used for reactor control. A possible direction of development of neutron detectors may be toward the use of liquid or gaseous neutron sensitive materials which can be made to flow through the active element of a scintillation counter or semiconductor detector.

From the above outline of single element nuclear radiation detectors, it will be recognized that while great progress has been made in developing the detectors and their associated electronic equipment to the point where they answer in a fairly staisfactory way many of the problems relating to the measurement of radiation, there is, nevertheless, need for further research and development. Areas in which improvements are urgently needed are in the detection of neutrons, the better measurement of particle energy, particularly for gamma rays, and increased detection efficiency of devices capable of very high time resolution. Of course, there is always need for improvement in reliability, stability, and simplicity of equipment. On the one hand, there is need for very large detectors for work in nuclear biophysics and for survey problems and, on the other, for very small efficient detectors for medical and biological applications. The research paths for achieving some of these objectives are fairly well marked; however, others will depend upon new inventions and discoveries.

Imaging Detectors

The final class of detectors to be reviewed is that of the imaging detectors. It is convenient to divide the imaging detectors into two groups. The first are those which display a two-dimensional pattern representing the distribution of nuclear radiation or radioactive material. This type of imaging finds widest application in the biological and medical field. The second is particle track imaging.

Area Imaging

Photographic: The most frequently used means of area imaging is the photographic film. All ordinary photographic film is sensitive in varying degrees to nuclear radiation. However, special emulsions less sensitive to visible light and more sensitive to nuclear radiation have been developed. At best the sensitivity to gamma rays is not very high, and frequently intensifier screens, in the form of sheets of a heavy metal, or fluorescent screens are used.

A typical example of the use of this form of imaging radiation detector is radioautography.[13] It is used to determine the distribution of radioactive materials absorbed in an object. For example, a fertilizer may be tagged with a radioactive atom and fed to growing plants. Later, the plants are laid against photographic films and allowed to remain long enough to produce an exposure. The degree and location of blackening indicates the distribution of the tagged molecules within the plants. This technique, suitably modified, can be used with small animals and other biological objects.

Scintillation Counter Scanning: The second imaging technique which has been successfully employed, particularly for large objects, is to scan the specimen with a scintillation counter whose angle of sensitivity is limited by a system of apertures. The output of the scintillation counter is recorded as a series of dots by a pen which moves over the recording surface in synchronism with the motion of the scintillation counter. This technique has been used, for example, to trace out the distribution of radioactive iodine in a patient suffering from a metastasized thyroid cancer. Imaging experiments have been carried out with arrays of scintillation crystals which are viewed with an electronic image intensifier. This work is still exploratory, and its usefulness cannot at present be forecast.

Track Imaging

Wilson Cloud Chamber: The second group of imaging detectors displays the paths of nuclear particles through matter. The earliest of this group was the Wilson cloud chamber.[4] This detector consists of a container filled with a gas having a high moisture content arranged so that the gas can be rapidly expanded. This rapid expansion causes the gas to become supersaturated with the vapor. A nuclear particle passing through the gas will produce a track of ions which serve to nucleate droplets of water so that the particle track becomes visible as a thin thread of condensed liquid. By providing suitable windows for illuminating and photographing these mist trails, the paths of particles can be accurately determined. Frequently such chambers are immersed in a strong magnetic field which will bend the particle trajectory. Observation of the density of the mist trail and its curvature under a known magnetic field gives information as to the particle energy, momentum, mass, and charge. Much valuable information in the field of nuclear physics has been obtained with the Wilson cloud chamber.

Bubble Chamber: A second type of track imaging device which had its origin within the last decade is the babble chamber.[14] The sensitive medium is a volume of liquid super-heated by decompression. The passage of a high-energy charged particle through such a volume of liquid leaves a trail of ions which nucleate bubbles of vapor. Sharp, clear tracks are obtained in this way. Of course, these tracks can only exist for a small fraction of a second before the entire volume of the liquid starts to boil. However, by using a high-speed light flash and recording camera, excellent tracks of considerably higher resolution than is possible with the Wilson cloud chamber can be obtained. The high resolution and high density of the sensitive medium gives these bubble chambers a decisive advantage over the earlier track imaging device. Obviously, the equipment required for the bubble chamber is much more elaborate than that for the Wilson cloud chamber. There are at present under construction several very large volume bubble chambers which give promise of contributing very

[14] H. Bradner, "Bubble chambers," *Ann. Rev. Nuclear Sci.*, vol. 10, pp. 109–160; 1960.

valuable information about the physics of very high-energy particles.

Nuclear Emulsions: A third method of obtaining particle track images is through the use of nuclear emulsions. When an ionizing particle passes through a thick photographic emulsion (especially prepared fine-grained emulsions are used for the purpose), a trail of exposed grains marks its trajectory. These tracks are generally microscopic in size and therefore microphotography is used to record them. Nuclear emulsions have proved particularly useful in showing the interaction of high-energy particles with nuclei of matter. When a nucleus is struck by a high-energy particle, it frequently disintegrates releasing a variety of high-energy particles which leave trails in the emulsion. Analyses of such "stars" have yielded a great deal of information about the creation of new elementary particles as a consequence of energetic collisions.

Spark Chamber: A track imaging system which is presently receiving a good deal of attention and may be the solution to problems requiring low resolution and very large sensitive volume also has the advantage of being simple both in concept and execution. This is the spark chamber.[15] It consists of an array of parallel metal plates with a gas, (*e.g.*, argon, air, etc.) at about one atmosphere pressure between them. If a potential is applied between the plates giving a field strength of a few thousand volts per centimeter, a spark will be formed when a high energy ionizing particle passes through the system of plates. The spark appears to originate at a point where the particle passes through the negative plate and may either follow the particle path or go normal to the surface of the plate (giving a stepped path). The spark paths can readily be photographed from two directions to give a stereo pair.

Scintillation Track Imaging: The final track imaging technique to be considered is scintillation track imaging.[16] When a high-energy charged particle passes through a scintillator, it produces a trail of excitation which, in turn, produces a luminous path or track. The luminosity of the track is so low that it cannot be seen with the unaided eye. However, by the use of electronic image intensifiers, excellent tracks can be obtained.

Two types of scintillators have been used for scintillation track imaging. One is the homogeneous block of scintillator material implied in the above paragraph. The second consists of a bundle of scintillator fibers. As a high-energy particle passes through the bundle, it produces light in each fiber traversed which is then transmitted to the end, the fiber serving as a light pipe. Therefore a projection of the path will appear as a luminous track on the ends of the fibers. Again, electronic intensification is required to bring the brightness of the tracks up to a point where they can be seen or photographed.

Two types of electronic intensifiers have been used for track imaging. One of these, the multistage intensifier image tube, presents the enhanced image on a phosphor screen at the end of the tube where it can be seen and/or photographed. The second is the intensifier orthicon where the reproduced track information is in the form of a video signal which can be reconstructed into a visible image by conventional television techniques, fed directly to computing equipment, or stored on tape for future reference.

Although much research has been done on electronic intensifiers, they are still in their infancy. Basically, the intensifier consists of a primary photocathode and electron current amplifying intensifier screens with electron optical systems between them to image the electrons. The electron image from the intensifier screens is focused onto an orthicon target for video reproduction or on a phosphor screen for direct viewing. Two types of intensifier screens have been used. The first consists of a thin phosphor film in close optical contact with the photocathode. Current gains of 50 to 80 are obtainable. The second is a thin insulator or semiconductor film capable of giving transmission secondary emission. Gains of 4 to 6 are generally obtained with such screens. For track imaging, cascaded intensifier screens are employed since total current gain required is 10^3 or 10^4. Scintillation track imaging appears to offer many advantages but it is too early to predict the full extent of its usefulness.

Conclusion

This paper has attempted to summarize the problem of nuclear radiation detection as it stands today, both in terms of the requirements for radiation detection and the instruments available. It is clear that the development of nuclear radiation detectors has a long road ahead of it before the field is complete. Even at the present rate of development, it will be many years before practical detectors will be able to accomplish all that can be theoretically predicted for them. Many advances in both single element and imaging detectors will come through application of semiconductor and solid-state principles to the detector field. It can be forecast with a great deal of confidence that the development of detectors will continue at its present high rate and that in the future not only will there be major improvements along the lines being investigated at present but also there will be new discoveries which will make radical changes in the field.

Nuclear Reactor Plant Kinetics and Control*

M. A. SCHULTZ†, SENIOR MEMBER, IRE, AND J. N. GRACE†, MEMBER, IRE

Summary—**Radio and control engineers have contributed significantly to the understanding of nuclear reactor stability and transient response over the last 15 years. The successful application of frequency response and analog simulation techniques to reactor kinetics problems, together with experimental confirmation, has allowed increased dependence on inherent feedback mechanisms for self-regulation and self-protection. Digital techniques are becoming increasingly important in transient analysis and in automation of reactor systems. Modern large reactors employing boiling coolant and/or natural circulation require thorough study of reactivity feedback, hydrodynamic effects, and spatial stability of the power distribution to assure successful performance. Many important areas exist for future analytical and experimental research, including prompt feedback mechanisms during fast excursions, stochastic fluctuations, reactor noise, and nuclear-thermal-hydraulic interactions.**

Introduction and Scope

THE DEVELOPMENT of reactor kinetics and control had to follow the development of basic nuclear reactor theory. The discovery of fission by Hahn and Strassman[1] in the late 1930's and the intensive exciting work that followed immediately thereafter on chain reactions indicated that a reactor would have an exponential response, and hence was going to be difficult to control. The role of the delayed neutron was appreciated in 1939, and indicated the possibility of setting up a pile or a reactor whose response was based primarily upon the control of the delayed neutrons. This reactor would still be an exponentially responding device, but one whose kinetic response would be slow and more easily restrained.

Early wartime production reactors were built and in some, such as the Hanford reactors, it was discovered that the reactors would run for a while and then shut themselves off. This effect was soon determined by E. P. Wigner and his associates to be caused by the kinetic buildup of xenon 135 acting as a reactor poison. Once the effect was understood, it was possible to design around it.

In this same era, temperature effects in reactors were hypothesized and observed. It was fortuitously noted that many reactors possessed a negative temperature coefficient of reactivity; that is, as the temperature of the reactor rose, the reactor had the tendency to shut itself off.

Up until the late 1940's, the kinetics of the few early reactors were accomplished by the same physicists who did the static criticality calculations. Interest in the kinetics of reactors by engineers did not come about until the art reached the stage where the responsibility of reactor and nuclear plant design began to transfer from the physicist to the engineer. Then the radio engineers who were diverted to the instrumentation and control problems of the plant began to realize that to test the existing kinetic theories on actual reactors could be disastrous. Hence, some form of electronic analog was needed to check reactor response safely in the laboratory and to determine the effects of changing variables.

Once the radio engineers became seriously involved in the reactor control field, they quickly recognized that xenon poisoning effects, temperature coefficients, and other effects could be treated as internal feedback in the reactor, and that the then existing feedback theory could be used to handle reactors as well as amplifiers and other circuits. The success of this approach was so pronounced that as the reactor industry grew up and engineering concepts and methods took over the design and construction of reactors, the transplanted radio engineer became a recognized and acknowledged partner in the reactor design. In this role, he was then able to follow and, in some instances, lead the parallel radio, TV and computer industries and adapt new techniques in the electronics field over into reactor design philosophy and calculations.

This article will present the principal historical developments of the industry from the reactor and plant kinetics point of view, and then elaborate on some of the current and future developmental areas.

Principal Developments in the 1940's

It was recognized that the nuclear reactor was mathematically a very complex device, particularly if one were to treat the kinetic effects on a spatial basis throughout the reactor. Soodak[2] first indicated what the response of the reactor would be if all of the spatial effects were lumped and the reactor was considered as a

[2] H. Soodak and E. C. Campbell, "Elementary Pile Theory," John Wiley and Sons, Inc., New York, N. Y.; 1950.

simple entity, all portions behaving the same way at the same time. The equations for the response of the neutron level in a reactor to any change in reactivity were:

$$\frac{dn}{dt} = \frac{\delta k - \bar{\beta}}{l^*} n + \sum \lambda_i C_i + S \quad (1)$$

$$\frac{dC_i}{dt} = \frac{\bar{\beta}_i n}{l^*} - \lambda_i C_i, \quad (2)$$

when:

n = the neutron level or the power level

l^* = the mean effective lifetime of a neutron in a given reactor design

δk = the reactivity (crudely the amount the multiplication factor of the reactor differed from 1)

S = an internal source of neutrons

$\bar{\beta}$ = the effective fraction of the total neutrons that are delayed

$\bar{\beta}_i$ = the effective fraction (accounting for different birth energies) of the total neutrons that are delayed neutrons in the ith group

C_i = the concentration of the delayed neutron precursors of the ith group

λ_i = the decay constant of the ith group of precursors.

The solution of these equations for the neutron level as a function of time after a step change in reactivity was quickly recognized to be a series of exponentials of the form

$$n(t) = n_0 \sum_{J=1}^{j=i+1} A_j e^{P_j t}, \quad (3)$$

where the first exponent had the same sign as δk, the input disturbance, and where the other exponents were negative.

From this starting point, work went ahead concurrently in a number of laboratories. At the Oak Ridge National Laboratory, Bell and Strauss[3] took these equations and built up the analogs for each term, thus constructing the first reactor kinetics simulator. This crude device, containing an early form of operational amplifier, dispelled a great deal of the fear of the ability to control a reactor with an automatic control. This work turned into the preliminary design of the control system for the LITR and MTR.

Similarly, at the Knolls Atomic Power Labs., Piggott and Owens[4] constructed a simulator, and also began manipulating Soodak's equations toward more familiar engineering forms. A chart was constructed which gave the coefficients and exponents of (3) for input values of step reactivity for reactors having different values of l^*.

In addition to the observation that for any one reactor type there was a definite relationship between A_j, P_j and δk, Piggott and Owens noted that the Laplace transform of (3) was of the form

$$n(s) = n_0 \sum_{j=1}^{j=i+1} \frac{A_j}{s - P_j} \cdot \quad (4)$$

Hence, some type of transfer function or frequency response of the reactor could be obtained. They indeed derived such a transfer function for five groups of delayed neutrons, thus again indicating the parallel-form of development between the reactor and the TV and radar fields. This derivation occurred within a few years of most of the basic work on network theory relating pulse output shapes to frequency and phase response of networks. Franz,[5] using the same approach, in 1949 refined this work to cover the presence of six groups of delayed neutrons. The first experimental measurement of the reactor transfer function was done later at the Argonne National Laboratories.

Once the reactor transfer function was derived, engineering proceeded at an accelerated pace. Pagels at Bettis simplified the reactor simulator by using conventional computing operational amplifier techniques and even built a small portable simulator for demonstration purposes.[6] Concurrent with this work, Harrer and Deshong at Argonne National Laboratories had tied an automatic control system around the reactor simulator and began to accumulate data on the peak and shape of the transient response of the controlled reactor as a function of the external control system parameters.

The reactor by this time had evolved into a relatively simple device. The control engineer approximated Soodak's equations further by ignoring the energy dependence of the delayed neutrons. The internal source was usually ignored as at reactor power levels it was swamped out by the fissioning neutrons. Much of the early intensive kinetic work in the late 1940's involved uranium 235 as the fuel. Therefore, β, β_i, λ, and λ_i were all to be fixed immutable quantities. Consequently the control engineer's concept of a reactor at this time was that of a simple four-terminal network black box in which the only important variable left to the reactor designer was l^*, the mean effective lifetime of the neutrons. The reactor thus had the transfer function block diagram of Fig. 1, and for all practical purposes could be treated as a network component. Pagels'[7] version of the reactor simulator in use in the late 1940's is given in Fig. 2. It will be noted that the only basic peculiarity of these systems was the ever-present nonlinearity in

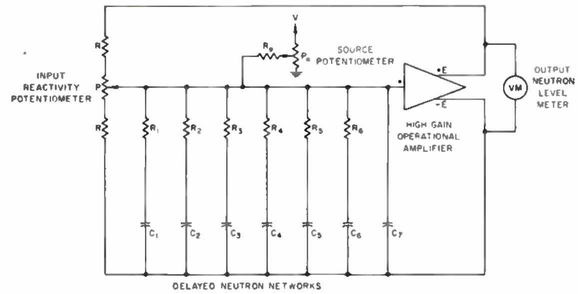

Fig. 2—Reactor kinetic simulator.

which the gain of the reactor depended on the level of operation. In most active networks within the control engineer's experience, linearity might be present over a limited range and then some form of nonlinearity such as saturation would take place. Here the nonlinearity was such that the gain of the reactor, in terms of the ratio of power output to reactivity input, was always a function of the level at which the reactor operated.

Progress in the Early 1950's

After the war, the transfer function concept took hold with the reactor engineers as it did with servo engineers in all other fields. The reactor physicist remained somewhat skeptical of the entire process. It was not until Harrer, *et al.*,[8] obtained the transfer function of an actual reactor that this skepticism disappeared. Their experiment was performed on the CP-2 reactor at the Argonne National Laboratories, and consisted of oscillating a neutron absorbing control rod in and out of the reactor in a nearly sinusoidal manner. They recorded both the position of the control rod and the neutron output of the reactor as a function of frequency and assumed for small excursions that rod position and reactivity were directly related. The transfer function thus obtained compared almost perfectly with the theoretical model and hence with the simulated electronic model.

The faith in the reactor simulator having been vindicated, work could then proceed to refine the automatic reactor control system. A typical block diagram of an automatic reactor control system in the early 1950's is shown in Fig. 3. The only unique feature of this loop is

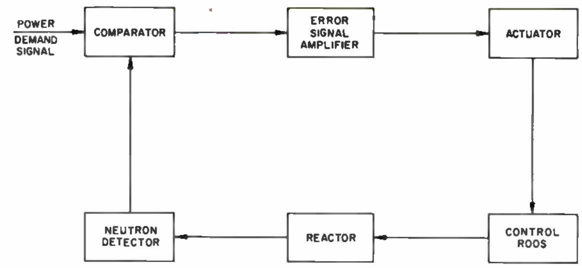

Fig. 3—Reactor automatic control loop.

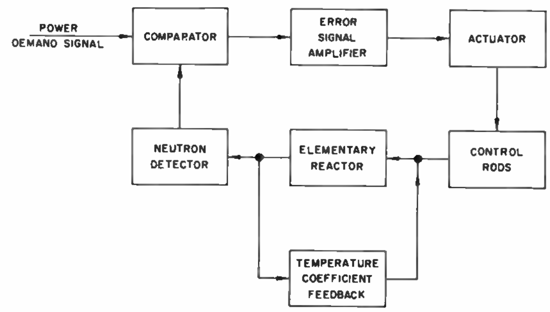

Fig. 4—Reactor control loop with temperature coefficient feedback.

in the comparator. Here, because of the reactor nonlinearity that its gain depended upon its level, a series circuit was introduced in which the gain was inversely proportional to the level. Thus, the nonlinear embarrassment was canceled out. This type of control system was studied intensely in many laboratories, and all of the external parameters were optimized for various reactors.

All of this work was done for plain, simple U-235 reactors with only the internal parameter l^* being somewhat variable. The temperature coefficient effect now came to be recognized as a servo problem, and it was added to the system of Fig. 3 as an internal feedback network around the reactor as indicated in Fig. 4. It was now necessary to optimize the automatic control system again. J. C. Simons and his group[9] at Bettis did extensive simulator work in which they showed that for most practical reactors the temperature coefficient controlled the peak of a fast transient, but the external control system was responsible for the duration and shape of the response. The temperature coefficient in these studies was a lumped coefficient acting with a lag expressed as a simple time constant.

The first attempt to approximate plant feedback effects through the temperature coefficient was done by Henry[10] in 1950. He set down some 13 first-order differential equations describing the thermal and hydraulic behavior of a pressurized water reactor and indicated the means whereby a temperature change affected the reactivity. A transport time delay was then introduced

[8] J. M. Harrer, *et al.*, "Transfer functions of the Argonne CP-2 reactor," *Nucleonics*, vol. 10, pp. 32–36; August, 1952.

[10] A. F. Henry, unpublished work; October, 1951.

to get this heat to the heat exchanger. Then the equations of the heat exchanger were written for both its primary and secondary sides to indicate how the heat transferred to the working load. The cooled primary coolant was then returned to the reactor via another transport delay in the piping. The average temperature in the reactor was obtained by averaging the returned inlet temperature to the reactor with the outlet temperature leaving the reactor. It was this average temperature that was used to affect the reactivity through the temperature coefficient.

The 13 simultaneous equations describing this system were set up for digital solution. This solution showed that such reactor plant systems were stable.

The reactor control engineers at the time immediately recognized that here was a means of putting more fine structure into the origin of the temperature feedback, in that it now could really have two detailed parts: a local part which acted very quickly, and a delayed part which contained some form of positive feedback for an increase in reactor outlet temperature would result in an increase in inlet temperature. As for stability, servomechanism theory had by now provided a large number of tools which were far more revealing than a single digital computation for the solution of such problems.

The first reactor plant simulator was constructed at Bettis in 1951 to study further the feedback effects on plant transients. This simulator was of the block diagram form of Fig. 5 and did not contain any automatic control loop around the reactor. Stubbs and Single contributed the first all-pass variable transport delay circuit. It was at once apparent that the external plant constituted an inherent control loop and that if the reactor had a negative temperature coefficient, the loop could easily be stable and, in addition, the plant would be self-regulating and follow the power demanded of it.

This situation can be seen as follows. Let the plant of Fig. 5 operate at a constant output load. Now suppose that more output is required by the load caused, for example, by opening the throttle to the turbine. This greater loading causes more heat to be extracted from the heat exchanger, and, for a short period of time, the heat capacity of the heat exchanger and coolant can usually supply the additional load. However, this extra energy extracted from the system requires that the temperature of the coolant into the reactor must drop. If the reactor has a negative temperature coefficient, the reactivity will increase. If the reactor was initially in a critical state, it now temporarily becomes supercritical. The output temperature of the coolant rises, and more energy is then available from the reactor. Finally, in the steady state the reactor returns to its critical condition with the average coolant temperature the same as it was initially. It will be noted that, without any external control mechanism whatever, the reactor system has stabilized itself about a given average temperature and automatically supplies the new power demand placed upon it.

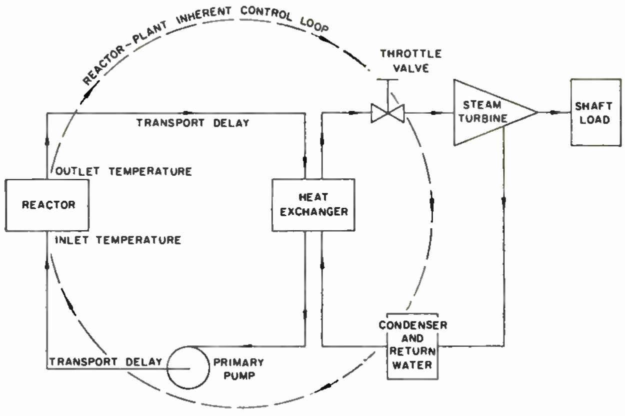

Fig. 5—Block diagram of reactor and associated plant showing inherent control loops.

Analog simulation of reactor plant transients successfully demonstrated the inherent self-regulating and self-protecting characteristics afforded by a negative temperature coefficient coupled with plant feedback. This initiated the exploitation of inherent control as a means of simplifying automatic control of power demand and accident protection. The methods of analysis used were 1) frequency response techniques, for stability analysis and control system synthesis, and 2) analog simulation, for reactor plant transients.

The development of frequency response techniques for application to nuclear reactor plants was the natural inclination of radio engineers familiar with the principles of feedback theory. In 1952, G. S. Stubbs, *et al.*,[9] calculated transfer functions for each reactor plant component using the small perturbation treatment. These transfer functions were then used in both the analysis of inherent feedback loops and the synthesis of automatic control systems, and were supplemented by simulator studies of transients.

The inherent feedback mechanisms which required analysis, in addition to the temperature coefficient, were the effects of 1) system pressure, and 2) fission product poisons (principally xenon) on the reactivity, as indicated in Fig. 6. Understanding of these effects was required before inherent control could be assumed.

Pressure feedback was found to depend on the coupling between the primary loop and the pressurizer. A resonance occurs, illustrated in Fig. 7, which depends on the inertia of water in the surge pipe. Too little damping results in sufficiently strong feedback through a pressure coefficient of reactivity that self-sustaining reactor power oscillations can exist, at a frequency of typically 1 cps. The resonant peak is reduced and the system stabilized simply by orificing the surge pipe.

Xenon poisoning had already been found experimentally to introduce a significant transient control

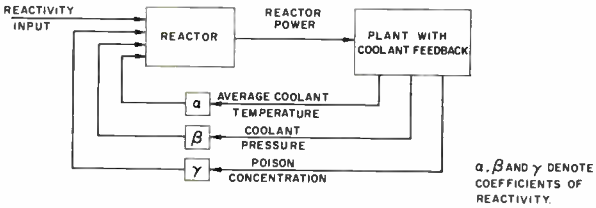

Fig. 6—Inherent reactivity feedback loops.

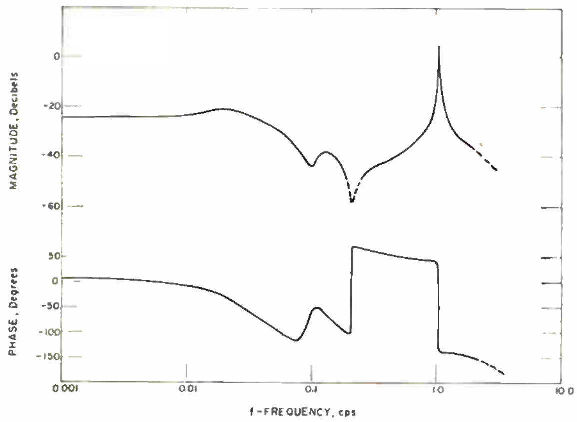

Fig. 7—Loop gain through pressure reactivity feedback (with T_w feedback). Full flow, full power, 4-in surge pipe.

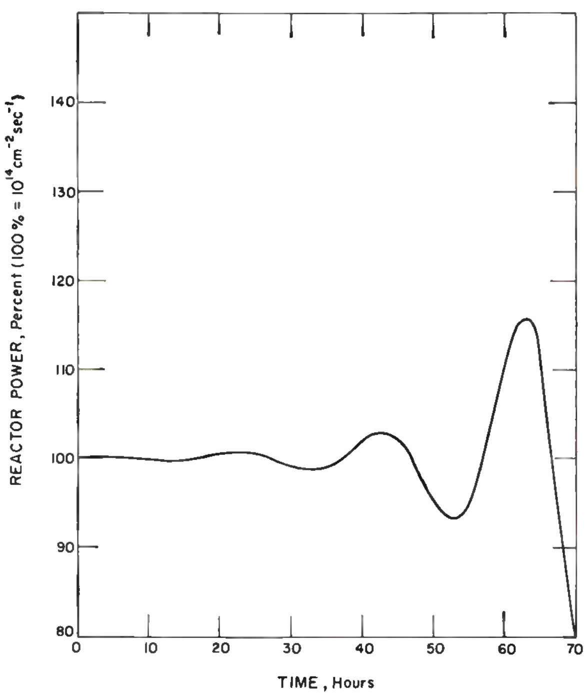

Fig. 8—Reactor power vs time. Average flux $=10^{14}$ cm^{-2} sec^{-1}. Actual gain $=1.1\times$ "critical gain."

problem requiring increased excess reactivity and more control rods. However, it remained to be examined as to whether self-sustaining oscillations could ever occur, although they had never been observed experimentally. A frequency response analysis[11] of the problem revealed that such systems could oscillate when the negative temperature coefficient of reactivity is not large enough (see Fig. 8). However, the frequency of oscillation is typically only 1 cycle per day, which is easily controlled by very slow automatic or manual means. Some reactor plants in operation today would be found unstable if left uncontrolled for several days.

In parallel with the development of the understanding and the means of circumventing inherent instabilities, attention was being given to synthesis of automatic control systems.[12] Two types of control systems were developed. The earliest was a power demand system which did not depend on inherent self-regulation. Control rods were moved in response to a power level error signal, the difference between measured reactor power and a synthesized power demand signal. The power demand signal was the sum of a steam flow signal, representative of the load on the plant, and a temperature error, needed to reset and shim the water temperature to the design level. Rods were moved either continuously or in an on-off manner, based on an early nonlinear systems analysis which today would be called the describing-function method.[7]

The second control system developed depended on inherent feedback for power regulation, and employed only a temperature error signal to move rods—no power error was used.[13] Thus, the principal control loop was that of the inherent temperature coefficient, and the role of the automatic system was reduced to a slow, follow-up, temperature regulating junction.

Both types of systems (Figs. 9 and 10) were analyzed for stability by frequency response techniques and were tested transient-wise by analog simulation. It was found that the simpler system resulted in quite satisfactory stability and transient performance. This, combined with the greater reliability of inherent self-regulation, resulted in the abandonment of power demand-type control systems for reactors having a significant negative temperature coefficient.

The understanding of inherent feedback mechanisms and the methods of stability and transient analysis developed during the early 1950's served as a basis for the design of many reactor plants and control systems.

The Last Six Years

The last six years has shown a tremendous expansion of reactor kinetics and control studies into many allied fields including boiling reactor kinetics, self-shutdown mechanisms, spatial stability and flux tilt transients, and stochastic effects at low neutron flux levels. Analog simulation techniques have continued to keep pace with the needs, and digital computation has become an important tool in transient analysis.

Pioneering work in boiling reactor kinetics was done by J. M. Harrer, J. A. De Shong, J. A. Thie, *et al.*, at Argonne National Laboratories, using EBWR. Their work included transfer function measurements at various operating conditions and extrapolation to higher power levels.[14] More recently, Margolis, Reihing, *et al.* at Bettis developed analytical methods of predicting the onset of void reactivity instability which were later substantiated experimentally.[15] The frequencies of oscillation predicted analytically are compared with the experimental result in Fig. 11. Zivi and Wright at Ramo-Wooldridge have succeeded in measuring feedback transfer functions experimentally, out-of-pile.[16] Plant feedback on boiling reactor kinetics has been studied by MacPhee[17] and Fleck.[18]

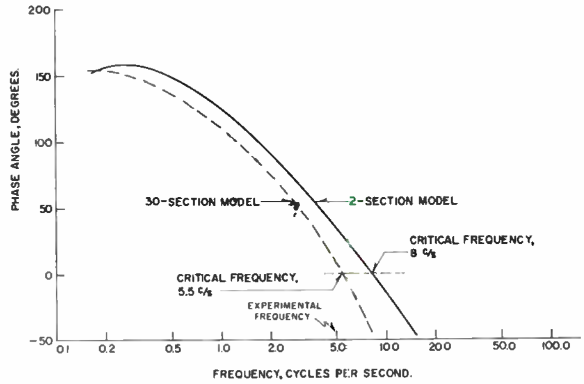

Fig. 11—Phase shift. Boiling reactor reactivity feedback loop.

Many investigators have used the correlation of reactor noise as a means of obtaining the reactor transfer function.[19–23] This method enables a transfer function to be obtained at any power level and is a powerful tool in determining whether a reactor coolant is boiling.

In addition to reactivity instability in boiling reactors, various modes of hydrodynamic instability can occur. Basic bubble generation instabilities and loop instability have been investigated at Ramo-Wooldridge by Zuber, Wright and Zivi and by Beckjord of General Electric.[24] Boiling channel instabilities have been investigated experimentally by Green at Bettis and the results used by Quant, Meyer, Rose *et al.*, as the basis for analytical predictions of oscillations.[25]

Self-shutdown capabilities of reactors were studied experimentally by Argonne in the BORAX reactors, by Phillips in the SPERT reactors, by LASL in the Godiva reactors, and by Atomics International in the KEWB reactor. Considerable success has been realized in the development of empirical correlations for prediction of peak power and energy release of runaway transients down to 5-msec exponential periods and even lower, at atmospheric pressure. More recently, analytical methods for prediction of the entire transient excursion have been under development by Langmuir at Ramo-Wooldridge and by Johnson and Chock at Bettis.[24] In water moderated cores the principal feedback mecha-

nisms were found to be fuel element expansion, heating of water by conduction and radiation, Doppler effects, and microbubbles generated by neutrons and protons. The work of Johnson and Chock on the effect of system pressure (Fig. 12) indicates the importance of mechanisms other than steam void formation which predicts self-shutdown even without boiling.

Spatial instabilities of power distribution caused by xenon feedback were observed experimentally in several large reactors, which then led to a number of analytical investigations of the phenomenon.[26–28] Unlike the xenon instability of the total power level predicted earlier, spatial instability is neither easily detected nor easily controlled. Not only is stability in the absolute sense required, but flux tilt transients should be prevented in cores that are subjected to nonuniform perturbations. The newest analytical tools for the study of space-time reactor kinetics employ modal analysis techniques. Stewart at KAPL developed a simple method which Harris at Bettis formalized[29] and applied to experimental data obtained from the Shippingport reactor. This method involves the assumption that the flux and the xenon deviations from equilibrium are everywhere 180° out of phase. Kaplan[30] has developed what have been called the natural modes of the system, which include all pertinent equations in the matrix operator defining the modes, such that the complex eigenvalues obtained indicate directly the frequency and damping factor. Margolis[31] has developed a Nyquist-type stability criterion for overtone spatial modes and successfully applied it to an experiment. Ewen[32] has developed digital programs for calculating the various types of modes. Margolis and Kaplan[33] also have shown the effect of delayed neutrons on flux-tilt transients, as illustrated in Fig. 13. Investigation (by analog simulation) of the effect of nonlinearities on spatial oscillations revealed amplitude limitation and precession, shown in Fig. 14.[34] Space-time kinetics studies become more important as reactors grow larger in size, making them poorly coupled and more sensitive to nonuniform perturbations.

Low-level reactor kinetic behavior differs from conventional power reactor kinetics in that the average neutron population is so low that a statistical treatment rather than a continuous or average treatment is required. Such low levels are actually encountered in some reactors having weak natural sources of neutrons.[35] Transients involving these low levels are not predictable in a deterministic manner and require statistical treatment. Hurwitz[36] assumes that delayed neutron effects dominate the behavior and integrates the stochastic equation by an approximate technique. Harris[37] includes both prompt and delayed neutrons and analyzes the time behavior of the moments of the probability distribution, thus requiring knowledge of the nature of the distribution. Hansen[38] has had some success in appling theoretical methods to transients initiated from low levels. Too little experimental data exists at this time for thorough comparison of the theories.

The analog computer continued to be a useful tool during the late 1950's in the investigation of many of the problems described. General-purpose equipment replaced the homemade special-purpose simulators, and greater flexibility was thereby achieved. The new kinetics problems led to the development of unique circuitry for their solution. Boiling reactors with flow redistribution and void reactivity effects, two-phase coolant loops with condensing heat exchangers, natural circulation with plant motion effects, flux-tilt transients, simultaneous hydrodynamic and reactivity instabilities, fast power excursion transients, and the statistical moments analysis of low-level reactor transients all were simulated on analog computers.

During the last six years, digital computers gradually were coming into use in reactor kinetics problems. Digital programs were written for reactor thermal transients[39] incorporating considerably more spatial sectionalization than was practical on an analog machine. The pattern that predominated was that the analog continued to be the standard tool for 1) reactor plant systems studies involving the simultaneous solution of combinations of the problems cited above, and 2) survey or exploratory studies of new concepts, requiring the flexibility of the analog, while the digital computer was used for more detailed representation of problems of more limited scope. The writing of a digital program was well justified when a problem became a production type, that is, when repeated use of the program was

anticipated. Frederickson and his engineering analysis group at Bettis have developed very useful digital programs to solve hydrodynamic stability, two-dimensional flow transients, heat exchanger oscillations, etc., all of which have found considerable production use.[40,41]

Although reactor plant system studies, even today, are better solved on analog computers, notable progress has been made in finding the right approximations to make digital solutions of reactor plant transients practical. For example, Arker and Greene at KAPL neglect the prompt neutron lifetime in the reactor kinetics equations, allowing precursor delays to dominate the transients. Such a treatment should be adequate and economical of computer time for many of the slowly varying system transients of long duration.

Meanwhile, as external reactor plants become more complex, automation has crept into both reactor startup and secondary plant equipment. The reactor shutdown system has always been highly automated, in that even the first reactor contained many devices for "scramming" or shutting down the reactor quickly. With the addition of a small amount of analog or digital logic, single pushbutton startup has become available in a few installations.

The Future

The continuing trend toward inherent reactor control requires more theoretical work on self-shutdown of fast excursions. Doppler effects, steam generation, and radiation-induced micro-bubbles are not well understood. Prediction of transients initiated from low levels requires an experimental program as a basis for comparison of theoretical treatments of stochastic effects.

Nonlinearities are usually readily taken into account in analog and digital transient analyses. However, more study is desirable on nonlinear instabilities to determine limiting amplitudes, although one would never intentionally design a reactor system to sustain such oscillations.

Digital methods have replaced analog simulators for transient studies of limited scope and short-time duration. There is room for improvement in the digital area to treat reactor plant transients for long duration. One remote possibility is to combine analog integration techniques, on a continuous time basis, with digital techniques, for algebraic manipulations, thus using each machine to its greatest advantage. Another possibility is to exclude automatically the representation of costly short-time-constant effects during those portions of a transient that are slowly varying.

The trend in reactor control and protection in the direction of inherent self-regulation and self-protection will certainly continue in the future. Similarly automatic control of all external functions will proceed at an accelerated pace. Without self-stabilization the inherent instabilities which would require detection and control when added to a power demand system will result in an automatic system of considerably less reliability than a self-controlling reactor. A negative temperature coefficient of reactivity, when sufficiently large, has been found to stabilize pressurizer oscillations, fundamental mode xenon oscillations and, most important in modern large reactors, spatial oscillations.

The control engineer is approaching inherent feedback loops from a synthesis point of view. He is exercising influence on the course of nuclear design and reactor engineering to enhance the desirable self-controlling features. Simultaneously the increasing knowledge of process control speeds the day toward completely automated plants. A marriage of the design of the self-regulating reactor and the completely automatic external plant control obviously will be made.

Energy Conversion Techniques*

K. G. HERNQVIST†, SENIOR MEMBER, IRE

Summary—The conception and evolution of the basic principles of thermionic energy conversion, the newest of the heat-to-electricity conversion methods, are described. The application of thermionic energy converters to its ideal heat source, the fission reactor, is discussed. It is believed that the state of the art is far enough advanced to make such a thermionic-reactor system practical within the next decade.

The combination of an incandescent electric lamp, a circuit including the vacuous space within the globe of said lamp, and electrical apparatus controlled by the current in such circuit—T. A. Edison (1884).

The method of controlling space charge in an electron discharge device—which consists in generating positive ions in said device independent of ionization by electron impact—I. Langmuir (1929).

Introduction

THE ABOVE claims of Edison and Langmuir describe the basis of operation of the thermionic energy converter, the youngest member of the family of heat-to-electricity conversion devices. There are several reasons for the delay in practical application of this device, paramount of which are the *demand* for a high temperature conversion device and the *technology* necessary for making a practical thermionic converter. Perhaps the most important demand has arisen with the development of the fission reactor. Advances in electron tube technology, primarily the metal-ceramic sealing technique, have made it possible to construct practical converters. Both demand and technology have developed only after the Second World War.

Fundamental Principles of the Thermionic Converter

What Edison had discovered was that an incandescent lamp having two filaments, only one of which was lit, could deliver electrical power, though minute, to an external circuit connecting the two filaments. Electrons emitted from one filament had sufficient thermal energy to overcome the retarding electric field developed between the filaments as a result of the current flowing through the external load. Thus, some of the heat generated in the hot filament was converted into electricity. Later work in the field of physical electronics taught that the conversion efficiency could be improved by making the electron collector of a material with a lower work function than that of the emitter. This difference in work functions, also called the contact difference of potential, can add to or, if large enough, completely override the voltage developed due to the thermal energy of the electrons.

Even with the improvement in performance resulting from the work-function optimization, the vacuum type thermionic converter has an impractically low efficiency. This low efficiency is due to the electronic space charge effects. The negative space charge of the electrons depresses the potential in the interelectrode space and seriously reduces the transmitted electron current. The most practical way of overcoming this effect is to introduce positive ions to neutralize the negative electronic space charge. These ions, continuously lost due to recombination, mainly at the walls, must be generated very efficiently in order to preserve high conversion efficiency. Langmuir's work provides one answer to this problem of efficient ion generation: a hot high-work function electrode (such as tungsten) immersed in cesium vapor provides an excellent ion emitter. Cesium atoms have an ionization potential lower than the tungsten work function and become ionized (resonance ionization) when they touch the hot tungsten electrode and are emitted as positive ions.

Extensive work in establishing the scientific principles of the cesium-vapor type thermionic converter has been performed recently.[1] Two types of converters have emerged, namely, a diode and a triode type.[2] In the diode both electrons and ions are generated at the cathode, which has a relatively high work function. This converter requires heat source temperatures of 1500°C or higher for efficient operation. The triode has a separate high-work function ion emitter and a bias must be applied to overcome its contact difference of potential with respect to the cathode. Operation in the range 1000°C–1500°C appears promising for the triode.

Cesium has other beneficial effects in the converter other than providing space charge neutralization. It provides a cesium coverage of the cold anode, thus automatically keeping its work function low; the other effect has to do with the electron emitter. One of the main requirements for achieving high conversion efficiency with long life is to provide an efficient, durable electron emitter. An excellent approach[3] to this problem is to operate the converter at such a high cesium pressure that a partial cesium coverage on the electron emitter is ensured. Such an emitter, extensively studied by Langmuir, emits both electrons and ions, and it is

self-healing since the cesium is constantly resupplied from the vapor phase. The high cesium pressure (~1 mm of mercury) necessitates the use of a relatively close electrode spacing (of the order of a few thousandths of an inch) to minimize the internal impedance.

Operation of cesium vapor converters, especially of the high pressure type, has led to the discovery that under some conditions improved performance is obtained when the converter is operated in an arc discharge mode.[4] Here all, or at least the major portion of the ions, are generated by impact ionization. The relative merits for the thermionic converter of impact ionization compared to resonance ionization is being investigated extensively at present.

After only about 5 years of development work, the state of the art of thermionic converters is such as to yield conversion efficiencies in the range 10–15 per cent for the 1300°C–1800°-C temperature range and 5–10 per cent in the 1100°C–1200°C range. Further improvements in materials are expected to lead to even better performance.

Construction of Thermionic Converters

In its simplest form the thermionic energy converter is a thermionic diode; thus, the techniques known in electron tube manufacture can be used in converter construction. Special problems are caused by the fact that the heat supplied to the cathode must be conducted through the tube envelope. Also, the presence of the chemically active cesium vapor sets limitations on the choice of materials suitable for tube construction. Work on materials compatibility indicates that the metals normally used in tube construction, such as copper and the refractory metals, are not seriously attacked by cesium. Glass-to-metal seals appear to be unsuitable, but, fortunately, high purity alumina ceramics can be used as insulators in envelope construction. Much work is presently being done on materials for thermionic converter construction.

Fig. 1 shows a typical example of thermionic converter construction. The cathode and the anode are plane-parallel circular disks, the separation between which is accurately set by means of small metal pins resting in insulators fastened to the anode. The thin cathode lead serves as a heat insulator for the cathode and also forms a part of the tube envelope.

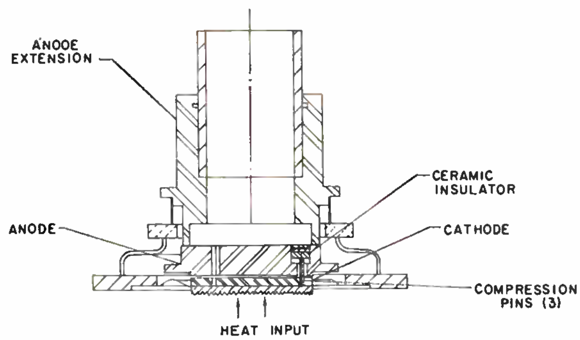

Fig. 1—Diagram showing typical construction of a thermionic converter of the diode type.

When chemical- or fossil-fuel type heat sources are used, one is faced with the severe problem of gas penetration through the hot part of the converter envelope. As will be discussed below, this difficulty can be readily overcome when using nuclear fuels.

Reliability in converter construction, of course, is subject to the same rules as in electron tube manufacture. One hundred per cent reliability is never reached, even in such an inherently simple device as a thermionic diode. Clearly, pretesting of the individual converters must be done before insertion into a power producing system.

In summary, the status of today's tube technology allows manufacture of thermionic converters having long life and good reliability. Future work will widen the choice of materials needed for specialized applications.

The Thermionic Reactor Concept

An idealized form of a thermionic-converter fission-reactor system is shown in Fig. 2. Here the thermionic converter is incorporated in the fuel element. The region occupied by nuclear fuel is bounded by cathode bearing walls. The moderator and anode coolant separate the fuel elements. It is required that the neutron absorbtion be low for the materials making up the thermionic converter and that these materials be undamaged by the nuclear radiation. Although the actual system will look quite different because of the necessity of using a multiplicity of converters in a single fuel element, the system shown in Fig. 2 illustrates the basic thermionic reactor concept. As will be discussed below, there are two important motivations for developing such a system: first *the thermionic converter fills the demand* for a high temperature conversion device *for the fission reactor;* secondly, *the nuclear fuel is the ideal heat source for the thermionic converter.*

[4] L. Malter, E. O. Johnson, and W. M. Webster, "Studies of externally heated hot cathode arcs," *RCA Rev.*, vol. 12, pp. 415–435; September, 1951.

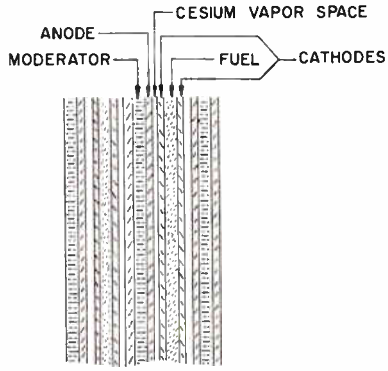

Fig. 2—Schematic diagram showing idealized thermionic reactor. Fuel elements are flat plates.

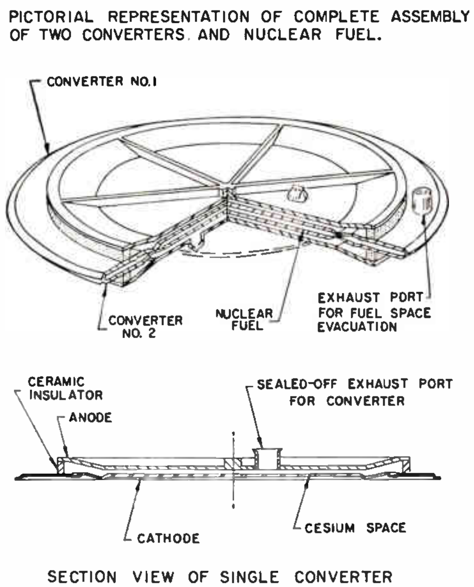

Fig. 3—Sandwich design of a thermionic converter.

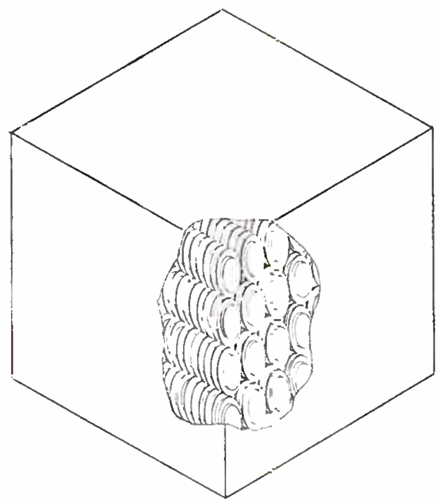

Fig. 4—Diagram showing array of thermionic converters making up a fission reaction.

Nuclear Considerations

The nuclear fuel is naturally capable of delivering heat at high temperatures. The fission fragments have very high energies, and the upper temperature limit is set primarily by the mechanical and thermal properties of the fuel and of the materials confining the fuel. To take full advantage of this property of the nuclear fuel, one must look for a heat engine having a working fluid which can be handled at these high temperatures. The free electron gas of the thermionic energy converter is precisely such a working fluid.

There are two basic requirements on the thermionic converter for its incorporation in a fission reactor: the materials of which the converter is made must not be damaged by the nuclear radiation, and their neutron absorbtion must be small in order to achieve criticality. The first of these requirements is believed to be fulfilled by a metal-ceramic type cesium vapor converter. The requirement on low neutron absorption necessitates the use of a minimum of thickness of converter materials; it may also call for a new type of tube construction materials such as zirconium and niobium.

Fig. 3 shows a proposed[5] thermionic converter assembly for a nuclear fuel heat source. It consists of two converters which can be pretested before insertion of the fuel.

Another factor of importance in criticality considerations is the effect of the inactive volume caused by cathode leads. Since the size of the individual converters is limited, terminals for each converter must be incorporated as shown in Fig. 4. Note in comparison with Fig. 2 that the space occupied by the cathode leads does not contain fuel and that here only neutron absorbtion is taking place. However, calculations show that carefully designed converter units allow criticality.

Converter Requirements

As noted earlier, from the point of view of the thermionic converter the nuclear fuel represents an ideal heat

[5] Design conceived by F. G. Block, RCA, Lancaster, Pa.

source. The neutrons passing through the converter cause fission in the fuel region which can be completely isolated between two converter cathodes as shown in Fig. 3. This assures a minimum of extraneous heat losses, and it allows the hot parts of the system to be completely enclosed in the low-pressure cesium chamber.

The thermionic converter places several requirements on the fission reactor for optimum performance. The high sensitivity of converter performance to emitter temperature sets high demands on power flattening for the reactor. Careful systems engineering is called for to solve this problem.

Another problem is caused by the formation of fission products in the fuel element region. These products must not be allowed to enter the cesium chamber, since some of the elements may condense on the anode and change its electrical properties. The design shown in Fig. 3 fulfills this requirement since the fuel element region is separate from the cesium cell. Also, such a design allows the removal of fission products should they build up intolerably high pressures in the fuel container. It is expected that a system of electromagnetic pumps may provide continuous fission product removal for a considerable period of time.

Conclusions

Although the basic principles of the thermionic energy converter are as old as the electron tube, extensive work on this device has been done only during the last five years. Considerable progress has been made, and this progress has already opened up many promising fields of application for this energy conversion device during the next decade.

The most promising of these applications appears to be the fission reactor which, for many reasons, is an ideal heat source for the thermionic converter. The thermionic reactor has many desirable features such as no moving parts, silent operation, and high coolant temperature, all of which are important for specialized applications. However, the use of the thermionic converter as a topping generator with conventional systems to convert the lower grade heat rejected by the thermionic converter may have wider economic implications.

It appears that the technical know-how for a thermionic reactor is near at hand. Such a power generator will require the use of the best resources and techniques of two highly specialized and separate fields of technical endeavor, namely, electron tube technology and reactor technology.

PRODUCT ENGINEERING AND PRODUCTION

Organized with the assistance of the IRE Professional Group on Product Engineering and Production

The Influence of Product Design on Radio Progress*

R. R. BATCHER†, FELLOW, IRE, AND A. R. GRAY‡, FELLOW, IRE

Summary—A survey of the typical construction methods and style concepts that were used during the past seven decades provides an index of progress. From rather haphazard constructions that prevailed during the first quarter of this century, the industry soon reached a period when mass production of radio equipment was possible, whereupon the role of the product engineer, who takes the concepts and ideas of the scientists and devises suitable designs that are effective, reliable, and producible, and of the production engineer, who handles the problems attending the manufacturing of these designs, became important. In this review, the design techniques of several eras will be noted, particularly those that influenced the utility of the equipment. The many developments leading up to new processes, the ever-changing objectives, closer tolerances and increasing complexity taking place during the second quarter of the century, lead us into the space age with the emergence of the transistor, missiles, computers and automation.

Printed-wiring and other assembly techniques are described, from the simple manual operations to the programmed automatic insertion of component parts. The roles of dip soldering and wire-wrap, flexible cabling, and standardization are recounted. The progress of miniaturization is reviewed, from using conventional parts through various methods up to the micromodule and other arrangements with different form factors and integration methods. Finally, more sophisticated microminiaturization approaches—thin films, and fabrication of solid-state circuits by forming, "growing," and electron-microscope techniques. Automatic testing, dynamics, cooling, and audio-visual aids are touched upon.

The roles of the product-design engineer and the production engineer are discussed in relation to current critical needs of the industry, such as the product-development cycle, reliability, and producibility. Trends and predictions indicate that engineers in these fields can look forward to a great future with many challenges and numerous opportunities.

Introduction

This survey presents several aspects of the design of electronic equipment during the many stages of its development and the work of the designers toward making apparatus that is useful, reliable, less expensive and, above all, producible. It will not just report who did what and when, but rather the constructional philosophies prevailing in each era and how designers handled those problems as they arose. The referenced periods used are not to be considered as being bounded by the precise dates noted, but as the eras where certain distinctive concepts and constructions existed. It is impossible to give here the credit due those who made the notable contributions to this progress in each period.

The equipment styles prevalent during an era provide an index to the advancement of radio communication and its associated arts. Progress was rapid, and a notable piece of equipment in any year usually became just a museum piece before another decade had passed. Equipment construction and styles found during the first four decades of this century will probably be viewed cynically by most of our younger readers. However, in spite of the apparent crudeness of some of the apparatus, judging by present-day standards, many of the current basic techniques were developed during this period.

The Embryonic Period (Prior to 1905)

The final decade of the nineteenth century and the first few years of the twentieth witnessed many independent scientific and technical developments: wireless, X-rays, cathode rays, the automobile and airplane, and the emergence of electricity from the novelty stage into a useful source of power. All of these captured the imagination of the public. In each field usable items of equipment and component parts were not readily available, and improvising was usually necessary. The field of wireless particularly captured the imagination of experimenters. The ease of setting up simple experiments and the desire to know more about the reasons for the effects noted sparked many studies. Advances were reported continually—both real and imaginary—many of which were accompanied by commercial speculation and promotion. The main production problem was that of enhancing the spectacular aspects of the apparatus. The availability of equipment in other fields dictated the type of construction. However, advancements in the theoretical aspects brought about new assembly concepts.

It is probable that Hertz's early experiments were within the range of 50 to 500 Mc, the resulting frequency being incidental to the convenient dimensions for resonant radiators which he used to signal over short distances.

Following the later disclosures of Marconi, the reasons for the switch from the relatively high frequencies of Hertz to low frequencies toward the other end of the spectrum may make little sense now. However, these were two different matters. Few people at the time even realized that Marconi's waves and those of Hertz were even akin. Lack of amplification and effective means for detecting signals over appreciable distances demanded the use of high-powered transmitters. Early transmitters utilized discharges of large capacitor banks charged at high voltages. These large banks dictated relatively long antennas and low transmitting frequencies. The component parts of a transmitter were large and thus were separately placed about the room, sometimes passing through the ceiling into the room above.

Progress in other electrical sciences had usually depended on steady-state concepts, which were inadequate in accounting for wireless phenomena. Measurements using cathode-ray tubes and rotating mirrors trained on the visible sparks in a transmitter provided the early experimenters with proof regarding some of the principles surmised. Tesla, Stone, Fessenden, Fleming, and others had worked out basic theories on some of these. The importance of tuning was well recognized at the turn of the century, when, with more stations in operation, the "other" became saturated with signals. Tesla had stressed the importance of coupled circuits as early as 1891, but the practical realization of any noticeable selectivity was not attained for a decade. It was news when Slaby reported simultaneous operation of two stations at about 240 and 540 m, an indication of the general state of the art at the turn of the century.

Meanwhile a search was on for a better means of detection, and many basic effects were pursued by numerous "inventors." The rectifying properties of many natural mineral ores proved most promising, and hundreds of natural crystalline substances were investigated for use in the "cat-whisker" detector. Incidentally many of these early "solid-state" materials are now being re-examined for application in diodes and transistors. At the end of this period the usual receiver of commerce still used cruder rectifying devices, even coherers.

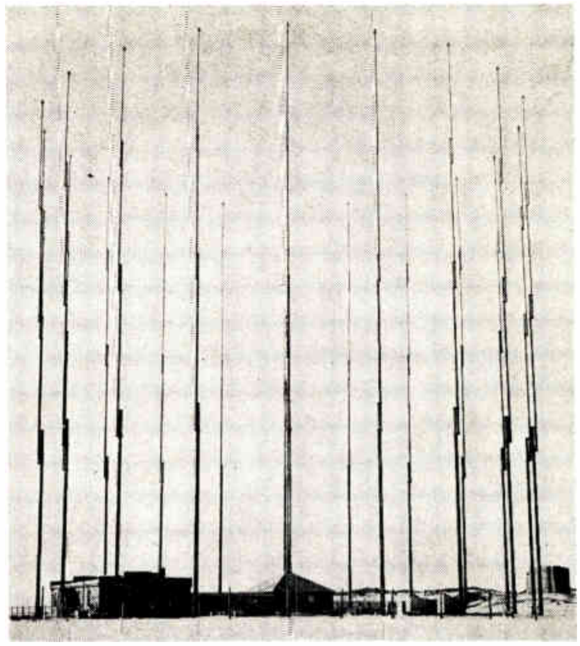

Fig. 1—Marconi station "CC" on Cape Cod in 1901 for trans-Atlantic service by high-powered spark discharges into large antennas. Worked with similar stations at Poldhu. 20 masts, each 210-ft high. They were seen wrecked by a hurricane, but replaced with four-mast array.

The Wireless Era (1905–1917)

By this time more sophisticated equipments were in use. The principles of tuning, quenched-gap discharges and even sustained-wave radiation possibilities were under more intense investigation.

New ideas altered the constructional techniques during the first decade of the century, but many of them were developed by experimenters who were not overly concerned with theories or handicapped by the task of keeping records of results in scientific terms. Whole arts were discovered and lost. Although the newly-discovered tube detectors were produced, they varied over a wide range, so that those having the greatest variations were prized the most. Experimenters spent considerable time playing up these vagaries to obtain the greatest detection "sensitivity," such as using magnetic fields applied across a tube to direct the electron beam on an effective path. Luckily other scientists pursued a principle to a conclusion and laid the foundation for radio electronics. By application of scientific principles and competent measurements a few definite rules for good construction were formulated.

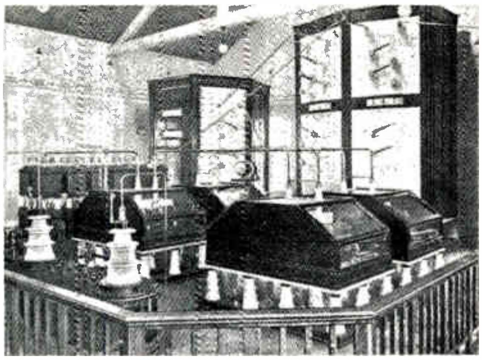

Fig. 2—Transmitting station at Nauen, Germany, in 1912. The transformer (lower left) extends through to floor of room below. 100-kv capacitors in the cabinets in left background, with four cases of quenched gaps in center. Inductances behind marble-panelled cabinets. Wavelengths up to 7000 m.

Fig. 3—Typical receiver and transmitter for shipboard in use around 1910. Receiver (right) consisted mainly of the coupler with its hinged primary and large tuning condenser (below). Detection by crystal rectifiers, usually molybdenum.

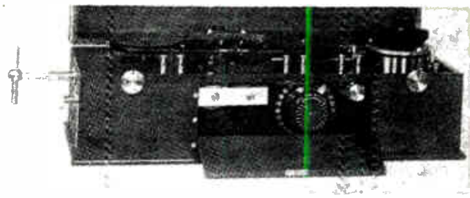

Fig. 4—English Marconi magnetic detector, this assembly being specially designed for receiving time signals. Used until after World War I, when tube receivers became standard. These detectors had to be wound up periodically, a clock-spring motor supplying power to the rotating iron-wire endless cable.

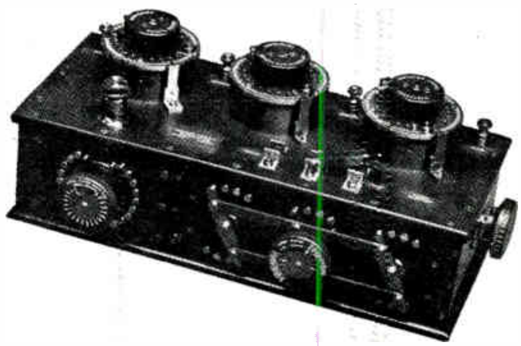

Fig. 5—Standard Marconi tuner also in common use during World War I on British ships. The variable condensers had hard rubber insulation between rotor and stator plates to handle the low carrier frequencies covered.

It is now difficult to imagine radio communication without electron tubes. However, focused and deflectable electron beams were well understood and in common use, in the form of cathode-ray tubes and gaseous path devices, at least a decade before grid-controlled tubes became known. Even oscillation was accomplished early, years before the appearance of triode oscillators.

The production of tubes was advanced during the latter part of this interval by the discovery of the importance of having high-vacuum and precisely located and dimensioned electrodes. However, the cost and fragility of these electrodes led to fantastic attempts to improve other parts of the circuit, so as to obtain the greatest effectiveness from each tube. The era of "low-loss" parts was in full swing. Production efforts were applied to a wide variety of experimental parts.

Continuing the early ideas of Marconi, transmitters used even greater amounts of power with attending lower carrier frequencies. An early "wonder" station was located at Clifden, Ireland, to communicate with Glace Bay, Nova Scotia, powered by a 6000+ cell storage battery delivering some 15,000 v. This battery, charged by steam-driven dynamos (three in series), delivered 300 kw to the capacitor. This capacitor in itself was quite fantastic. It contained dozens of plates spaced about a foot apart, each plate being some 6 by 26 ft in area, requiring an enormous shed to house it. These plates were hung from heavy charging cables. The capacitor was discharged by a rotary gap at a wavelength of around 5900 m. This installation calls attention to some of the unusual difficulties encountered by designers before 1907; a special railroad had to be built to carry peat from the near-by bogs to fire the steam boilers. Operation of this communication circuit continued until after World War I.

The carrier frequencies for some other intercontinental communication circuits extended into the audio-frequency range. Approaches using continuous-wave carriers were becoming popular with some companies, employing vacuum-tube oscillators, oscillating arcs, and high-frequency alternators. Companies were quite patent-minded, and commercial equipment was generally developed around only those methods covered by the organization's patents or its patent licenses. This prevented early utilization of some new developments otherwise useful. To stabilize the operating procedures in marine operations and to simplify the training of operators, a trend began toward the use of rack-and-panel construction to house transmitter parts, and of cabinets for receiver items.

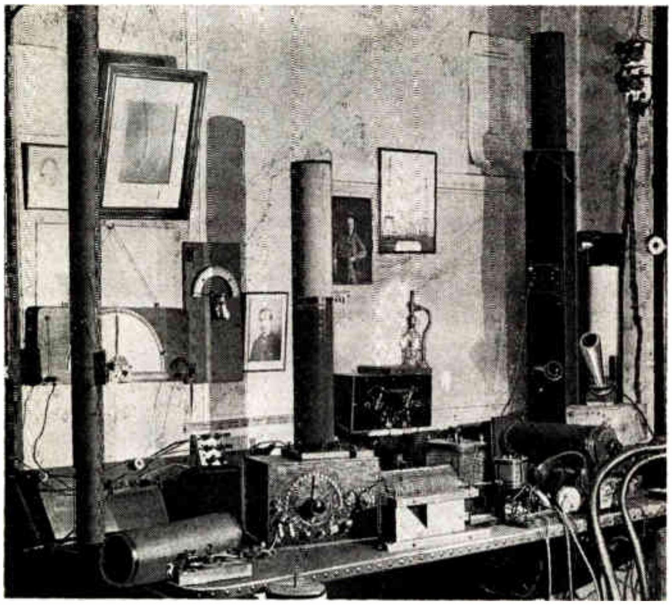

Fig. 6—A typical amateur station found around 1914 to 1917, with long-wave tuning and oscillator inductances hand wound on paper tubes. These circuits were capable of receiving continuous-wave signals from Nauen, Germany, but this particular receiver, owned by C. Apgar of Westwood, N. J., was tuned on the German station at Sayville, N. Y., and recorded (on the phonograph) messages which proved the violations of neutrality and caused this station to be closed down in the autumn of 1915.

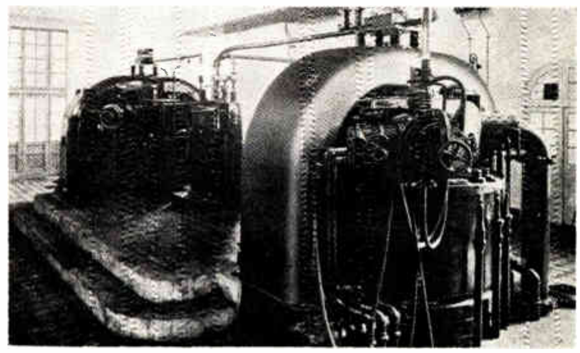
Fig. 7—Signal Corps field set developed during World War I. A spark set powered by hand-driven generator.

(a)



(b)

Fig. 8—(a) Assembling 65-ton electromagnets for 1000-kw Poulson arc transmitters during World War I, the most powerful continuous-wave transmitters. (b) Two of these arcs, installed at the historic Lafayette station in France during the war for the U. S. Navy. Several decades later, some of these magnets were utilized in a new role in a cyclotron.

While commercial wireless was concerned mainly with intercontinental and marine services, experimental and amateur applications were countenanced. The use of radio methods for overland uses, where wire circuits were possible, received little attention. The influence of amateurs upon construction processes was marked, and soon the public also became interested when time signals could be picked up each day without having to learn the code, and weather, crop and news reports could also be heard, although in code.

Cascaded amplifiers became commonplace, and packaged receivers with self-contained fully-wired parts became popular. Simplicity of operation was not a factor of design; the greater the number of controls, the greater the impressiveness of the apparatus and the prestige of the operator. Most receivers were of the regenerative type, adhering to the practice of getting the most gain from each tube used. Heterodyne principles, long championed by Fessenden, were then beginning to take hold. More extensive use of radio communication by the military was under way, mostly by the Navy. The Army Signal Corps also started experiments in short-range communication applications.

World War I

At the beginning of the hostilities by the United States, all amateur and most experimental and commercial services were curtailed as a war measure, not as a means of conserving manpower and materials but in order to prevent their use by the enemy for spying. Intensified production schedules were put into operation. A greater amount of information was passed between engineers of competing companies through the media of early IRE meetings. Equipment-design concepts prevalent in other countries also became known here since ships from all countries were used as troop and supply carriers. Even German liners were put to use after being "caught" in United States ports at the sudden start of the hostilities. Many excellent design practices were examined and utilized, such as the use of Litzendraht, and the design of precision variable capacitors for tuning, where the rotor and stator were milled from solid blocks of metal with closely-spaced airgaps.

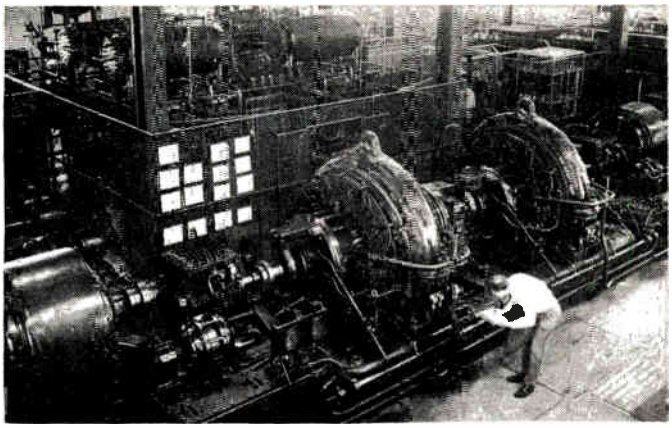


Fig. 9—Another notable attempt to produce high-power radio carriers, the Alexanderson alternator. These two alternators generated 200 kw each and were coupled to separate antennas, properly phased to give directed signals. Frequencies generated were in the range of 12 to 28 kc.

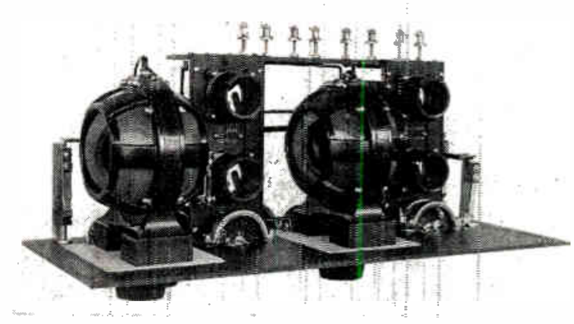

Fig. 10—Amateur receivers in the early twenties made great use of molded phenolics. Inductively-tuned receivers were particularly desired for sensitivity and ease of tuning. This "Grebe" receiver also served for broadcasting reception for those who "had the price."

Wartime equipment designs generally followed the practices of prewar construction, incorporating only such changes that made production easier. The methods of producing tubes with improved and stabilized characteristics was a most important factor, permitting what was then considered their "mass" production. Simple radiophone transmitters using tubes were produced by Western Electric toward the end of the war. These started the trend away from communications by code. A larger radiophone-transmitter design by General Electric used dozens of 50-w tubes in parallel.

Multitube amplifiers were improved for reliability and stability. Also noted were stabilized oscillators, more effective use of heterodyning, and directive communications using either rotatable or crossed loops. The invention of the superheterodyne was disclosed by Armstrong before the close of the war.

The Broadcast Era Starts

The practicability of radio-telephone transmission had been demonstrated before this country entered World War I, and subsequent improvements simplified the equipment. Broadcasting, a new service for home entertainment, started shortly after the termination of the war. Sparked by the great interest in the reopened experimental field, amateurs participated in promoting home construction for broadcasts.

Weekly newspaper supplements disclosed procedures for assembling all sorts of receivers, having to push hard to fill their pages with *new* processes each issue. Hundreds of manufacturing operations were set up, and a great many forms of common component parts were made available. Receiver construction was slanted toward the most impressive appearance. Home constructors often bought only the bare essentials that were difficult to build without extensive tooling (headphones, tubes, variable condensers, etc.), and put together the tuning coils, loops, fixed capacitors and even large storage batteries with arrays of test-tubes and strips of lead pipe.

This rush of construction served to popularize the art, but at the start did little to improve the components. During the early part of this period, factory-constructed receivers were built from designs previously popular for amateur reception. These were often well planned and used many new production processes, particularly the molding of phenolics. For several years these receivers exhibited the general characteristics of the time: they were bulky and spread out, had many controls, boasted many gadgets, and used low-loss elements, the designers striving to get the greatest sensitivity with the fewest number of tubes.

Regenerative effects were encountered and usually encouraged. Fantastic but tricky reception records were expected. Tuned RF receivers became popular, particularly after the disclosure of the neutrodyne principles by Hazeltine, even though more tubes were needed. Reflexing was resorted to in some cases, where the same tubes were used in both the radio-frequency and the audio-amplifier parts of the circuit. Superheterodyne circuits were beginning to be used in deluxe receivers.

Construction Processes

The wiring of the receivers during most of the early broadcast era used bare tinned-copper bus wires carefully arranged in exactly parallel or right-angled paths in an effort to at least stabilize, if not to minimize, regenerative effects. Soon three-dial neutrodyne receivers, containing RF tuning coils that were so positioned (or else wound with toroidal concepts) as to avoid regeneration, were popular. Such receivers, showing far greater operating stability, doomed the use of regeneration as a means of obtaining sensitivity. The growing popularity of the superheterodyne-type circuit completed this change.

Factory-assembled receivers soon replaced, in general, home-built models. The introduction of heater-type vacuum tubes in the midtwenties brought the ac power-line operated receiver into common use. En-

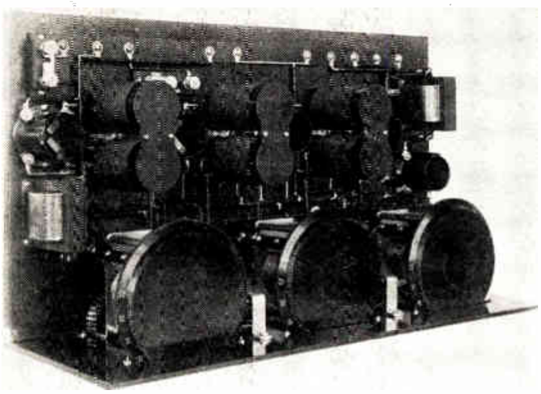

Fig. 11—Broadcast receiver of the neutrodyne type with litz-wound coils that simulated the low-field toroidal coils. This Grebe receiver used the first straight-line frequency shape of tuning capacitor plates. Wired with spaghetti-covered bus wires.

(b)

Fig. 12—Two early home receivers popular after the start of broadcasting. (a) An RCA-Westinghouse Radiola I, an early "modular" concept, a radio-frequency tuner, and amplifier, detector and audio amplifier. (b) Rear view of a Radiola II—a regenerative battery-operated "portable."

larged production schedules made producibility a most important consideration. During the late twenties, another noteworthy change was introduced when vacuum tubes became cheaper and more reliable. It had become apparent to designers that, if *more* tubes were used in a receiver, not only a *better* set resulted but a *cheaper* one. Two tubes interconnected with simple components could be more effective than a single tube surrounded with highly efficient, precisely adjusted components, which was the previous practice. Thus the era of the "low-loss" circuit was over, and the use of more tubes in roughly-adjusted noncritical circuits was customary. This apparently simple concept, viewed in retrospect, was not easily arrived at. Actually it was the result of several causes: lower cost of tubes, their greater adherence to established rated characteristics, the recent availability of multigrid tubes which permitted greater gains without internal regeneration, and a change in attitude of the public away from the desire for elaborate, mysterious assemblies to simple nontemperamental sets.

Also, strangely enough, it was the financial depression that spelled the end of expensive gadgetry. Perhaps for the first time, manufacturers of radio equipment regarded production as a science, and the role of the production specialist became important, second only to the sales promotion department (who figured that if a few tubes could be added to improve operation, why not add even more?). Purely as a sales feature, it became popular to add tubes to handle minor effects. The greater the number of tubes, the greater the prestige of the set. As a result, a plethora of new tubes were developed with special functions and characteristics. The pages in the tube manuals increased rapidly.

The Electronic Age Expands

New applications of electronics outside of the home-entertainment field appeared: sound pictures, public-address systems, new forms of electronic measurements, electronic phonographs, high-frequency heating, electrocardiography, and others.

From a single long-distance radiophone circuit operating in 1927, this field expanded in a decade to embrace 93 per cent of the world's telephones in 29 countries, incorporating such new developments as *single-sideband suppressed-carrier operation*, *voice-scrambling*, and *voice-operated switching* [1], [2]. Greater economies in space, weight and power consumption increased the use of equipment in aircraft and in flight-control applications. The success of car radio receivers (in 1940 some 2,300,000 were manufactured) spurred activity in related communication fields: two-way radio police channels for taxicabs, trucking fleets, maintenance crews, harbor craft, fishing fleets, and others [3].

The advent of practical frequency-modulation methods spurred some of these applications later. Other innovations included, before 1940, facsimile and television broadcasting. The latter, embracing the first highly complex circuits that had to be mass-produced at economical levels imposed many production problems which were not answered until after the War.

In all of these diverse applications the product designer was the direct link between the abstract discoveries of the scientists and the practical application into equipment that could be sold in a users' market. Such sales, even with the large drop in prices brought about by the market crash at the start of this period, allowed mass production. Home-entertainment receivers then provided the main source of income to back the research and technical development programs. Designing for military applications was again only a minor operation, imminent hostilities not being foreseen at the time. Designing for production simplicity and reliability for special environments gained stature. To improve equipment in several new fields of communications, specialized studies in new production techniques were undertaken along many lines. A brief survey of the trends in constructional methods is of interest.

Conveyor-Line Production

During the thirties, designers had to save every possible penny of manufacturing cost. The individually-placed bus-wire connections of the earlier periods gave way to random-placed flexible-wire connections. With production-line assembly systems, precut and stripped bundles of leads could be prepared in advance for the operators, these being placed and soldered along with other types of components.

As equipments became more complex, another major change took place, to facilitate assembly and maintenance. Here similar parts were placed in aligned rows on subplates which were provided with suitably-placed terminals in advance. Hand-assembled and laced cables tied these subassemblies into the circuit. This method of assembly has long been a standard technique for many types of apparatus. In spite of the introduction of the many more-sophisticated arrangements, it still finds some use in many early conveyor assembly systems, where production chassis were pushed along by hand from operator to operator, as each completed his assigned task. When conveyors were motor-powered, each operator handled from one to six or more items, the assignments being fixed by time requirements. With specialized test equipment, alignment and testing were reduced to simple routine procedures. Conveyor methods are practical only when continuous production over extended periods is possible.

For smaller runs the earliest method assigned a complete assembly to a skilled technician. This method was replaced by the *coach and team* method where this expert and a team of, say, nine others worked simultaneously on ten units. They followed the expert's instructions and demonstrations, and all finished at about the same time, whereupon another group of ten instruments was started. This scheme is actually an antecedent for the visual-and-sound aid programs of operator instruction, to be described later.

The World War II Era (1941–1945)

Near the beginning of 1941, the United States, although still playing the role of a neutral, was committed to be the "arsenal of democracy," and the year marked a gradual transition to a wartime footing. A rapid conversion took place from the low-precision home-entertainment type of radio to high-precision military equipment [4],[5]. Thereafter, in spite of material shortages, production reached many times the normal peacetime level. Complete strangers to radio-construction methods became proficient when the details were laid out by others. Physicists were assigned to communication and electronic problems, and many seemingly fantastic developments were started. The work of making things producible, originated by scientists with so many backgrounds of experience and training, fell to production engineering specialists.

Construction of standard radio-broadcasting transmitters was terminated to conserve critical materials. The production of electron tubes was restricted to a relatively few standard types for military needs. The production of cathode-ray tubes was similarly controlled to the particular types needed for radar and similar uses.

This period marked a transition from independent equipment to the large-system concept, where several or many separated equipments or devices were tied together for coordinated operation. Servomechanisms for remote control or for the transmission of display data and indications to central points brought about new requirements in the matter of precision, by whole orders of magnitude.

Prewar designs of equipment for military applications did not meet requirements in the matter of environmental operation. A change to militarized and ruggedized designs required tying up considerable amounts of engineering manpower. New specifications were quickly established, and soon every major manufacturer had invested heavily in environmental test equipment to cover high shock conditions aboard battleships, vibration in aircraft, the high and low temperatures encountered in some of the fields of action, and the fungus problems in the South Pacific. Other tests were set up for rapid acceleration, humidity, altitude, sand and dust, and salt-spray hazards. Many of these represented entirely new problems for the designers.

In addition to the purely physical and mechanical problems introduced by designing to withstand such environmental conditions, many new classes of components were needed which required development of entirely new manufacturing processes. Naval fire-control problems required new systems of switching and automatic control; submarine uses of Sonar needed new forms of transducers of both the magneto-striction and crystal types. Radar required means for rapidly swinging, large scanning antennas, which introduced mechanical problems of great magnitude. The introduction of pulse techniques into the philosophy of design was a major factor in the expansion of electronic techniques to new applications.

Later the proximity fuze replaced the time fuze in some cases, featuring miniature tubes, the most compact of printed circuits, and the ability to withstand many thousands of g's accelerations [6], [8]. This development, together with the walkie-talkie set [7], represented early steps toward miniaturization by the product engineer. These steps in later years influenced many areas of design.

This entire era of hostilities might be characterized as the period when the most ingenious and seemingly-fantastic ideas of the physicists and scientists were turned over to production-engineering departments and made to work in practical embodiments.

Postwar Trends (1945–1952)

At the end of the hostilities, a period of taking stock of all wartime accomplishments began. It was evident that the use of electronic methods in many fields was an absolute *must*, but also that much of the effectiveness of these methods was missing because of the inherent unreliability [67]–[73]. For one thing most equipments had been worked under all sorts of field conditions by operators who had only meager training.

In general, in the field electronics had suffered a loss in prestige. A lack of feedback of failure information from such field operations usually prevented early corrections. Speed of getting new designs into production for needed apparatus caused design and production responsibility to be divided among many groups. Each group strove for perfection as far as his own work was concerned, but usually without full knowledge of over-all design objectives, and without knowledge of how associated design details were being handled by other groups.

A common fault of the period was over-engineering, starting with the circuit designers. Many relatively unessential parts were added to gain only minor improvements. This added to the over-all complexity and frailty of the product since more parts were present that could go wrong. Another common principle of design of the period developed from an interest in logistics: the *variety* of parts used had to be kept at a minimum. As a result, a particular type and size of component would be used in many places in a given design. This part probably would serve satisfactorily in nine out of ten spots, but in the tenth it might break down consistently in a very few hours, possibly due to some special field condition not anticipated by the designers. How to *use* parts correctly, as well as how to design them, became a problem.

Another part of this stock-taking related to the commercial evaluation of all the applications of electronics resulting from military developments. The carrier frequencies had been extended upward several orders, many interesting applications for pulse techniques were then known, and many forms of automatic control through the use of newly developed transducers, servos, and rapid switching systems, and new ideas in the field of computers became known. These were but a few of the advances that were to be expanded upon.

Computer design problems challenged the product engineer anew, since major mechanical contributions involving many new construction concepts were needed for both the analog and digital types. This field was particularly adapted to the use of subassemblies and modules, and the application of miniaturization, encapsulation and the automation of assembly and testing. The invention of solid-state devices in 1948 was probably the most important event of the era, making possible new approaches for handling circuits of all degrees of complexity.

Meanwhile home television emerged from modest prewar beginnings. In 1946 and thereafter most receivers were completely redesigned so that mass-production methods could be introduced. In 1947 some 175,000 receivers, valued at over $75,000,000 were manufactured. During succeeding years, TV receiver design objectives related mostly to obtaining larger pictures, with even smaller cabinets, and more sensitive receivers, and to increase their range and so reduce the necessity for highly complex antenna arrays which were needed in many areas. Designs included a reduction in circuit complexity and the number of minor controls that had to be readjusted from time to time. By 1951 round and rectangular cathode-ray tubes of both glass and glass-metal construction and a steady parade of smaller improvements were noted. Cobalt-iron magnets replaced electromagnets for focusing. A 3000-mile coast-to-coast microwave relay system augmented the services provided to networks via cables, and by the end of that year 108 TV stations were in operation.

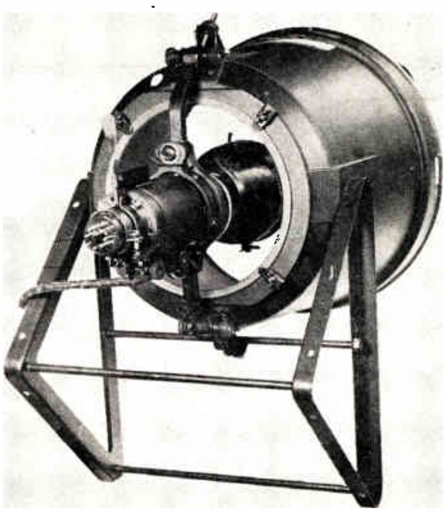

Fig. 13—Television-receiver designers achieved large picture sizes in various ways. The Philco projection receiver (circa 1948) gave the largest picture of any home receiver at the time, using Schmidt optics (shown here) to enlarge the picture from a 4-in diameter tube. Ingenious principles were used to gain picture size equivalent to that from a 24-in tube with equal brilliance at a nominal cost.

Product Engineering and Reliability

A direct result of military applications was a gradual revision of the prevailing idea among many potential users that tubes, *per se*, were fragile and their use should be avoided if possible. The greatly increased "socket" population in the typical equipment challenged the ingenuity of both equipment and component designers. Mass production of many items which previously had been hand-assembled was then possible.

The quest for reliability called for new goals concerning precise tolerances, the maintenance of initial characteristics over long periods, and the handling of a wide range of operating parameters and environmental hazards. A significant step was the establishment of new sets of standards covering many of the common components by joint action of industry and military agencies. To meet these closer limits, intensive programs of the study of all phases of component construction were undertaken independently by many manufacturers. The importance of correct design, the precise control of materials, and better inspection at critical stages of the construction became the rule in many places and were responsible for upgrading the quality of many parts.

Quality control usually caused higher rejection rates, which, combined with greater testing expense brought forth the belief that reliability can be attained only at appreciably higher prices. However, improvement programs in plants which made mass-produced items proved a new maxim: reliability must be *designed* into a product, and no amount of inspection and culling will ever compensate for designs that contain ill-planned dimensions, or an inferior material or uncontrolled construction process at some vital point. In many cases it was found that properly-designed component parts, even complicated ones, could be greatly improved *and* mass-produced at a cost below that previously found with the earlier construction methods which relied mostly on operator training.

Many equipment designers were slow to take advantage of such improvements, believing that the lower costs of mass-produced items were, *per se*, evidence of their inferiority to custom-made components commanding higher prices.

Design-Policy Confusion

Designs were becoming so specialized that engineers could no longer remain individually informed on all details. In the case of military electronics, some companies have been, and in some cases still are, passing through a state of design-policy confusion as a result of these efforts, but new industrial production concepts are emerging.

Military types of electronic systems are presently developed in three basic phases. First, one or more engineering models are designed, built and tested for performance—the so-called breadboard phase. Next, the component parts are extensively tested and a design review is then made, after which any redesign needs are accomplished to rectify environmental weaknesses—the reliability phase. Finally, still another redesign is attempted in the interest of conservation, producibility, automation, etc.—the "industrial" phase. These three phases of development leave much to be desired, especially when it is necessary to perform them in tandem.

In this age of expanding technology, engineering departments use many newly-graduated engineers for the first breadboard phase, because of their knowledge of latest theories and circuits. This reserves the more widely-experienced engineers for the later phases. Sometimes, when poorly supervised, the first stage designs leave much to be desired, requiring extensive changes later. Then too, a system sometimes becomes obsolete because of new discoveries and objectives, even before the breadboard phase is completed. This prompts those concerned to try to compress, time-wise, the over-all development. This, in turn, demands a long lead-time for configuration planning, parts selection and procurement against anticipated future models. The effectiveness of various approaches in this matter are still being evaluated.

The Systems-Engineering Approach

A few years ago certain members of the aircraft industry sensed that the manned military aircraft might be on its way out in favor of the guided missile. It seemed that each guided missile had to be designed as an integrated system, with a single contractor given complete responsibility. Missiles and weapon systems were becoming more and more complex, and most government agencies found it increasingly difficult to supply the detailed technical management required: a complete system design, the assignment of the multiple contracts for parts of the system, and approval of the facilities of the major subcontractors. The systems-engineering concept resulted, which placed over-all responsibility for each major program upon a single organization. Three slightly different solutions emerged. The Army assigned systems-engineering matters to its Ordnance Missile Command at Redstone; the Navy to its prime contractors, and the Air Force to the Space Technology Laboratories. In any case, the efforts of many different organizations were correlated to produce each complete integrated development.

In other prominent areas involving smaller developments, a policy has been considered by Military Agencies which puts more funds into research and development, rather than the actual manufacture of large quantities of apparatus, many of which might become obsolete even before they could be produced, by the emergence of other systems. Instead, an industrial "planning" phase has been substituted in some instances to provide, in theory at least, a well-organized mobilization schedule with all production phases, and in some cases tooling, considered in advance. Such a schedule could be put into immediate action should any national emergency arise. Realistic accomplishments that can be expected from such a plan have not been evaluated or proven as yet.

Integrated Operations Engineering

In regard to general policy problems associated with large systems contracts as they relate to in-plant development programs, it seems that an entirely new approach is being considered. The three phases each contractor must handle—the basic designs for performance, the reliability and value-engineering phase, and a redesign for producibility—should not be done in tandem, as is the usual case at present. On the other hand, it is a gross simplification to infer that these three product-engineering programs can be handled simultaneously.

A new design philosophy seems to be emerging, called by some *integrated operations engineering*—the application of operations research. Here all phases are correlated in an over-all program that provides the right number of engineers with the required talents and experience at the right time during the production schedule of large complicated systems having many development facets. Actually this might be considered as an expansion of a practice long used among smaller limited-product organizations dealing with less sophisticated problems than computers and missiles, where complete coordination of all design and production factors is easily accomplished.

The Space Age (After 1952)

Both the military and industry completed their reexamination of the various impacts made by electronics on their operations, arriving at similar general objectives. Because many of these plans envisioned large arrays of complex equipments, the matter of reliability was uppermost in everybody's mind, and this phase was tackled from all directions. Few doubted the ability of the scientists to devise plans for handling almost every problem put up to them, no matter how fantastic they may have seemed at an earlier age. The problem of devising means for implementing such ideas with equipment that was conveniently sized, producible, trustworthy, simple to handle and economical was then an assignment given to the new expanded field of product engineering.

Standardization Efforts

To increase reliability, many groups, committees and commissions were set in motion, but for the most part, for a long time, the outcome of these groups were warnings and dire predictions as to the results of even minor deviations from absolute reliability in any part. However, other more realistic approaches to the problem were also undertaken, and a number of jointly-operated study groups were set up by, for example: the Joint Electron Tube Engineering Council, RETMA (now EIA) product standardizing committees, the Armed Services Electro-Standards Agency, the Electronic Applications Group (of RETMA) and the Advisory Group on Reliable Electronic Equipment (AGREE), the latter having joint participation by the three Military Services.

Closer studies of ratings, a better insight into the conditions where appreciable derating of component capabilities, means for handling design changes to lessen the extreme operating conditions (by warming, cooling, shock mounting, stabilizing, etc.) were publicized. New specification instructions, procurement policies, test procedures acceptance rules were devised. Above all, a great deal of study was authorized and sponsored relating to the capabilities of current materials and construction processes and to the development of new materials that would better serve the designers' needs in critical applications. A review of early and current progress along these lines follows.

Automation

Printed-wiring and printed circuits had been used before and during World War II [9]–[13] and miniaturization also had been accomplished in some fields: hearing aids, proximity fuzes and walkie-talkies, for example. Neither field had become a serious contender to alter construction concepts, until the last decade [14]–[16], [19], [20]. By 1952 several programs were under way to bring about automatic assembly of standard components using two approaches: automatic insertion of parts into printed-wiring boards and means for integrating small units or modules into large assemblies [17], [18].

The automatic component insertion machine of the United Shoe Machinery Corporation, a conveyor-connected system with 12 insertion heads, can deliver an assembled board every three seconds. By the end of 1954 several manufacturers had trial installations in operation, one of which contained 50 insertion heads, each accounting for a single component. Meanwhile Admiral, Sylvania, and others were using automatic assembly machines of their own designs, all with a relatively high output volume. These also generally used the conveyor-connected "in line" insertion heads.

In 1955 General Mills demonstrated its 24-head "Autofab" in which, in addition to usual features, wrap-

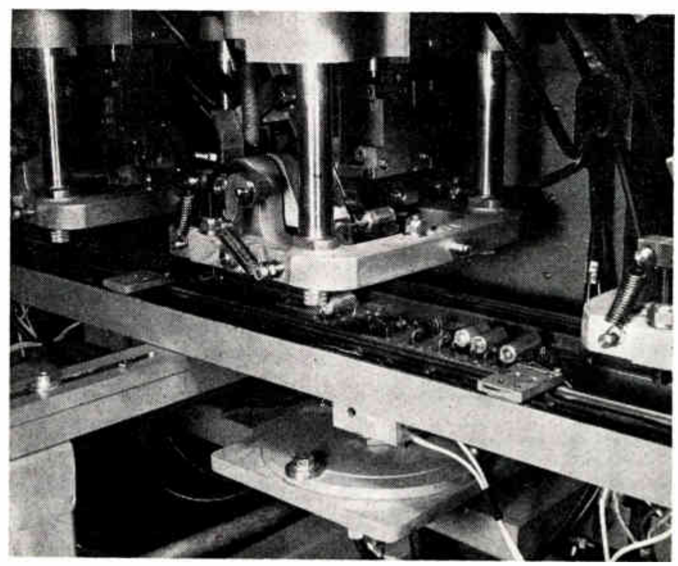

Fig. 14—"Autofab" head inserts pulse transformer. This closeup shows one of the 24 heads about to insert a pulse transformer (dummy parts were used in the early demonstration—1955).

around component lead tips were applied to the formed leads produced by an AMP lead-former. These provided capillary paths for the solder from the dip-soldering operation to simultaneously provide top-side soldering. A General Mills insertion machine had been ordered by IBM for the assembly of printed-wiring cards for the Air Force SAGE computers. Since the equipment in this particular application would be installed in locations practically free from vibration, the mounting of the parts away from the printed-wiring board was feasible, whereas it might not have been acceptable for a subassembly used in high vibration environments, such as in a missile. These wrap-around lead tips also proved useful by increasing soldering reliability even under extreme stresses.

There are now perhaps fifty large conveyorized insertion machines in use throughout the country, about half being home-designed and built by their users. From a long-range viewpoint, at least for many applications, it may be that standard sized components (that now make up the bulk of all construction) are on their way out in favor of integrated circuitry. Therefore these 50 installations may represent a near-saturation point.

Programmed Insertion Systems

If automation is to become generally useful for the assembly of electronic equipment, the set-up time must be greatly reduced in order to permit the system to handle small batches of assemblies, as well as large runs extending over considerable periods. With a programmed insertion machine it would be desirable to be able to assemble a *single* engineering model automatically. To study this idea further, the Navy contracted with Melpar and the Army with General Electric to develop programmed assembly machines. By 1956 Melpar had completed a model which could continuously assemble different circuits on 6- by 6-in boards from tape-controlled programming. GE also completed its program-inventory and programmed-insertion machinery, called ACAS, a much more elaborate development. The insertion speed of both systems was about two or three seconds per head.

In 1958 IBM announced its "punched-card-controlled component insertion machine," featuring a light-weight insertion tool positioned by differential binary air cylinders, the storage of the component parts on reels, and an insertion speed of one-half to one second (with a potential insertion speed that might approach 1/10 second). Other companies have also worked on different approaches to this problem, but to date not much production is being handled by any of them.

Semiautomatic and Methodized Insertion

For standard component parts individual insertion heads have been available from several of the above-mentioned insertion-machine pioneers. In 1955 Minnesota Engineering introduced a head that also drills the holes automatically, thus easing the problems encountered with fibre-glass boards. Many companies use these and similar machines individually or in groups, gaining much of the savings and reliability advantages of the larger conveyor systems, at a reasonable cost. Frequently, four or five such machines

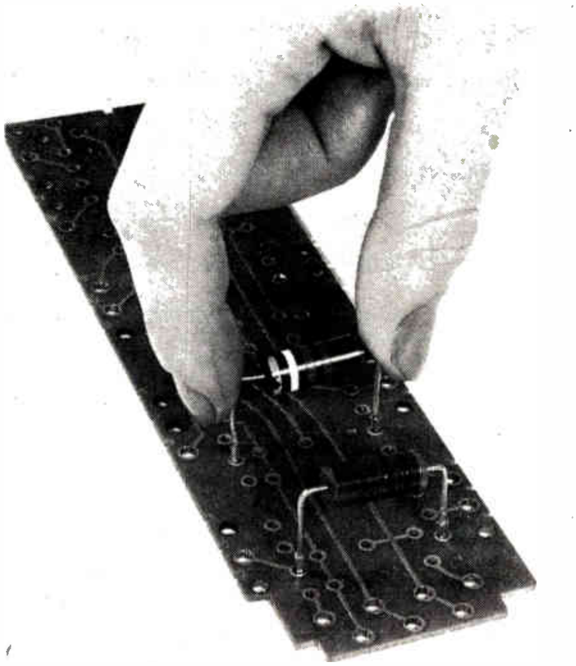

Fig. 15—IBM "Sage" computer board. This board was assembled in 1955 on the General Mills "Autofab" conveyorized automatic assembly machine. Note the wrap-around component tips on the ends of the resistor leads. The board had wiring patterns on both sides and plated-thru holes.

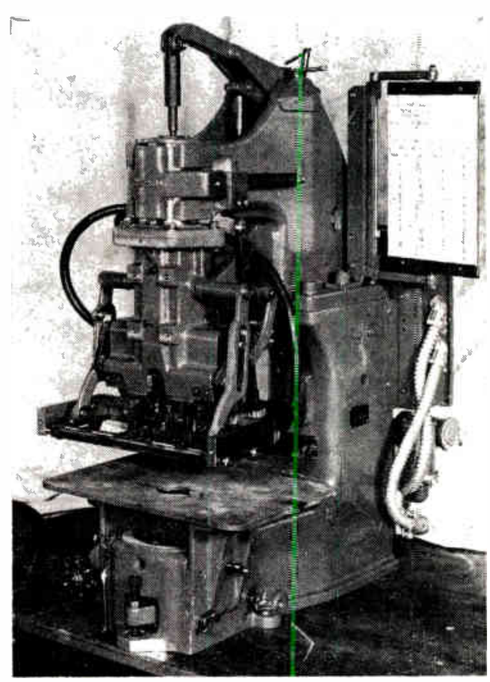

Fig. 16—United Shoe's "Dynasert," an individual component-part machine designed for bench installation. This was in fairly sizable production about 1955.

are arranged in a circle, with one or more operators moving the boards from one machine to another.

Similarly there have been several *methodizing* approaches, which refer to systems that are just short of full automation. Some of these are finding increasing use. Home-entertainment receivers use a considerable amount of automation. Test equipment manufacturers also have taken advantage of such methods, using "walk around," "push-along," and "roller-skate" conveyor systems. RCA made early use of semiautomatic "cut-and-clinch" machines, where the operator inserted four to eight parts in a printed-wiring board, whereupon a foot-controlled air cylinder cuts and clinches the leads of all components simultaneously. Later nearly all manufacturers of missiles and other military electronic equipments used variations of this system. Automation, or at least "methodizing", is being used quite extensively in assembling most forms of military, industrial and home-entertainment equipments [21]-[30].

Fig. 17—"Wheel of fortune" lazy Susan assembly fixture, a *methodizing* approach first used successfully about 1955 to assemble Matador IF strips (and other similar assemblies) at The Martin plant in Baltimore, Md.

Automation WITHOUT Printed Wiring—the Solderless Wrapped Connection

Printed wiring did not have an exclusive monoply on the application of automation. Mallina reported in 1956 that Western Electric had been using a punched-tape-controlled "wire-wrap" machine for several years. This machine wired complicated electrical circuits by means of a six-turn 29,000-psi "solderless wrapped connection," at the rate of 10,000 connections per hour. Three TV manufacturers were also using this method. Clevite-Brush and Keller Tool participated in its commercial development. Assembly for "wire wrap" could be accomplished by either automatic or manual means, provided that the component parts had suitable rectangular terminals. At that time 300,000,000 wrapped connections had been made without a single reject. In 1961 wire-wrap was being used in many assemblies of the Polaris weapon system.

Standardization, the Key to Automation

The success of automation using conventional components depends on *standardization* of the parts themselves, of the engineering layout dimensions and of the machines for their insertion. In recent years the Electronic Industries Association made considerable progress, through its committees, in the standardization of the parts. The United States Signal Corps and others promulgated specifications for the layout of conventional component parts. Other groups set up anvil dimensions and spacing for automatic insertion machines.

These brought us realistic automation with attending lower construction costs, but at a sacrifice of miniaturization goals. Ground-based equipment can afford the latter sacrifice in the interest of reducing assembly costs, but airborne computers, missile guidance systems and satellites can *not* afford to disregard miniaturization [31]-[37].

Miniaturization

Early Miniaturization Programs

Many of the early studies made before 1946 were augmented by new studies which incorporated utilization of automatic methods. Mallory disclosed packaging techniques for integrating five different types of prototype systems at volumetric efficiencies ranging from 2 to 12 per cent. These subassembly units were designed for automatic assembly. Hughes Aircraft has shown a well-integrated airborne digital computer. Other early studies were concerned with conformal coating of printed-wiring assemblies, eyelet failures, improvements in the methods of interconnections, and the use of flexible-printed cabling and flexible-printed assemblies. The studies of eyelet failure brought about the "funnel" eyelet design, and the plated-through hole [38]-[42].

The Miniature Module

In recent years numerous companies have been producing or using miniature modules assembled from conventional but smaller component parts. The new sizes were about as numerous as the companies concerned: Sylvania, Diamond Ordnance Fuze Laboratory, Martin, Ansley, to mention a few. More recently Burroughs, Amphenol (with its micromin connector in a modular package), and Republic have contributed new sizes and shapes.

The Welded Module

Intermediate between the miniature module and the micromodule in size and uniformity, the proponents of the welded module claim high reliability, basing their claims on vacuum-tube lead welding experience, where one failure in 7 million is attained. Francis Associates, Sippican, Raytheon and Litton are heavily engaged in producing welded modules, and others are building development models.

Project Tinkertoy

An attempt to develop realistic modules automatically was undertaken by the National Bureau of Standards for the Navy Bureau of Aeronautics. The NBS process was basically the same as that used by Sprague, Aerovox and Centralab as early as 1942 in building multiple-component plates. Notched steatite wafers, 7/8-in square by 1/16-in thick, were made right in the facility from raw materials. One to four component parts were placed on each wafer. Resistors were applied by an automatic printer. Another machine assembled and soldered four to eight of these wafers on to twelve riser wires to form a module. Other machines tested them automatically. All machines were tied together by an automatic conveyor, geared to produce 1000 tested modules per hour. Sanders Associates later applied the principle of stacked-wafer modules, using printed wiring, to the Navy's Sonobuoy and produced about 1800 units, using semiautomatic assembly methods [43]–[45].

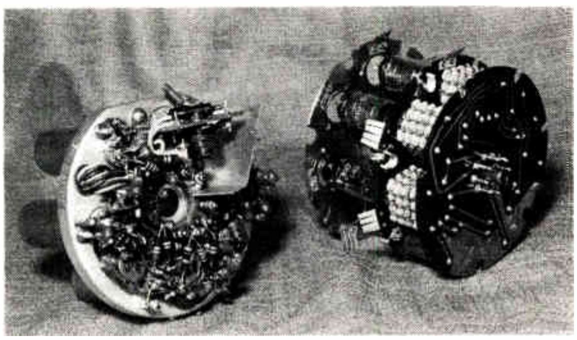

Fig. 18—Modularized Navy sonobuoy. At the left is one of the chassis of the original sonobuoy stacks. At the right is the sonobuoy after conversion to "Tinkertoy" modules by Sanders Associates (about 1955).

By the end of 1954, Project Tinkertoy had served its purpose as a large-scale evaluation program and the whole concept was released to industry to carry on. The construction of a second Tinkertoy facility was started at ACF Electronics, and a complete TV receiver was converted to a stacked-wafer module. ACF also delivered modules in production quantities to other radio and TV manufacturers. But in spite of this progress, it became evident in 1958 that the 7/8-in square stacked-wafer module would not become the standard packaging method of the future.

The Micromodule

In 1958 the RCA completed a study for the Signal Corps on how to microminiaturize functional electronic circuits using current process technology. The Signal Corps then asked industry to carry on, under RCA guidance, most of this followup going to component manufacturers who would change only the size and form factors. Deposition and solid-state approaches beyond the existing state-of-the-art were to be avoided. Size, weight (and cost) factors were required to be a full order of magnitude better than the current *best* techniques, and two orders better than the current *average* techniques [46], [47].

Early in 1961 resistors, applied to a wafer with a form factor of 0.310-in square by 0.01-in thick, were being built by a number of companies. Capacitors, inductors, transformers, diodes, transistors and other items were also being made available by many other companies. As in the earlier Tinkertoy project, twelve vertical risers are used. The integration of these wafers presents the same printed wiring problems, but with a smaller tighter-tolerance scale. Many types of circuit functions were commercially available, but at a cost about double that of more conventional assemblies.

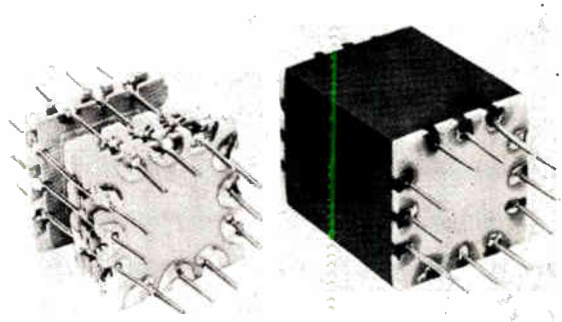

Fig. 19—Signal Corps-RCA micromodules—unencapsulated and encapsulated versions of about 1959. As you read this, there will have been 12 telephone-book size reports circulated to industry on this Signal Corps industry-wide program by RCA, the leading contractor.

Other Microminiature Form Factors

Paralleling this micromodule program of the Signal Corps, other programs were noted in 1961 using other dimensions. General Electric's TIMM program incorporated their ceramic wafer with heaterless tubes and other components to form a cylindrical stacked wafer 0.32 inch in diameter. Part densities reaching one million parts per cubic foot have been attained in functional circuits. An example was shown of a 1.25-in cube system having a density of 2,080,000 component parts per cubic foot after integration. Mallory has combined individual components into pellets of a height equal to the thickness of a printed-wiring board (0.062 in) and of various diameters from 0.100 to 0.25 in [48]–[50].

Integration of Micromodules

The repair of micromodules, when integrated by printed-wiring methods, is usually a difficult procedure, a particularly important problem when used in ground based equipment. Even when used in one-shot missile or satellite equipment, corrections or changes may be necessary. AMP's interconnection system of MECA seems to have answers to many of these problems for ground-equipment maintenance. IBM is using a 7090 computer to establish interconnections, but even without such a facility AMP claims a 25–30 per cent saving in design time [51].

Microminiaturization by Thin-Film Techniques

At present such essentially two-dimensional techniques are mostly in the development phase, but they are of such moment that they are receiving much attention. Development is underway in many places: Bell Laboratories, Sylvania, IBM, CBS, Sprague, Vare, Philco, Servomechanisms, Litton, IRE, Motorola, to name a few. IBM has built up to 17 layers on a 0.300-in insulating substrate. At present thin-film techniques are confined to passive elements (resistors, capacitors, etc.). Although active elements are at present difficult to duplicate, semiconductors grown in thin single-crystalline silicon layers from the vapor state offer promise. Many transistor manufacturers are now working on this phase of the process [52].

RCA and Philco have disclosed progress with evaporation approach. The Diamond Ordnance Fuze Laboratory, Westinghouse, Fairchild and Texas Instruments have completed such items as multivibrator switches, direct-coupled transistor circuits, video amplifiers, oscillators and other functional items.

The formation of laminar layers by vapor growth is another concept. Vare's deposition of vacuum-mixed metals from gaseous atomic forms represents a promising approach. Vitramon suggests a construction where a strata of solid particles of several layers of conducting, nonconducting and semiconducting materials would be fused to form a solid [53], [54].

Microminiaturization by Solid-State-Circuit Techniques

The term *microsystems electronics* has been used to cover many approaches and needs to be clarified for the solid-state-circuit condition. We refer here to either 1) *formed* solid-state circuits, 2) *grown* circuits, or 3) *electron-microscope* forming. The several techniques in microsystems have been given many names with many meanings—microelectronics, molectronics, nanocircuits, microminiature functional electronic blocks, and others.

"Formed" Solid-State Circuits: A number of companies (Texas Instruments, Pacific Semiconductor, and others) have worked independently in this field for several years and have produced operable devices. For example, a typical solid-state method starts with a silicon semiconductor wafer. An integrated single-crystal circuit is formed by a combination of mechanical surface shaping, diamond sawing, sand blasting, mechanical forming or etching, electron-beam machining, oxide and photoresist masking, diffusing, metallic deposition and evaporation alloying. Resistances are formed by the bulk resistance of a certain area in the silicon wafer, sometimes after antimony diffusion. Capacitors are produced by large area biased *p-n* junctions. Semiconductor devices are diffused onto the wafer, and leads are installed by welding, thermocompression bending or with a fusion furnace.

Here, as never before, production engineers work hand-in-hand with physicists in pioneering many radically new processes that may ultimately have wide applications in other fields as well.

"Grown" Solid-State Circuits: Westinghouse has developed for the Air Force functional blocks without using wired junctions or cementing of parts. Their approach used dendritic silicon and germanium providing an excellent surface for epitaxial growth. Motorola is also participating in this approach.

Electron-Microscope Forming: Stanford Research Institute is working on solid-state techniques that have possibilities for obtaining packaging densities more than a million times that of the others by using an electron microscope in combination with mechanical manipulators and molecular-beam etching and deposition equipment. The components have dimensions of about one micron, which makes possible the placement of an entire data-processing system with 10^{11} components in a cubic inch of volume [55], [56]!

Automatic Testing

This phase of the production problem has kept pace with the automatic production advances. Missile and satellite launching facilities are now packed with automatic checkout facilities. Manufacturers of all types of equipment are using forms of automatic testing, often programmed to handle complex tests by punched cards or tapes. Tubes can be tested automatically at the rate of 1800 per hour in one instance, going through twenty static and dynamic tests each [57]–[61].

Dynamics and Cooling

Considerable research on the theoretical aspects of heat-transfer and vibration problems has supplied product engineers with much useful information about the correct placement of parts and other means of alleviating effects of these and other hazards.

The literature will be of interest to those engineers who specialize in design for environment and reliability [62]–[69].

Audio-Visual Aids for Operator Training

During the last few years of the era, the production techniques of the previous decade were not only supplemented by automation for high-production items, but were given an important assist for small-lot production. An audio-visual-aid method is practiced by numerous factories, especially where few-of-a-kind type of production does not permit assembly-line techniques. Here each step of the work is described in a head receiver worn by operator while the particular point on the chassis referred to is projected on a convenient-sized screen. The slides advance as each step is completed. The operator does not have to learn any sequences in the assembly, as the instruction is repeated with every new chassis. Changes in the assembly require only the substitution of one or more new slides and accompanying voice and the replacement of the stock items involved [66].

Product Engineering and Production Techniques

A Challenge and an Opportunity

There is a great future for the product engineer and the production engineer. Since World War II, collegiate curricula for electrical engineering has stressed mathematical and theoretical concepts, physical concepts, and circuits. With such a background, any follow-up activity relating to the conversion of basic ideas and research developments into realistic equipment has been usually left to others. Developing and building the "hardware" has been considered to be unglamorous. The jobs of both the product engineer, with his attention focused on dimensions, tolerances, environments, and the like, and the production engineer, dealing only with machines, schedules, soldering irons, and other mundane matters, have appeared equally unglamorous.

Actually, this work now involves such a variety of specialized knowledge that future product and production phases can be very stimulating and rewarding. The opportunities afforded engineers who operate in these fields are very great, whether they do the initial planning and product engineering, or whether they follow up those designs which provide the articles of commerce that support research. Sales are now at levels reaching many billions of dollars a year, and this can be credited to no small degree to engineers who have created and produced equipment that is desirable to the customer. These engineers are expected to be conversant with a greater variety of skills than anyone else connected with the product, because each year brings forward new approaches to construction.

Whether modules should be repairable or "throwaway," which construction is the most versatile, and other similar matters, have not, and probably never will be, resolved. In any event, the modular-type construction, supplemented by solid-state circuitry, is clearly the main route to future construction. It is in this general area where engineers of our Professional Group will find both the greatest challenges and rewards.

Trends and Predictions

These predictions have been ventured because the panorama resulting from an intimate association with the past provides some vision of the future.

Items like television will undoubtedly use printed wiring and automatic insertion of conventional component parts for many years.

Satellites will use the micromodule and thin-film techniques as fast as they can be adapted. Missiles and giant computers will be only slightly behind satellites in this matter. Later, these techniques will be adopted by airborne electronics.

Printed wiring will get smaller and smaller as registration-capability and machining techniques improve, in keeping step with the availability of ever-smaller component parts.

Conveyorized automatic insertion of conventional component parts has already leveled off. Programmed insertion of conventional component parts may level off within the next 5 to 10 years.

The data-controlled assembly for the future is assured, but directed toward the fabrication of micromodules and other integrated circuit units for subsequent assembly into larger encapsulated units, in an integrated system.

Methodizing, just short of complete automation, will probably always be with us.

For production quantities of large systems, integration harnesses and cables will rapidly narrow down to the use of taper pins, wire wrap, or printed wiring. Flexible printed wiring and flexible printed cables will come into greater usage.

Conventional components may ultimately disappear (20 years?), but they will gradually be reshaped into modular versions.

The micromodule will make great impact on electronic production in a few years, having greater industry support than earlier modular schemes, and having some fifty times the earlier packaging density. However, one or two other promising micromodular concepts will compete with the micromodule during the next ten years.

Integration, cabling, connectors, and reliability will continue to be a major problem—probably indefinitely.

Until the relative reliabilities of the thin-film and the micromodule have been firmly established, it will be hard to predict whether or not the micromodule substrate dimensions will be extended to thin-film techniques. If thin-film reliability turns out to be equal to speculative figures, possibly some multiple of the micromodule dimension may be established, perhaps 2- to $2\frac{1}{4}$-in square. Semiconductor techniques for thin films will anticipate strictly solid-state methods for production units by several years.

Formed solid-state circuits will appear in production quantities by 1968, *grown* solid-state circuits by 1970, and *micron-sized* circuits by 1972, developed using Shoulders' "quantum mechanical tunneling of electrons" principle, or the like.

Automatic testing will continue to expand, and will be supplemented with many computer-controlled functions.

Following another decade of progress, an electronic system will be produced by a truly automatic factory, "engineered" on the typewriter keyboard of a master computer which will create a master memory, representing the desired equipment, from countless standard functional-circuit memories reproduced from its storage. This master memory will then requisition the more common functional devices from an automatic stock-room, and will automatically perform any missing deposition or other necessary operations of integration. The final result will be the desired electronic system which passes all tolerance and functional tests at all levels—from the component-part equipment to the complete equipment.

RADIO FREQUENCY INTERFERENCE

Organized with the assistance of the IRE Professional Group on Radio Frequency Interference

Evolution of Regulatory Standards of Interference*

E. W. ALLEN, JR.†, FELLOW, IRE, AND H. GARLAN†, MEMBER, IRE

Summary—This paper traces the development of interference regulations from the original requirement that waves be pure and sharp to the present complex formula for attenuation of spurious emissions. It also shows how different philosophies of regulation developed. In broadcasting, the regulations grew up around the concept of a "protected service area." In the communication service, on the other hand, regulations developed in the direction of limiting the bandwidth and confining emissions within the authorized band.

The paper also traces the history of ISM regulation with its philosophy of assigned frequencies on which unlimited radiation is permitted with an associated requirement for severe limitation of radiation on other frequencies. It also discusses the "low-power rules" which establish the conditions under which low-power equipment may be operated without becoming a source of interference. The paper describes briefly the voluntary work in this area by industry, and touches on local regulations concerning interference.

Introduction

THE HISTORY of the regulation of radio interference is essentially the history of the regulation of radio itself. Many of the operating regulations and a substantial part of the technical regulations had as their basic objective the elimination or the control and the prevention of radio interference. The very first international agreement—the Final Protocol signed at the Berlin Conference in 1903—contains a provision in Article 5 that services be organized in such a way as to avoid interference with other stations [1]. This principle was carried over into the Convention drawn up and signed at the Berlin Conference in 1906, and was incorporated in legislation in this country in 1912.

The first radio law passed by the U. S., the Wireless Ship Act of 1910 (36 Stat. 629), required certain ocean-going vessels to be equipped with "an efficient apparatus for radio communication, in good working order, in charge of a person skilled in the use of such apparatus." This act did not impose any technical regulations beyond requiring the apparatus to be capable of transmitting and receiving messages over a distance of a hundred miles, day and night.

The earliest legislation providing in some detail for the technical regulation of radio was "An Act to Regulate Radio Communications" (37 Stat. 302), adopted on August 12, 1912. This act, which implemented the Berlin Convention of 1906, established a licensing procedure for stations and operators and set out specific technical regulations for radio stations. It provided that every license state the wavelength or wavelengths authorized for use by the station for the prevention of interference; it provided for the use of "pure" waves by requiring that, where energy was radiated on two or more wavelengths, "the energy in no one of the lesser waves shall exceed ten per centum of that in the greatest"; it required the use of "sharp" waves by specifying a maximum "logarithmic decrement of two-tenths" except when sending distress signals; the operator was required to listen on the channel before transmitting; he was required to use the minimum power to provide communications.

* Received by the IRE, August 18, 1961.
† Federal Communications Commission, Washington, D. C.

The subsequent approach to the control of interference between radio stations has consisted in a continued emphasis on proper operating procedures which promote time and geographical sharing, in refinements of the initial requirements as to purity and sharpness of waves, and in the development of new requirements as new concepts, new systems, and new techniques have evolved. The old requirement for purity, that no one of the lesser waves exceed 10 per cent, has long been obsolete. Purity of waves is now specified in terms of the required attenuation of spurious, including harmonic, components. Present requirements limit spurious emission at discrete frequencies to fractions of 1 per cent and permit no more than 1 per cent of the total radiated energy to be outside the assigned band. As the earlier use of damped waves (type-B emission) gave way to continuous waves, the sharpness became defined as bandwidth rather than in terms of decrement. The authorized wavelength has changed to assigned frequency upon which continually stricter tolerances for frequency stability are placed.

Although the useful radio spectrum has been expanded many fold during its history, the uses and demands for this spectrum have increased at an even faster rate. Thus there is continued need for ever stricter requirements, both operational and technical, to improve the effectiveness of spectrum use. As new techniques have been devised, they have in general been adopted at national and international levels as rapidly as is economically feasible. The improvement in radio techniques is reflected in the provisions of the Radio Regulations developed at Geneva in 1959, and now being adopted by countries which are signatory to the International Telecommunications Union. Of particular interest are the definitions in Article 1, Section III, and the tables in Appendices 3, 4, and 5 of frequency tolerances, spurious emissions, and bandwidths.

However, the specific figures for frequency tolerance, for spurious radiation, and for bandwidth do not of themselves insure noninterference. While the International Radio Regulations and the FCC Rules require compliance with these limits, the specific figures must be considered basically as design parameters for insuring good practice in the design, manufacture, and use of equipment, in order to minimize the probability of interference. These limitations must in every case be buttressed by a further requirement to take additional measures in the event that harmful interference is caused. The controlling requirement is that the interfering radiations be reduced to the point where well-designed and properly operated equipment can perform satisfactorily in its actual environment.

Improved frequency utilization by the reduction of assigned bandwidth is a concept which has long been emphasized. More recently it has been recognized that this practice does not always make for the optimum spectrum usage. Transmission systems using frequency modulation and pulse-code modulation provide improved systems performance, including discrimination against noise and interference, albeit at the expense of increased bandwidth. Improved discrimination against interference permits greater geographic sharing of frequencies, thus making possible increased frequency utilization. It is necessary, therefore, in each case to weigh the advantages of these improved transmission systems with their need for increased bandwidth against the benefits to be derived from the arbitrary reduction of bandwidth.

A second aspect of frequency usage, which is not apparent on its face and which has been developed over the years, is that increased spectrum usage in some services can be obtained by not providing protection against interference from other stations out to the maximum range at which the signal might otherwise be useful. In domestic broadcasting, duplication of assignments is intensive and neighboring assignments are generally so spaced geographically that service range is more severely limited by station interference than by receiver sensitivity or by other sources of interference. The limits of permissible interference are set in terms of protected contour of field strength and desired/undesired signal ratios, or an estimated protection is given by a table of minimum mileage spacings between stations.

Broadcast Services

The first broadcast rules issued by the Federal Radio Commission during the period 1927–1931 provided for the control of interference between stations by taking into account frequency separation, frequency tolerance, power, and geographic spacing of transmitters. Clear, regional and local channels were established, as well as the 10-kc channel spacing. On the recommendations of the IRE Committee on Broadcasting [2], a 500-cps frequency tolerance was established initially, followed by a reduction to 50 cps in 1932, when a minimum modulation requirement of 75 per cent was also imposed. Although the Committee had recommended a limit of 5 per cent and the need for control of harmonic radiation had been recognized [3], no limit for spurious, including harmonic, radiation was imposed at that time.

The approach to station assignment was changed in 1932 following the development of reliable groundwave and skywave propagation curves, ground conductivity maps, signal ratios, and information on urban and rural noise levels [4]. The field-strength and atmospheric noise-recording program inaugurated for this purpose in 1936 by the FCC was extended in 1938 and has continued until recent years. In 1946–1947 further tests on signal ratios and on urban noise were made by joint FCC-Industry committees in the clear-channel proceeding.

In FM and television broadcasting also, protection against station interference has used both the protected contour method and the mileage separation method at different times. These methods have been supplemented by channel allotment plans, in which specific channels are listed as available for station assignments in each city. These plans are developed in rule-making proceedings, in which interested persons may comment on the rules proposed by the Commission, and they may be supplemented by rules for the relatively simple procedures involving mileage separations or the more complex rules using signal ratios, propagation curves, etc. In general, in these two services, interference protection is afforded by the specification of minimum mileage separations for co-channel and adjacent-channel stations. In the UHF television rules, additional mileage separation requirements are imposed to protect against interference from receiver oscillator radiation and the spurious responses of receivers due to images, intermodulation, etc. Propagation curves and required field strengths and field-strength ratios are specified in the regulations for the purpose of estimating the location and extent of urban and rural service, so as to assist in decision-making processes, rather than for the purpose of providing specific protection to the service so indicated.

Specific limitations on spurious emissions were not included in the broadcast rules until 1953, when a limit of 60 db was imposed on TV stations [5]. Limits for AM and FM stations were imposed in 1959 [6], which provide for suppression of spurious emissions in accordance with a formula (more fully discussed below) which essentially limits the radiation of spurious emission to an absolute level of 50 microwatts.

Communication Services

In contrast to broadcasting, where regulations to minimize interference took the form of developing the concept of a protected service area, an entirely different concept of interference control grew up in the communications services. Since many of these services operate intermittently, it is feasible to assign more than one station to the same frequency for communication over the same, or overlapping, ranges. Accordingly, interference regulation was directed toward improving time-sharing of assigned frequencies. The early regulations required "monitoring before transmitting" (Parts 7 and 8), or "cooperation in the use of frequencies so as to avoid interference" (Parts 10 and 11). Stations were also required to reduce emissions outside the authorized band and to suppress spurious emissions, including audio and radio harmonics, to the "lowest practical level."

After World War II the enormous demand for radio stations in the communications services made it clear that more rigid control over spurious emission would be necessary. Accordingly, in 1947 the FCC proposed [7] that all emissions of land mobile stations outside the authorized band be attenuated at least 60 db. The comments received persuaded the FCC to dismiss this proceeding and to issue a new proposal [8] in June, 1948, which recognized that out-of-band components near the carrier require different treatment than harmonics and other emissions far from the carrier. In this new proposal, which did not apply to sideband components arising from frequency modulation, the required attenuation varied from 40 to 80 db depending on power. This regulation was seeking to provide essentially the same absolute power level for harmonic radiation from all transmitters. These rules became effective on July 1, 1949.

In 1950 spurious limitations were proposed for radiotelephone transmitters above 30 Mc in the maritime radio services [9] in which emission lying between 50 and 100 per cent of the authorized bandwidth removed from the carrier would be attenuated 25 db, and emission falling outside of this band would be attenuated from 40 to 80 db. In this proceeding the FCC also introduced a control technique, type acceptance of transmitters; however, this program was not fully formalized until January 5, 1955, when, in connection with type acceptance for the land mobile services, rules were promulgated [10] specifying in detail tests to be made and the information to be submitted. However, these limitations for spurious emissions were still not satisfactory. The transition from 25 db at 100 per cent of the bandwidth on each side of the carrier to 40–80 db was too abrupt, and the attenuation table included a number of discontinuities.

The first action to eliminate the discontinuities in the attenuation table was taken in 1954, in the rules to add spurious emission limitations for AM and FM broadcast stations [6] which substituted a formula ($50+10 \log P$) for the table. This formula implied an absolute level of harmonic radiation of 10 microwatts. In 1956 the formula was changed to $43+10 \log P$, based on a 50-microwatt level of harmonic radiation, when type acceptance and spurious emission limitations were added to the aviation radio services [11].

In the same year the FCC undertook to review the requirements [12] for out-of-band emissions close to the carrier for all its services. The first order in this proceeding, dealing with ship radio stations, established a three-step requirement by adding a step covering the range 100 to 250 per cent of the authorized bandwidth removed from the carrier. In this range spurious emissions must be attenuated 35 db. This three-step requirement was subsequently applied to maritime stations on land (Part 7) in 1958, to AM and FM broadcast stations in 1959, and to most aviation stations (Part 9) and land mobile stations except domestic public (Parts 10, 11, and 16) in 1960. Action to apply this requirement to the Domestic Public Land Mobile Service (Part 21) is still pending.

Industrial, Scientific and Medical Equipment

The first complaints of interference from equipment which we now group as ISM arose about 1930 when doctors started to use medical diathermy equipment [13]. Since these equipments operated on frequencies between 4 and 25 Mc, interference was particularly troublesome on long-range, point-to-point radio circuits. For the same reason, the interference from diathermy apparatus was experienced at distant points. Reviewing the background of the diathermy interference problem in 1940 [14], E. K. Jett, then Chief Engineer of FCC, reported that a diathermy machine keyed as a transmitter in Boston had been read in Washington, D. C., and at the FCC Monitoring Station at Great Lakes, Ill. Similar observations had been reported by Canada [15] in 1937.

The problem of diathermy interference was considered at the First [16] and Second [17] Inter-American Radio Conferences. The agreement drawn up at the Second Conference urged the participating countries to adopt standards of good engineering for diathermy apparatus.

Although the FCC had been aware of diathermy interference essentially since its inception, and had made a detailed investigation in 1937, it did not come to grips with this problem until 1939 when a conference [18] was held to bring this matter to the attention of the medical profession and the manufacturers of electromedical equipment. A second conference [19] was held in 1940 to implement the Santiago recommendations. Further work on standards for diathermy machines was interrupted by World War II. During the war, diathermy equipment was required by FCC Order No. 96 (May 18, 1942) to be registered to forestall its use for espionage and subversive purposes, since it was known that radiation from diathermy apparatus was capable of being received at great distances.

The question of frequency space for diathermy and industrial heating applications was raised in the allocation proceedings [20] in 1944–1945 when evidence was presented to show the importance of RF heating and that the number of installations and the amount of RF power used was increasing at a startling rate. The importance of diathermy as a therapeutic tool and in surgery was reiterated.

In the face of the demands of the industrial and medical interests for the allocation of large segments of the spectrum and of the conflicting demands of radio users for additional channels for communications and for protection against industrial and diathermy interference, the FCC in 1945 allocated [21] three frequencies—13.66, 27.32, and 40.98 Mc [22]—for medical and industrial purposes, which came to be known as the ISM frequencies. With this action, the FCC took the first step to implement the philosophy that had been suggested at the 1940 Santiago Inter-American Conference, that is, to provide frequencies on which unlimited radiation would be permitted and to prescribe severe limitations on radiation on other frequencies. This philosophy, however, was not specifically enunciated until the FCC adopted Part 18 of its rules in 1947. The same philosophy was accepted internationally in 1947 at the Telecommunications Conference at Atlantic City, N. J. The international frequency allocation adopted at this conference set aside three frequencies—13.56, 27.12, and 40.68 Mc—for industrial scientific, and medical purposes, and required communication circuits operating on these frequencies to accept any ISM interference that may be received.

An engineering conference held in 1946 to discuss standards was followed in 1947 by the adoption of Part 18 of the FCC rules [24]. The rules for medical diathermy equipment were essentially the standards that had been discussed at the 1946 Conference. It is interesting to note that FCC engineers had to build a diathermy machine to prove to industry that it was possible to comply with these rules at a reasonable cost [23]. However, Part 18 also included regulations concerning industrial heating equipment which were new. These rules called for operation on the ISM frequencies allocated previously, and imposed a limitation on radiation on all other frequencies. As a control mechanism the rules provided for type approval of equipment that operated on ISM frequencies and required certification of all other equipment. Although changes have been made from time to time, the basic philosophy and the basic limits—25 μv/m at 1000 feet for medical diathermy equipment and 10 μv/m at one mile for industrial heating equipment—have been retained [25].

Several changes are worth noting. Microwave frequencies were allocated [26] for ISM purposes in 1947, although they were not added to Part 18 until 1956 [27]. In 1948 the ISM rules were extended [28] to encompass other equipment "in which the action of the RF energy is directly on the work load," later changed to "in which the action of the RF energy is applied to materials to produce physical, biological or chemical effects." Separate and more severe provisions were promulgated in 1955 for RF equipment used to generate ultrasonics [29]. The radiation limits for industrial heating equipment were extended [30] into the microwave spectrum (up to 5775 Mc) in 1957. The most recent action (1961) promulgated [31] a standard form (FCC Form 724) to be used in certifying industrial heating equipment as a step toward tightening up the control mechanism over radiation from such equipment.

Low-Power Rules

At the same time that the FCC was struggling with the problem of diathermy interference, a second source of interference came to its attention. Early in 1938 the Philco Radio and Television Corporation placed on the market its Mystery Control, a miniature transmitter remote-control device for its standard broadcast receivers, in the belief that it could be operated without a radio station license. In view of the probability that similar devices would be developed and sold by other manufacturers and that these devices—esentially miniature transmitters—could develop into a serious interference problem unless adequately controlled, the FCC re-examined its position regarding licensing of low-power RF devices.

After a careful study the Commission came up with a proposal [32] to permit the operation of low-power devices without a license on the premise that devices that complied with the proposed standards would not be a source of interference to interstate communication and were therefore not subject to licensing. These rules came to be known as "The Low Power Rules." In addition to requiring the use of minimum power and precautions against interference, these rules required the radiated field to be limited to 15 μv/m at a distance equal to the wavelength divided by two pi ($\lambda/2\pi$). This regulation is often referred to as the "lambda over two pi rule." Much was made of the difference between the induction and radiation fields as justifying the use of $\lambda/2\pi$. The rules were adopted on November 21, 1938, essentially as proposed, and remained in effect for low-power communication devices until 1957. These rules are still in effect for campus radio and other carrier current systems.

The expansion in the use of radio after World War II brought with it an increase in use of low-power devices. But of more significance it brought a demand for use of frequencies above the broadcast band where the $\lambda/2\pi$ formula rapidly became meaningless. Accordingly, on April 13, 1949, the FCC instituted a proceeding [33] looking toward an over-all revision of Part 15, "The Low Power Rules."

The comments received in reply to this proposal indicated that comprehensive studies of the technical and economic aspects of the proposed regulations were necessary before any regulations were put into effect. Such studies were made by joint government-industry committees. On April 14, 1954, a Notice of Further Proposed Rule Making [33] was issued, in which the FCC divided the devices into two categories: incidental radiation devices in which the RF energy is generated as a by-product of normal operation, and restricted radiation devices in which RF energy is generated deliberately. The proposed rules contained a table of field strengths that increased with frequency. These limits were essentially the lowest practical values of radiation that the manufacturers of TV receivers were able to achieve [34]. This second notice also introduced a specific control procedure, certification, which the FCC borrowed from its ISM rules.

The comments received to this proposal were generally unfavorable except with respect to receiver radiation. Since the latter was the most pressing problem, the FCC finalized its receiver rules on December 21, 1955, and established a table of permissible radiation limits for all receivers operating (tuning) between 30 and 890 Mc. These rules provided a conducted interference limit (RF voltage into the power line) on frequencies below 25 Mc and a radiated field strength limit between 25 and 1000 Mc. These limits with two minor changes are currently in effect [35]. As a control mechanism, the rules require certification and permit each certificated receiver to be so labeled.

A second report and order in Docket No. 9288 was issued in 1956 to promulgate limits [35] for radiation from community antenna television systems, a type of carrier current system for the distribution of television programs. Rules for low-power communication devices—essentially miniature transmitters—were adopted in 1957 [36]. The FCC retained its $\lambda/2\pi$ formula recast in a new form as (2400/F) μv/m at 1000 feet for the frequencies 10 to 490 kc, and as (24,000/F) μv/m at 100 feet for 510 to 1600 kc. These rules also permitted use of the ISM band at 27.12 Mc with a power input of 100 milliwatts and a 5-foot antenna. To accommodate the maufacturers of radio controllers for garage door openers, the rules also permitted the use of frequencies above 70 Mc with radiation limited to the value permitted for receivers and subject to a duty cycle limitation of one second on in thirty seconds.

As of the date of this writing, action has been taken only in three categories of devices: radio receivers, community antenna television (CATV) systems, and low-power communication devices. All other restricted radiation devices are still subject to the original "$\lambda/2\pi$ rule" and the various proposals to modify this rule which are contained in FCC Docket No. 9288.

Interference Contributions by Industry

While this paper is written principally from the viewpoint with which the authors are most familiar, government regulation of interference, the extensive contributions of industry [37]–[41] must not be overlooked. These contributions take two forms: 1) Industry has developed a number of voluntary standards for the control of interfering radiation, most prominent of which are the SAE standard for ignition interference [42] and the NEMA standards for electrical equipment [43]. 2) A large part of the information on which industry-adopted limits and governmental regulation are based is derived from work carried on in private laboratories or by industry and joint government-industry committees. Space does not permit a delineation of this work, but this discussion would not be complete without mention of the more important committees such as: the Joint Coordination Committee of the NELA, NEMA, and RMA; SAE Vehicular Radio Interference Subcommittee; ASA Committee C-63; the many IRE committees, such as the committees on Broadcasting and Wave Propagation; the AIEE Subcommittee on Induction and Dielectric Heating; the National Television Systems Committees for monochrome and color television; the Radio Technical Planning Board for the post-World War II expansion of radio uses; the Joint Technical Advisory Committee (JTAC); the Radio Technical Commission for Marine (RTCM); the Radio Technical Commission for Aeronautics (RTCA); the International Radio Consultative Committee (CCIR); and many special committees such as the Ad Hoc Committee for FM and TV, and the Clear Channel Broadcast Committees. The reader is referred to the proceedings of the above committees for details of their contributions to the many facets of interference regulation and control.

Local Governmental Control of RFI

No discussion of interference regulation would be complete without mention of the ordinances that have been enacted by many communities toward the control of radio noise and other interference stemming from the police powers of the community to abate a public nuisance. These ordinances are primarily directed against interference to broadcast reception. The FCC has helped the National Institute of Muncipal Law Officers (NIMLO) to prepare a model ordinance in the interest of promoting uniformity in local regulation. These ordinances basically provide a field-strength limit with penalties for failure to comply. While legally simple, this approach involves many difficult technical problems; one of the most difficult of these is the problem of making reliable measurements. Inability to solve these problems within the means of the local community is undoubtedly one of the major reasons for the lack of success of this approach.

Radio Frequency Interference Measurements and Standards*

HAROLD E. DINGER†, FELLOW, IRE

Summary—**Radio frequency interference has been a particularly difficult area for achieving effective standardization, principally because of technical considerations, but also because it is of concern to so many interests and activities. Prior to World War II, standardization efforts were mainly confined to the medium-frequency broadcast band. During the war it became evident that the problem must be considered on a much broader basis. More recently, highly critical systems being used in space research have placed additional requirements on system engineering for interference-free operation. Radio frequency interference can mean the difference between success and failure of a costly space project.**

There are four general categories in which standardization efforts are required: 1) terms and definitions, 2) measurement methods, 3) instrument characteristics, and 4) interference limits. Various professional, industrial, and governmental organizations are working at both national and international levels on standards in these areas.

Introduction

Reaching agreement on any standard is often a long and controversial process, but radio frequency interference (RFI) has proved to be an exceptionally difficult area for effective action. There are a number of reasons why this is so:

1) Most radio noise voltages are of such a nature that they are difficult to specify and measure. They may be periodic or random. They may be narrow band or broad band. The waveform of ignition noise or a radar pulse is greatly different from that generated by a motor or a gas discharge device.
2) The range of levels encountered (the ratio of peak-to-average values of a radar signal or the ratio or the fundamental-to-harmonic power of a transmitter output) requires a large dynamic range, good sensitivity, and good instrument shielding. Direct-reading instruments are usually desired, and this introduces problems concerned with logarithmic vs linear scales and with attenuator design. The problem is further complicated by bandwidth considerations.
3) Specified limits for the interference voltage to be measured are usually quite low, which means that ambient radio noise levels can prevent measurement unless shielded enclosures are used. This is not always possible, as in the measurement of radiation from high-tension lines, for example. The use of shielded enclosures introduces other problems, both technical and economic.
4) Antenna considerations such as size, tuning, directivity, antenna factor, impedance matching, near-field effects, and bandwidth become complicated because of the wide frequency range required, particularly if the antenna is to be used in shielded enclosures.
5) Portability is desired for field measurements. This introduces problems of weight, size, power source, and provision for calibration—all demanding compromises.
6) RFI may be propagated by radiation, induction, or conduction, each of which requires special measurement techniques and specifications.
7) The subjective effect of interference varies with the kind of system affected. An interference that would disrupt television reception might not affect certain radar devices, even in the same part of the spectrum.
8) Many different groups are interested in standardization of radio frequency interference instruments and techniques, and they place different emphasis on certain requirements. Some groups are interested in the complete spectrum; others are interested only in broadcast and television services. Some groups are primarily interested in only one form of interference, others in all forms. Some are interested as manufacturers or users of interference-producing devices, others as manufacturers or users of devices subjected to the interference.
9) Considerable technical skill is required. This is not always readily available.
10) The economic aspects of the problem are often difficult to resolve. If, in order to meet the requirements of several different contractors, a single device must be measured in accordance with several different measurement standards for compliance with several different limit specifications, the cost of such tests can easily be a major factor in determining the selling price. This is, of course, in addition to the cost of any interference-reduction measures required.
11) There has been a tendency in some quarters to downgrade radio interference work, with the implication that this field is rather routine and does not challenge the efforts of the ablest engineers. Fortunately, this attitude is now less prevalent since the complex and many-faceted character of RFI problems is becoming dramatically apparent.

* Received by the IRE, July 5, 1961.
† U. S. Naval Research Laboratory, Washington, D. C.

To attempt a discussion, or even a brief mention, of all the various technical aspects of the radio frequency measurement problems that have been injected into standardization deliberations would require more space than is available. Nor is it practicable to discuss all of the current standards and specifications; what is current at the time of writing may be obsolete by the time of publication. Rather, an attempt will be made to outline the historical development along this line in a general way and to indicate current trends. Since the development of instrument specifications and measurement standards has been interrelated, they will, in general, be treated concurrently. The references will furnish more detailed information in the various areas treated. Frequency allocation questions are not under consideration here, although they constitute one of the major problem areas.

Radio Noise Parameters

One of the first things to be decided in radio noise measurement standardization is what parameter or parameters of the radio noise voltage should be measured. There are several choices: 1) average value, 2) effective value, 3) peak value, 4) a quasi-peak value, or 5) certain statistical distributions. Each of these has been used at one time or another. These parameters are not necessarily uniquely determined since they are influenced by the receiver bandwidth in a manner that varies with the type of noise. Sometimes measurements are desired in terms of power, and frequently the end result will be in the form of a signal-to-noise ratio. The ideal arrangement would be to have one instrument specification, one measurement standard, and one limit specification. Attempts have been made to achieve this, but it turns out that different objectives require the measurement of different parameters. For example, a world-wide program for measuring atmospheric radio noise uses different parameters than those generally used in measuring the interference created by a radar transmitter or an ignition system.

A condensed topical outline of the various sources of radio interference and certain receiver characteristics that must be considered in an over-all RFI measurement or standardization program might appear as follows:

1) Transmitters (including Industrial, Scientific, and Medical)
   a) Co-channel
   b) Adjacent channel
   c) Harmonic
   d) Spurious
   e) Intermodulation
2) Receivers
   a) Selectivity considerations
   b) Cross modulation
   c) Intermodulation
   d) Image response
   e) Hum
   f) Tube and thermal noise
   g) Radiation from receiver circuits
3) Atmospheric radio noise
4) Precipitation static and Corona discharge
5) Extraterrestrial radio noise
6) Man-made (from electrical and electronic devices of many kinds).

It is generally desired to measure these sources in order to determine their interference capabilities to other radio services, but in some cases it is necessary to determine the extent to which they are a hazard to the human body or to the safety of combustibles or explosives. In addition, undesired emissions from receivers and man-made sources can also endanger military security. In general, each of the above kinds of interference requires its own method of specification and measurement.

Prior to World War II the principal RFI standardization efforts were almost entirely confined to the medium-frequency broadcast band of radio frequencies. The first attempts at radio noise measurement were in terms of "nuisance value," and since the primary concern was of broadcast interest, the nuisance value was determined subjectively by listener tests. However, there are now many types of signal display devices, and nuisance value has become rather meaningless. Even in listener tests it was not unique since there was considerable disagreement in its determination. A completely objective system of measurement would require the use of a prohibitively large number of parameters; thus, some form of compromise is essential.

Early History—Some RFI Firsts

The first case of man-made interference that has come to the author's attention was that mentioned in the "Reminiscences" of Dr. A. Hoyt Taylor, a Past President of the IRE, who recalls hearing ignition interference from a two-cylinder automobile driven by R. E. Olds in Lansing, Michigan, in the year 1902. Serious transmitter interference was reported during the press coverage of the International Yacht Races in 1901, and again during the Russo-Japanese War in 1904. The first IRE paper devoted to radio noise elimination was published in 1917,[1] and the first on radio noise measurement in 1921.[2] A paper on electromagnetic shielding appeared in 1925.[3] From 1926 on the general problem of radio interference began to receive increased attention from a limited number of investigators.

The first attempt at standardization of radio noise measurements was made by the Joint Coordination Committee (JCC) on Radio Reception of the Edison

Electric Institute, the National Electrical Manufacturers Association, and the Radio Manufacturers Association. This committee was organized in 1931 and published a report[4] in January, 1933, in which certain desirable characteristics for a radio-noise meter were specified. The first meter designed expressly for radio noise measurement appeared in the same year,[5] but it was not suitable for impulse-type noise. The first radio noise meter employing a weighted response circuit was probably one built by the Central Electrical Laboratory of Belgium in accordance with specifications published by the International Special Committee on Radio Interference (CISPR).[6] This was followed shortly by a British model. Neither of these instruments were available in quantity, however. In 1938 an American meter incorporating the recommended CISPR time constants was put on the market.[7] In May, 1939,[8] and February, 1940,[9] certain U. S. interests recommended a change in the time-constant values of the weighting circuit and specified other desirable characteristics. In March, 1940,[10] a meter incorporating the new specifications was described. Some of the papers cited above also discussed early attempts at standardization of measurement methods. A more detailed account of the above developments has been treated by Burrill.[11] Several thousand radio noise meters have been manufactured in accordance with the 1940 specifications.

During World War II the frequency range of interference measurements was extended, but otherwise the same instrument specifications and measurement methods were generally used. The military services set up accelerated interference-reduction programs which began to consider some of the problems brought about by the introduction of new and complicated electronic systems, but the available manpower was generally limited to using available instruments and techniques on specific interference-reduction projects. It became apparent, however, that a more objective type of measurement was required. The use of pulse systems and visual display devices called for a reappraisal of the noise parameters to be measured. Measurement accuracy and repeatability left much to be desired, and since meters built to the same specifications often gave different results, the existing specifications were apparently inadequate. In the meantime the American Standards Association War Committee on Methods of Measuring Radio Noise had cooperated with the Armed Forces in the development of a uniform method for the measurement of the conducted interference and the interference field intensity produced by many kinds of electrical equipment being furnished for military purposes. This became known as Joint Army-Navy Specification JAN-I-225, and American War Standard C63.1-1956. It was dated June 14, 1945 and approved August 6, 1946. It became the first widely used standardized RFI measurement technique, but because of rapid advances in radio technology, it was soon supplemented or replaced by more specialized requirements.

Post-War Efforts

During the war some of the factors affecting the accuracy of radio noise meters had been noted, but little effort could be spared for systematic study. Immediately after the war these problems began to receive attention in government laboratories[12] and universities.[13] The frequency range of interference-measuring instruments was extended, both upward and downward, and new measurement specifications were issued by various agencies. The general radio interference situation as it appeared in 1954 was reviewed in a report by staff members of a prominent trade journal.[14] A survey of RFI instrumentation currently in use is given by Haber and Showers.[15]

In the meantime several organizations had been working on standards. There are four general categories in which radio frequency interference standardization is required:

1) terms and definitions,
2) measurement methods,
3) instrument characteristics,
4) interference limits.

The following organizations have issued specifications or standards in one or more of the areas of interest:

1) Military (Army, Navy, Air Force, Department of Defense),
2) FCC,
3) American Standards Association (includes representation from industry, universities, government, and professional organizations),
4) Professional societies (IRE, AIEE),

5) International organizations (CISPR, CCIR, URSI),
6) National organizations in other countries.

Several agencies that were working in this area during the war or immediately thereafter have ceased to exist, such as the National Defense Research Committee (NDRC) and the Research and Development Board (RDB).

As previously mentioned, the first radio interference standardization was attempted in 1931–1933, by a group of industrial organizations (JCC). The first report issued by the International Special Committee on Radio Interference (CISPR) was that of a meeting held in Paris in June, 1934. This group was formed as a special committee of the International Electrotechnical Commission (IEC) for the express purpose of reaching international agreement on radio interference standards. Except for the war years, the CISPR has been meeting more or less regularly since 1934 and has issued a number of reports[16] containing recommendations for specifications on instruments, methods, and limits.

The American Standards Association (ASA) Committee on Radio-Electrical Coordination (C-63) was organized under the sponsorship of the Radio Manufacturers Association. During the war it was redesignated the War Committee on Methods of Measuring Radio Noise. In addition to working on American Standards, this committee (now sponsored by the National Electrical Manufactuers Association) is in effect the group that, working through the U. S. National Committee of the IEC, represents the United States for cooperation with the CISPR.

Also working in the international radio interference field are the International Radio Consultative Committee (CCIR)[17] and the International Scientific Radio Union (URSI).[18] The CCIR makes recommendations to the International Telecommunications Union (ITU) which is charged with the international control of radio communications. The URSI is a purely scientific organization which enters the picture only from the viewpoint of international cooperation in scientific research programs. A chart showing some of the interrelationships among these organizations is given in Fig. 1. In general, excellent coordination of effort is being achieved among these groups.

The professional societies of the IRE and the AIEE are concerned with standards in their respective fields of interest. The IRE has several committees and subcommittees charged with producing standards in terminology and methods of measurement. The AIEE has been concerned with methods of measuring radiation

from radio frequency heating equipment, or more generally, equipment falling in the industrial, scientific, and medical categories. This category is subject to regulation by the FCC, which is itself concerned with measurements to insure conformity with its rules and regulations. In practice, these various groups work together very closely with some overlapping memberships on the various committees dealing with radio interference.

In 1957 the IRE Professional Group on Radio Interference was formed. This group co-sponsors radio interference conferences such as those held annually at the Armour Institute of Technology, and also holds annual symposia on current RFI topics. In addition, it publishes a TRANSACTIONS and a *Newsletter*, and in general provides an excellent medium for the exchange of ideas and for inciting action toward better measurement and control of radio frequency interference.

It has not been possible to make mention here of all the RFI standardization activities occurring in other countries. Reference to much of this work can be found in the CISPR reports.[16]

It may appear that the RFI problem has been plagued by too many organizations attempting to set up standards in the same field, but, as pointed out in the Introduction, this situation occurs because of the widespread need for standards which are technically difficult to attain, resulting in numerous attempts to achieve a measure of standardization in specific areas. Each organization has had its own field of interest and its own

sphere of action. In general, the various efforts have been well coordinated and progress has been made. Nevertheless, much remains to be done.

Current Trends

The Department of Defense has recently embarked upon an extensive program referred to as Electromagnetic Compatibility. This program entails new specifications and standards as well as some rather complex and sophisticated measurement techniques. A facility called the RFI Analysis Center has been established at Annapolis, Md., which will collect and analyze spectrum signatures of both new and existing electronic equipments and systems. The proper analysis of the spectrum signatures for all equipments to be used in a particular electronic environment should permit the prediction of the degree of compatibility and indicate where further RFI reduction efforts must be exerted.

Initially, considerable research and development is necessary to determine the essential data requirements and suitable test methods. Manufacturers will be required to submit spectrum signature data with preproduction models of equipments and eventually it is hoped that this data can be supplied with design proposals on the basis of prior knowledge of results to be expected for certain design considerations.

This program shows promise of being a definite step forward in achieving an organized engineering approach to the control of radio frequency interference.

In the "space age" costly failures arising from preventable interference cannot be tolerated, whether the interference be due to desired or undesired emissions.

Analysis and Prediction of Interference Factors and Their Impact on the Future*

R. M. SHOWERS†, SENIOR MEMBER, IRE

Summary—**This paper is based on the theme that although there have been, admittedly, many instances of spectrum crowding, and many specific examples can be cited, no one knows just how crowded the available spectrum is. This is because quantitative measures of the use of this important natural resource are not established. The factors contributing to spectrum crowding are outlined briefly and suggestions for the development of methods for determining their importance are made.**

Introduction

PREDICTION of the amount of interference to be expected in any given situation is or should be the ultimate objective of all interference work. The accuracy to which this can be done may be assumed to indicate the degree to which this field has developed from an art to a science. In this paper the present state of the art will be reviewed and some ideas offered as to how this work may develop in the future. There seems to be little doubt that interference considerations will continue to become much more important in the design of electrical and electronic equipment than they are at the present time.

Interference Factors

The definition of an "interference factor" must necessarily be somewhat vague since almost any "electrical" characteristic of a device or its "radiation" could in some way determine interference in some particular case. All such factors used to describe a communication system or its components should be included in a broad definition. Then interference analysis can be thought of as the process of determining the order of importance of such factors in so far as they contribute to specific interference situations and the methods of utilizing these factors in evaluation of such situations.

The model of Fig. 1 which is used extensively in information theory work is also convenient to use here in modified form.

Interference can be classed as arising from two causes. It may be man-made or natural. In this paper we are primarily concerned with the man-made variety. However, except for lack of control of the source and the usually extremely broad-band nature of natural interference, essentially the same considerations are involved in predicting interference from both.

It is convenient to classify a factor as either a "primary" or "secondary" factor. A primary factor is one which describes a function essential to the transmission purpose, whereas a secondary factor is one which it would be desirable to eliminate in order to get maximum efficiency in spectrum utilization. This distinction is significant for most factors. However, in the case of propagation, a factor may be primary for one circuit and secondary for another depending on the way it is involved. The broadcast service, where ground wave propagation may be used locally and sky wave for longer distances, is an example of this. However, usually both are not used at the same time so that in most instances the distinction is useful.[1]

Allocation of frequencies is usually made on a clear or shared channel basis. A clear channel is defined here as one in which the natural "noise" exceeds man-made noise arising as a consequence of a primary factor. Thus, taking advantage of propagation and geographical factors (describing in part the "channel" above), one can effectively have many clear channel users on the same frequency. The shared channel basis is one in which interference will be experienced if all or some of those assigned to it try to use it simultaneously.

In order to predict interference one must have detailed data on each of the elements shown on Fig. 1, which are outlined in more detail in Table I. It must be recognized that assigning numerical values to the factors must be done statistically. All receivers are not the same, even though they come off the same production line. Likewise, spurious outputs from transmitters will vary from one production unit to the next, and will vary with tube replacement in an unpredictable manner. Thus, a given factor can be specified quantitatively in terms of a mean value and mean square deviation from this mean square value. Design objectives for many of these factors have been stated in some detail in the literature.[2] These objectives have been established on the basis of 1) the apparent importance of each factor and 2) what appears to be technically feasible.

In the last year or so the military services have developed the concept of "spectrum signature."[3] The spectrum signature of any transmitter is essentially a description of the power output as a function of frequency. For a receiver, the spectrum signature, in addition to information on power radiated, contains information on its response as a function of frequency. This includes cross-modulation and desensitization data. In addition to the above, the spectrum signature will include antenna pattern characteristics and data on types of modulation or other descriptions of waveform. In other words, much of the information listed in Table I is included in the spectrum signature.

In some cases one can make a prediction within close tolerance if he takes care to measure all parameters or factors involved in sufficient detail. However, usually the usefulness of a prediction is in direct proportion to its remoteness from such detailed measurements. Furthermore, characteristics of individual devices are subject to variation from time to time, not to mention propagation effects. This is clearly a complex situation. It is obvious that in specific situations many of these factors will be unimportant. On the other hand, any of them may be significant in a particular situation.

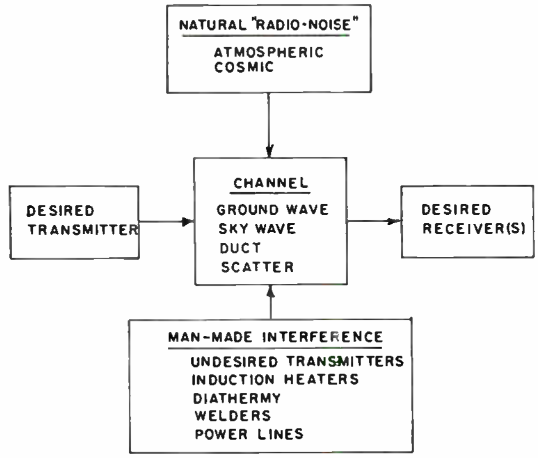

Fig. 1—Model of a communications circuit operating in the presence of noise and interference.

TABLE I
FACTORS IN INTERFERENCE PREDICTION

Transmitter
- Antenna height, pattern, and polarization
- Power spectral output
- Modulation type
- Intermodulation or cross-modulation characteristics
- Frequency stability.

Natural Noise (specified as function of geographical location)
- Spectral and amplitude characteristics (described statistically).

Man-Made Noise
- Where appropriate (for example, ignition and power line corona), spectral and amplitude characteristics (described statistically).
- For Incidental Radiation Devices (Induction heaters, diathermy)
  - Power spectral output
  - Waveform
  - Bandwidth.
- For Undesired Transmitters
  - Same as for (desired) transmitters above.

Channel
- Propagation characteristics (for particular frequencies and geometrical locations of sources and receivers).

Receiver
- Antenna height, patterns, and polarizations
- Bandwidth (of input stages as well as over-all)
- Type of detector
- Nonlinear characteristics of early stages
- Overload
- Desensitization
- Cross- and Intermodulation
- Harmonic and other spurious.

[1] The terms "primary" and "secondary" used in distinguishing factors should not be confused with similar terms used in specifying service areas of broadcast transmitters.

Analytical Techniques

Techniques used in analysis of interfering situations have varied from relatively simple calculations of received power level based upon free space propagation formulas, to extremely complex programs on electronic digital computers. In any case, the objectives may have simply been to determine the extent of interference to be experienced, or to specify an appropriate frequency allocation.

At the more sophisticated end of the techniques spectrum is the computer program. A number of these have been described.[4,5] In general, the usual approach is to feed into the computer data on each element of the system and its electronic environment listed in Table I. Then the computer considers each source and receiver combination in sequence and compiles results. Even with the digital computer, however, it is almost always necessary to resort to approximations in storing the data and in carrying out calculations in order to keep the data storage and computer calculation time within practical bounds. Spectrum signatures and antenna patterns must be "quantized," and parameters subject to statistical variation must be handled so as to produce results that can be correspondingly interpreted. One of the most involved factors in this respect is propagation. Related to this is the question of what value of signal to "noise" (or "interference") ratio should be considered acceptable.[6] Clearly this is a function of various transmitter and receiver characteristics, the frequencies of signal and of interference, their "modulation" characteristics, propagation characteristics of the channel, etc.

Many other methods of interference prediction on smaller scales have been used. Most of these have not been reported in the literature.

In the frequency assignment area a number of specific problems have been solved. These may generally be described as determining the minimum number of frequencies required in a given communications complex under certain stated or assumed restrictions. A formal approach to this type of problem has been described.[7] In one form the restriction is geographical with transmitters and receivers located in a specified way.[8] In another the restriction takes the form of an equation giving a relationship between two frequencies which will produce interference with a third (intermodulation problem).[9]

Another instance of the application of computers is in the case of radar mutual interference. By inserting data on pertinent factors including antenna patterns and geography the average rate at which pulses would be received at various locations can be computed as a function of receiver sensitivity.[7]

Because of the limitations in "brute force" application of computers, consideration must be given to the possibility of "simplifying" the program by various techniques. One should be careful to set up the program in such a manner that unnecessary calculations are avoided. Usually only the strongest received signals will be of interest. To avoid tedious searching of computer files, the data should be stored in some selective way. It is known that such techniques can improve computer efficiency substantially in many types of problems requiring withdrawal of selected data from a large total storage.[10]

Another technique is to adopt the "integrated" approach. In one example of this the point of view was adopted that the only significant measure would be the "probability that interference would occur," it having been granted that it would be difficult, if not impossible, to guarantee that interference would not occur. Thus it was possible to locate transmitters and receivers "statistically" initially, to describe the propagation statistically as well as transmitter and receiver characteristics, and by manual computations to obtain desired results relatively quickly and inexpensively.[11]

Measures of Effectiveness of Spectrum Utilization

When one has calculated the data and made a prediction, how does one evaluate whether the situation is good or bad? A little reflection will reveal that very little is really known about how crowded the spectrum is. Little is available in the form of technical reports which are available generally to those in the technical communications area giving data on such results. Undoubtedly the techniques referred to above have been quite useful in specific areas of interest, and those applying them have definite opinions on the extent of interference in their own provincial environments.

Foundation, Chicago, Ill., p. 111.

Most of us use commercial broadcasting as a point of reference. Here very high standards have been set. Relatively little interference is experienced by the majority of listeners, so that excellent reception quality is obtained. Historically, this desirable result has been obtained because of technical and economic feasibility.

The same standards should not be applied to other radio spectrum uses arbitrarily. It seems clear that in many instances the channels are not used to the maximum extent possible, such as where the service involved is operated for only a small percentage of the time, or where the signals transmitted cover only a fraction of the surface of the globe. Evaluating the efficiency of use is, of course, a very complicated problem which should take into account many aspects of the service involved.

The value of the radio spectrum is to transfer information (information used in its broadest sense). One should, therefore, develop a suitable measure for the amount of information transferred. Factors that must be considered clearly include the information rate, number of receivers of the information, and the "value" of the data or information transmitted or received. Costas, in a stimulating article[12] has described a concept of spectrum use which tolerates a substantial amount of "interference" as in radio amateur practice. He also discusses the implication of new methods of modulation in this concept.

Other factors which might be considered are cost (in dollars and men), time delays, and areas served by the transmission system. These we discard, at least initially, as being either irrelevant to the question of spectrum utilization, or incorporated in the other measures.

To apply the measures previously listed, one must attempt to find some means for attaching importance to information. Those familiar with operations research techniques have recognized for a long time that generally dollar value is one of the most useful measures for evaluating different situations. In the case of distress frequencies, it would be necessary to place a value upon human life. This has been done in a number of instances already in other situations. The value of information is frequently a critical function of timeliness (especially in military situations) and consequently there is a basis for comparing clear channel and shared channel operations. The developments of information theory in recent years have provided us with an excellent basis for comparing various types of modulation for efficiency of data transmission.

It is relevant to mention specific examples to which these concepts might be applied.

1) *The Broadcast Band:* The amount of information transmitted is extremely high, although at a relatively low rate, and of relatively small importance when received. However, a relatively high commercial value is placed upon such transmission. The number of receivers is extremely large and the geographical coverage almost complete.

2) *Mobile Services* (for example, taxicabs and police vehicles): Information rate—high, geographical coverage—fair, timeliness—adjustable in accordance with requirements, number of receivers—moderate, over-all efficiency of spectrum use—good.

3) *Radar:* Number of transmitters and receivers variable, depending on the application. For certain functions, such as navigation, geographical coverage is fairly complete; number of transmitters and receivers—large; information rate—relatively low; and commercial value—substantial. For military applications, such as air defense, the geographical coverages are fair, average information rate is extremely low (useful information obtained only in times of emergency), timeliness is extremely important, the value of the information is extremely high.

Other examples could be given. The above would seem to indicate that on the basis of questions that are at the moment only qualitative, the assignment of spectrum space is logical and one begins to get suspicious that when more quantitative means are used we may only justify the arrangements which now exist. This is not surprising. What then is the value of these concepts? Simply, that by attempting more qualitative evaluation of spectrum utilization we shall be able to better determine the relative importance of various possible actions with regard to the secondary factors. For example, consider the seriousness of harmonic radiation which could cause losses of time delays in information transfer. How much harmonic radiation should be tolerated in a given situation? To what level is it economical to use suppression techniques? What will be the economic gain in the application of any given technique for control of a secondary factor? Applications of information theory would give a quantitative basis for changing coding and modulation techniques.

Future Developments

In summary, areas in which one can expect significant developments in the future are as follows:

1) Techniques of prediction.
2) Development of suppression techniques.
3) Frequency allocation.
4) Application of efficient methods of modulation.

A. Techniques of Prediction

The current vogue for using computers to make interference predictions will undoubtedly be extended in the next decade. However, it seems reasonable to expect that not all users of communications facilities will be able to afford such an extensive approach. Furthermore, it stands to reason that requirements for prediction will vary substantially from one user to another so that the

[12] J. P. Costas, "Poisson, Shannon, and the radio amateur," Proc. IRE, vol. 47, pp. 2058–2068; December, 1959.

nature of the problem involved in given cases may be very specialized. Indeed, as the nature of interference becomes better understood, and as the factors contributing to it come under better control, we may expect predictions to become simplified. Until more experience is gained with their use, it may be possible to write computer programs in such a way that specialized problems can be quickly performed. However, the more simple problems will likely be handled by graphical or slide-rule techniques.

B. Development of Techniques for Suppression

The importance of suppressing secondary factors (harmonic and spurious radiation in transmitters and spurious response in receivers) has always been recognized, but relatively little has been done in some cases because of apparent economic factors. Present frequency allocations are based upon avoiding the "worst case" situation. Clearly, if the standard deviation can be reduced through improved methods of manufacturing control, the worst case condition will be alleviated and more use can be made of the frequency spectrum. Reduction of the mean value of secondary factors will probably take more time, require technical advances in the state of the art (such as the development of harmonic-free tubes), and involve substantial expense. Secondary factors can be improved by filtering or by increasing directivity of antennas, as examples, and in many cases the methods used will depend largely upon economic considerations.

Spurious and harmonic suppression is extremely important in some of the modern high-power transmitters, and, indeed, the design of output stages in some of these has been influenced in a major way by the choice of harmonic-and-spurious-free designs. In the case of receivers, the feasibility of new techniques of circuit design in the input stages has been demonstrated,[13] and very likely the additional cost can be justified in many instances. Of course, the importance of suppression techniques, such as the insertion of output filters, has stimulated a great deal of work in the development of new components and it is quite likely that independent of the economic question we can look forward to the development of many new components and techniques in the future.

C. Frequency Allocation

Eventually, a more explicit concept of efficient spectrum utilization with regard to primary factors will evolve. This will include consideration of frequency assignment so that more optimum use can be made of inherent directivity of antenna structures, special modulation techniques, natural propagation conditions and the service requirements. Undoubtedly, present frequency allocations are in many cases sound, and will remain with us for this reason, in addition to the fact that there are large equipment investments involved. On the other hand, as techniques for frequency stabilization improve and new methods of multiplexing information in specific frequency bands are developed, it will become apparent that changes will have to be made in the frequency spectrum. The shortage of spectrum space may force spectrum allocation changes, in spite of the equipment change-over costs involved. This becomes a political problem rather than a technical problem and undoubtedly will be implemented one way or another.

D. Modulation Techniques

In recent years considerable effort has been directed towards examining the relative efficiencies of various methods of putting information on a carrier, from the point of view of bandwidth consumption, signal-to-noise ratio, and reliability (for both data and voice). Implications with regard to spectrum usage have also been considered, but, as previously mentioned, the criteria for efficient spectrum use have not been established. Thus, we may expect to see the development of such criteria take place as this problem is brought into sharper focus.

Conclusions

It is seen from the above discussion that much pioneering work is necessary in the general area of radio interference. What is needed is a truly operational approach to the problem of spectrum utilization. At the present time there is much complaint about shortage of space in the radio spectrum, but as yet no one has come up with a quantitative measure of this shortage. In fact, it is not absolutely certain that a shortage exists. Admittedly, there are numerous instances of interference, many of which could be classified as critical or as of serious consequence.

Undoubtedly, it is essential that the users of the radio spectrum become accustomed to experiencing a certain amount of interference in order that maximum use be made of available channel facilities. We are entering an era in which a better understanding of the relative efficiency of various techniques, including the proper use of such things as the various modulation schemes, directive antennas, the incorporation of coding techniques and assignment of frequencies will take on a new meaning in terms of the required qualities of service.

RELIABILITY AND QUALITY CONTROL

Organized with the assistance of the IRE Professional Group on Reliability and Quality Control

The Reliability and Quality Control Field from Inception to the Present *by Clifford M. Ryerson*

The Reliability and Quality Control Field from Its Inception to the Present*

CLIFFORD M. RYERSON†, SENIOR MEMBER, IRE

Summary—**Starting with a brief discussion of the implications to Reliability of the parallel accelerated growth of modern technology the history of Reliability is traced through four decades. Following the early groundwork of the years before 1940 the decade of the 30's has been described as the Standardization Decade. Here the new emphasis was on specific standards of all kinds. The following decade of the 1940's has been described as the Quality Control Decade. This new field was developed with emphasis on process control and the uniformity of product. This was followed by the Reliability Decade during which the new emphasis was on the inherent reliability of design and the time degradation of performance. The 1960's have ushered in a new decade and new emphasis on coordinated controls in all areas and phases of design, development and production. The new decade has been described as the Product Assurance Decade, wherein the emphasis is being placed on assurance to management and to the customer that all the important product characteristics are being optimized and that all the technical specialties involved in providing the highest value product on schedule are being integrated effectively. This new emphasis is on coordinated programs embracing all the related control specialties sometimes referred to as the Big R approach. These specialties include Reliability Engineering, Maintainability Engineering, Total Quality Assurance, Value Engineering and System Integration among others.**

I. Introduction

A PROMINENT characteristic of this new field of reliability and quality control is the rapid change and growth which has occurred in recent times. In order to clarify the causes and emphasize the pace at which this growth is accelerating, this introduction reviews briefly the parallel growth of modern technology. A brief review of some of the milestones of general progress is presented in a way to emphasize the implications for the reliability field.

* Received by the IRE, July 31, 1961.
† Vice President, EL-TEK Corp., Hawthorne, Calif.

The rate at which technological progress has been made can be illustrated by a brief look at military equipment progress. For example, it was only a little more than 100 years ago that military cannons were cast of iron or bronze and bolted solidly to wooden carriages. A foundryman and a carpenter were the only two specialists needed to design and build a first-quality large-calibre weapon. Since few, if any, drawings or specifications were involved, every model was hand-made and distinctively different. The only design criteria were that the bore be reasonably straight, smooth to the touch, and slightly larger than the balls to be fired. If the artisans decided to make an extra fine firing piece, they might engrave the outside of the barrel or add fancy iron wheels.

Some fifty years ago, the best cannon had become steel rifles with a complicated array of gears and cams for manually cranking the barrel into position. At this stage of development, ballistics became a science, and the mad rush for perfection of power drive and automatic control began. Weapons of this era presented a blossoming array of design criteria ranging from steel specifications to construction and assembly techniques. Not two craftsmen, but hundreds, were required to design, construct and install these advanced weapons. Excellence was no longer a matter of external appearance, but of utility and adherence to strict specifications which had been worked out in accordance with long shop experience and engineering design.

Finally, just a few years ago, the large-calibre automatic weapons used at the end of this last war dwarfed to insignificance those first rifles, by virtue of automatic radar control, long range, high rate of fire, maneuverability, accuracy, and precision. In addition, many uncommon materials were beginning to appear. New processes of construction, radar direction, hydraulic electric drive, automatic interlocking, remote control, and many other factors made military armament into a big business. It became so big that the identity of any one intellect, type of trade or profession, specialist, or personality was lost in hundreds of pages of specifications, thousands of drawings, and hundreds of man-months of all types of technical effort. Now modern missiles with their fire control and self-navigation features are in a different order of magnitude in both functional performance and complexity.

Although this example illustrates the advances made in recent years in the field of military ordnance, similar illustrations can be drawn in other fields. It is so easy to take for granted many of the near-miracle devices of our time that the rate of technological progress they represent is easily overlooked. Consider the airplane, for example. It is hard to realize that man could not fly only some 60 years ago. The first flights of seconds duration were made by the Wright brothers in 1903. Some ten years later, the airplane was still a kite-like affair used for experimental observation and contained no instruments. Several instances are on record during World War I where aerial dogfights occurred using pistols and rifles as armament. Some small explosives were dropped by hand near the end of the war in 1918.

Less than 20 years later, and by the time World War II began, the airplane had become an effective machine with powerful engines and many meters and power controls. In the following four or five years the airplane became a maze of electronic instruments, and today, only a decade or so later, completely automatic, self-guided, self-navigated and computer-controlled world-girdling missiles are commonplace.

Today, we are talking seriously about manned space craft capable of sustained flight for long periods in the vacuum of space. The complexity of functions necessary to support life completely independent of earth environment is a new level of advance in the world of flight.

To emphasize the rate of this advance, let us consider the number of electronic parts employed in a typical equipment at various stages. In 1921, just 41 years ago, no electronic equipment was generally available for use in airplanes. By 1936, simple communication sets containing perhaps 25 to 30 tubes, and from 200 to 300 other parts had become commonplace. By 1956, the all-weather interceptor carried over 600 tubes and the heavy bomber over 2000 tubes. The electronic parts per plane totaled many thousands. Today, although the transistor and other solid-state devices are replacing tubes, the number of electronic parts needed for automatic navigation, communication, and control, is running into the hundreds of thousands for large military aircraft.

We are now in a period in history when a complete revolution from manual to automatic is "booming" in every field. The electronic industry and all its related engineering aspects is perhaps the key element in every phase of this revolution. Born from the merger, not long ago, of the mechanical age to the electrical age, this new electronic offspring has developed to bewildering magnitude in comparison with its still young parents. Friends of the parent fields are frequently ill at ease in the company of this gigantic young progeny. Their attempts to work with it can perhaps be likened to the absent-minded professor trying to put rubber baby pants on an elephant. The trouble is not only with the size of the pants but in the complete inadequacy of the normal techniques.

Coincident with the unprecedented growth of the progeny, new techniques and procedures must be and are being developed to keep pace. The magnitude of this growth can be better understood by comparison of a few interesting statistics. Recent figures indicate that, whereas the population of this country has increased on the average less than 2 per cent each year during the past 15 years, the electronics industry over this same period has averaged better than 15 per cent per year increase. Further, the curve of electronic industry growth has an upward trend which has every indication of continuing for some years. (The 0.4 billion industry in 1940 grew to 2.6 billion in 1950, then to 10 billion by 1960, and is projected to go over 20 billion by 1970.[1] Beyond this, there is still tremendous growth potential.)

The reasons for this enormous growth are many. Furthermore, most of the reasons are of a semipermanent nature which are not apt to reduce in urgency for many years. The progress of aviation, atomic energy, automatic business machines, automatic factories, improved communication, increased standard of living, industrial use of television, complete mechanization of farms, military advances, newly developed materials, and the shortage of technical manpower itself are all factors. Further, these are factors in the true algebraic sense in that advances in one field multiply the problems for electronics in others.

As the trend from "manual" to "automatic" mushrooms in size and the industry growth outstrips the population growth, and as the machine performance requirements outstrip the performance capabilities of the human, it becomes more and more important to replace humans with electronic devices. This occurs in engineering organizations where complex automatic computers do the work of many; it is occurring in the military through the use of automatic navigation, gun-laying and logistic control equipment; it is common in aviation where radio operators are being replaced by compact automatic communication equipment and pilots are being replaced by controls which have a faster reaction time plus automatic computing provisions. There is thus a vicious circle which adds up to a continually increasing requirement for more electronic

[1] EIA figures.

developments which, in turn, create problems which can only be solved by more electronic developments and increased complexity.

An even more powerful factor than the preceding looms on the horizon as a reason for future electronic-industry growth. This involves the process and by-product control of the atomic industry. To date, the atomic industry has not appreciably affected the electronic field. As the atomic industry grows, however, new areas requiring automatic and complex electronic control will become common. In addition to the approximately 500-million-dollar expenditure predicted by 1963 for reactor controls and instrumentation, there is the large field of fuel-fabrication-process control, and the equally large field of waste disposal.

The "ashes" from atomic reactors present a future contamination hazard of staggering magnitude. This problem can only be solved by a new chemical process disposal and by-product manufacturing methods, each with their own special electronic controls. Further, as new liquid-fueled homogeneous reactors replace the present heterogeneous piles, the age of atomic-powered space craft will be ushered in. In all this, the continually increasing need for electronics is readily apparent. It seems reasonable, then, that the present upward trend in the magnitude of the electronic industry will continue unabated for some time.

It seems equally apparent that, as civilization comes to depend more completely on complex automatic equipment, the reliability of this equipment becomes of paramount importance. The higher the dependence on automaticity, the higher becomes the penalty of equipment failure. Indeed, the limiting factor to future advance in nearly all the modern technological fields will be the complexity which is permissible as set by the state-of-the-art in reliability.

The modern quest for higher reliability had its major beginning with the onset of World War II, but the rudiments were established at a much earlier time. The following sections present a chronology of specific events important to this new field.

II. Early Groundwork for Reliability (The Years Before 1940)

At the risk of some controversy, it can be stated that the first step in the new field of reliability can be traced to discussion generated by the AIEE Standard No. 1, published in 1913. The title of this document was "General Principles upon which Temperature Limits are Based in the Rating of Electric Machines and Apparatus." This Standard started the first cycle of appreciation for the chemical composition of electrical materials. During the subsequent development of the electrical and electronic fields, there has been a cyclic recurrence of this emphasis which can be recognized today as "analysis for the basic mechanism of failure in materials used in highly reliable electronic parts." However, in all fairness, it should be stated that the element of time-dependent degradation was not a part of the referenced first document. This element did not become a formally recognized factor until the great upsurge period for reliability in the 1950's.

Perhaps one of the first clear-cut examples of what would now be called a reliability-control program occurred in 1916. The Western Electric Company and the Bell Telephone Laboratories cooperated in a planned program to produce good performing and trouble-free telephone equipment for public use. The following elements of a good reliability program were involved:

1) An ably planned, forward looking R&D program considering the system needs.
2) Development programs leading to mature designs verified by design reviews and engineering model tests.
3) Part improvement projects using test-to-failure methods, consideration of tolerances and performance under stress loading.
4) Standardization and simplification in design.
5) Product evaluation under field application conditions for prototypes and pilot production models.
6) Quality control during manufacture to assure achieving the reliability inherent in the design.
7) Feedback from the field to provide information for the designers.

This same proven approach was later used for several other successful developments in the telephone and communication field. One early application in the military equipment field occurred in 1917 and 1918, when Bell Laboratories and Western Electric cooperated to develop and produce the CW 924 and CW 936 radio equipment. These were installed on submarine chasers at New London, Conn., and were used up and down the East Coast from New London to Galveston, Tex. Daily feedback of failure information was made a part of the program schedule.

Early work for the Navy used similar reliability controls to develop the first vacuum-tube transmitter (1918–1919), the first wide-band superheterodyne receiver (1923), and the special 6-kw tube transmitter installed on the S.S. *Leviathan* (1924).

In 1918 the American Standards Association was founded by five engineering societies to coordinate the development of national standards. It has since served as a national clearing house and coordinating agency for voluntary standards in the United States. In 1948 the ASA was incorporated under the laws of the State of New York as a nonprofit organization. It now is a federation of 122 trade associations and professional societies. In addition, it also has more than 2000 company members. From its earliest beginning, the ASA has had an important influence on the factors contributing to reliability. More specific contributions will be described later.

The 1920's witnessed the birth of our mass-production component-parts industry. In the very early days the processes were crude. For example, grid-leak resistors were even made from lead pencils. The process consisted essentially of screening a supply of "lead" to find those which had the approximate resistance required. Today, the standard molded composition resistors are made automatically on complex and costly machinery. In a similar fashion, many other major lines of parts had come from crude beginnings to a comparatively advanced state of technical development by the end of the 1930's.

The vacuum-tube industry became well established during this growth period, and in the late 1930's came the initial attempts at commercial production of miniature tubes. This development was sparked by the need for small high-gain amplifiers for hearing aids. It was in this service that the first solder-in tubes were used in quantity. Reliability was beginning to be a problem.

The greatest impetus to further miniaturization of electron tubes was felt early in 1941, when rugged tubes were urgently needed for use in the proximity fuse. Early attempts to use hearing aid types of tubes for this purpose were quickly set aside on the basis of unreliability. Not only were the hearing-aid types not reliable enough in ordinary service, but they now had to be rugged enough to withstand the impact of the propellant explosion in the gun. Since that time, the development of reliable subminiature tubes has been pushed forward relentlessly, largely under the sponsorship of military agencies such as the Bureau of Ordnance, the Bureau of Ships, the Air Materiel Command and the Signal Corps.

During the 1930's, a new profession called standards engineering was born. With the quantity production of many types of component parts came the need for standards of all sorts. Standard types came first, then standard methods of specification, and finally, standard methods of measurement and testing. The National Bureau of Standards and the American Standards Association both owe their present strength to the developments of this period.

Test methods have usually been divided into two categories: simple, nondestructive tests for rapid inspection, and the sometimes-simple but sometimes-complicated destructive tests. Throughout the three preceding decades, to date, the same general divisions of testing have been recognized. However, the emphasis on standards during the decade of the 1930's was to define arbitrary limits on the parameters being measured and to specify tests based on a go—no-go basis. This qualitative approach was a real step forward at the time and helped to achieve acceptable reliability for the state of simplicity of the then-current equipment. The emphasis on standards shifted during the 1940's from the go—no-go limits to close regard for the actual variance or "scatter" of the data obtained in performing tests. This change ushered in what might be called the decade of quality control, which is discussed in the next section. This change was brought about by forces resulting from the rapidly increasing technology.

After the 1930's, the end products of mass production began to change complexion. While the considerable volume of home-entertainment receiver production continued to increase (except for the war years), and was finally given tremendous new impetus by the commercialization of black-and-white television, other applications for electronic components began to develop at an even faster rate. These include: radar, sonar, seismic surveys, mobile communication, electronic computers, and various industrial applications of electronics.

Between World War I and World War II, aviation experienced a rapid expansion period, and electronic equipment in military and civil aviation had opportunity to gain service experience. The equipment in use by 1938 had reached a fairly high degree of reliability, and the communication needs of the aviation industry could be satisfied. Suddenly, however, radar appeared and, almost simultaneously, the World War II adventure began. The service that radar could deliver in military applications was so valuable that it was permissible, even mandatory, to produce it without going through the ordinary stages of development and design which are essential to reliability with an entirely new service. Radar and its related equipment was rushed into production and service use without opportunity for adequate attention to important details.

Radar quickly proved to be so effective that, under the urgencies of war, together with all related electronic devices, it came to be handled with short-cut procedures, and with the same minimum attention to reliability and practical details in general. This became regular procedure, and apparatus finally was being chosen almost entirely on scientific merit, with minor attention to operational evaluation of such factors as reliability, complexity, suitability to personnel and training, etc.

Of course, routine attention was given to various standard specifications aimed at reliability, and many were the environmental and functional tests performed. But, frequently, the only results of the tests either damaged the equipment or introduced changes which made the devices even more complex. Often tests were disregarded completely in order to obtain equipment quickly. The atmosphere was such that the ideals of technical performance—more sensitivity, selectivity, range, or intriguing new functions—always won out over the prosaic demands of simplicity, ruggedness, and reliability. There were cases where electronic equipment was installed in planes and carried around unusued, because time was not available to train the crews in its operation and maintenance.

The same frenzy of design—build-and-ship regardless of reliability—appeared in all aspects of industry. For example, there was the case of the magnetic influence torpedo which was manufactured for months and put through a complete series of formal tests long after field evidence of unreliability had caused an order to be issued to use them only for contact firing with the influence feature turned off.

Before the days of radar, common sense and thorough evaluation were familiar ingredients in electronic design, but the recklessness of the times caused a new way of life in industry. Unfortunately, this way of life has left its stamp on many of the current generation of managers engineers, and companies.

What actually happened was that the new creation, "radar," appeared in the category of radio equipment, and, therefore, there was immediate pressure to make it similar and by using the same parts and methods. It could be made small, light, and quickly—as can all electronic gadgets—and the industry responded to these pressures. But one of the costs of this process has been in reliability. The pressures for returning to the former analytical "system-need" approach did not develop until the 1950's, and these pressures have still not achieved their full objectives.

However, some progress was made in the reliability field even as early as 1939. The Ordnance Corps worked out and established statistical methods of surveillance of ammunition in storage. These methods have been standard ever since for controlling the "liveness" of ammunition. In effect, the time deterioration (reliability of ammunition is controlled by a repetitive sampling of typical stock. A quality survey performed on a repetitive schedule was thus demonstrated as a valuable tool to maintain reliability of one-shot devices during storage. This storage phase was recognized as only one area where statistical methods might be helpful, and whetted by this success, leaders in the field worked diligently to usher in the quality-control decade.

III. The Quality-Control Decade (1940–1950)

The emphasis of the standards decade prior to 1940 left many weaknesses in approaches to the manufacture of uniform high-quality products. It was becoming a national scandal that so few products manufactured to the same specifications were similar. Factory inspection had become common, but the basis for acceptance or rejection was frequently a matter of individual choice. Military effectiveness was being severely hampered by poor quality of equipment.

Upon request by the War Department, in December, 1940, the ASA initiated a project on the Application of Statistical Methods to the Quality Control of Materials and Manufactured Products. In the national emergency there was urgent need for the prompt development of standards relating to the control of variability in products and processes. The ASA Emergency Procedure was, therefore, applied to this project and an Emergency Technical Committee was appointed to develop the required standards.

An active committee of six men was chosen which included the following: H. F. Dodge, Bell Telephone Laboratories, *Chairman*, A. G. Ashcroft, Alexander Smith & Sons Carpet Company, W. Edwards Deming, Bureau of the Census, Leslie E. Simon, Ordnance Department, U. S. Army, R. E. Wareham, General Electric Company, John Gaillard, ASA, *Secretary*.

Two American Emergency Standards (since called American War Standards) were published by the ASA through the efforts of this group during 1941, and a third during 1942. The exact titles of these documents follow:

ASA-Z1.1—1941: "Guide for Quality Control"

ASA-Z1.2—1941: "Control Chart Method of Analyzing Data"

ASA-Z1.3—1942: "Control Chart Method of Controlling Quality During Production."

The basic policies and procedures for statistical quality control were established in these three documents. Much of the 1940 decade was expended in an uphill struggle to upgrade inspection procedures and to obtain recognition for the validity of statistical process control as described in these standards.

The Machine Tool Builders Association was one of the first industry groups to accept the challenge of quality control. The spearhead of the supplier group was the Electrical Committee of the National Machine Tool Builders Association. These men worked for "something they could live with." The discussions at their meetings were lively and generally ended in clarification of what the users wanted in quality and what they could reasonably hope to obtain. The first Machine Tool Electrical Standards were introduced by the NMTBA late in 1941, and became the basis of the American War Standard ASA-C74-1942. These dealt with specific quality standards on motors, conduits, cables, etc.

Prior to World War II, military equipment was relatively simple and simple good practices were adequate to produce reliable equipment. With the onset of war, however, the frenzy of produce-and-ship, previously described, set in, and, in addition, came military demands for increasingly complex equipments. The new military demands required developmental efforts for new tubes, new circuitry, new applications of components, new functional components, and an increased ability for equipments to withstand higher levels of environmental stress. One of the major problems in these jumbled times was concerned with tube reliability.

Several organizations, including the M.I.T. Radiation Laboratory, recommended in 1942 that a national coordinating body be established to encourage and direct tube development work as a first step to reliability improvement. This recommendation was approved by the Navy in 1943, and an initial joint Army-Navy Vacuum Tube Development Committee (VTDC) proposal was transferred for implementation to the newly formed National Defense Research Committee (NDRC).

On June 7, 1943, the first meeting of the VTDC was held with Dr. I. I. Rabi as Chairman. This group, under various sponsorships, performed a valuable service throughout the war.

On June 6, 1946, the Joint Research and Development

Board (JRDB) was established. On October 24, 1946, the VTDC was transferred as a specialty panel to the JRDB, and the Panel on Electron Tubes (PET) was formed. Later, a support contract for this panel was established at New York University.

A major technical breakthrough occurred in the spring of 1943, when the noted mathematical statistician, Abraham Wald, devised his now celebrated basic theory of sequential analysis for analyzing U. S. war problems. Initial application of the theory in analyzing combat experience demonstrated its value in obtaining reliable conclusions from a minimum of information, swiftly and economically. This seemed like an ideal tool for use in quality control at this crucial period in our history when speed, precision, reliability, and economy in production were of the essence. To give the new tool a thorough trial, the military released a multiple sampling plan based on Wald's sequential theory. This plan was first released to a limited number of strategic manufacturing firms for use in acceptance sampling. The early success of the plan and the subsequent widespread demands for its use resulted in removal of its "restricted" classification in 1945.

The advantages claimed for the sequential-analysis technique when used for multiple sampling by skilled inspectors included the following:

1) It required a far lower average amount of inspection than did previous methods.
2) It did not require a specific sample size for a given lot.
3) It decided to accept or reject for itself, revealing its decision to the inspector when his last entry of information crossed a line on a graph.
4) It made decisions very quickly and accurately for extremely "good" or "bad" lots.
5) It made equally accurate decisions on "dubious" quality lots when additional information was provided.
6) It greatly reduced the chance of a wrong decision when compared with any other plan, thereby insuring a more consistent product with substantial reductions in costs.

Although the new plan was altogether a remarkable advance, it had weaknesses. Its principle disadvantages were the time-consuming necessity for skilled inspectors to either plot and record after each sample, or to record results of a set of samples, and then compare results to a set of Military Standard Tables. Moreover, if the first sample group yielded no decision, another group of equal size had to be selected and the entire process repeated until a decision was made. This complexity in use and the requirement for skilled inspectors were major factors in causing the plan to be much less of a boon to quality control than the early enthusiastic reception had led many to believe.

In 1944 the Navy began a program to obtain more rugged tubes for ship-board use. The severe shock and vibration accompanying gunfire caused many tube failures in fire-control radars and related equipment. Shock and vibration equipment was developed to aid in the testing, and structural modifications were made in standard tube types to increase their resistance to shock. As a result of this program, the Navy "ruggedized" W-series tubes were evolved, covering some 40 tube types.

In 1944, also, the first plans were established by civilian employees of the Naval Gun Factory in Washington, D.C., and the Naval Research Laboratory in Anacostia, D.C., to establish a National Symposia on Shock and Vibration. Under the able chairmanship of Dr. Elias Klein, a program and format were established which has done much to solidify the thinking on Shock and Vibration in this country. Yearly, symposia are still being held in this series, and this program has proven to be of major national value to reliability.

In 1945 the automotive industry joined the enthusiastic supporters of statistical quality control. Automotive standards and recommended practices were established, following the formation of the forerunner to the Joint Industry Conference (JIC). A basic paragraph numbering system was adopted, which has been retained by many groups and used in JIC and NMTBA standards since 1948.

In 1946 the American Society for Quality Control was formed. Key individuals in this effort to undergird the new field included: W. A. Shewhart, H. F. Dodge, E. G. Olds, H. G. Romig, Leon Bass, and others. During the years in which this society has been active, it has done much to upgrade the professional stature of the practice of quality control. Today statistical quality control of factory operations is an important factor in preventing the reliability inherent in designs from becoming degraded by poor workmanship and uncontrolled processes.

In 1946 Aeronautical Radio, Inc. (Airinc) was established by the Airlines to collect and analyze defective tubes in commercial airline service and return them to the tube manufacturers. As a result of these analyses, certain tube types were improved by exercising extreme care in assembly, giving maximum attention to production details, and checking each part as well as each complete assembly. After manufacture, all improved tubes were tested for shorts, continuity, shock, and transconductance. Samples were subjected to vibration, filament cycling, and life tests.

Special tube specifications were written, and about 10 tube types were improved before the work was discontinued at the start of the Korean hostilities. The Airinc program after 1950 was focused on the military tube problems under a joint services contract. Failed tubes were collected at various military installations, together with reliability data on the failure or cause of removal, hours of use, and use conditions. One of the key results revealed by the Airinc study in 1950 was that only about 33 per cent of the Navy Electronic Equipment on board ship was operating satisfactorily at any one time. This information set the stage for the big reliability push, described in the next section.

Before leaving the chronology of the quality-control decade, some mention should be made of the efforts of the International Electrotechnical Commission during this period. When Technical Committee No. 12 "Radio Communication" resumed its work after World War II, it decided (Stockholm, Sweden, 1948) to establish a special subcommittee to deal with components. After some deliberation, this subcommittee arrived at the opinion that the preparation of a general document for climatic and mechanical robustness tests should be the first consideration. The international efforts on this project resulted in a first draft for discussion at the Paris meeting in 1950, and a second draft for discussion at Estoril and Montreux in 1951. Partial approval was obtained, but the difficulties of obtaining agreement on the required tests and conditions of testing required several years more before final agreement could be reached and the document published in 1954.

Although the IEC Standard "Basic Climatic and Mechanical Robustness Testing Procedure for Components," begun in 1948 and published (1st edition) in 1954, was essentially a type-test environmental condition document, it did contribute to reliability testing in two ways: "Section 4.3 Test C Damp Heat (Long Term Exposure)" called for continued exposed operation for periods up to a maximum of 84 days; and "Section 4.8 Test H Storage" called for degradation in storage tests up to a maximum period of 12 months. These are among the first reliability life tests formally published.

IV. The Reliability Decade (1950–1960)

Early in 1950, the Defense Department, through the Research and Development Board, noted that difficulties with electronic equipments were not governed solely by a focus upon electron tubes. Many other parts were serious causes of unreliability. It became evident that many factors were involved. Consequently, on December 7, 1950, the Research and Development Board formed the Ad Hoc Group on Reliability of Electronic Equipment through its Committee on Electronics.

The Ad Hoc Group contained members from the three military departments, the Joint Chiefs of Staff, the Munitions Board, and various civilian organizations and professions. The Chairman of the group at the start was J. A. Chambers, who later was succeeded by A. F. Murray. The Panel on Electron Tubes was included as an advisor.

During the years in which the Ad Hoc Reliability Group was active (1950–1952), the three military departments undertook increasing numbers of studies in order to add to their knowledge of equipment failures. For example, the Navy contracted for the Vitro Corporation to investigate component failures, for Aeronautical Radio, Inc., to investigate electronic tube failures, and for the Bell Telephone Laboratories to study component-part failures. The Army, through the Signal Corps, entered into a long-term tube analysis program with Cornell University. The Air Force requested the Rand Corporation to investigate the general problem of electronic reliability.

Partially in response to the work of the Ad Hoc Group, and to meet other pressures, General George C. Marshall, then Secretary of Defense, issued on September 12, 1951, the Department of Defense Directive 150 21-1, "Reliability of Electronic Equipment." In this document he reviewed the important work of the Ad Hoc Group and stated that " . . . reliability must be a prime objective in *all* phases of the procurement and use of . . . equipment." He went on to direct that " . . . increased emphasis on reliability of military electronic equipment by all agencies of the Department of Defense is required."

It was in January, 1951, that the American Society for Testing Materials, through Committee E-11, issued its final "Manual on Quality Control of Material." The ASTM, organized with 70 members in 1898, had grown to more than 10,000 individuals and 6,000 company members by 1951. The development of standards had been carried out by more than 80 technical committees of which E-11 had been given the "Quality Control of Materials" assignment in 1933. The early work was done with the ready cooperation of the Joint Committee on the Development of Applications of Statistics in Engineering and Manufacturing, jointly sponsored by the American Society for Testing Materials and the American Society of Mechanical Engineers. W. A. Shewhart was Chairman of this Committee, which later (1946) formed the nucleus of the new American Society for Quality Control.

For a period of some 15 years, the material in the ASTM Manual had undergone a number of modifications and preliminary editions. Its nomenclature and symbolism were adopted in 1941 and 1942 in the American War Standards on Quality Control previously mentioned (ASA-Z1.1–Z1.2 & Z1.3). The manual has since been reprinted seven times, the last edition in July, 1960. The contents are considered by many to be the "bible" on quality control.

This term is also frequently applied to the book entitled, "Economic Control of Quality of Manufactured Product." written by W. A. Shewhart of Bell Telephone Laboratories in 1931. This has been reprinted eight times by D. Van Nostrand Co., Inc., and is still a good seller.

Another development in 1951 illustrates the point that neither the problems of reliability or solutions to the problems are restricted wholly to electronics-type equipment. During 1951, the "roll-pin" was introduced to replace the taper pin as a general-purpose mechanical fastener. Installation was easier, for the roll pin required only a drilled hole and not the additional taper-reaming operation. But a bonus for reliability was realized in high-speed equipment. At 12,000 rpm and above, taper pins, predominantly heavy at one end, tend to disengage and throw out. The roll pin eliminated this trouble.

In 1952 the Ad Hoc Group on Reliability of Electronic Equipment issued a final progress report,[2] making seventeen major recommendations for action by various agencies. The recommendations advised that:

1) Failure data reports be compiled on the basis of field use and be summarized, evaluated, and placed in the hands of designers.
2) Tube, component, and especially system-reliability, programs be continued by appropriate groups.
3) Reliability requirements be added to military characteristics prepared by the Joint Communication Electronics Committee.
4) A study be made of maintenance minimization.
5) A study be made of affects of unreliable equipment.
6) Reliability concepts be involved in procurement, production, and quality control of electronic equipments.
7) The RDB reliability activity be extended from the initiation of military characteristics through its operational use, and that a permanent RDB reliability group be established.
8) Educational activities be expanded and a reliability information center be established to provide reliability data.
9) Testing of equipment, simulating use in the field, be expanded.
10) Analyzing and approving new designs with regard to easy maintenance and reliable performance be established.
11) A reliability section be put into specifications.
12) The training of inspectors be improved.
13) Engineering supervision of installation of equipment by the material agencies and their contractors be improved.
14) Training of operators be improved, with reference to results of operational abuse of equipment.
15) Maintenance problems be investigated to secure better preventive maintenance, training, and simpler test equipment.
16) Reliability organizations be set up in the military department.
17) Requirements of classification as to degree of reliability necessary in specific items be adopted and integrated into military characteristics.

At the IRE National Convention, New York, N. Y., March, 1952, a very significant paper was presented which summarized many facets of the national reliability problem. Such aspects of reliability as the product rule, accelerated testing, designing for safety margins, dependency on the human, and the affects of environment were presented by Capt. A. C. Packard, U.S.N., from the Naval Air Missile Test Center. (The paper was jointly authored by Capt. Packard and Dr. Royal Weller.)

Another significant event for reliability occurred, during 1952, at the suggestion of Dr. W. R. G. Baker. Three planning groups in the Radio and Television Manufacturers Association (RTMA),[3] covering the broad fields of tubes, components, and systems, were merged into one committee entitled "Electronic Applications Committee" (Reliability). The title of this Committee has been variously labeled, but the most common abbreviations are EA(R), and CEAR. Lewis M.Clement was Chairman of EA(R) and M. A. Acheson, Dr.Preston Robinson, and J. A. Chambers were the initial Vice Chairmen.

A major contribution of EA(R) was the distribution of the *Electronic Applications Reliability Review Bulletins* to a list of 4,500, which did much to awaken many people in the military and industry to the problems in reliability.

During 1952, the Navy Bureau of Ships became very active in supplier liaison in order to establish better control of reliability in specifications. The "General Specification for Naval Ship and Shore Electronic Equipment, 16E4 (Ships)" was rewritten and sent to various electronics contractors for comments and recommendations. These comments were reviewed and, where applicable, included in the new "Specification, MIL-E-16400 (Ships)," dated May 1, 1953. This specification stressed greater use of preferred and standard parts, U. S. Navy reliable tubes, and high-quality materials. It also stressed simplicity in design and ease of installation and maintenance. It required the use of check points for fault location, human-engineering analyses during design, and many other specifications aimed at better reliability.

It was also during July, 1952, that the coordinated "Specification MIL-E-5400" was issued to supersede AN-E-19. In addition to many requirements which were beneficial to reliability indirectly, there was one paragraph that was specifically intended to help reliability. Because of the historic nature of this paragraph, it is quoted in full:

> Par. 3.2.9 *Life.*—The equipment shall be capable of 200 hours of operation without servicing. The total operating life shall be as specified in the detail equipment specification. Replacement of vacuum tubes operated within their specified ratings is not considered a failure. The equipment shall furnish specified performance after a life test. The cycle of operation shall be as specified in the detail equipment specification.

[2] Ad Hoc Group Rept. No. EL200/17, 2 vols; February 18, 1952.

[3] Various names for the same organization:

1) RMA—Radio Manufacturers Association, 1924–1950.
2) RTMA—Radio and Television Manufacturers Association, 1950–1953.
3) RETMA—Radio, Electronics, and Television Manufactuers Association, 1953–1957.
4) EIA—Electronic Industries Association, 1957–Present.

This was a wonderful tool for controlling reliability, but, although MIL-E-5400 was specified for years on hundreds of contracts, it remained unenforced for several years. Finally, the Air Force interpreted the first sentence to mean that all production equipment should be put on a special 200-hour life test to prove that the 200-hour requirement had been met. Each batch on test would be accepted if 80 per cent of them passed the 200-hour test. When a total of 22 equipments had been accepted, a reduced sampling of 1 in 12 would be used as the test sample. Failure of any composite sample caused the return to 100 per cent testing.[4]

An interesting document, "Electronics Equipment Reliability," was issued by the Navy (NAVSHIPS-91957) on June 15, 1953, in answer to the Department of Defense Directive Number 150.21-1, issued on September 12, 1951. In the foreword, Rear Admiral H. N. Wallin, U.S.N. Chief of Navy Bureau of Ships, explained:

> This pamphlet contains information showing the broad scope and the many factors involved in the effort to increase reliability of electronic equipment. Also included in this pamphlet is a summary report on the Navy Department's participation in the over-all Defense Department Electronics Reliability Program.

On August 21, 1952, six months following the final report of the Ad Hoc Group, and as one consequence of its recommendations, the Advisory Group on Reliability of Electronic Equipment (AGREE) was formed by the Department of Defense under the RDB. The first step taken by the new AGREE after its establishment was to review all the recommendations of the Ad Hoc Group and place them in priority categories for further study.

The next incident of importance occurred in 1953, when the Rand Corporation issued a research memorandum (RM-1131, dated August 14, 1953) entitled, "A Survey of the Current Status of the Electronic Reliability Problem," written by Dr. R. R. Carhart. This was an excellent survey analysis that set the stage for years of reliability work. One of its immediate uses was to provide information and impetus to the first major reliability-control program in an industrial company established at the Radio Corporation of America, Camden, N. J. Shortly thereafter, the head of this program, C. M. Ryerson, released the first reliability calculator for use in equipment design. It was a later outgrowth of this program that provided the now-well-established reliaability prediction technique known as application stress analysis.

On July 15, 1953, the Bell Telephone Laboratories submitted their final report on the Naval Bureau of Ships component-parts failure analysis program. This report covered the period from July 1, 1951 to June 30, 1953. Many thousands of returned failed parts from the Airinc, Vitro, and other collection programs were analyzed. Specific types and causes of failure were noted and this information made available to the parts manufacturers. Some significant facts were revealed by this analysis. For example, "62 per cent of all returned failed power resistors did not conform to the JAN specifications." Again, "The principle cause of potentiometer failures is overloading due to the failure of another component, primarily vacuum tubes."

An important summary of reliability problems was written by Russell H. Lindsay of the Boeing Airplane Company, in 1954. This was entitled, "Practical Expectations and Limitations of the Reliability Problem," and was printed in the *Aeronautical Engineering Review*.[5]

When the Research and Development Board was abolished in 1953, AGREE was transferred to the Assistant Secretary of Defense (Research and Engineering), and reestablished in 1954 as part of the Office of the Assistant Secretary of Defense (Applications Engineering). The final directive for AGREE, dated March 31, 1954, established the purpose of AGREE as assuring that " . . . the best available scientific, engineering, production and operational talent are applied to the achievement of reliability in the field of military electronics. . . . "

At the same time (March 30, 1954), the Panel on Electron Tubes was redesignated the Advisory Group on Electron Tubes (AGET) with essentially the same charter.

A few months later, (June 8, 1954), the Advisory Group on Electronic Parts (AGEP) was formed. This group's objective was to assist " . . . in achieving a sound, coordinated, and integrated research and development program in the field of electronic parts."

During the period following the formation of AGREE, AGET and AGEP, the question of unreliability in military equipment became a legislative issue. In July, 1954, the House of Representatives' Committee on Government Operations had before it for study a report[6] by its Sub-Committee on Military Operations concerning the development and procurement of a revolutionary new airborne radio transceiver. The sub-committee noted that the stress of the Korean war was a major factor in the need for the new equipment, but felt that the unreliability of the equipment should have been resolved before the Air Force ordered production quantities of the equipment. They stated, "The Sub-Committee is of the opinion that it is not enough to design equipment which meets complex performance requirements. To be of real value, the equipment must be economical in initial cost, operating cost, and maintenance costs, and in providing the flexibility necessary to meet changing operational demands."

In March, 1955, the same sub-committee reviewed the merits of an important piece of air navigation equip-

[4] This requirement of 80 per cent passing a 200-hour test was actually specifying a mean-time-between-failures of 1000 hours according to the exponential law.

[5] Vol. 13, No. 10; 1954.

[6] House Rept. No. 2578, 83rd Congress, 2nd Session; 1954.

ment.[7] Once again, unreliability was discussed and, again, the sub-committee noted that the reliaibility of a piece of gear should be determined before production is authorized.

The National Bureau of Standards', "Preferred Circuits Manual," was published in 1954, containing 17 suggested circuits. These were derived from a study of many equipments, both commercial and military, representing designs that were well stabilized. In all cases, similar circuits had been in use for at least ten years without major improvement. This project was sponsored by the Navy Bureau of Aeronautics and was aimed at reducing drastically the multiplicity of circuits in Navy aeronautical equipment. Later editions of the manual have given more emphasis to modern circuits improved from the reliability standpoint.

An important national event for reliability occurred in New York, N. Y., on November 12–13, 1954, when the first of the National Reliability Symposia was held in the New York Statler Hotel. This symposium was financed by the IRE Professional Group on Reliability and Quality Control, and jointly sponsored by the IRE and the ASQC. Additional sponsors (AIEE, AIA, and EIA) were added for subsequent events which have been held according to the following schedule:

Symposium	City and State	Hotel	Dates
1st	New York, N. Y.	Statler	November 12–13, 1954
2nd	Washington, D. C.	Statler	January 9–10, 1956
3rd	Washington, D. C.	Statler	January 14–16, 1957
4th	Washington, D. C.	Statler	January 6– 8, 1958
5th	Philadelphia, Pa.	Bellevue Stratford	January 12–14, 1959
6th	Washington, D. C.	Statler	January 11–13, 1960
7th	Philadelphia, Pa.	Bellevue Stratford	January 9–11, 1961
8th	Washington, D. C.	Statler	January 9–11, 1962
9th	San Francisco, Calif.	Palace	January — 1963

All the National Reliability Symposia have retained the same general theme, "A Progress Report on Reliability." The concept has been to report to the Nation, at the beginning of each year, concerning the present status and to challenge and spark progress in reliability for the coming year. There have been only minor variations on this theme year by year.

One interesting facet is that the early symposia were restricted almost entirely to reliability in electronics. After the first few symposia, however, it became obvious that the coverage was becoming broader and more general. As the field of reliability control in electronics developed, it became obvious that the principles and techniques involved were applicable to any type of industry. There has been considerable pressure from many groups to drop the limitation entirely, and thus the title of the 8th National Symposium no longer contains the words "in Electronics." Reliability is a universal subject which embraces all fields and technical engineering specialties.

Two important publications were issued in 1954. One was the NEL "Reliability Design Handbook,"[8] published by the Navy Electronics Laboratory, San Diego, Calif., under Capt. Henry E. Bernstein. The other was the companion NEL "Reliability Bibliography."

On March 17, 1955, the Department of Defense issued the directive DOD 4105.10. This directive made possible the award of the first production order to the developer and designer at a price higher than that of the low bidder. This provision is important to reliability for two reasons:

1) The developer has an incentive to invest his own money in doing a good job in developing a mature design.
2) A problem exists in that the developer knows the equipment better than anyone else and also knows the high costs of making it reliable; thus, his bid is not likely to be the lowest.

In April, 1955, the Air Force issued the "Reliability Factors for Ground Electronic Equipment," prepared by the McGraw-Hill technical writing service for the Rome Air Development Center, Griffis Air Force Base, N. Y., under contract NO AF 30(602)-912. Later, McGraw-Hill was given permission to put this book on the market as a commercial book. It was edited by Keith Henney.

In 1955 two important events developed from the progress in reliability which had been made at RCA. First, early in the year the program director, C. M. Ryerson, released the first Industrial Manual on Reliability entitled "The RCA Reliability Program and Long Range Objectives." This book was affectionately referred to as the "Brown Book" by many who used it as a basis for their own programs.

The second related event was a National Conference on "The Reliability of Military Electronic Equipment," held in the Warwick Hotel, Philadelphia, Pa., on August 16–17, 1955. This was jointly sponsored by the Air Force and the Radio Corporation of America. The purpose of the conference can best be described by quoting from the introductory remarks by Major General T. P. Gerrity, Assistant for Production Programming, Deputy Chief of Staff, Materiel, USAF.

> . . . Electronics has come to play a primary role in building modern air power. . . . While the substitution of electronics equipment for human control has given us the high performance we need, it has also greatly increased our dependence on the equipment for the success of our missions. At the same time, it has imposed a heavy responsibility and obligation on the electronics industry to develop and produce equipment of the highest degree of reliability. . . . As time goes on, our dependence on electronic . . . reliability will become even more urgent.

This same plea of urgency and importance has echoed and re-echoed in hundreds of similar meetings since that time. The interesting aspect of this meeting was the amount of valuable technique and information given

[7] House of Representatives Hearings, 84th Congress, 1st Session, 1955.

[8] Dept. of Commerce OTS-PB121839.

out to help bolster reliability efforts in industry. This theme can be explained best by further remarks from General Gerrity:

> ... I am confident that the scientific and production genius of American industry will find a solution to the urgent problem of combining high performance and reliability. . . . Further, I feel that we in the Air Force, jointly with RCA, have gained some very valuable experience over the past few years that will be helpful to industry in the solution to this problem. For this reason we have invited you here to participate in the Air Force-RCA Story on Electronic Reliability.

On October 24, 1955, a significant booklet was released by the Naval Ordnance Laboratory, Corona, Calif., dealing with instrumentation error and other factors in reliability measurement. This was written by Jerry L. Hayes, and was entitled, "Factors Affecting Measurement Reliability."

On December 9, 1955, the Lincoln Laboratory of the Massachusetts Institute of Technology released a helpful booklet for designers, written by N. H. Taylor, entitled, "Designing for Reliability."

In the spring of 1955 the DOD decided that AGREE could contribute more directly to the solution of the problems of reliability if it were reorganized and given specific assignments. Accordingly, a program of nine tasks was established in these areas: numerical reliability requirements, tests, design procedures, component parts, procurement, packaging and transportation, and storage operation and maintenance. A task group of members from the military departments and industry was assigned to each of the tasks early in 1956.

As a result of its investigations, a report of major magnitude was issued by AGREE on June 4, 1957, entitled, "Reliability of Military Electronic Equipment." The core findings of this report serve as a technical basis for the current national approach to military system reliability.

The successful results obtained on many contracts in which the information in this report has been applied and AGREE testing required proves the value of formal reliability control programs. Many applications of the AGREE report could be cited in a more complete history. However, at a minimum, it should be mentioned that the report of Task Group 4 on obtaining reliability in developmental contracts (R&D) was later issued as MIL-Std-441. Also, the test requirements of Task Groups 2 and 3 were included in MIL-R-26667 (USAF).

On October 1, 1956, RCA provided industry with the first breakthrough on the subject of specific part failure rates and derating information. The now famous TR-1100 report was issued as an engineering aid to design and reliability prediction. Later versions of this report were released through OTS Department of Commerce, and now the latest version is available as Section No. 8 of the RADC Reliability Notebook.[9]

The Radio Electronics and Television Manufacturers Association became active in reliability during 1956. At least three major efforts are worthy of mention, as follows:

1) On May 21 and 22, 1956, RETMA sponsored a symposium on "Reliable Applications of Electron Tubes." This was held at the University of Pennsylvania, Philadelphia, and was cosponsored by AGET, the IRE Professional Group on Electron Devices, and the Joint Electron Tube Engineering Council (JETEC).
2) On December 19 and 20, 1956, RETMA also sponsored a symposium on "Applied Reliability." This was held at the University of Southern California, Los Angeles.
3) Also in December, 1956 RETMA published a report prepared by its Systems Reliability Analysis Task Group, under the chairmanship of G. M. Armour of the General Electric Company. This was entitled "A General Guide for Technical Reporting of Electronic Systems Reliability Measurement."

In December, 1956, the Air Force issued the "Design Factors for Aircraft Electronic Equipment,"[10] prepared as a compilation of important work from a group of Air Force consultants.

The Air Force approach for some years, prior to 1956, had been to influence their contractors in every possible way to establish formal reliability programs. A major step in this direction was taken late in 1956 by General Baker, Director of Procurement and Production of AMC. Letters were sent to the major Air Force suppliers, requesting them to describe in detail their reliability-control programs. Then, in order to properly evaluate the answers, an Ad Hoc Committee of AMC-ARDC personnel was established and indoctrinated for this purpose. The Committee consisted of a representative from each of the following: within AMC—The Directorate of Procurement and Production, The Aircraft and Missiles Division, the Aeronautical Equipment Division, the Directorate of Maintenance Engineering, and the Office of Quality Control; from ARDC—The Directorate of Systems Management; and from WADC—The Directorates of Operations, Research, and Development. In all cases, representatives were selected for their knowledge and interest in the reliability area. In addition, representatives participated from the particular Weapons System Project Office or the Buying Office related to the contract program being reviewed.

The first task of the committee was to establish criteria for the evaluations—to create a yardstick against which the submitted programs could be measured. Ten elements for rating were established as follows: Concept and Approach; Organization; Programming; Quality Control; Reliability Requirement Studies; Qualification Testing; Acceptance Criteria;

[9] ASTIA Doc. No. AD-148868.

[10] WADC Tech. Rept. 56-148.

Failure and Deficiency Reporting; Analysis and Correction; Relationship with Vendors and Sub-Contractors; and, Training or Reliability Indoctrination. Eight manned-aircraft contractors, eight missile contractors, and ten subsystem contractors were evaluated. The analysis showed that most of the programs fell short of being good.

Of the ten rated elements, the poorest were Programming and Training. The next poorest were Reliability Requirement Studies, Organization, and Concept and Approach. These five are, of course, closely related and embody the planned, organized and directed approach so essential to good reliability results.

As might be expected, Quality Control was the strongest element, followed closely by Failure and Deficiency Reporting, then Analysis and Correction. Qualification Testing, Acceptance Criteria, and Relationship with Vendors and Sub-Contractors were on the better side of the balance. These five elements have all had considerable attention over a long period of time. They are recognized essentials to any good production program and are important elements in a reliability program. However, they will not by themselves assure *high* reliability.

The preceding is quoted directly from a report of the analysis given by H. G. Spillinger, Colonel, USAF, Chief, Product Engineering Staff Division, Directorate/Procurement and Production Headquarters AMC. This report was presented several times, once at the Air Force-Aircraft Industry Conference sponsored by the Directorate of Flight Safety, The Inspector General, USAF, Santa Barbara, Calif., March 12, 1957. Each time the report was given it included the important statement: "Over-all, our evaluations reveal that too much reliance is being placed on 'fix-it' procedures—insufficient attention to the principle that reliability must be inherent in the basic design." Unfortunately, this is a truism valid to this day.

In January, 1957, the Air Force issued "Techniques for Application of Electronic Component Parts in Military Equipment."[11] This is a very thorough manual on part application which contributed greatly to design reliability.

From 1955 through 1958, the reliability program at the Army Redstone Arsenal was in full swing. Many interesting and thought-provoking booklets were released. Outstanding among these is "The Notorious Unreliability of Complex Equipment," dated September, 1956, and "Reliability Through Safety Margins," dated October, 1958, both by Robert Lusser; and "Optimum Allocation of Funds for Reliability Programs of Guided Missiles," dated January, 1955, revised, April, 1958, by Dr. Erich Pieruschka.

On July 1, 1957, the International Geophysical Year began officially. Actually, a great deal of the research work associated with IGY had been going on for months prior to the starting date and did not finish through several extensions of the IGY. Considerable significance for reliability relates to the IGY effort. Perhaps one of the outstanding achievements was the high-altitude balloon flight of Air Force Scientist Major David G. Simons. This flight reached the height of 100,000 feet and produced evidence of the high-radiation content of the upper atmosphere, later identified as the Van Allen Belts. Many other developments of the IGY have helped take the space satellite out of the realm of science fiction. In this connection, the notorious unreliability of the Vanguard equipments should be placed at the top of the list of examples from which to learn reliability lessons.

In 1957 the Air Force coined the word "air/space" to describe the single operational medium once conceived by many to be two separate mediums: "air" and "space." This term was later modified to "aerospace." Thus, a modern aerospace craft is a vehicle designed to operate both within the earth's atmosphere and in the vacuum of outer space. An example is the Air Force dyna-soar. A true spacecraft is one designed to operate only in the vacuum of space. The implications to reliability of these new operational environments are only beginning to become apparent. Entirely different orders of magnitude of effort, urgency and expense are involved now than were required in the past.

In October, 1957, the Advisory Group on Electronic Parts (AGEP) made a good contribution by issuing a manual entitled "Environmental Requirements Guide for Electronic Parts." This guide was subsequently issued as MIL-Std-446.

Three months prior to the publication of the AGREE report in June, 1957, the Ad Hoc Committee for Guided Missile Reliability (ACGMR) was formed (March, 1957), under the Assistant Secretary of Defense (Research and Engineering). This committee was transferred to the Office of the Director of Guided Missiles on November 15, 1957. The ACGMR was to design a ". . . uniform monitoring program and management procedure that can be used effectively for all types of guided missile projects."

In April, 1958, the ACGMR published a report,[12] frequently referred to as the "Red Book." The management and monitoring program proposed starts when the contract is awarded and continues through all phases of design, development, production, and major product improvement. To ensure compliance with reliability specifications, and to aid the contractor in knowing whether these goals are being reached, eight test points or "milestones" are established in each project, at which time a fully documented report from the contractor, concerning either the predicted or the verified reliability, is required.

These eight reliability monitoring points were based on several conclusions of the committee. First, the committee believed that ". . . reliability is a parameter that can be predicted, assessed, measured and controlled

[11] WADC Tech. Rept. 57-1, vol. 1, ASTIA Doc. No. AD110672.

[12] "Proposed Reliability Monitoring Program for use in the Design, Development, and Production of Guided Missile Systems," DODOA SD-GM; April, 1958.

during the design, development, production, and major product improvement phases of guided-missile weapon systems." Second, they believed that ". . . it is technically feasible and sound to specify and monitor reliability in guided-missile weapon sytems during their growth cycle."

One of the recommendations in the AGREE report of June 4, 1957, was that a permanent group be established at Department of Defense level to include representatives of industry and the three services, and to be charged with the tasks of developing military-component specifications, testing component parts for design capability, and developing inspection methods. This group would serve as a National Reliability Center.

A year later, action was taken to do something about this recommendation. On July 14, 1958, an agreement was made between the Director of Production Policy, OASD (Supply and Logistics) and the Director of Electronics, OASD (Research and Engineering)[13] to establish the Ad Hoc Study Group on Parts Specification Management for Reliability. The assignment to the new Ad Hoc Study Group was to ". . . analyze the recommendations established by the AGREE Task Group 5 in order to advise the Assistant Secretaries of Defense (Research and Engineering and Supply and Logistics) regarding efficient implementation methods and procedures." Expanding upon this objective the group studied specification preparation, requirements for reliability, support from industry and documentation, and also questions of qualified product lists and the need for a management organization for military part specifications at the Department of Defense level.

The report of this Ad Hoc Study Group was issued in two volumes in May, 1960.[14] In addition to establishing three prototype specifications for reliable parts and proposing new procedures for refining the technical documentation of parts characteristics, a proposal was made to establish a new advisory group to report directly to the Assistant Secretary of Defense (Supply and Logistics). The proposed title for this group is AGMEPS, the Advisory Group for the Management of Electronic Parts Specifications. It is understood that negotiations are now underway on methods to implement these latest recommendations.

During the period in which the Ad Hoc groups were active at the DOD level, the military departments were also working on reliability. The Navy (Bureau of Ships) had continued its tube analysis and improvement program, and other Bureaus had pursued various projects for better reliability. A major Navy effort for reliability was initiated by the Chief, Bu Aer, Rear Admiral R. E. Dixon, on October 13, 1958. In Bu Aer Instruction 5420.13, Admiral Dixon announced the establishment of a Bu Aer-Industry Advisory Board on Reliability and Operational Design Requirements of Aeronautical Material (BIMRAB). A brief charter described the function as advisory to the Chief Bu Aer on the reliability, maintainability, and safety requirements for maximum operational integrity. The charter also specified that the Assistant Chief for R&D Bu Aer would be Chairman of the Board, and that a mixed group of Bu Aer and Industry members not to exceed 15 people would be appointed (10 from industry).

An Ad Hoc Group of Bu Aer and industry members met on February 13, 1959, and established the preliminary organization and procedures for the board. Working groups were appointed for Management Procedures, Engineering Procedures, Production Quality Control, Field Maintenance and Support, Information and Education, and Data Processing. Under the initial Chairmanship of Rear Admiral L. D. Coates and others, the Advisory Board performed a valuable service in funneling advice and recommendations from industry and Bu Aer activities to the chief of the bureau.

On February 13, 1959, shortly after the Navy Bureau of Weapons was formed from a coalition of the old Bureau of Ordnance and the Bureau of Aeronautics, a directive (BU WEPS 5420.3 FQQE-21) was released transferring the BIMRAB to the Chief of the Bureau of WEPS, Rear Admiral Paul D. Stroop.

During the years following 1957, a series of Navy-Industry Conferences were held. The later conferences were taken over as a major function of BIMRAB. These can be listed as follows:

Number	Date	Location
1st	October, 1957	Naval Aviation Safety Center, Norfolk, Va.
2nd	November 5–6, 1958	Virginia Beach, Va., Cavalier Hotel
3rd	November 4–5, 1959	Virginia Beach, Va., Cavalier Hotel
4th	November 1–2, 1960	Washington, D. C. Shoreham Hotel
5th	Planned for Fall, 1962	Washington, D. C.

Many events important to reliability occurred during 1958 which were continuations of programs already described, such as the 4th National Reliability Symposium, which was held in Washington, D. C., in January. But an event at this symposium deserving further comment was an evening panel discussion on reliability definitions. This subject is probably one of the major problems in our national reliability picture. Very few conclusions could be drawn from the panel discussion at the symposium, except that nearly every tentative definition was highly controversial, and that the semantics problem was a serious deterrent to reliability achievement. It was obvious that a great deal more work on definitions was needed.

On December 15, 1958, the National Definition Pro-

[13] E. J. Nucci, "Progress report on ad hoc study on parts specifications management for reliability," 1959 IRE NATIONAL CONVENTION RECORD, pt. 6, pp. 120–129.

[14] PSMR-1 Parts Specification Management for Reliability, Supt. of Documents, U. S. Govt. Printing Office, Washington, D. C.; May, 1960.

gram, jointly sponsored by IRE-PGRQC, the ASQC Electronics Division, DOD, and the AIAERP, issued an "Interim Dictionary of Terms and Definitions for Product Assurance and Related Fields." This program was chaired by C. M. Ryerson of RCA, and the interim dictionary contained a compilation of definitions from many sources screened mainly to eliminate major contradiction.

On August 1, 1958, the Air Research and Development Command (ARDC) issued a booklet, "Technical Program Planning Document (TPPD) Release Program." The objective of the TPPD Release Program was to "engage the engineering and scientific talent of the United States under an Air Force-Science-Industry team concept for the purpose of providing a more comprehensive and integrated effort in achieving Air Force goals in research and development."

Quoting from the introduction of the TPPD document, "In the final analysis, national security is founded on our ability to produce quality (reliability) perhaps even more so than quantity,—and it is only common sense that everyone on the team should be kept fully informed of our technical goals as we see them. These technical goals are furnished by qualified people in Science and Industry in the form of documents known as Technical Program Planning Documents (TPPDs)." The efforts of many people to induce the vision of reliability research as a major need to be incorporated in the TPPDs has to-date borne little fruit.

In December, 1958, AGEP[15] issued the first "Capsule Summary of the AGEP Program in the Area of Electronic Parts and Materials," GEP245/1. This document is a compilation of brief summaries on the active and completed research and development projects sponsored by the Army, Navy, and Air Force on parts and materials. Since that date, five other summaries have also been issued at about six month intervals. The last issue (October, 1960) consisted of two volumes; the active projects and the completed ones. Current project sheets on all active projects can also be obtained on a need-to-know basis. The AGET[16] also issues similar sheets and summaries related to projects on tubes.

Just prior to the January, 1959, 5th National Reliability Symposium, the Radio Corporation of America released a "Manual on Product Assurance," prepared by C. M. Ryerson, then newly appointed Staff Manager of Product Assurance. Quoting from the introductory abstract, "Product Assurance is the new management centered program for giving assurance to management and to the customer that all product attributes such as reliability, quality, maintainability, productibility, value, system integration, etc., comply with commitments and will satisfy the customer's needs." The product-assurance program extends into all operations of each division from early contract negotiations to final field follow-up, and includes the responsibility for assuring an optimum effective trade-off among all the controls of product characteristics. Since this manual has been issued, many organizations have adopted similar programs to integrate their various control operations.

In March, 1959, the Inter-Service Data Exchange Program (IDEP) was born. The purpose of this program was to provide for the free and automatic interchange of data among the ballistic missile major contractors, subcontractors, and government agencies of unclassified, nonproprietary reliability data. Three centers for the three services were established: BMD (now BSD), Low Angeles, Calif., for the Air Force; NOL, Corona, Calif., for the Navy; and ABMA, Redstone Arsenal, Ala., for the Army. Data was to have been exchanged on dual aperature microfilm EDP cards. These have since been found to be inadequate and a microfilm strip attached at the top of a printed summary page is now being used. The civilian leader for this project is Martin Barbe, the Aerospace Corporation, Los Angeles, Calif.

Mention should also be made of the Battelle Memorial Institute data exchange program. In March, 1959, Battelle established its Electronic Component Reliability Center, subscribed to at $20,000 per year by a group of industrial firms, all large users of electronic parts. In addition to exchanging test data from its subscribers, the ECRC performs research and data analysis pertaining to the reliability of electronic parts.

On May, 18–20, 1959, the Air Force held a review conference at AMC Headquarters, Wright Patterson Air Force Base, Ohio. This was entitled, "Reliability of Weapon System Equipment," and was jointly sponsored by the Air Materiel Command (AMC) and the Air Research and Development Command (ARDC). Its purpose was to indoctrinate the representatives of the Air Material Areas, Depots and Centers in the philosophy and policies of Reliability. This was a part of the general Air Force reliability training program planned for all divisions and groups. Both military and industry people were invited speakers to present the best known about reliability control.

On July 14, 1959, the Space Technology Laboratories released "STL Reliability Policies and Procedures." Under this system, technical management contract with the AFBMD STL was required to give technical assistance and direction to the various contractors on the subject of reliability. A committee was formed, with H. R. Powell as Chairman, under the technical direction of James H. Allen, to develop a complete guide to reliability. Much of the contents of this document is identical with previous guidance material issued by Allen on the Thor and Atlas programs. It also was closely allied with the contents of AFBM Exhibit 58-10, which is now referenced on nearly all missile contracts.

A significant event occurred during the two weeks

[15] AGEP Secretariat, 200 South 33rd Street, Philadelphia 4, Pa.
[16] AGET Secretariat, 346 Broadway, New York, N. Y.

from October 19–30, 1959. This was the first "Reliability Training Course for Business Management, given under the auspices of a special Reliability Training Committee, jointly sponsored by IRE-PGRQC and ASQC-Electronics Division. This first course was a dual session event given at the Traymore Hotel, Atlantic City, N. J. Sixty-five students from all over the country attended. Twenty-two similar, but one session and one week, courses were given in various parts of the country during subsequent months. C. M. Ryerson was the organizing General Chairman of the joint training committee and the IRE representative. F. M. Gryna, Jr., was general Vice Chairman and the ASQC representative. A training text had been prepared during the preceding year, based on contributions from over 35 authors. An editorial board, under the direction of C. M. Ryerson, performed the final editing.

Many specifications and directives have been written by the military services and it would be futile to try to describe them all here. However, the following paragraphs review some of the more important of these documents as they relate to AGREE and subsequent DOD documents.

On March 23, 1959, Headquarters, USAF, sent a letter to the Commanders of AMC and ARDC stating, in part, that a real ". . . need for increased emphasis on reliability. . ." had arisen as a result of the increased complexity and costs of present weapon systems. As a result of this need, Headquarters, USAF, directed that ". . . all new weapon systems contracts include a meaningful reliability requirement . . .," and it proceeded to define "meaningful" by asserting that ". . . a contract should state clearly what the contractor is to achieve and, of equal importance, what specific tests or means the contractor must use to demonstrate achievement." The letter went on to deal with current contract and contractors, making the point that these ". . . contractors should be required to define present reliability goals and establish suitable tests to demonstrate that the reliability achieved meets operational needs." Although merely a letter to two subordinate commands, this letter is important in that it constitutes the first statement concerning reliability made by one of the military services headquarters.

A few days later, with a primary aim at aiding the quality-control personnel, Headquarters, AMC issued AMC Pamphlet 74-1 (March 31, 1959), "Reliability Evaluation Procedures for Pilot-Production and Production." This Pamphlet is basically ". . . a detailed explanation of the reliability index evaluation procedures recommended by Task Group Number 3 of the Advisory Group on Reliability of Electronic Equipment (AGREE). Specific emphasis is placed on methods for determining and evaluating the reliability index (mean-time-between-failure) of electronic equipment during pilot-production and production." Containing tabled and graphed figures of various functions such as "equipment reliability as a function of mission time and MTBF," "sequential sampling plan," and the like, the pamphlet assists quality control persons to become relatively knowledgeable in those statistical evaluation techniques concerned with sampling for reliability evaluation.

This was followed a month later by Department of the Air Force Letter 84-1, (April 30, 1959), subject, "Reliability Monitoring Program for Weapon Systems."[17] Attached to this letter was a modification prepared by representatives of both AMC and ARDC, of the Department of Defense's Ad Hoc Committee for Guided Missile Reliability (ACGMR) report. In this publication, directive in nature, the Department of the Air Force promulgated three rules: 1) each contract must include a meaningful reliability requirement; 2) the contractor must be prepared to submit to continuous monitoring of his reliability efforts; 3) the contractor must *prove* that the established reliability requirements are satisfied through a formal series of acceptance tests.

Immediately following the issuance of the Department of the Air Force Letter 84-1, USAF Specification Bulletin 506 (May 11, 1959), "Reliability Monitoring Program for Use in the Design, Development and Production of Air Weapon Systems and Support Systems," was published. This specification bulletin, also a modification of the ACGMR report, was a close copy of the attachment to Department of the Air Force Letter 84-1. With the publication of this Bulletin, procuring officers were provided with a document that could be used "externally," in contradistinction to Department of the Air Force Letter 84-1, which was an "internal" document.

During the two-month period following the publication of USAF Specification Bulletin 506 (May 11, 1959), numerous reliability publications were issued most of which drew upon the ACGMR and the AGREE reports. The day after "506" was produced, the first version of MIL-R-26667 (USAF) (May 12, 1959), "Reliability and Longevity Requirements, Electronic Equipment General Specification For," was issued by the Directorate of Laboratories, Wright Air Development Center. On June 2, 1959, it was superseded by MIL-R-26667A (USAF). This specification ". . . covers the analysis and estimation of reliability and longevity, the method of measuring reliability and longevity, the analysis of deficiencies and report of effort to achieve specified reliability and longevity." To assist the contractor, the specification provides for a design analysis to be performed by the contractor in order to establish ". . . the failure rate for each part application and the expected reliability and longevity of the equipment." Repeated analyses are to be performed in order to account for ". . . effects on reliability and longevity which may

[17] An Air Force letter is administrative in nature and general in application. It contains ". . . regulatory material considered to be temporary in duration, or informative matter that may be of either temporary or permanent interest."

occur because of changes in manufacture and supply." If variance does occur and the equipment is below the specified reliability, the contractor has to develop a plan which can raise the expected reliability to the required level. When referenced by a detail specification, the described analyses are added to contractual requirements and are considered part of the acceptance testing.

This general specification also outlines how reliability test environments should be established, how equipment for test should be selected, and how test procedures should be followed. In addition, it requires initial, special, prototype evaluation, progress, and part-failure-rate reports in order to provide the procuring activity with as much information as possible concerning reliability. MIL-R-26667A is an attempt to utilize the test plans of AGREE Task Groups 2 and 3.

On June 18, 1959, the Directorate of System Management, Headquarters, ARDC, issued MIL-R-26674 (USAF), "Reliability Requirements for Weapon Systems," the purpose of which was to cover ". . . the general requirements for the establishment of an organized reliability program by the contractor to assure the attainment of the reliability requirements specified for the weapon system." The specification notes that this program should take into account the efforts of subcontractors and vendors. The remainder of the document discusses those factors which can affect the reliability of equipment, factors such as "trade-offs," derating, redundancy, testing, and quality control. This particular specification, together with USAF Specification Bulletins 506 and 510, presents a complete program for a contractor to follow in establishing his reliability organization and program.

Shortly after this version of MIL-R-26674 was completed, the Air Research and Development Command released its May, 1959, Special Study Group report, "Reliability in Missile Programs." The Study Group, at the direction of the Commander, ARDC, was to investigate the problems associated with current missile reliability programs and develop recommendations for action by the Department of the Air Force to improve its program. When the study was completed, it was sent to forty-four industrial and military organizations for comment and criticism. Thirty-five responded in detail.

Soon after the special Study Group report was released, the Air Force Ballistic Missile Division, ARDC, and Ballistic Missile Center, AMC, issued a new exhibit pertaining to missile reliability. Designed specifically for ballistic missile systems, AFBM Exhibit 58-10 (June 1, 1959), "Reliability Program for Ballistic Missile and Space Systems," provides ". . . optimum requirements and procedures for contractor reliability programs." The exhibit requires that the contractor prepare a description of the reliability program that he intends to follow during the contractual period. His program must include a sequence of monitoring points which provide for time-phased reviews of reliability efforts and the results achieved by that program. These planned reviews will be made by the contractor as well as by the procuring agency. In order to assure that the specification's reliability requirements are met, the program must include provisions for considering reliability during the design stage. The reliability requirements are to be determined and demonstrated by the contractor. Major portions of the document are concerned with the details of the associated reporting system.

In order to provide "internal" direction, as contrasted with "external" direction as represented by MIL-R-26674 (USAF), the Directorate of System Management, ARDC, produced Directorate Office Instruction No. 57-3 (June 23, 1959), "System Reliability." The instruction established ". . . reliability policy, objectives, responsibilities, and procedures for system programs." Applying to all joint ARDC-AMC System Project Offices, the instruction provides the project officers with procedures for system programs and a list of the officers' major responsibilities, including among them, the following:

1) Define and negotiate quantitative reliability requirements in contracts.
2) Require contractors to formulate and implement a comprehensive reliability program.
3) Establish and chair a system Reliability Review Board to monitor the program and results achieved.
4) Designate within the project office a Reliability Monitor.

In addition, a periodic review of each contractor's reliability efforts and results is to be performed by the "Reliability Review Board." This board, organized as a subcommittee of the Weapon System Phasing Group, draws its members from the ARDC System Project Office, the AMC System Project Center, and the ARDC Test Center System Project Office, each supporting ARDC Development Center, the Logistics Support Manager, and the Operating Command. At the end of each review, the board issues a report ". . . summarizing the status of reliability effort, results achieved, and any recommendations on design changes, reorientation of the program, funding, or other actions necessary to insure that the required reliability will be achieved." The board may call upon technical advisors to guide it.

To provide a continuous effort, the instruction further requires that one or more Reliability Monitors be appointed the following responsibilities:

1) Insuring that the provisions of this instruction and the reference documents are applied to programs in a timely fashion.
2) Exercising continuous surveillance of the contractor's reliability effort.
3) Providing the Systems Project Officer with the reliability factors that must be considered in all management decisions which can affect the operational reliability of the system.

4) Insuring that all available and applicable reliability methods, techniques, and criteria are employed by contractors and supporting Air Force activities.
5) Insuring that revisions to existing published procedures and criteria are applied to programs without undue delay including revisions to general specifications applicable to all programs.

Combined with ARDC Regulation 80-21, this instruction completed, for the moment, the ARDC contribution to a formalized internal program. The regulation provided the over-all policy; the instruction told how it would be managed and applied.

With the publication of U. S. Air Force Specification Bulletin No. 510 (June 30, 1959), "Guides for Reliability Organization," the managerial aspect of the Department of the Air Force reliability program was expanded further. This bulletin was designed to aid contractors in establishing their reliability organization. The program required for the reliability organization is complex and varied and, in turn, requires a fine organizational setup. For the administration of the setup, the bulletin presents three alternative means for determining the adequacy of a proposed reliability organization. The first is based upon the criteria developed by ARDC and AMC for their review efforts. The second is based upon the general experience acquired in numerous industrial programs. The third ". . . takes the form of a Master Check List of Reliability Program Practices based on a specific weapon system program and observation of similar programs."[18]

The next publication to appear was the Aeronautical Accessories Laboratory's MIL-R-27173 (USAF), (July 6, 1959), "Reliability Requirements for Electronic Ground Checkout Equipment." This document was designed to detail ". . . the minimum requirements which must be followed by a contractor to assure the design and manufacture of reliable equipment." Like the other specifications, this specification covers the reports and requirements laid upon the contractor. A minimum MTBF is given (300 hours) to be used when the detail specifications do not provide an MTBF. Tests are required, as are reports similar to those required by preceding specifications.

The next major step in reliability occurred on August 22, 1960, when ARDC issued ARDCR 80-1, "Reliability." This new regulation did not rescind ARDCR 80-21, but added, in addition to other things, the very important phrase ". . . reliability will be a major factor in all source selection actions. . . ."

Soon after ARDCR 80-1 had been published, the Air Force issued AFR 375-5, "Reliability Program for Weapon, Support and Command and Control Systems," dated October 17, 1960. This regulation, too, is indicative of the major steps which have been taken in the reliability area since the early days. Because Air Force contracts are so important to the industrial manager, the policy for the Air Force reliability program is given here in its entirety.

a. Reliability is considered a fundamental characteristic of every part, component, module, and complete system.
   (1) Reliability will be stressed during early system studies, source selection, design, development and production.
   (2) Maintenance, storage, transportation, and operation activities should exercise appropriate controls to maintain the reliability of the delivered article.
   (3) Systems in development and production and future systems will be analyzed, and an appropriate reliability program with realistic requirements will be established for each. Each program will include numerical probability values from a minimum acceptable to the desired goal, with such intermediate quantitative values required to measure progression, and a stated minimum acceptable confidence level for each probability value.

b. Specifications, exhibits, and product descriptions and contracts for systems and associated materiel, including GFE for inventory, will include specific minimum acceptable reliability requirements as one of the major engineering factors.

c. Contracts for systems and major sub-systems will include a requirement for a compehensive contractor reliability program.

d. The Air Force will maintain surveillance during all phases of development and production over the contractor's reliability program, his reliability testing, and quality control activities. Collaboration by reliability, production, and quality control personnel with engineering personnel during concurrent development and production will not relieve the engineering agencies of the responsibility for engineering approval.

e. Contractors' reliability capability, both past performance and proposed programs, will be a major factor in all source selection action.

f. If contract reliability requirements are not met, or if the contractors' reliability effort is decreased, the decision to accept or reject the end item or the revised reliability program will be considered with a view toward monetary penalties, unit price decreases, or other considerations deemed equitable.

g. The adequacy of planned reliability efforts, including funds availability, shall be considered when reviewing new programs. Proposals for increasing reliability efforts and funds on programs in existence shall be considered on the basis of the net effect on the over-all Air Force capability and economy, including such factors as spare parts requirements, maintenance workloads, engineering changes, operating costs, and the effect on the system concerned.

h. Reliability monitoring points will be generally established in the following sequence:
   (1) Detailed design study.
   (2) Preprototype.
   (3) Prototype.
   (4) Preproduction demonstration.
   (5) Demonstration of service readiness.
   (6) Service evaluation.
   (7) Full-scale production.
   (8) Demonstration of major product improvement.

   However, this generalization is not intended to delineate the complete or ideal system life cycle, but to emphasize the typical points at which the program should be monitored.

Paragraph F should be particularly noted, since this indicates the first time that monetary or other penalities for failure to meet reliability goals have been officially sanctioned by the Air Force. The various Air Force subordinate commands are assigned the responsibility of actually carrying through these policies.

During this period among the many good publications from DOD which helped achieve better reliability was the "Quality Control and Reliability Handbook," H 108, issued on April 29, 1960. This contains sampling procedures and tables for life and reliability testing based on the exponential distribution. Other handbooks of this series were also helpful.

[18] This "Master Check List" was taken from the "Reliability Handbook, 7-58-2954-9," compiled by W. J. LeVan of Bell Aircraft Corp., Buffalo, N. Y.

Another event for reliability during early 1960 was the establishment of the National Standards Committee for Reliability C-31 at IRE. The chairman chosen for this Committee was C. M. Ryerson. This committee is now organized and places emphasis on top management participation.

On October 30, 1959, the Air Force issued the "RADC Notebook," in loose-leaf form. This is a comprehensive reliability manual intended to be kept up-to-date by subsequent issue of replacement sheets. Various sections treat different subjects. Section 8 now contains the latest revised version of the RCA TR-1100 Stress Analysis and Prediction information.[19] The sponsor of this book at Rome is Joseph J. Naresky, General Engineering Laboratory, Rome Air Development Center.

On December 15, 1959, the Air Force issued a technical report (RADC-TR-59-243), "Reliable Preferred Solid-State Functional Divisions," prepared for Rome Air Development Center by the West Orange Laboratory of Vitro Corporation. This report was an attempt to determine those circuit functions in which revolutionary increases in reliability are achievable by solid-state designs.

On January 8, 1960, the Army Ordnance Corps issued the handbook prepared by H. Walter Price, Chief of the Reliability Branch at the Diamond Ordnance Fuze Laboratories. This is entitled "Reliability Engineering Notes," and contains a collection of application notes obtained by the Fuze Laboratories in recent months.

V. The Product-Assurance Decade

The preceding sections have covered the years before 1940, including the standards decade; the quality-control decade to 1950; and the reliability decade to 1960. A prominent characteristic of all these periods is that, as new control specialities come into the picture and blossom into full technical fields, the old fields continue to grow and bloom. For example, there has never been any secession of the pressing need for standards as quality control and reliability have come into emphasis. Rather, the need for quality and reliability standards has greatly increased the scope and importance of the standards field. Likewise, as reliability came to the front for special emphasis, quality control has also taken on new facets of importance and new duties. The best design has no value unless it is manufactured into hardware with a minimum of degradation to its inherent reliability.

The end of the decade of the 1950's has witnessed the phenomenal growth of many other control specialities. For example, the best design from the reliability standpoint may be very poor from the standpoint of maintainability. Likewise, a system which is very effective functionally, if operated by itself, may not be reliable if operated in close proximity to other systems. System integration is a new specialty which must be given its necessary support. Of course, there are other product abilities, such as producibility, which have long been important design considerations. But now we have new control specialities, such as value engineering. This recital of new specialties in recent history could review a dozen or more, each of which is the most important in the eyes of its devotees.

But no military operation, and surely no company, can long afford to support a dozen or more independent and across-the-board control agencies and programs. Fortunately, if each of these control specialities is analyzed, it is found that they all have many functions in common. They all aim at a form of technical direction by providing information and operational guide lines. They all depend for their effectiveness on some form of auditing or monitoring. They all need data input from essentially the same sources and feed it back to essentially the same people. They all are based on a modern analytical approach which substitutes numbers for intuitive qualitative decisions. They all take advantage of an unbiased and independent second look to "see the woods and not the trees." And, finally, they all must give some form of assurance to management that optimum teamwork in their speciality is being achieved between all organizational groups.

When these similarities are considered from the management standpoint of the necessity of obtaining an optimum trade-off among all the speciality objectives and project restraints, the stage is set as at the present time for the entry of the product-assurance decade.

When good value can be sold at a good profit and on schedule, this is good business for all concerned. But this requires good cost control and good technical management. An all-out effort to achieve this objective is clearly the challenge confronting this nation and the world in the next decade.

By definition, the management program to achieve good value consisting of good quality, reliability, maintainability, producibility, system integration, system effectiveness, etc., at a low sales price and good profit is product assurance. Welcome to the decade of product assurance, and may your specialty prosper.

VI. Addendum

This partial history of reliability has been compiled with the sad realization that many important events probably have been omitted. If those who become aware of an omission or incorrect entry will charitably advise the author of the full correct details, corrections will be made in any subsequent issue.

Although indebted to many too numerous to mention for their suggestions, the author feels obligated to make special mention of Dr. Joseph Spiegel of the Human Factors Department of the Mitre Corporation, and L. M. Clement, for their special contributions.

[19] Copies of this Manual may be obtained as RADC-TR-58-111, ASTIA Doc. No. AD-148868.

Section 26

SPACE ELECTRONICS AND TELEMETRY

Organized with the assistance of the IRE Professional Group on Space Electronics and Telemetry

Milestones in Development of Electronics for Remote Measurement and Control*

CONRAD H. HOEPPNER†, FELLOW, IRE

Summary—**The developments in electronic remote measurement and control as applied to aircraft, rockets and satellites are described. The highlights are considered to be those developments which have contributed most to the technical progress made in the last twenty years. The impact of magnetic tape recorders, automatic digital computers and transistors upon telemetry and remote control is shown. The transition from remote control to automatic control and guidance is noted and the advent of the remote control-computer-telemetry closed loop is discussed. The characteristics of data transmission which differentiate it from ordinary radio communications are introduced and new horizons in the industrial applications of telemetry and remote control are described.**

IT HAS BEEN a rare privilege to witness and participate in progress made in the short interval of the last two decades, progress which, if it had not been for the stimulus of defense and war, might have required a period of several lifetimes. Although the basic research which made the technical developments possible preceded this period, the applications of that research have borne fruit as practical and spectacular new methods of remote measurement (telemetry) and control. In these past two decades there have been dozens of significant advances worthy of mention and a few of a character which may be classified as milestones. In the opinion of this author the significant milestones may be listed as follows:

1) The development of telemetry and remote control for missiles and spacecraft.
2) The development of instrumentation recorders employing magnetic tape.
3) The recognition of data handling as a problem and the subsequent development of automatic data handling equipment.
4) The development of automatic remote control for guidance.
5) The union of telemetry, remote control and automatic computers in a closed loop.
6) Industrial uses of telemetry and remote control.

Telemetry and remote control are old as employed by the electric utilities for remote switching and metering. These systems, while adequate for their purpose, were slow and generally very specialized. The revolution of telemetry and remote control came about as a result of the need for high-speed systems and the requirement for measurement from and control of moving vehicles. The early development of radio telemetry and remote control was centered around the drone and missile programs of the armed forces. It began slightly before World War II and has been growing and expanding to embrace the testing of aircraft and missiles and the transmission of data from and remote control of mis-

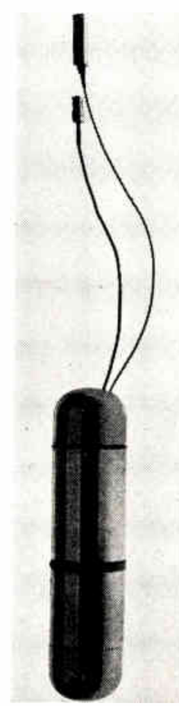
* Received by the IRE, October 9, 1961; revised manuscript received, November 27, 1961.
† Electronetics Corp., Melbourne, Fla.

siles, satellites and spacecraft. Early drones were nothing more than aircraft with the pilots removed and remote radio control substituted. During test phases a pilot was usually carried to perform takeoffs and landings and to observe the performance and deficiencies of control equipment. When the drone was used as a weapon, the pilot was removed and it functioned both automatically and by remote control. It soon became apparent that these missiles could be made better, smaller and more economically if they were originally designed to be pilotless.

One of the early missiles of pilotless design, designated the JB-2, was a copy of the German V-1 buzz bomb. Remote control equipment from the drone programs was adapted to the JB-2. Telemetry was developed to measure the performance of the control equipment and the missile. Meanwhile similar development was carried on to support other programs of strictly "American" design. Remote control developments preceded telemetry by some years, but remote control, as it was initially used, was an "on-off" system, rather than one which provided proportional control. Furthermore, remote control was an intermittent function inasmuch as the vehicles were stabilized by internal automatic equipment. Telemetry, on the other hand, required proportional and linear transmission of measurements on a continuous basis. Consequently, the remote control systems were "adapted" in concept only and telemetering equipment development proceeded quite independently.

Before continuing with the history of remote measurements and control it is well to describe a few of the technical characteristics of typical systems. Remote measurement is generally referred to as telemetry, which may also be considered the inverse of remote control. Telemetry is a special form of communication characterized by 1) the transmission of steady-state (dc) information, 2) flat frequency response from zero to as high as twenty or thirty kilocycles per second, and 3) the multiplexing of numerous different channels of information on a single radio carrier. It is seldom that all of these characteristics are required at one time, but instead, there are many different applications of telemetry with a variety of combinations. Consequently a number of telemetry systems have evolved. A common denominator of telemetry systems and remote control is multiplexing because, with rare exception, data from many sources and commands to many functions are required. Two principlal methods of multiplexing have been utilized; *viz.*, frequency mutiplexing and time multiplexing. In the first, a number of subcarriers are employed, each at a different frequency. All modulate a single radio carrier and then are separated by filters at the receiving station. In time multiplexing a multiplexer or commutator samples each channel successively and applies its voltage to either a subcarrier or the radio carrier. Both methods of multiplexing are used widely. Typical frequency multiplex systems utilize both amplitude-modulated and frequency-modulated subcarriers—usually frequency modulating the radio carrier. Typical time multiplex systems are pulse position modulation, pulse duration modulation, pulse amplitude modulation and pulse code modulation and the radio carrier may be either amplitude or frequency modulated. Characteristics of these systems have been previously published. The frequency multiplex system utilized well-known communication techniques while the time multiplex system developed along lines guided by more recent considerations of information theory. The number of channels, the number of samples per second per channel, and the accuracy of each data sample are the basic considerations of telemetry. The product of these three quantities represents the capacity of the telemetry system and determines the width of radio spectrum which is required to transmit the information.

A simple representative system of FM/FM telemetry is shown in Fig. 1. It was designed to telemeter one or more channels of information over relatively short distances. In this system the output from a resistance bridge tranducer (typically) is transmitted over a radio carrier to a receiving station where a permanent graphic plot is made by a recorder. A resistance bridge controlled oscillator generates the frequency-modulated subcarrier that in turn frequency modulates a radio carrier. An unbalance of the resistance bridge changes the frequency of the subcarrier in proportion. Thus, the frequency of the subcarrier represents the quantity being measured; strain, temperature, pressure, etc. The FM/FM radio carrier is then radiated from an antenna. At the receiving station, an antenna receives the signal and feeds it to a radio receiver which



(*Courtesy of Electronetics Corp.*)
Fig. 1—Two-channel telemetry transmitter.

amplifies and demodulates it to reproduce the subcarrier. The subcarrier is fed to a signal converter which provides an electrical output proportional to the unbalance of the resistance bridge. When more channels are to be telemetered, additional subcarriers are added to modulate the same radio frequency carrier. Simple filter networks are usually added at the transmitter to isolate one subcarrier oscillator from another and at the receiver to separate the channels into corresponding discriminators which in turn provide the voltage analog of the information to recorders. In Fig. 2 is shown a two-channel receiving station. For multiplexing a larger number of channels a mechanical commutator such as shown in Fig. 3 is often employed.

Another system of telemetry finding increasing use is pulse-code modulation telemetry. This is a time multiplex telemetry system which applies analog electrical signals sequentially to an analog-to-digital converter. In some cases the sensors themselves may provide digital outputs. If they do, their outputs are multiplexed with the output of the converter to provide a sequence of voltage pulses whose presence and absence represent the encoded data. This "pulse train" controls a radio transmitter to convey the information through space. In Fig. 4 is shown an advanced type of digital telemeter which employs an error-correcting code.

Fig. 5 shows a digital telemetering receiving station. At the receiving station the code may be restored to

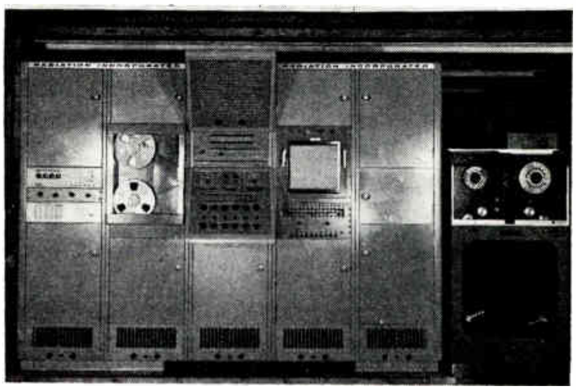
analog form for real time viewing. In most cases, however, it remains in digital form, feeding digital printers, plotters and computers. Then, after it is processed it is viewed as graphs or numbers. Very often the data processing equipment is the largest portion of the "telemetry" system. A typical digital data processing system is shown in Fig. 6.

Remote control systems have also employed frequency-modulated subcarriers to frequency modulate a carrier. The subcarriers are often for the purpose of security rather than for simultaneous controls, particularly in missile range safety equipment. Several subcarriers are utilized concurrently as a code providing the impulse to destroy the vehicle. Remote control systems also utilize pulse-code modulation. In the Telebit system as many as 64 commands to satellite functions are provided by binary digital code transmission. Other remote control systems include radar beam riders, automatic navigation on hyperbolic grids from fixed ground stations and inertial guidance control systems.

The advantages of combining tracking, telemetry and remote control have also been recognized. In the Telebit system these three functions have been combined to provide Doppler tracking in a two-way radio phase locked loop with the earth-to-satellite portion of the loop being utilized to convey command controls and the satellite-to-ground portion for telemetry.

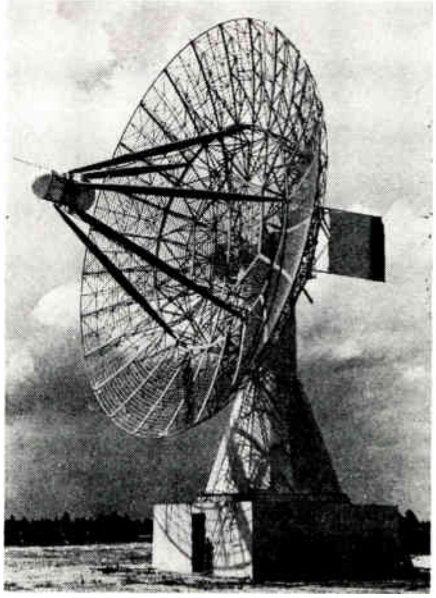
During the development of telemetry and remote control, the impact of generally improving electronic technology was felt. With the advent of transistors and other solid-state electronic components size, weight and power consumption of missile born equipments decreased and reliability increased making it possible to perform many functions of telemetry and remote control that were previously not feasible. The development of large automatic tracking ground antennas (Fig. 7) permitted further reductions in size, weight and power consumption in the vehicle. Consequently the usefulness of telemetry and control were greatly expanded to permit many different measurements to be made in missiles and satellites. These include measurements of the performance of servo systems, remote control and guidance systems, the internal performance of the vehicle, the structure, aerodynamics and propulsion, temperatures, pressures, vibration, external environment such as radiation intensity, magnetic fields, charged particles, micrometeorites and solar light intensities. In order to convert these measurements into electrical analogs capable of being transmitted by radio, it was necessary to develop many new and different transducers. These appeared very quickly and soon vast amounts of data were being assimilated by telemetry receivers and the problem of data handling became severe. Many measurements had to be studied, analyzed and reduced for days after the data was received. Analysis of vibration is an example of such a procedure.

As a consequence, telemetry receiving stations, recording data photographically, oscillographically and by means of pen recorders, grew tremendously in size and complexity as required to record the many concurrent channels of high-frequency data. Certainly then, the appearance of an adequate recorder, the magnetic tape recorder, which replaced the other recorders in the telemetry receiving station, can be hailed as a milestone of progress. With the advent of the instrumentation tape recorder, real time observations and data analysis gradually diminished to be replaced by electrical recording with post-flight playback. A typical telemetering station now consists of an antenna, a receiver and a tape recorder. Recording in the vehicle of electrical data by tape recorder also became feasible. The task of adapting the magnetic tape recorder to telemetry data was not easy, however. Neither its frequency response nor its flutter characteristics were adequate for the task. It was necessary to extend frequency response from 10 kc to 100 kc; tape speed variations (flutter) had to be reduced



(*Courtesy of Radiation, Inc.*)

Fig. 6—Digital data processing system.



(*Courtesy of Radiation, Inc.*)

Fig. 7—Sixty-foot automatic tracking telemetry antenna.

to less than 0.1 per cent and multiple channel capability had to be developed. The fact that these problems have been solved and that satisfactory tape recorders have evolved is a major advance in the telemetry industry. The magnetic tape recorder has also been useful in the remote control field, recording electrical signals from a control system in actual flight and then applying them to a similar vehicle in the laboratory to study its behavior.

Once the ability to assimilate large quantities of data by electrical recording had been developed, the vast possibilities in data processing were soon realized. By far the largest use of telemetry has been in the post-flight analysis of data from internal instruments. Data taken by the telemetry is used for: 1) determining the performance of the vehicle, 2) gathering data for improving the design of the vehicle, 3) determining causes of failure, 4) determining the time occurrence of events and 5) measuring the basic properties of the upper atmosphere and the space beyond the atmosphere. In many cases redundant, unwanted and useless data are taken. It becomes necessary to sort these from the wanted data and the process called "data reduction" evolves. This term is also applied to the correlation of telemetry data with data taken by other means and the computations which may be done to calibrate, convert, smooth, interpolate or extrapolate data. For these computations, since data is already in electrical form, it is possible to enter it directly into digital computers.

In general, measurements made in a test vehicle are recorded as a function of time. Then, on the basis of time comparison, telemetry data may be compared with tracking data and other measurements. In the post-flight computations the parameter time is usually eliminated and the internal measurements are plotted against altitude, velocity or acceleration. Graphic plots are usually acceptable but on occasions numeric prints of the data are required. Special purpose and general purpose computers, both analog and digital, have been employed to perform these functions.

The use of automatic equipment for performing the data processing as described above may be considered another milestone of progress. Automatic equipment is now used to: 1) correlate data, 2) calibrate data, 3) provide numeric printed data, 4) provide graphic plots of data, and 5) perform extensive computation on data. General purpose digital computers with magnetic tape input and output capability are finding extensive use in telemetry programs.

While the art of recording and processing data automatically was developing in the telemetry field, a companion development took place in the field of remote control. This was a transfer of basic concept from remote command control to automatic guidance. The human element and its delay in making decisions has been gradually removed and navigation data transformed directly into guidance and control. A concurrent multivehicle capability soon became practicable and guidance systems employing the principles of: 1) hyperbolic navigation, 2) radio beam riding, 3) target seeking, 4) celestial navigation and 5) inertial navigation have all been outstanding technological developments.

Another ambitious program just now coming into being combines telemetry, remote control and automatic computers for the high speed and automatic testing of aircraft, missiles and spacecraft. A test may be pre-programmed into an automatic computer and the vehicle under test commanded through remote control systems by the computer. Data returned by the telemetry link is used by the computer to verify or modify the test program. In this manner the number of vehicles required to gather sufficient data may be reduced from that required when slower manual methods are employed. Strangely enough it is the general purpose automatic digital computer which fails short in the accomplishment of a complete computer commanded closed telemetry-remote control loop. Its processing speed is not adequate for the programs which are involved. In one current plan, two of the largest computers are multiplexed in order to provide sufficient processing speed.

Still more recent is another trend soon to become a milestone in telemetry and remote control, *viz.*, its application to industry. The techniques perfected for aircraft, missiles and rockets are finding many applications in industry. It is only necessary to apply engineering ingenuity to the old principles to produce long-lived, adjustment free, reliable remote control and measurement devices. Among a few of the applications are: 1) measuring strains on rotating equipment, 2) measuring vibrations, currents and temperatures on high-voltage electric transmission lines, 3) measuring strains in submarine cables, 4) detecting and removing flaws in steel during production, 5) field testing of vehicles such as tractors, cranes, dredges, etc., and 6) biological and medical research. While these applications are only now beginning, they may be expected to outrun the military applications of telemetry and remote control.

Electronics in Planning Space Flights*

ERNST STUHLINGER†

Summary—The phenomenally rapid growth of space flight has placed stringent demands upon the electronics engineer to develop instrumentation of modest size, weight, power consumption and heat dissipation, but of maximum sensitivity, stability, lifetime and reliability. Space flight is creating situations for which no well-developed precedents exist, thus requiring the evolution of new techniques or new basic ideas. Attitude control equipment of space craft will utilize infrared sensors, or the earth-magnetic field, or a radio beam from earth. Cryogenics will be applied to create low operating temperatures. Communications must be maintained by line-of-sight links; the NASA Deep Space Instrumentation Facility will be capable of serving space shots planned for the next few years. Communication systems can be substantially improved by using quantum-electronic devices and light-weight electric power supplies. Telemeter problems include the enormous amount of data which must be transmitted from giant launch vehicles, and the transmission from a space probe of a maximum of data over large distances with a minimum of power. The Saturn C-1 and Mariner telemeter systems are described to illustrate these problems. Space operations such as orbital rendezvous, orbital assembly and launch, approach and descent to the moon and planets will require automated equipment to an extent not previously faced on earth. Electric power supplies with long life, low weight and high reliability are required for the electric and electronic devices on board a space craft; solar and nuclear power appear most attractive to satisfy the requirements. The success of our future space programs depends heavily upon the accomplishments of the electronics engineers today.

Introduction

ROCKETRY BEGAN almost a thousand years ago when Chinese warriors fastened powder-filled pipes to their spears in order to obtain greater throwing ranges. The door to rocket-powered space flight opened only twenty years ago; it began when the first electric instruments were successfully used to force a rocket precisely on a preconceived trajectory. From that time on, evolution assumed a breathtaking pace. Fifteen years after a V-2 accomplished the first fully guided rocket flight, Sputnik I orbited our Earth as an artificial satellite. One year later, in 1958, the Van Allen radiation belts were discovered by Explorer satellites. Another year later, Lunik III photographed the rear side of the moon. In 1960, the Tiros satellite provided more than 22,000 television pictures of the earth's surface from an orbital altitude of 400 miles. During the same year, Pioneer V established a record in communications by transmitting signals from a distance of 22.5 million miles. Our Earth, if seen from that point, would not look much larger than the planet Venus as seen from here. Again one year later, and only 3½ years after the first satellite began to orbit around the globe, Major Gagarin achieved his historic satellite flight. Instrumented probes to Mars and Venus, and deep into interplanetary space, are imminent. Our country is presently at the doorstep of its greatest technical project of all times: to land a man on the moon, and to bring him back safely.

An adequate propulsion system is a mandatory requirement of a space vehicle, but a complex system for control and communications is as indispensable as are the rocket motors. Precise control must be exercised over the performance and the attitude of the vehicle; data must be transmitted to ground stations, and commands must be received and carried out onboard the craft; guidance of the vehicle along the desired trajectory must be accomplished; and finally, each space vehicle has the mission of taking scientific measurements, and of radioing its observations back to earth. Planning for this very elaborate system of guidance, control, and data transmission of a spacecraft is at least as demanding as the planning for its propulsion system. It is of utmost importance that both areas of endeavor find equal emphasis. The National Aeronautics and Space Administration (NASA), being deeply engulfed in the development of spacecraft for an ambitious program of space exploration, therefore pursues very vigorously the principle of concurrency between the development of propulsion and the development of systems for control, guidance, measurements, and communication. Needless to say that the responsibility for these systems rests with the electronics engineer, as the responsibility for propulsion rests with the propulsion engineer.

In planning for space flights, the electronics engineer is confronted with a set of basic requirements which has become almost standard: his systems must be very modest with respect to size, weight, power consumption, and heat dissipation, but they must give a maximum of sensitivity, stability, lifetime, reliability, and resistance against the encumbrances of outer space. The telemeter system which helped to develop the V-2 missile was a 7-channel, amplitude-modulated monster as big as a medium-sized coffin. Two men were required to carry it around. Today, a telemeter system of that capacity, and for that range, is not much bigger than a match box. Thermionic tubes have been supplemented by transistors, ample use is made of printed circuits, and the entire structure is neatly embedded in plastic (Figs. 1 and 2). While the countdown during a V-2 launching became traditionally stalled at "X minus telemeter," the telemeter systems of modern space vehicles are remarkably absent in failure analyses. The solar-powered transmitter of Vanguard I is still transmitting after three years of operation; Explorer VII, after more than two years in orbit, still sends down its

telemeter signals. Pioneer V was at a distance of almost 23 million miles from the Earth when its batteries were exhausted; up to that time, a 60-ft antenna (28-db gain) received strong signals from the 160-w transmitter, and the 250-ft antenna at Jodrell Bank recorded even signals from the 5-w transmitter over that range. These accomplishments prove that the experimental techniques for these more conventional functions are satisfactorily in hand, and that the limits to our capabilities, at least for present-day projects, are imposed by laws of physics rather than by poor engineering. However, the art of space flight is rapidly approaching situations for which no well-developed precedents exist. They require the evolution of new techniques, and in some instances even the breakthrough of new basic ideas.

Spacecraft Control

Control functions onboard a space probe are required for the propulsion system, for the vehicle attitude, and for the temperature of sensitive equipment. Control of the propulsion system may be achieved by command signals from the ground, or by signals generated by distance or direction sensors. The latter are of particular importance when the craft is to make a slow descent to the surface of the moon or one of the planets. In that case, the distance to the surface will be measured continuously by radar methods, and the propulsion system will be operated according to these measurements. This scheme has been studied in detail for a lunar landing craft in 1959,[1] and more recently as part of the Surveyor Project.[2] The attitude of a space vehicle must be controlled for a number of reasons: to apply thrust in the desired direction, to have narrow-beam antennas or ground observation equipment point in the right direction, to maintain a desired attitude with respect to the sun, or to land on a predetermined point of the lunar or a planetary surface. While close to the surface of a planet or the moon, a space vehicle may use horizon sensors to control its attitude with respect to that surface. Infrared seekers are preferable to seekers using visible light because the difference between day and night signals is less for long-wave infrared than for the visible wavelengths. In typical flight tests, the "black body" temperature of the earth in the 2- to 15-μ spectral region was measured to 250–270°K;[3] the temperature of space may be assumed to be close to 0°K. The most sensitive sensor materials are lead sulfide, lead telluride, and lead selenide. Their response curves are shown in Fig. 3. Present-day seekers employ thermistors of less sensitivity, but

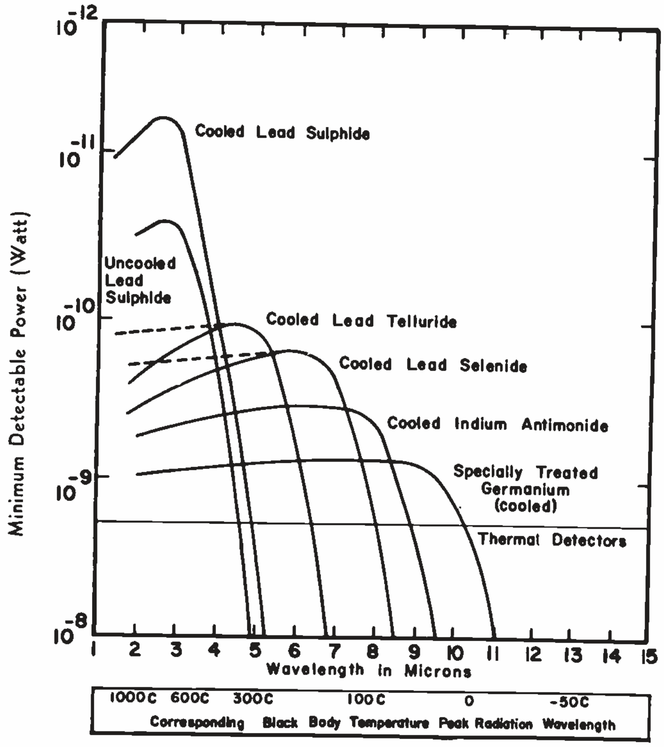

Fig. 3—Response curves of various infrared detectors.[4]

with a flat response curve over the entire spectral range. Germanium, transparent in the 2- to 16-μ region, and with a refractive index of four, is ideally suited for focusing lenses.[4] Attitude-control systems using infrared seekers are installed in Discoverer, Midas, Tiros III, Ranger, and other spacecraft. They maintain the desired earth-oriented attitude within an error angle better than $\pm 1°$. If the infrared-sensitive cells are cooled to the temperature of liquid nitrogen, their inherent noise level decreases considerably, and higher sensitivity is achieved.

An interesting method of controlling the attitude of a satellite evolved from Project Tiros.[5] It is possible to program the current in a satellite-borne coil in such a way that almost any attitude of a specified satellite axis can be obtained through interaction of the current-carrying coil with the local earth-magnetic field. It is also possible to use two permanent magnets instead of the coil. One of the magnets must be pivoted according to a control program.

Earth-oriented attitude control is of particular importance for satellites whose missions are directly related to the Earth.[6] Weather satellites, for example, should orient their cameras with reference to the center of the Earth, and the same is true for communication satellites. A 24-hour equatorial satellite, hovering permanently above the same spot on the ground, will probably take its bearing from a radio beam transmitted from the ground. If solar cell panels are used as power supply, they must remain oriented toward the sun.

Space vehicles traveling beyond satellite orbits on coasting trajectories will keep a specified orientation with respect to the sun in order to keep thermal design problems to a minimum. If thrust maneuvers for midcourse guidance should be necessary, the vehicle would either use an earth-based radio beam, or a star-fixed coordinate system, as a reference. The latter requires two seekers that maintain their directions toward two fixed stars approximately 90° apart.

A star-fixed reference system will be the basis of an inertial space guidance system. The guidance platform may carry gyroscopes to facilitate its control, although they would not be mandatory. It will carry accelerometers to measure thrust forces in three orthogonal directions. Besides the star seekers, several planet seekers will continuously measure the directions toward planets with respect to the star-fixed coordinate system. These directions, if referred to the known positions of the planets within the solar system at any specified time, will immediately give the location of the space vehicle at that time.[7] Strictly speaking, only three planets would be necessary to determine the location in three-dimensional space. However, one or more of the planets may be hidden temporarily behind the sun or the moon, or two of them may be in line with each other; for that reason, four or five planet seekers will be used. The location coordinates will be obtained from the angle measurements with the aid of computers which contain the natural motion of the planets, and the time, as preset programs. A two-dimensional diagram of a vehicle in space, determining its location with a system of star and planet seekers, is shown in Fig. 4.

Once a spacecraft approaches its target—the moon or a planet, or, on a return trip, the Earth—it will use infrared seekers to find the exact direction of the target, and to adjust its attitude. The distance D to a target of diameter $2R$ will be obtained from a simple measurement of the angle α subtended by the target. This measurement, as illustrated in Fig. 5, will give an accuracy below one per cent for distances from the surface between 0.001 and about 80 times the radius of the target, if the angular accuracy of the sensors is ± 1 minute of arc.

An electronics engineer responsible for the control, the guidance, and the communication system of a spacecraft will find that the principal components of these diverse systems share one common feature: they work better at low temperatures. Infrared seekers have a much lower noise figure, and therefore a much greater sensitivity, at cryogenic temperatures. Gyroscopes operate with almost vanishing power requirements if

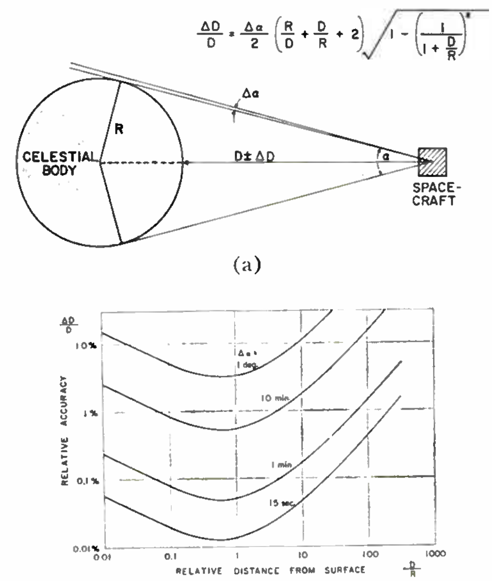

Fig. 5—(a) Distance measurement with angular sensors. (b) Accuracy of distance measurement as a function of distance; angular accuracy of sensors as parameter.

superconductivity techniques can be applied.[8] The same holds for accelerometers and integrators, and also for reaction wheels. Highly efficient binary computer elements have been developed on the superconductivity principle.[9] The noise level of semiconductor amplifiers can be greatly reduced if cooling techniques are introduced. Of particular success is the cooling principle in connection with parametric amplifiers using cavities, and with maser-type circuits. The space vehicle of the future will therefore be equipped with a "cryopackage" inside its guidance and control compartment. The cryopackage will house the gyrostabilized platform with accelerometers, infrared horizon seekers, star seekers, planet seekers, and radar altimeter, and also the low-temperature components of digital computers, programmers, command receivers, radio communication equipment, and television storage and transmitting facilities. The package will be kept at low temperature by means of a cryostat which may be powered by solar energy, or by a nuclear-electric power supply, if this should be carried onboard for other purposes. It is anticipated that the total heat power generated within this cryopackage will not be more than 50 to 100 w, an amount which can be handled easily even by a small cryostat.

Spaceships will keep at least their attitude-control system and their complex communication links active during the entire flight. Spacecraft of the low-acceleration type, like electrically propelled vehicles, will be subject to active guidance throughout their interplanetary trip. In both cases, the cryopackage will be the heart and the brain behind attitude control, launch guidance, mid-course guidance, approach guidance, digital computers, thrust maneuvers, radio communication, data transmission, and even some of the scientific measurements to be made in space and on other celestial bodies. Development, design, and building of such a cryopackage stands out as one of the intriguing challenges that beckon the creative mind of the space electronics engineer today.

Communication Problems

Unmanned space flight would be without value unless means of communication existed that keep the ground team informed of the spacecraft's trajectory, and of technical and scientific data which the vehicle gathers during its flight. Besides, the ground team will desire to control certain functions of the craft by radio control. Even manned space vehicles, which may be completely self-dependent for the duration of their space trip, will maintain their communications with the Earth on a continuous basis.

The electronics engineer entrusted with the planning of all electronic systems of a major space project will leave the details of this gigantic task to specialists. However, he will make a careful assessment of the principal capabilities and limitations of space electronic systems to set the cornerstones in his master plan. First, he must accept the finite velocity of signals transmitted through empty space, 3×10^{10} cm sec^{-1}. Table I lists the one-way times of transmission between the earth and other celestial bodies. When an operator on the earth sends a command to the moon immediately upon receiving a signal from there, the delay between signal generation and command reception on the moon will be almost three seconds. Obviously, the control of lunar operations from the earth therefore can never be as intimate as the control of earthbound operations. In the case of Mars,

TABLE I

ONE-WAY TRAVEL TIME OF ELECTROMAGNETIC RADIATION BETWEEN EARTH AND OTHER CELESTIAL BODIES

Target	Distance from Sun		Shortest Distance From Earth km	Travel Time		
	10^6 Miles	10^6 km		Seconds	Minutes	Hours
Sun	0	0	1.49×10^8	497	8.3	
Mercury	35.9	57.7	9.1×10^7	303	5.0	
Venus	67.2	108.0	4.1×10^7	137	2.3	
Earth	92.9	149.3	—	—	—	
Mars	141.5	228.0	7.9×10^7	263	4.4	
Jupiter	483.5	776	6.27×10^8	2.09×10^3	34.9	0.6
Saturn	886.2	1424	1.27×10^9	4.23×10^3	71	1.2
Uranus	1783	2870	2.72×10^9	9.07×10^3	151	2.5
Neptune	2793	4500	4.35×10^9	1.45×10^4	242	4.02
Pluto	3676	5905	5.75×10^9	1.92×10^4	320	5.3
Moon			3.5×10^5	1.17		
α-Centauri			4.03×10^{13}	4.3 Years		

the delay time amounts to nine minutes even when Mars and Earth are closest. Direct control of Martian operations by television and command links from Earth would be hopeless. On the other hand, the initiation of programmed mid-course guidance functions, or of a surface operation program, may well be handled by commands from the Earth.

Line-of-sight will be essential in all space communications problems. If it should be interrupted temporarily by intervention of a celestial body, data storage must be applied. A relatively small number of stations on the earth, if well coordinated, will be sufficient to maintain line-of-sight contact with almost any space vehicle. At present, the NASA Deep Space Instrumentation Facility (NASA-DSIF) has a network of three fixed stations with 85-ft parabolas[10] in operation: Goldstone in California, Woomera in Australia, and Johannesburg in South Africa. Each of these stations can measure angles with an accuracy of the order of $\frac{1}{10}$ to $\frac{1}{20}$ of 1°. Since deep space probes, at least within the next few years, will remain relatively close to the plane of the ecliptic, the NASA-DSIF will be capable of serving all space programs which are planned for the foreseeable future. This is true even for electrically propelled spacecraft whose trajectories may form angles of 25 or 30° with the plane of the ecliptic.[11]

[10] R. J. Parks, "The U. S. planetary exploration program," *Astronautics*, vol. 6, pp. 22–25; May, 1961.

[11] J. W. Stearns, Jr., "Applications for Electric Propulsion Systems," Jet Propulsion Lab., Pasadena, Calif., Rept. No. 33–47; April 10, 1961. Committee Report, "Utilization of Electric Propulsion in Spacecraft," Jet Propulsion Lab., Pasadena, Calif., Rept. No. 33–21; October 1, 1960.

The power required to transmit a signal over a given distance, the optimum choice of carrier frequency, the influence of bandwidth and noise, and the capabilities of modern receivers are discussed elsewhere in this volume. The following formula[12] may be useful for a quick determination of the range of a transmitter-receiver link, assuming a signal-to-noise ratio of about ten:

$$D = \tfrac{1}{3}\sqrt{W_T A_T G_R / 4\pi k T \Delta f}. \qquad (1)$$

A range of $D=6\times10^9$ km, equal to the distance between Earth and Pluto, could be obtained with the following figures:

$W_T=200$ w
$A_T=1$ m² (parabola)
$G_R=45$ db (Goldstone, 85-ft parabola)
$k=1.38\times10^{-23}$ w sec deg^{-1}
$T=100$°K (parametric amplifier)
$\Delta f=10$ cps.

Eq. (1) indicates that substantial improvements of space communication systems will come from the use of space-borne masers, and from light-weight electric power supplies. Both subjects present most fruitful research and development areas for space electronics engineers.

TELEMETER DESIGNS

Telemeter technologies have been developed to a remarkably high standard in connection with space

[12] E. Rechtin, "Deep space communications," *Astronautics*, vol. 6, pp. 37–46; April, 1961.

projects of the past years. Two distinct problem areas face the electronics engineer who indulges in present-day projects; both deserve his particular attention and his sincere effort. The first concerns data transmission from such giants as the Saturn vehicle. The problem lies simply in the enormous number of independent data that must be transmitted. The second refers to small, but far-reaching probes with scientific missions. Here, the problem consists of transmitting a maximum of information over a large distance with a minimum of power. Instead of discussing these problem areas in general terms, a short description will be given of the Saturn C-1 telemeter system as used in the single-stage test firings, and of the Mariner system which will transmit telemeter signals over a distance of 6×10^7 km.

The telemeter system which has been developed for the Saturn booster flight tests at the Marshall Space Flight Center (former Army Ballistic Missile Agency) is specifically adapted to the accuracy and response requirements of Saturn booster measurements.[13] Most of these measurements involve engineering data such as flow rates, vibrations, temperatures, and functional procedures. Consequently, some of the telemeter channels must have a frequency response up to about 3000 cps, while others will carry data that vary only at a low rate. Some channels must provide continuous information, others transmit intermittent data at sampling rates not more than a few points per second. The desired accuracy varies with the type of information.

On the basis of these requirements, four different telemeter types were developed and combined into a complex data transmission system. The first uses a single-sideband modulation of AM subcarriers which frequency modulate the carrier (SS-FM); a baseband utilization efficiency of 60 per cent is obtained. The second is a 216-channel PAM-FM-FM system for LF response. Each of 27 submultiplexers has ten channels; eight for one specific measurement on each of the eight engines, and two for identification and voltage reference. The main multiplexer samples each of the 27 submultiplexers in sequence. The third type is an FM-FM system with 15 continuous channels, and also 54 multiplexed channels applied to two subcarriers. The fourth kind consists of the previous type, but modified by seven additional sub-subcarriers that modulate one of the subcarrier channels. This modification is applied to three identical telemeter packages. A schematic sketch of the complete Saturn telemeter system is shown in Fig. 6. The system will weigh 220 pounds. Total input power is about 1600 w, most of it to be consumed by the RF transmitters, and by power amplifiers. The total number of information channels of this system is 546.

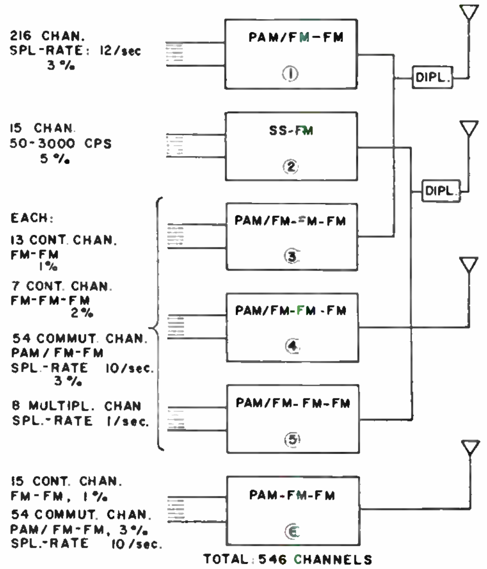

Fig. 6—Schematic diagram of Saturn booster telemetry system[13] (accuracy in per cent).

The Mariner spacecraft, under technical direction of the Jet Propulsion Laboratory,[14] will carry a directed parabola of 1.22-m diameter with 18.8-db gain at a frequency of 960 Mc, and of 26.0-db gain at 2295 Mc. The full cone angle of the antenna beam is 16°; a conical helix provides a circularly polarized beam. The receiving antenna (Goldstone) has a gain of 45 db for the lower, and of 52 db for the higher frequency. The lower frequency will be used until January 1, 1963. After that time, the DSIF stations will operate only at the higher frequency.

The subcarriers transmit the information in digital form. Modulation consists of switching a binary-symmetric channel between two possible states. The two states are represented by two phase conditions of the subcarrier frequency, such as $\phi_0+90°$ and $\phi_0-90°$. This "phaseshift-keying" represents the most efficient digital method of data transmission. A transmitter power of 3 w permits 12.8 bits per second over a distance of 6×10^7 km. The information to be transmitted includes about 90 engineering measurements of the Mariner systems

performance, and about 15 scientific measurements of cosmic radiation, ion densities, cosmic dust, meteorites, magnetic fields, and solar radiations. A maximum of 10^6 bits of information can be stored during any 24-hour period for rapid playback upon command.

Automatic Space Operations

The rapid evolution of space projects confronts the electronics engineer with a requirement that has not existed in the past; it is that of fully automatic equipment for space operations like orbital rendezvous, orbital assembly and adjustment, orbital checkout and countdown, approach and descent to the surfaces of the moon and of planets, take-off from these surfaces, and scientific exploration on other celestial bodies. The number of technical problems associated with these operations is almost endless; their degree of sophistication is limited only by the capability of the engineer, and by the techniques at his disposal. The normal functions which constitute these space operations can be carried out by robot-type devices that act according to a preset program. However, functions such as trouble shooting, failure analysis, locating of faulty parts, repair or exchange of components, or recalibration of subsystems present situations which require judgement, and even decisions, that cannot be preprogrammed easily. Techniques to handle such situations have not been developed thus far. There is no doubt that they will be based at first on a combination of automatic devices, telemeter and television equipment, and man-controlled command signals from the ground. However, the trend will be to eliminate the link to the Earth as far as possible; consequently, the orbital manipulators must be equipped with a complex system of sensors, with a vast store of commands that can be stimulated in many different combinations by sensor signals, and with versatile organs that can carry out these intricate commands.

Problems of this kind involve a degree of automation which has never been even approached in the past. It is not possible to predict how successful our technology will finally be in replacing with electronic circuits the sensory organs, the memory, the capability of intelligent decisions, and the marvelous dexterity of the hands of a human astronaut. Requirements for complex logic procedures under space conditions are by no means restricted to projects of the far future. They are encountered, at least in preliminary form, by the planners of a manned lunar landing project that uses a satellite orbit around the Earth as staging area. The question of the exact role in orbital operations which should be assigned to the human space travelers will not be answered before the capabilities of manipulators, equipped with sensors, memories, computers, and logic circuits, can be assessed. Success in the development of this technology will be one of the most influential factors that determine the rate of progress in future space programs.

Electric Power Generation

The great variety of electric and electronic devices to be built for spacecraft have one feature in common: they need electric power. A supply of electric energy is needed by sensors, by amplifiers, by control and guidance equipment, by communication systems, and, within the near future, for electric propulsion systems. The development of reliable, long-life, light power supplies therefore belongs to the most urgent tasks of the space engineer. Existing batteries with a specific energy of 100 to 150 wh/kg (low discharge rate) are suited for short-time flights up to days or weeks. Solar converters have the advantage of infinite reliability of their prime source, but their effective specific power is not greater than about 0.01 kw/kg. Even thin-film photo-electric converters do not exceed this figure because of reduced conversion efficiency.[15] Nuclear fission energy is presently the most attractive prime source for power supplies in the multikilowatt range. The SNAP-8 project will result in a 60-kw supply with a specific power of 0.04 kw/kg. Larger supplies, also built on the steam turbine and rotating generator principle, may provide 0.3 to 0.5 kw/kg.[16] Much hope concentrates at present on thermionic converters, and particularly on plasma-electric generators in which the kinetic energy of a gas, heated in a fission reactor and seeded with alkali ions to make it conductive, is converted into electric energy by interaction with magnetic fields. Each of these types of converters may eventually generate 1 to 2 kw/kg. Thermonuclear fusion generators promise an even greater specific energy. However, their development is still in a very early state. Considerable progress in our basic knowledge of plasma physics is required, either by breakthrough or by a concentrated effort of many years, before a practical thermonuclear generator can be visualized.[17]

Outlook to the Future

Space flight began a few years ago as an art whose purpose was solely the expansion of our basic knowledge. Space engineers approached their tasks like pure scientists: without looking for immediate recompensation, they were guided by a desire for superior accomplishment. Less than four years after our first steps into space, we are witnessing today how a new element, and a very healthy one, begins to rise in our space effort: it is the practical use of space for weather and communication satellites. Both have been recognized as extremely valuable in the daily needs of modern, civilized nations. Both have passed the state of exploratory research, and both have developed into engineering

[17] G. Warfield, "The present outlook for controlled nuclear fusion," *RCA Rev.* (*Energy Conversion*), vol. 22, pp. 122–130; March, 1961.

enterprises of highest order. The electronics engineers are primarily concerned with bandwidth utilization, with bits-per-second capability, with coding techniques, with read-out speed, with storage volume, with command capability, and with the achievement of longevity. The engineers are joined by lawyers who must concern themselves with problems such as company vs government interest, antitrust laws, proprietary rights, and competitive bidding, because a system of well-functioning communication satellites may easily develop into a multibillion business within a few years. It is evident that the foremost goal of the engineer must be the superior technical quality of his systems. The success of the orbiting communication system will depend almost entirely upon the reliability of its electronic equipment.

While a considerable part of our national space effort will branch out into projects of practical usefulness, a strong endeavor will continue to concentrate around space research. Existing instruments will be refined, and new ones will be invented. Quantum mechanical amplifiers, representing one of the most intriguing areas of modern electronics, have already proven their superior value for space instrumentation. With a maser-controlled transmitter on a spacecraft, and a similar transponder on another spacecraft or on the earth, it will be possible to measure the relative velocity between the two transmitters with an accuracy of centimeters per second.

The greatest challenge is always offered by the unknown. The probing spirit of the research scientist, matched by cleverly designed instruments, will find an unlimited pasture in outer space. The Van Allen belts, showing the strange ways in which our earth catches and stores charged particles thousands of kilometers above its surface, and dumps them toward the poles in beautiful auroras upon a solar disturbance; the hyper-energetic protons which are ejected by the sun from time to time in violent outbursts; the meteoritic dust particles which approach the earth after millions of years of interplanetary travel—these are our first glimpses into outer space. What will we find when we achieve the next step in the exploration of space, the landing on the moon? And what will our first instrumented probes tell us after descending gently to the surface of Mars? The answers will come in the future; they depend on what our electronics engineers accomplish today.

Data Processing and Information Transmission for Space*

ELLIOT L. GRUENBERG†, SENIOR MEMBER, IRE

Summary—**This paper reviews and predicts the roles that data processing and information transmission have played, and will play, in space. The trend toward digital transmission is shown to be a result of increasing requirements for precision, reliability, high information rates, and long paths. Thus, data processing and transmission techniques appear to be converging rapidly, both because of the advantages of digital communication systems and because of the predicted weight and volume reductions for computer equipment. Many improvements in transmission efficiency will result from this merging of techniques, notably in the areas of data compaction and computer-controlled adaptive communications.**

The problem of maintaining a satisfactory SNR in spite of the signal loss from space attenuation is reviewed. General trends in the techniques designed to improve this ratio are reported and several promising developments are emphasized. Among these are the use of signals with large bandwidth-time products, maser amplifiers, and a novel telemetry system which provides high antenna gain with a greatly reduced orientation problem and eliminates spacecraft transmitting equipment by transferring it to earth.

Introduction

SPACE ACTIVITIES are, in reality, an enormous array of experiments. Some of these experiments must be done in real time and some must be done separated by great distances. It is inconceivable that these experiments could have been and could continue to be made without reliance on the most modern methods of data processing and the most advanced methods of transmitting information.

The type of communications with which we are concerned here falls under the heading of telemetry, an art which has developed from the scheme for reading "meters" remotely over wired communications links. The term "telemetry" may be rightfully extended to include all communication of measurements; hence, message accuracy is a specific requirement. Because accuracy is a fundamental consideration, it is appropriate that the unit of information developed in information theory, the bit, be used to tie together the diverse areas involved. In a typical space mission the experiment must be planned, the trajectory determined, and the data gathered; and the required *information* must be extracted, transmitted, and reprocessed to present to the experimenter the reading of the meter in the form he requires. If, in the planning stages, the measure of effectiveness for the mission is recognized to be a function of the expected number of bits of information presented to the experimenter, each step can be evaluated according to its contribution to the total. Similarly, the completed mission can be evaluated in terms of the actual number of bits of information obtained, and the sources of inefficiency can be established.

Thus information theory has effected a marriage of the sciences of instrumentation, communication, and data processing. In addition, recognition of the bit as a common unit has led to the merging of the techniques of data processing and information transmission, and to a growing emphasis on digital methods of transmission.

The purpose of this paper will be to review briefly the important roles that data processing and information transmission play in man's entry into space, to predict future trends, and to suggest several ideas that might provide significant advances.

The Role of Data Processing in Space

Man's entry into space has depended upon a great deal of preparation and experimentation, much of which has required the use of high-speed data-processing equipment. Among the more prominent uses of ground-based equipment have been:

1) Design calculations for engine, structure, etc.
2) Static tests of rocket engines.
3) Stress analysis.
4) Flight simulation.
5) Determination of optimum trajectories.
6) Track prediction and orbital calculations.
7) Launch control and range safety.
8) Smoothing and reduction of remotely-sensed data.

Since these tasks have not imposed very specialized requirements on the processors, general-purpose computers have usually been employed. The basic trend in these activities seems to be toward higher speeds, with interest in real-time operation increasing. Examples of these ground-based activities abound. A few will now be mentioned.

In the Vanguard program, observations from the many Minitrack stations arranged as a "fence" around the globe were transmitted by teletype to a computing center in Washington, D. C. Orbits were computed for the satellites and ephemerides were established. One important result of these computations was the revelation of the earth as being "pear-shaped." This example illustrates the marriage of data processing and information transmission because continuous tracking would have been impossible without data transmitted from remote points on the globe. It also illustrates how data-processing techniques remove redundancy and noise from the enormous amount of data and provide the experimenter with the *information* he requires.

A significant example of the necessity for real-time data transmission and processing is Project Mercury. To achieve maximum safety the exact position and velocity of the Mercury capsule must be known at all times. To this end, a world-wide network comprising radar (FPS-16 and Vercort) and telemetry sites has been installed. To process the data into and out of the central computing facility, two types of communication paths have evolved. High-speed (1000 bps) communications lines are used for bringing impact prediction information from Cape Canaveral into the computers and for returning digital display and plotting information back to the Mercury Control Center to enable monitoring and control action to be taken. Low-speed inputs bring into the computers position information acquired at the radar sites. At the computing center two 7090 computers are used in parallel and are equipped with special data communication channels which enable real-time access by new data, as well as the processing of the necessary display and spacecraft acquisition information.

An example of an existing facility for reduction of space data is that located in Philadelphia Pa., at the Missile and Space Vehicle Department of General Electric Company. Programs have been written for this computing center to demultiplex data recorded from missile tests, to correct it for calibration, and to smooth it by digital filtering techniques.

It seems that the area of data reduction will probably see the largest increase in ground-based computer usage in the near future. Enormous amounts of data are accumulating daily from space vehicles that have already been launched. Consequently, a real need exists for computer programs that will not merely process these data by "brute force" techniques, but will minimize processing time by automatic redundancy removal and sophisticated statistical analyses. Such programs are the best way to provide the experimenters with *current* information in the most useful form.

With regard to spaceborne computers, the major role they have played in the past has been in guidance and flight control. One of the major requirements for this application has always been resistance to the considerable shock and vibration occurring during launch, the time of greatest activity of the computers. The trend has been toward digital processors for the increased accuracy they provide. The digital, stored-program guidance computer for Titan is shown in Fig. 1.

In the future one of the primary applications for spaceborne processors will be data compaction (or compression). There is an ever-increasing demand for reduction of the amount of data that must be telemetered to earth. Techniques for accomplishing this will now be discussed.

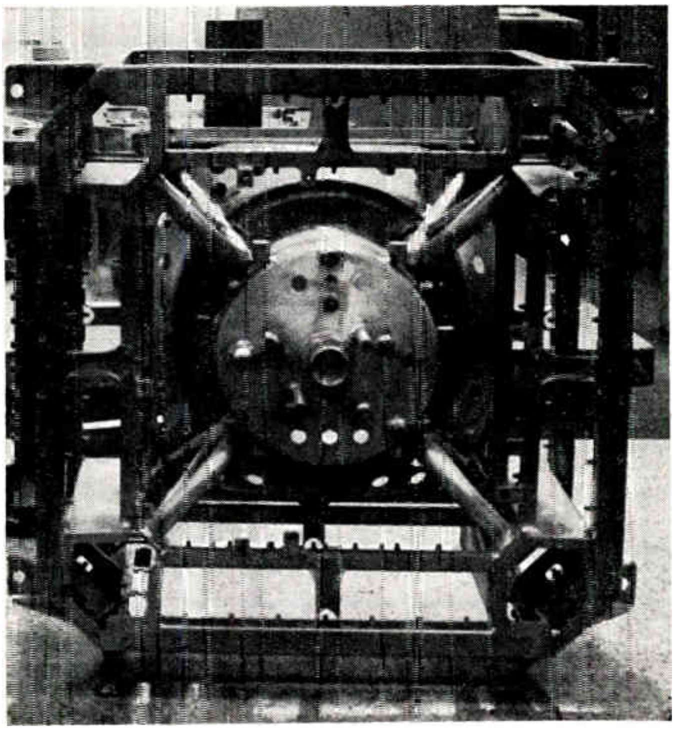

Fig. 1—The Titan guidance computer (IBM).

Data Compaction

Data compaction, or the reduction of the time or bandwidth required to transmit a message, can be conveniently described as either information-preserving or information-destroying. By information-preserving compaction we mean that the (compacted) data received by the experimenter on the ground must be sufficient to permit him to reconstruct exactly the sequence which caused these data.

Although both of these methods hold great promise for increasing the amount of information that can be obtained from a mission, most of the compaction techniques that have been implemented to date have been information-destroying. Examples of these are particle counters, peak detectors, and the spectrum analyzer proposed by Ratz [1]. In general, these devices can be said to extract those statistics of the input data that are of interest to the experimenter.

A generalized, information-preserving data compactor for use with a variety of input signals was recently proposed [2], [22]. One version of this device, which appears to be quite feasible for spaceborne telemetry, is shown in Fig. 2. This compactor exploits the fact that the probability of a change in a bit decreases as the "significance" of the bit increases (in a straight binary code). Run length coding is used because it requires only simple equipment to implement and because it has been shown by Elias [3] to approach the theoretical compaction limit closely.

One area that is now starting to receive more attention is the application to spaceborne equipment of some of the vast amount of research that has been done in

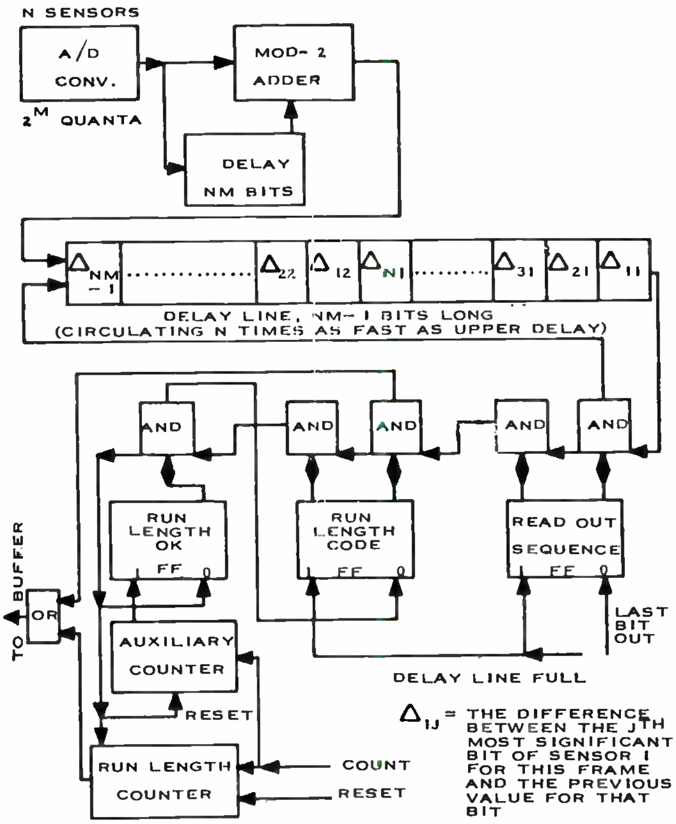

Fig. 2—A compactor for time-multiplexed sensors.

the compaction of television data. Information-preserving techniques appear likely to yield compaction ratios of 2 or 3. These techniques can probably be supplemented by information-destroying methods, but careful selection of the "information" is necessary. For instance, the "brute force" approach of degrading the resolution of the picture is probably inferior to the contour determination obtainable from the use of the gradient and the Laplacian operator as suggested by Kovasznay and Joseph [4].

As experiments and missions become more complex, it is probable that a general-purpose data processor will be included aboard advanced vehicles, having data compaction as one of its primary functions.

The Role of Information Transmission in Space

The second major topic of this paper is information transmission, which takes two forms for space: transmission between ground-based stations; and transmission from, to, and between space vehicles. Although we will concentrate on the latter form, the former deserves a few words.

An increasingly larger percentage of the capacity of ground-based transmission facilities is being used for data with extreme accuracy requirements (*e.g.*, telemetry, record transmission, data transmission between computers). To accommodate this traffic many transmission methods are being employed, special modems are being built, and special facilities are being supplied by the common carriers. All of these activities have a common goal: to increase the expected number of bits of *information* presented to the experimenter.

Most surface transmissions of space data result from the need to concentrate data at one computing point. This centralization allows the use of specialized programs and the correlation of data from several remote stations. The Mercury and Vanguard programs are excellent examples.

Data transmission from, to, and between the space vehicles affords the greatest challenge for communications. The major obstacle arises from the enormous space attenuation. The power received from a space vehicle is

$$S_R = \frac{P_T G_T A_R}{4\pi R^2}, \tag{1}$$

where

P_T = transmitted power,

A_R = effective area of receiving antenna,

R = range between transmitter and receiver,

$$G_T = \text{gain of transmitting antenna} = \frac{4\pi A_T}{\lambda^2}, \tag{2}$$

λ = wavelength,

A_T = effective area of transmitting antenna.

A_T, A_R, λ, and R must be in consistent units.

The power received must be maintained at a sufficient level, usually 10 to 100 times, above the competing noise N_R:

$$N_R = kTB_w, \tag{3}$$

where

B_w = effective receiving bandwidth,
T = effective receiver temperature in °K,
k = Boltzmann's constant.

The term least under the system designer's control is $1/4\pi R^2$, the space attenuation. There are three approaches to maintaining communications in the presence of this attenuation:

1) To reduce the required ratio of signal to noise (S_R/N_R).
2) To reduce the noise at the receiver input.
3) To increase the received power S_R.

Each of these approaches is being actively investigated and will be discussed in the subsequent sections.

Modulation Techniques for Reducing the Required SNR

Modulation techniques have probably been investigated more thoroughly than any other method for improving transmission efficiency. Since Shannon demonstrated that channel capacity could be approached more closely by the use of a large bandwidth-time product, modulation methods have been evaluated as a function of this product. Sanders [5] evaluates efficiency in terms of β, the received signal energy required per information bit transmitted in the presence of white Gaussian noise:

$$\beta = \frac{S_{R_{\min}}}{\epsilon^2 R}, \tag{4}$$

where

$S_{R_{\min}}$ = minimum received power required,
R = transmission rate (bps),
ϵ^2 = noise spectral power density (positive frequency).

Sanders' comparison of various modulation techniques is shown in Fig. 3. The Shannon limit, obtained when transmitting at channel capacity (for a given error rate), is

$$\beta_0 = (2^{1/\alpha} - 1), \tag{5}$$

where

$$\frac{B_w}{R} = \alpha.$$

If unlimited bandwidth is available, $\alpha \to \infty$ and $\beta_0 \to 0.693$.

The decrease in the theoretical limit of the required SNR with increasing bandwidth-time product (per bit) is especially interesting for space applications, where bandwidth is often readily available. It should be noted, however, that smaller and smaller gains result from increases in bandwidth as B_w/R increases past the knee of the curve.

Some systems, such as FM, do not even display this characteristic at minimum SNR because of the threshold effect. To reduce this effect the phase-lock loop [6] and the FM feedback system [21] have been proposed. In an analysis of the latter system Enloe [7] shows that reduction of the threshold is limited to 5 or 6 db because of cross-multiplication of in-phase and quadrature noise components.

The Shannon limit can be approached most closely by orthogonal coding techniques such as those investigated by Viterbi [8]. One example of these is the 5-bit-per-word Digilock system shown in Fig. 3. Further progress in improving communication system efficiency by going to higher bandwidth-time products and hence longer decoding words is limited in payoff. However, there are other uses for this technique such as the asynchronous communications system discussed later.

Many factors other than SNR improvement enter into the selection of a modulation system. Because precision is a fundamental requirement in telemetry, the modulation technique must guarantee the necessary accuracy at the required data rate. This must, of course,

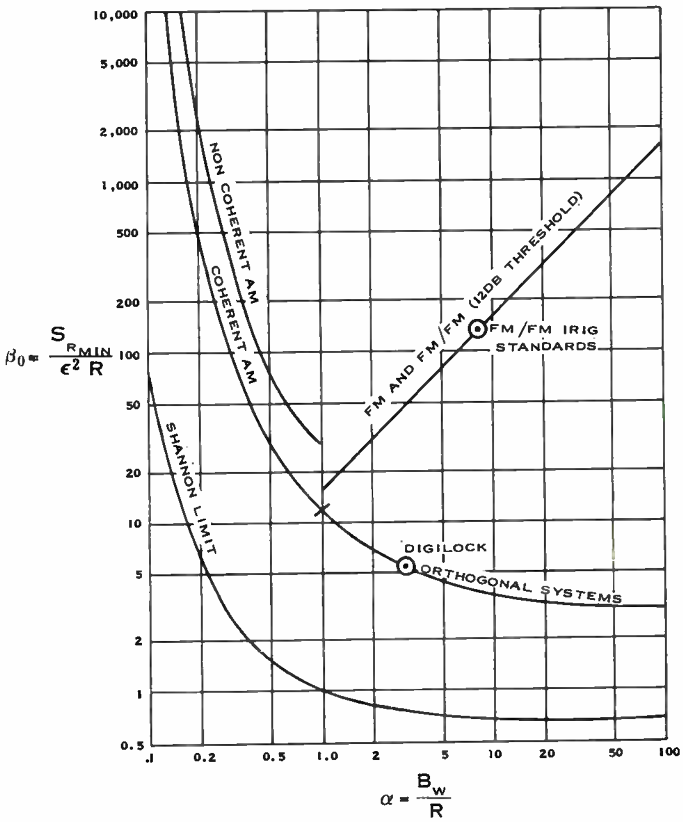

Fig. 3—β efficiency of various systems as a function of $\alpha = B_w/R$ for digital equivalent systems where the bit error rate $P_e = 10^{-6}$ (after: R. W. Sanders, "Communication efficiency comparison of several communication systems," Proc. IRE, vol. 48, pp. 575–588; April, 1960. Fig. 3, p. 578).

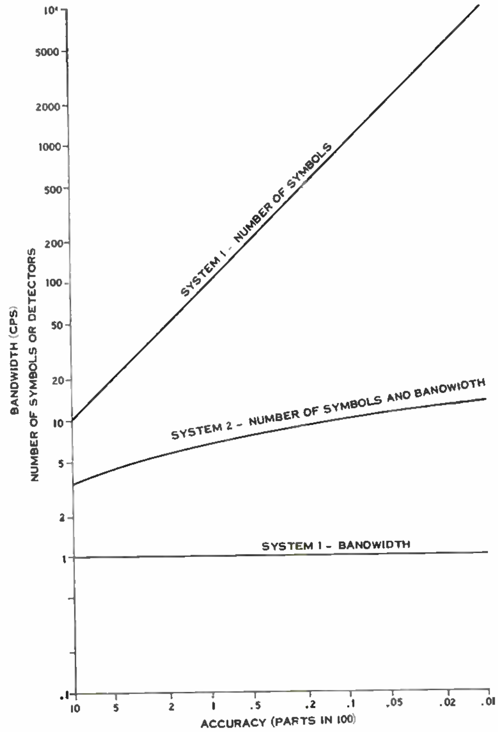

Fig. 4—Trade-off between bandwidth and number of symbols. (Sampling frequency = 1 cps.)

be accomplished within the weight limitations and with the desired reliability.

The fundamental factors determining the required data rate in a transmission system are the number of inputs (variables), the measurement accuracy of the variables, and their rate of change with time. The accuracy, expressed as the smallest recognizable difference in measurement in the range of possible values, establishes the number of messages that might be sent about a given variable at a given time. The maximum rate of change determines the sampling frequency.

Considering a single variable for the moment, one method of providing the N possible values for this variable would be to utilize N signal generators to obtain a set of N orthogonal symbols. This method achieves the minimum system bandwidth (and hence minimum transmitting power), requiring each filter in the receiver to have a bandwidth equal to the sampling frequency.

Such a minimum bandwidth system is shown as System 1 in Fig. 4. Here the sampling frequency was assumed to be one sample per second. Although the filter bandwidth can be seen to remain fixed as the accuracy increases, the number of symbols generated must increase. Thus 50 symbols are required for 2 per cent accuracy and 10,000 symbols for 0.01 per cent.

The number of signal generators could be reduced markedly by representing each possible value for the variable by a combination of several orthogonal signals.[1] One possible implementation would construct the N symbols from combinations of $\log_2 N$ orthogonal signals, each signal being either present or absent. This system is shown as System 2 in Fig. 4. The number of signals required has been reduced by an exponential factor; only 14 signals are required for 0.01 per cent accuracy. The price paid for this reduction is the increase in the effective bandwidth which is now $\log_2 N$ times the previous bandwidth.

The designer of modulation and demodulation systems must compromise between the considerations of symbol generation and bandwidth. Symbol generation really means circuit complexity since each symbol might be represented by a coded stream [8] or an orthogonal frequency. The choice depends upon the cost of the modulating equipment vs the cost and availability of transmitting energy, and will vary with the application. Some present systems might be classified:

System 1	System 2
QPAM/FM	PCM
PFM	
Digilock	

An attempt to compromise these conflicting trends is the PACM system [10]. Here pulse amplitude modulation is used for low accuracy and PCM for high accuracy. An extensive study has been made of the com-

[1] A method of combining the signals has been suggested by Franco and Lachs [9].

patibility of these systems [11]. Although PCM systems minimize the complexity of the space-craft modulator, bandwidth reduction is of such importance in space that attempts to employ System 1 types will continue by minimizing the size and weight of the generators.

It might be noted that sequential-type PCM systems have been the rule in the past. Some attention might be given to parallel symbol generation as a means for reducing peak power requirements aboard the vehicle.

Techniques for Reducing Receiver Noise

The noise with which the signal competes may be minimized by reducing either the information bandwidth or the effective temperature at the receiving antenna. This section discusses the advances anticipated in temperature reduction.

The effective temperature[2] depends upon a number of factors, as shown by de Rosa and Keller [12] in Fig. 5. This figure shows some of the unexpected noise sources which may be quite important in a poorly designed system. Careful attention to design will result in systems with effective temperatures determined primarily by the active receiver noise temperature (T_{RA}) and the space noise sources.

As an example, de Rosa and Keller consider the following system:

$f = 5.65$ kMcps,
$B_w = 25$ Mcps,
$G_R = 35$ db,
$T_{RA} = 10.5°K$ (TW maser).

If this system were well designed to minimize sidelobes and were operating in a quiet sky, the contribution from space noise would be approximately 6.0°K. The contribution from all other noise sources in this hypothetical system could be reduced to 2.0°K, resulting in an effective temperature at the output of the active receiver of 18.5°K.

This prediction coincides quite well with the performance forecast for the Goldstone antenna of Jet Propulsion Laboratory. Martin [13] indicates that the effective temperature for this receiving system will be reduced from 1430°K in 1961 to 20°K in 1964 by such measures as matching polarization, improving the antenna design, and utilizing a maser receiver.

Fig. 6 (from de Rosa and Keller [12]) indicates the limits of performance in terms of the space noise contributions from galactic, corona, ionospheric, and atmospheric noise. It must be pointed out, however, that this noise refers to open areas. If the antenna must be pointed at the sun or any other discrete radiator another component must be added. The most troublesome bodies for earth-based receivers will probably be the sun (up to 100,000°K) and the moon (200–300°K). The planets will subtend only a small portion of the beam and should not contribute more than 3°K. Thus, unless direct communication with the moon or within about 5° of the sun is required, the window in the 1–10-kMcps region appears to present a promising application for earth-based low-noise amplifiers (see Fig. 7).

For the receiver in the spacecraft, Fig. 7 indicates the considerable superiority of the maser throughout the useful frequency range. The maser in conjunction with a cryogenic computer appears attractive on space vehicles as pointed out by Stuhlinger [14]. However, such a receiver would drop in efficiency whenever its antenna points to a planet or the sun to receive from a particular direction, or if the earth must subtend an appreciable part of its beam. In such cases the simplicity of the Esaki diode amplifier might suffice.

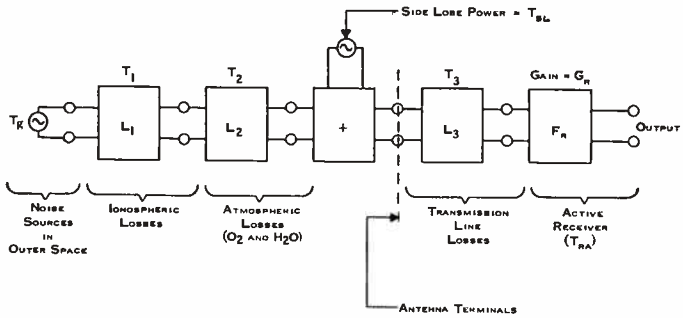

Fig. 5—Noise sources in a receiving antenna (after [12]).

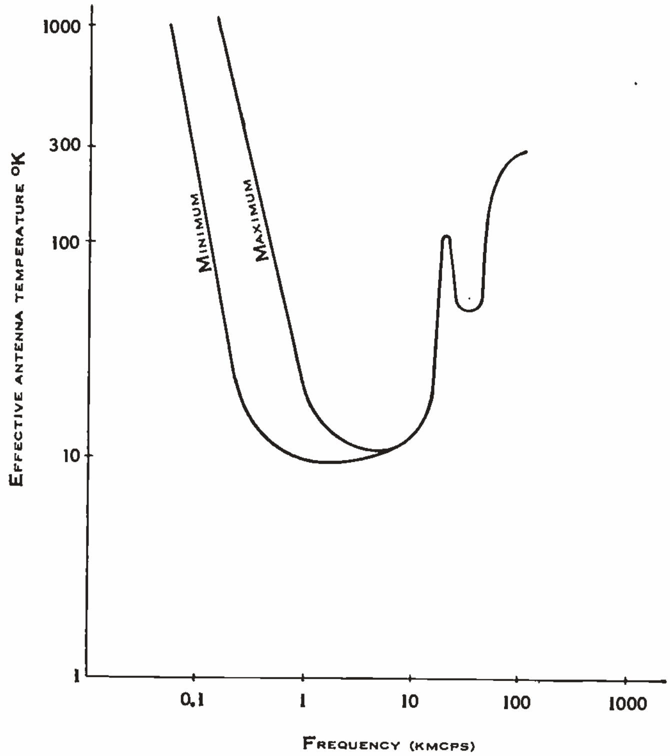

Fig. 6—Space noise from galactic, corona and atmospheric contributions (after [12]).

[2] Noise figures are not used here because noise temperatures can be measured readily, and added directly when referred to the same point, and because small errors in noise figure can make a very large difference in high performance systems. Actually, temperature can be considered to be noise power per unit bandwidth normalized by the Boltzmann constant.

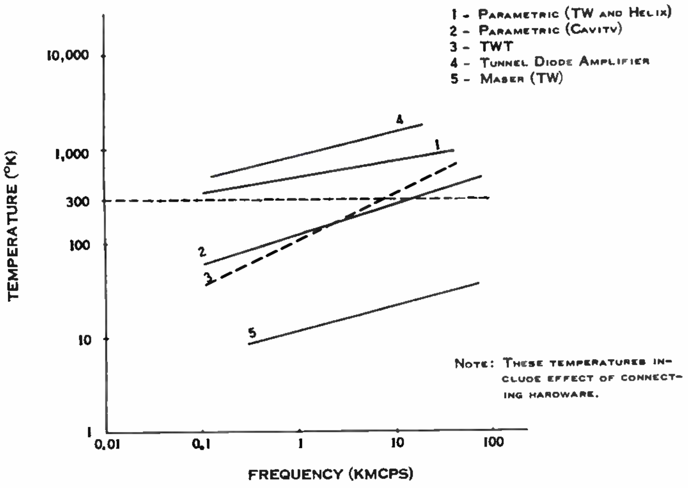

Fig. 7—Effective input noise temperatures of low-noise amplifiers (after [12]).

We conclude that we may expect to improve communications to space vehicles by reducing inherent noise by a factor of 10–70 under ideal conditions.

Augmenting the Received Power

Several methods exist for augmenting the received power:

1) Increasing the power transmitted.
2) Choosing the frequency judiciously.
3) Increasing the gain of the transmitting and/or receiving antenna.

These will now be considered in turn.

The power available in space is quite limited at present, and probably will continue to be in future missions. For the next few years solar power will be relied upon, with eventual transition to nuclear sources. Neither of these sources is particularly lightweight or efficient (typically, 10 per cent for solar cells). There exists the additional problem of converting the dc output of these sources to usable RF frequencies, usually at efficiencies of about 10 per cent. New transmitting components are becoming available to accomplish this conversion, particularly in the 1–10-kMcps region. Of particular note is the development of traveling-wave tube sources having high reliability and power in the 3–10-watt region. Solid-state components such as Esaki diodes are available up to SHF but are limited in power to milliwatts.

The standard approaches to increasing antenna gain are enlarging the antenna and increasing the operating frequency. By substituting (2) into (1),

$$S_R = \frac{P_T A_T A_R}{R^2 \lambda^2}, \tag{6}$$

it becomes apparent that the received signal is enhanced by the square of the operating frequency and directly as the aperture area of the antennas. There are these further considerations:

1) Atmospheric attenuation and noise increase sharply above 10 kMcps because of water vapor.
2) A window in the space noise exists between 1 and 10 kMcps.
3) The availability of components generally favors lower frequencies.
4) At high frequencies tracking problems are more difficult.

After careful consideration of these factors Rechtin [18] recommends operation in the 1–10-kMcps region.

For earth-based antennas the trend to large sizes is typified by the Jodrell Bank radio telescope, the Sugar Grove, W. Va., Project, the 250-foot dish planned for Goldstone, and the 1000-foot reflector to be embedded in a Puerto Rican hilltop.[3] A possibility for the future is the use of electronically steerable phased-array antennas. Though expensive, these antennas are a convenient way of phasing multiple transmitter power sources and augmenting the transmitted power greatly.

For spacecraft antennas, increases in size bring major structural and orientation problems. The structural problem is being alleviated by the advent of unfurlable antennas, feasibility models of which have been described by Kennedy [16].

A major step toward the reduction of the orientation problem has been devised.[4] A data-transmission system called TELARRAY uses a spaceborne Van Atta array [17] which modulates the ground-supplied power to return information from the spacecraft to the original transmitter, as shown in Fig. 8.

The unmodulated power from the earth-based transmitter is modulated by the microwave diodes in the interconnecting lines, providing identical modulation to the energy from each array element. Because the delay between a pair of interconnected elements is the same for any pair, the returned energy is reflected back in the same direction as the incident energy.[5] Thus, as long as the earth-based transmitter is within 60° of the center line of the array (*i.e.*, $\theta < 60°$), the antenna will provide the gain specified by (2).

The advantages of this system are then:

1) High gain with a much reduced orientation problem.
2) No transmitting power is required in the spacecraft.
3) Greatly augmented *reliability* because of the natural redundancy of the antenna configuration.

The high gain partially compensates for the space attenuation. The power is derived from the ground transmitter, where it can be economically supplied.

[3] There are some indications, however, that this trend may be reversing itself because of the cost of the larger antennas [15].

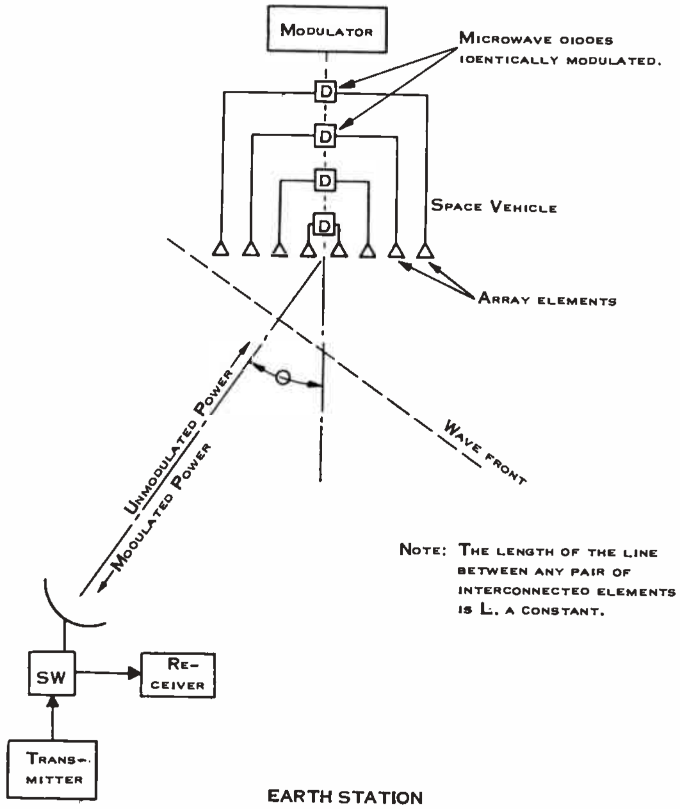

Fig. 8—TELARRAY data-transmission system.

The expression for S_R in this case is

$$S_R = P_T \frac{A_T^2 A_R^2}{R^4 \lambda^4}. \tag{7}$$

To illustrate the performance of this system consider the following example:

$P_T = 20$ kw
$f = 10$ kMcps (corresponding to $\lambda = 3$ cm)
$R = 4000$ miles
Ground antenna, 60 feet in diameter
Space antenna, 4×4 feet
Noise Temperature, 500°K.

If the bandwidth is 1 Mc, S_R will be 15 db above the noise. Thus nearly 10^6 bps can be transmitted.

It is possible to make use of this technique to provide a highly reliable communication satellite. For communication between spacecraft, the utilization of masers and optical frequencies appears most promising. Methods of modulation and efficiency of sources must be improved. Techniques of orientation stabilization must be found so that extremely narrow beamwidths may be employed. The quantization of energy in blocks[6] of $h\nu$ becomes a serious consideration at high frequencies, and extremely directive beams must be employed to concentrate sufficient energy at the receivers.

[6] Planck's constant times frequency.

Asynchronous Communications

The transmission of command and control information to a spacecraft is a special problem in itself. The time lag for communications[7] makes the acknowledgment of commands very difficult, and requires rapid and reliable synchronization of the spacecraft command decoder with the incoming message.

A promising solution to this problem is the use of an asynchronous communication system with a large "codebook" of stored messages (see Fig. 9). Any message would be decoded and recognized immediately with high reliability, regardless of the time of reception of the sequence. The large codebook would permit the receiver to operate at high detection efficiency and approach Shannon's ideal communication system. This efficiency increases with the number of symbols in the codebook, but the increase is relatively slow because of the required orthogonality of the symbols [19].

The requirement of this system for considerable message storage will probably be met by the increasing miniaturization of memory devices. An optical system using photoelastic delay lines appears to be the most promising system for implementing the configuration shown in Fig. 9.

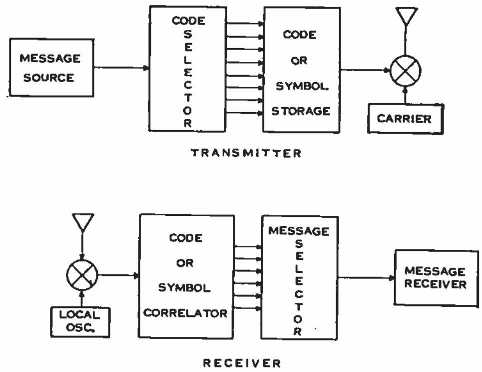

Fig. 9—A transmission system with a large codebook.

Component Development

The increasing complexity that has been discussed demands major reductions in the size of the components for future spaceborne data-processing and transmission equipment. That this matter is receiving increasing attention from many organizations is evidenced by Gerhold's volume and weight predictions [20], shown in Tables I and II. These tables compare a "conventional" printed wiring design, improved packaging techniques, an integrated micromodule design using advances in thin-film and solid-state circuits, and a future hybrid design incorporating the promising molectronics advances.

[7] For a round trip to the moon, 2.6 seconds; for a round trip to Mars, about 9 minutes minimum.

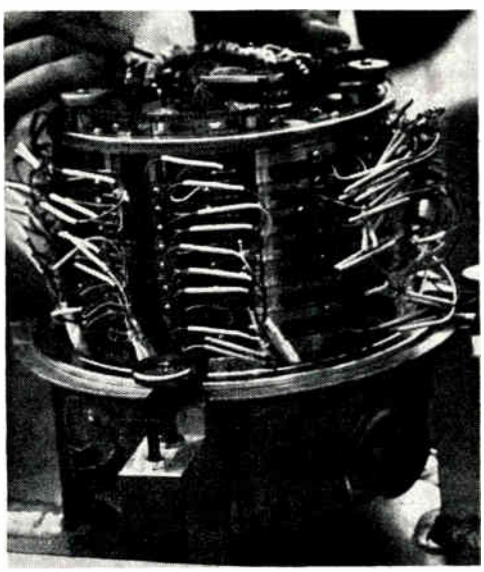

Fig. 10—Magnetic drum memory for the Titan guidance computer (IBM).

Fig. 11—Ferrite cores for random-access memory for NASA's Orbiting Astronomical Observatory (IBM).

A striking situation pointed up by Tables I and II is the small amount of reduction anticipated in the communications and power equipment compared with that predicted for the computer equipment. This situation emphasizes the desirability of increased utilization of those logical functions best performed by digital equipment. Examples of these are data compaction, "adapting" the transmission to the medium, and the asynchronous communication system of the preceding section.

In addition, more attention will probably be devoted in the future to those transmission systems that minimize the amount of power and communication equipment required on the spacecraft. The TELARRAY system described earlier is an excellent example of such a system. It reduces the spaceborne power and transmitting equipment markedly by increasing the ground-supplied power and the antenna gain.

Representative of the improvements in data-processing equipment expected in the near future is the comparison between Figs. 10 and 11. Fig. 10 shows the state-of-the-art magnetic drum memory utilized in the Titan inertial guidance system that was successfully demonstrated in a recent test firing. Fig. 11 depicts the random access (nondestructive readout) memory elements that will be incorporated in NASA's Orbiting Astronomical Observatory. It seems likely that densities of 10^6–10^7 bits per cubic foot will be achievable with ferrite elements similar to these in the near future.

The Future

An estimate of information transmission capacity in the near future for deep space vehicles has been made by Martin [13] and is shown in Fig. 12. The rising bit rate is expected to be achieved by such techniques as increasing spacecraft power, increasing ground antenna size, raising the operating frequency, and using masers, steerable directional antennas on the spacecraft, orthogonal coding, and coherent demodulation.

Further gains may be expected if techniques suggested in this article prove themselves. The compacting of data will result in the transmission of necessary information only, effectively increasing the channel capacity by a factor of perhaps 3 to 10. Other benefits, such as reduction of the time required to transmit the real message, may be anticipated from compaction.

Several orders of magnitude improvement in channel capacity could well result from the exploitation of very large antenna apertures in space, beyond those estimated by Martin. Orientation instabilities have been the limitation in the past, but the passive modulated antenna (TELARRAY) shows one way of alleviating this problem.

The startling difference in size reduction potential between computer components and transmitter and other components associated with the communications art suggests that computer components will take over more

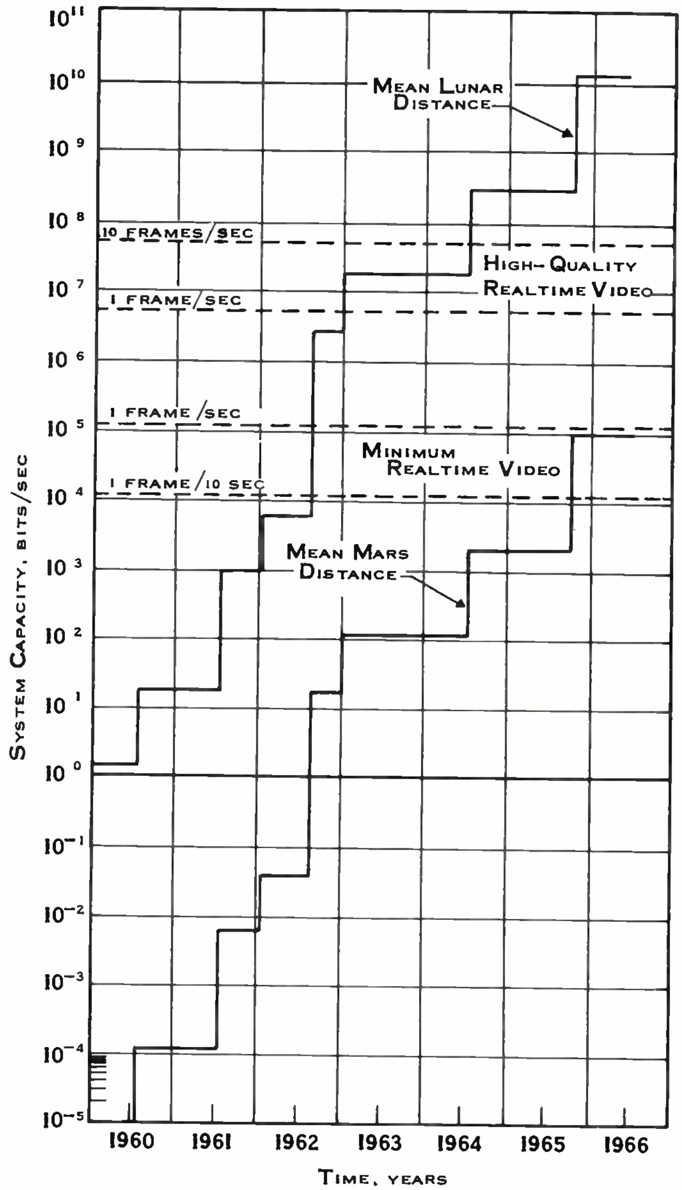

Fig. 12—Projected deep-space telemetry system capacity (after [13]).

of the data transmission job. Such functions as message programming, multiplexing, coding, and compacting are fair game for the computer. Others will be found.

Improvements in communication systems are appearing which will make possible, within the inner solar system, data rates high enough to permit real-time remote observations of the most intricate nature. The rapid and timely evaluation of such data will be a challenge requiring the most advanced data-processing equipment. We may then look forward to the performance of remote experiments by remote handling equipment under earth-based control.

Trends in Space Navigation*

K. N. SATYENDRA†, SENIOR MEMBER, IRE

Summary—The theme of this paper is based on the growing use of self-contained navigational systems in space navigation. A figure of merit, called the self-containment index (SCI), is defined in order to define quantitatively the degree of autonomy for which a system design is directed.

The navigational problem of spacecraft is divided into problems of point-dynamics and rigid-body dynamics and the major factors are defined which deserve consideration in the understanding of the space navigational problem. Consistent with the requirements for low size, weight and power allocations and for very high accuracy and reliability tolerances, optical techniques are found ideally suited for space navigation. Open-loop and closed-loop methods of earth satellite navigation are presented and extended to the lunar navigation problem.

Some advanced navigational concepts are given using nonrotating and track-while-scan instruments. The importance is emphasized of the increase in data-processing requirements and their part in accuracy enhancement through statistical techniques. A review of optical Doppler and lasers for measurement of distance and velocity is given. The concept of guidance management is proposed for consolidation of all the launch, orbital, midcourse, return and other guidance phases of a future multistage spacecraft into a single, integrated, self-contained navigation system within the final upper stage.

Introduction

THE PURPOSE of this paper is to point out some trends in space navigation and some advance navigational concepts which appear to be feasible and practicable, especially in the light of recent improvements in signal-sensing and signal-processing techniques. The paper is therefore not an original and detailed discussion of any specific navigational method; however, heavy emphasis is placed on optical celestial sensing techniques since these techniques appear to be an essential aspect of nearly all future space systems.

With increased skills in astronautics, the space traffic consisting of scientific and military payloads is rapidly increasing. An educated guess of five to six thousand objects in orbit during the next decade is not unreasonable. Some of these objects may be useful payloads, which may be manned or unmanned scientific or military payloads, while the others may be inactive payloads and space debris—booster tankages—and the like. The tracking and cataloging by ephemeris prediction of such a vast number of space objects creates a data-processing problem at a ground station resulting in possible denial of navigational data to useful orbital payloads which depend on tracking and computations made on the ground. Unlike the air traffic problem over modern airports where aircraft can be made to fly a pattern while awaiting landing instructions, orbital vehicles have a limited time for communication over the ground station before they get lost over the horizon.

The manned spacecraft, very much like the manned aircraft, demand on-board guidance and control capability. The term "self-contained navigation" has become a familiar term in the aerospace industry and an ever-increasing demand is made on the electronics industry to provide all navigational measuring and computational instrumentation on board the spacecraft itself with very little dependence on the ground complex. The extent of "self-containment" or the degree to which the spacecraft can navigate without receiving inputs from outside depends on the mission requirements, payload and equipment limitations, cost and reliability considerations. No clear definition of the term "self-contained navigation" appears to be present and therefore the following definition, which is especially illustrative for earth satellites, is offered:

Definition: A self-contained navigation system is defined as one which, for a given portion of the mission flight path, functions independently of concurrent man-made friendly signals originating from points external to the spacecraft.

For a long time to come, the earth will still be the main source of friendly signals which will be generated in ground-based communication and control stations. With the above definition of self-containment, three classes of self-contained or autonomous navigation systems may be studied:

Class I: Autonomous outside the horizon of ground communication and control center. This class covers those space vehicles which are independent of communication with the earth when outside the line-of-sight of a set of predefined ground tracking and communication control centers. During this time any navigation performed is accomplished by the on-board systems.

Class II: Autonomous for more than one pass over the ground communication and control center. This degree of autonomy may be necessary to accommodate those instances when the ground-based communication stations are saturated because of too many space vehicles overhead and cannot transmit updated navigational data to an individual spacecraft.

Class III: Indefinitely autonomous or continuous systems. This class covers those systems which are completely autonomous and do not depend upon earth-based tracking and communication networks to navigate. The degree of self-containment for this class actually depends on the reliability of the system.

* Received by the IRE, March 1, 1962.
† Nortronics, a Division of Northrop Corporation, Palos Verdes Estates, Calif.

A self-contained navigation system for Class III, requiring more advanced and sophisticated components, will chronologically follow the development of simple systems to cover Classes I and II. A fully self-contained navigation system is therefore the ultimate one can hope to accomplish and suffers from all the headaches such aspirations usually involve.

Quantitatively, one can define a figure of merit to distinguish between the classes of self-containment in terms of the ratio T_Q/T_o, where T_Q is the quiescent period during which there is no communication between the space vehicle and the earth, and T_o is the orbital period or time for a round trip. This ratio, rounded off to the nearest integer, may be defined as the self-containment index, and abbreviated as SCI. For example, if an earth satellite were autonomous for 260 minutes and its orbital time period were 90 minutes, then its SCI = 3. With this definition, the SCI of Class I–III systems would be respectively less than unity, greater than unity and approach infinity.

The methods involved in solving the three classes of problems differ, not in principle, but in technique and detail because of the differences in accuracies, component life times, duty cycles and degree of sophistication permissible. Present day technology is adequate to achieve values of SCI between 1 and 3.

Higher degrees of self-containment await improved techniques for developing components with reduced size, weight and power allocations and increased reliability in a hostile space environment. Almost all aerospace systems of the future will demand a fully self-contained navigation ($SCI \geqq 3$) as the *primary system* and a ground-based or earth-dependent navigation system as a *back-up*. Some illustrative examples of systems with different requirements for the SCI will be presented here.

The Navigation Problem and Its Solution

In its simplest form, the navigational problem of a spacecraft consists of two basic parts:

1) *Point dynamics*, defining the motion around the geocenter of the spacecraft treated as a point-mass.
2) *Rigid-body dynamics*, defining the interrelation between the body axes of the spacecraft and certain directional space references. This aspect of navigation includes the definition of a system of coordinate axes within the spacecraft, and their relationship to one or more systems of directional reference in space.

Before proceeding with the detailed exposition of the two problems, it is desirable to distinguish between the terms, *navigation*, *guidance*, and *control*, at least to classify the instrumentation associated with each of these terms.

The origin of the term *navigation* lies in the French words *navis* meaning *ship*, and *agere*, meaning *to move or direct*. Space navigation may be defined by analogy with sea navigation, by a modification of Webster, as "the art or science of conducting a spacecraft from one place to another, including the method of determining position, course, distance passed over, etc., by the principles of geometry and astronomy. . . ." Revising Webster's order, one may single out as navigation functions,

1) the determination of position, present course, distance covered, etc.,
2) the action of *conducting*.

Based on the line of reasoning above, Hoelker [1] defines *guidance* as follows: Guidance is the technological field concerned with the following sequence of action:

1) Measuring the data for the purpose of the determination of the current state of flight,
2) Determining the current state of flight from the measured data,
3) Determining the path ahead that joins the current state of flight with the desired terminal state of flight,
4) Providing to the control mechanism an immediate reference that serves for implementation of the determined path ahead.

The action of *conducting* may be interpreted as the enforcement of the course of action through the use of the *control* system. The above definition separates the functions of guidance and control, and guidance terminates at providing references, computations of maneuver ballistics and inputs to the control loop or loops.

With the concepts stated above, it may be desirable to relate the two broad problems of navigation with guidance and control as follows:

Guidance implies preparation of the *inputs* for solving the point-dynamics and rigid-body dynamics of a spacecraft. Control implies enforcement, through the use of control loops and additional force, of the point-dynamics and rigid-body dynamics of the spacecraft to a prescribed course of action.

The solution of the *guidance* problems and the preparation of the necessary *inputs* requires the use of instrumentation involving two basic functions, namely, *sensing* and *signal processing*. The sensing function involves establishment of directional and positional references through gyroscopic or celestial (planetary or stellar) means, or man-made optical and/or radio-frequency means. The signal-processing function involves the computation or extraction, usually by means of a computer, of the navigational parameters of the spacecraft from the sensed signals. The most demanding problem is the establishment of the orbital elements of a spacecraft to a high degree of accuracy in the shortest possible time. The accuracy in sensing direction references or velocity or position of a spacecraft has a physical limit set by the equipment and laws of physics. Space missions, especially those requiring self-contained navigation techniques, demand refinements in accuracy which, therefore, must be obtained by statistical techniques, yielding what is usually referred to as "smoothed" data. Such refinements are achieved mainly through high-speed computers and the trend in space navigation is therefore an optimization of the signal-sensing and signal-processing techniques, usually resulting in a higher burden being placed on the latter.

In summary, the following major factors deserve consideration in the understanding of the space navigation problems and their solution:

- I. Directional References
  - A. Inertial
    - 1) celestial (stellar)
    - 2) gyroscopic
    - 3) combination or astronertial
  - B. Local Vertical
- II. Position Determination
  - A. Static
    - 1) triangulation
    - 2) stadiametry
  - B. Dynamic
    - 1) active ranging
    - 2) explicit solution of point-dynamics
- III. Types of Measurement
  - A. Angular—angle, angle-rate, angular acceleration, etc.
  - B. Range—range, range-rate, range acceleration, etc.
- IV. Accuracy Refinements
  - A. Systematic Error Isolation—intrinsic and external to instruments
  - B. Statistical Techniques—time smoothing and space smoothing
- V. Forms of Solution
  - A. Time
    - 1) real-time solution
    - 2) delayed-time solutions
  - B. Location
    - 1) earth based
    - 2) on-board or self-contained
- VI. Signal Sources
  - A. Natural—stars, planets, fields of force
  - B. Man-made—radio or optical, both passive and active
- VII. Physical Description
  - A. Size, Weight, Area, Power, Volume
  - B. Reliability, Cost, etc.

Self-Contained Navigation of Earth Satellites and Lunar Spacecraft

Earth Satellites

The most difficult problem of navigation is the solution of the point-mass dynamics. In general, the motion of a point-mass is governed by Newton's and Kepler's laws which state, in effect, that the rate of change of momentum is equal to the total force acting on the point-mass. The total force F_T on a satellite, treated as a point-mass, is given by the following equation:

$$F_T = F_E + F_D + F_M + F_P \tag{1}$$

where

F_E = Most complete force field of the earth, such as the Jeffreys model of the oblate earth

F_D = Atmospheric drag

F_M = Force due to maneuvering rocket thrusts, such as those due to retro-rockets, ion-engines, etc., used for rapid *position* changes of the satellite

F_P = Perturbative forces due to solar photon pressure, lunar gravitational effects, rotation of earth, etc.

It is a fact that if F_T is completely known, and the initial values of position and velocity of the point-mass are known, the solution of the Newtonian force equation (1) is theoretically possible. However, uncertainties in several factors make it impossible to provide an ideal and true theoretical solution of the force equation and thus predict the position of the satellite point-mass. It is therefore necessary to make compromises in practice and be satisfied with the most reasonable, if not the best solution. The position and velocity accuracies of a satellite, based on such solutions, will be better for short flight times, as in Class I and Class II type systems, than for long flight times, as in Class III type of self-contained navigation systems. The mechanization of the computer for solving these equations depends also on the degree of sophistication employed. Two such methods are described below, the *open-loop* method for Class I and Class II types of satellite navigation and the *closed-loop* method for Class III type of navigation.

Open-Loop Method: For Class I and II types of self-contained navigation schemes for which the SCI is between 1 and 3, the explicit solution of the force equation (1) may be simplified by the help of some assumptions, such as the following:

1) That the earth is perfectly spherical,
2) That the earth's force field is perfectly central,
3) That the orbital elements of the satellite orbit may be accurately computed on the ground and transmitted to the satellite,
4) That there are no external perturbative, thrust maneuvering or atmospheric drag forces,
5) That the satellite is truly a point-mass.

The above simplifying assumptions yield a circular or elliptic orbit for the satellite. With known initial conditions, *i.e.*, with known position and velocity at any time of such an orbit, the subsequent orbital parameters after a time interval t may be easily computed algebraically rather than through a differential equation solution. The time difference t can be measured in the satellite by a simple clock or oscillator. The effects of earth oblateness, atmospheric drag, solar winds, etc., could be added, as refinements, in the form of empirical corrections. Specifically, the vehicle's position in spherical coordinates may be programmed into a small onboard function generator as trigonometric or power series. Thus, the latitude and/or longitude might be represented in the form

$$\theta = \theta_0 + \theta_1 t + \theta_2 t^2 + \theta_3 t^3 \cdots \quad (2)$$

or

$$\theta = \theta_0 + \theta_m \operatorname{Sin}(\omega t + \alpha). \quad (3)$$

The form of the function will be determined by the eccentricity, inclination of the orbit, altitude, etc. The block diagram for such a simplified navigation system is shown in Fig. 1. The output from the clock to the function generator serves to define the position and velocity. Position and velocity are channeled into the guidance computer along with vehicle attitude and thrust acceleration to be included in the guidance equations. Attitude control signals and thrust commands are generated by the guidance computer and are fed to the attitude control device and thrust actuating device, respectively. *A complex, high-data rate, general purpose computer is not necessary.*

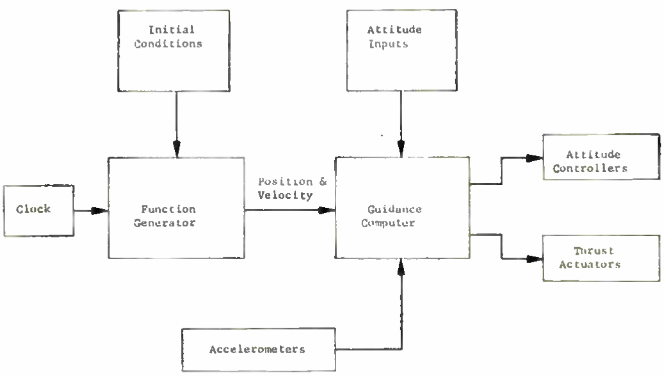

Fig. 1—Open-loop method—functional block diagram of self-contained navigation (Class I and Class II).

Closed-Loop Solution—Class III: In the previous method, position and velocity predictions are made by open-loop methods, with periodic updating from the ground. To obtain the accuracy and independence required for Class III type navigation systems, a closed-loop system will be necessary to improve system accuracy by up-dating refinements made by means of onboard measurements.

The basic refinement necessary for Class III type navigation schemes is the *explicit* solution of the force equation (1), taking into account as many perturbative factors as possible.

One such method has been presented by Satyendra and Bradford [3]. This method is built around the concept of sensing the satellite attitude by means of a prime reference established by a pair of star trackers; direct measurements, over a period of time, of the local geocentric vertical by means of a horizon tracker; and determining the orbital elements by a precision time reference and a data-processing computer.

The basic conceptual feature of this approach is that suitable stars are preselected and tracked. The initial star lock-on can be achieved by orienting the satellite from the injection guidance subsystem's gyroscopes. Once this lock-on is achieved, it is continually maintained to obviate a complex search and identification process implied by loss of orientation resulting from extended shutdowns of operation.

A typical design of a lightweight star tracker is described by Stevens [4]. Two star trackers are locked on two known stars, S_1 and S_2, as shown in Fig. 2. The selection of the stars S_1 and S_2 may be based on the techniques described by Stevens [5]. A coordinate reference frame consisting of three mutually perpendicular vectors, $\hat{C}_1$, $\hat{C}_2$, $\hat{C}_3$, is rigidly connected to the two star-tracker telescopes, which are represented by the vectors $\hat{P}_1$ and $\hat{P}_2$ in Fig. 2. With the star trackers locked on to the stars, S_1 and S_2, the orientation of the frame ($\hat{C}_1$, $\hat{C}_2$, $\hat{C}_3$) in inertial space is known. For convenience in analysis and mechanization, it is assumed that this orientation is such that the vector $\hat{C}_3$ is approximately normal to the plane of the orbit. The azimuth and elevation angles θ and ϕ between the inertial frame ($\hat{C}_1$, $\hat{C}_2$, $\hat{C}_3$) and the local vertical are measured by means of a horizon tracker.

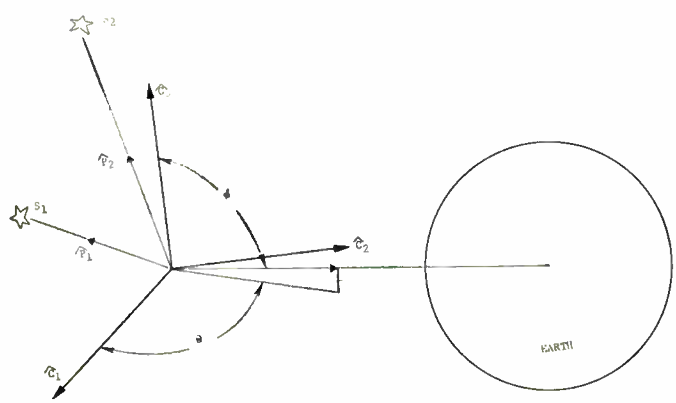

Fig. 2—Basic geometry of the Satyendra and Bradford method.

In the ideal case of perfectly accurate measurements and an exact knowledge of the force field about the earth, one would be able to determine an earth satellite's trajectory by measuring the direction of the local vertical at four distinct times. In such an ideal situation no new information could be obtained by collecting a greater amount of data. In reality, however, all measurements will be corrupted by noise; hence the above reasoning is not applicable to any practical situation. It can be clearly demonstrated that, if one has a large set of measurements of the local vertical, statistical decision techniques can be used to obtain a much more accurate estimate of the trajectory than could be obtained by using only four measurements. For this reason the use of approximately 1000 measurements of the local vertical is envisioned to obtain a good estimate of a satellite's orbit.

To estimate a trajectory it is necessary first to choose a model for the force field about the earth. Under such a choice, every possible trajectory will be completely characterized by six initial conditions—three of position and three of velocity. These six initial conditions will completely characterize a trajectory, for the period of time for which the model is applicable.

For this reason the problem of trajectory determination reduces to the problem of determining the six initial conditions of position and velocity.

The force model chosen for this method was the Jeffreys model of the oblate earth. This model neglects atmospheric drag and perturbations due to the influence of the moon; but these effects appear to be negligible for typical earth satellite trajectories for periods of time corresponding to at least several cycles of the satellite. If the only requirement is that the model give a satisfactory representation of a satellite's trajectory for a couple of periods, the assumed model is probably adequate for the present purpose.

The second step is to measure the various angles θ and ϕ, using the basic geometry shown in Fig. 2. Suppose that n measurements are taken of these angles. The data will then consist of the triples

$$(\theta_1, \phi_1, t_1),\ (\theta_2, \phi_2, t_2),\ (\theta_3, \phi_3, t_3),\ \cdots,\ \cdots,\ (\theta_n, \phi_n, t_n),$$

where t_i is the time at which the ith measurement was taken.

In the absence of any errors in the horizon tracker and inertial reference, the angles θ and ϕ would truly represent the direction of the geocentric vector. The graphs of θ or ϕ vs time would be straight lines or periodic curves for circular or elliptic orbits. The presence of instrument errors discussed by Jaramillo [6] results in data which are shown as points distributed along these curves for θ and ϕ as shown in Fig. 3.

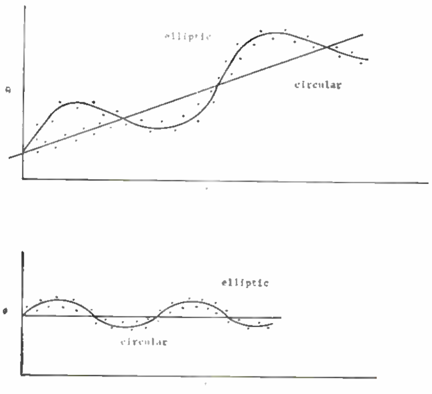

Fig. 3—Variation of θ and ϕ with time.

The basis of the method involves computing the difference between the calculated values of θ and ϕ from the force field model and the horizon tracker gimbal-pickoff measured values. These difference values are smoothed over as many full or fractional cycles to yield averaging values of θ and ϕ, from which the orbital elements can be calculated.

Error analysis based on a 400 statute mile circular orbit and assuming a 1σ error in angle determination of 1 arc minute, indicate the following 1σ errors in position and velocity over a 1 revolution smoothing period:

TABLE I
TYPICAL ACCURACIES OF 2-STAR HORIZON TRACKER METHOD

	1σ Position Error	1σ Velocity Error
X Component	335 ft	0.67 ft/sec
Y Component	674 ft	0.30 ft/sec
Z Component	291 ft	0.31 ft/sec

Of course, the accuracy figures depend somewhat upon initial conditions defining the orbital elements. These initial conditions can be established by ground-based measurements or by simple on-board techniques. Even with crude initial conditions, the smoothing techniques can be used to effect major improvements in updating the values.

The functional block diagram for a closed-loop Class III navigation system is seen in Fig. 4. The basic equipment consists of an astronertial platform, a horizon tracker, a clock and a computer.

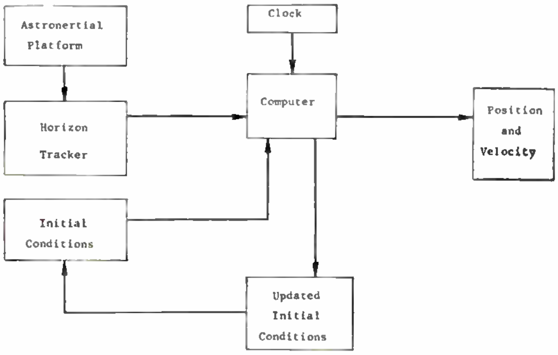

Fig. 4—Functional block diagram of a self-contained earth satellite navigation system (closed-loop method)—Class III.

The astronertial platform is used to maintain an inertial reference frame in terms of which the horizon tracker measures the angle describing the satellite-geocenter vector. The computer combines the measured angles with angles calculated from preliminary position predictions to obtain updated initial conditions. These updated initial conditions are used by the computer to make more accurate position and velocity predictions than can be made by an open-loop system. This method of periodic updating of initial conditions reduces inaccuracies due to errors in initial conditions and lack of completely accurate force field information.

The computer shown in the block diagram, Fig. 4, replaces the function generator shown in the block diagram of the open-loop system. In addition to this change from open-loop to closed-loop position and velocity determination, the system for the Class III satellites will require an attitude control system operable for a much longer time period than that required for Classes I and II.

The system described above is presented as an example of the methods of closed-loop position and velocity determination to be studied for Class III satellites. No attempt has been made here to describe a specific system, but rather the general method has been indicated. It is recognized that various instruments might be used, alternatively, in each of the instrument blocks.

Lunar Navigation

The navigational problems of lunar probes and manned lunar vehicles are receiving such detailed attention today that one cannot do justice to any given method or technique without a very detailed discussion. The purpose of this paper is not to go into such discussion but to point out the *trend* in lunar navigation which like earth-satellite navigation, once again shows a great emphasis on the concept of self-containment. Several types of lunar missions are in various stages of planning and progress. The guidance systems which have been used for space probes and those which are presently planned for other early programs have taken advantage of the current state of the art in systems and use off-the-shelf hardware. This generally results in a heterogeneous system consisting of independent launch and injection systems, in some cases separate for each boost vehicle stage; radio-controlled midcourse guidance with ground-based computation; and a variety of combination radio-optical-inertial systems for operation in the vicinity of the moon. The future *trend* will definitely be toward a nonradiating, fully integrated self-contained system. An excellent example is given by Hakes [7] in which the integrated guidance subsystem consists of an astronertial platform, a two-star tracker, wide-angle, and narrow-angle optical earth and moon trackers, an integrated computer-clock, and a radio altimeter. The utilization of these instruments by mission phase is shown in Table II (next page). Perhaps the most demanding of problems is the enhancement of navigational accuracies by self-contained methods. It is becoming increasingly clear that such accuracy enhancements can come more from employing statistical techniques than from over-design of sensors to achieve extreme accuracies, possibly jeopardizing cost and lifetime figures.

The statistical methods in the determination of the trajectory of a spacecraft are concerned with the problem of finding the "best" (in the sense of the statistically most significant) values of the position and velocity of a spacecraft, when the available data are redundant and, on account of the errors of measurement, contradictory.

As an example (Fig. 5), consider the radar R, at some point on the earth, which measures the range and direction (the azimuth and elevation angles) of a vehicle at V. From this data, a determination of the position of the vehicle (its x, y, and z coordinates, for example, in some reference frame) can be found. Here there is no problem, since one has a minimum of data. Three measurements, range, azimuth and elevation, are used to compute 3 position coordinates, and there is no redundancy.

Now, however, assume that another radar R', at another spot on the earth measures the corresponding quantities at the same time. From these measurements one can compute the x, y, and z coordinates of the vehicle in the same reference frame as before. Call these x', y', and z'.

Since each of these six measurements will inevitably be subject to error, no matter how carefully the measurements are made or how accurate the system, the position as calculated from R will not coincide exactly with the position calculated from R', and the question arises as to the choice of the position of the vehicle.

One simple answer would be to average the two positions:

$$\bar{x} = \tfrac{1}{2}(x + x')$$
$$\bar{y} = \tfrac{1}{2}(y + y')$$
$$\bar{z} = \tfrac{1}{2}(z + z').$$

Although this position would be better than either position separately, it does not generally represent the statistically best determination, *i.e.*, the most probable position in view of all available information.

Statisticians have worked with this problem, and have developed a simple criterion, referred to as the least squares criterion, by which the position of the spacecraft is so chosen that the sum of the squares of the errors is a minimum.

One complication immediately arises. The data include both distance and angle measurements. The question arises as to how to combine errors measured in feet with errors measured in degrees. To account for this difference, as well as possible differences in precision of various measurements of the same type, one minimizes the sum of the weighted residuals, where the weights are given by

$$w_i = \frac{1}{\sigma_i^2}$$

where w_i and σ_i are the weight and the standard derivation of the ith observation.

Suppose now that one makes a number of such observations at specified times. Since the vehicle during this interval must move in accordance with Newton's laws. the sum total of the known information consists of all the measured data and the laws of motion governing the trajectory, including all the forces acting on the vehicle.

TABLE II
EQUIPMENT REQUIRED BY MISSION PHASE

Subsystem	Mission Phase: Earth Launch	Earth Parking Orbit	Injection	Midcourse	Lunar Approach	Circumlunar Passage	Lunar Orbit	Lunar Landing	Lunar Launch	Return Midcourse	Earth Approach	Atmospheric Reentry
Astronertial Platform	X	X	X	X	X	X	X	X	X	X	X	X
Wide-Angle Earth-Moon Tracker		X		X	X	X	X	X	X	X	X	
Narrow-Angle Earth-Moon Tracker				X					X	X	X	
Computer-Clock	X	X	X	X	X	X	X	X	X	X	X	X
Radio Altimeter					X	X	X	X			X	X

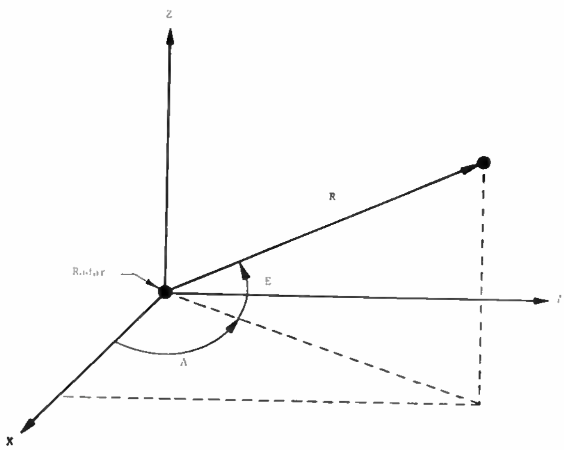

Fig. 5—Coordinates of spacecraft relative to ground-based radar.

A criterion for selection can thus be stated as follows: Select the trajectory which satisfies the laws of motion and for which the sum of the squares of the weighted residuals is a minimum.

In the case of a linear function, a least squares solution is a simple and straightforward computation to make. Unfortunately, in the case of a space vehicle, the differential equations of motion cannot be solved explicitly. This means that the trajectory must be calculated numerically and approximately, and the direct least squares solution cannot be made. Instead one is forced to expand the various functions in Taylor Series, of which one uses only the first term. For a given first approximation, the equations give an improved value for the trajectory. A second correction can give a still better estimate, and so on.

In many cases, the knowledge of the accuracy of the position and velocity determination is as important as the quantities themselves. Two methods are commonly used for finding these errors. The first, a numerical method, uses the Monte Carlo principle, in which a considerable number of trajectory cases are run with random errors added to the measurements. In the second, the usual formula for the propagation of errors is used. If the x-coordinate of position at a given time, for example, is thought of as a function of the measurements,

$$x = x(\psi_1, \psi_2, \cdots, \psi_n)$$

then the standard deviation of x, σ_x, is given by

$$\sigma_x^2 = \sum \left(\frac{\partial x}{\partial \psi_i}\right)^2 \sigma_{\psi_i}^2.$$

These calculations have been performed for a typical case of the re-entry vehicle from the moon. The Propagation of Errors Method gave the standard deviations in the six variables as

$$\sigma_x = \pm 155 \text{ ft} \qquad \sigma_{v_x} = \pm 0.50 \text{ ft/sec}$$
$$\sigma_y = 575 \text{ ft} \qquad \sigma_{v_y} = 0.20 \text{ ft/sec}$$
$$\sigma_z = 385 \text{ ft} \qquad \sigma_{v_z} = 0.52 \text{ ft/sec.}$$

The Monte Carlo method yielded

$$\sigma_x = \pm 172 \text{ ft} \qquad \sigma_{v_x} = \pm 0.41 \text{ ft/sec}$$
$$\sigma_y = \pm 438 \text{ ft} \qquad \sigma_{v_y} = \pm 0.22 \text{ ft/sec}$$
$$\sigma_z = \pm 411 \text{ ft} \qquad \sigma_{v_z} = \pm 0.48 \text{ ft/sec.}$$

This agreement is considered to be very good in view of the small number of samples.

Some Advanced Navigational Concepts

Advanced Navigation Requirements

The navigational requirements for aerospace vehicles differ from mission to mission and from phase to phase within a particular mission. In each mission, the navigation instruments, including the computer, must be capable of providing current position and velocity information and, in many cases, they must be capable of predicting the future position and velocity of the spacecraft. In addition, the navigation system in many cases is called upon to calculate maneuver ballistics and specify time, magnitude and direction of corrective thrusts.

The major variations in navigation requirements arise when one considers the accuracy and speed with which navigational data must be acquired and processed to provide the necessary guidance functions. In certain satellite missions, the navigational system must be capable of positional accuracies measured in feet, velocity accuracies of less than one ft/sec with a data acquiring and processing time measured in seconds. On the other hand, the navigational system of a deep space mission could tolerate midcourse positional errors measured in miles and take minutes, if not hours, to perform the necessary computations. However, in the interest of minimizing fuel requirements, maximizing payload, etc., it is desirable that the maximum accuracy and minimum time be obtained with due consideration for size, weight, power, cost and reliability. The consideration of these parameters and their trade-offs often lead to interesting and new navigational concepts. The trend is definitely pointed towards novel optical techniques which offer increased accuracy and reliability with reduced size, weight and power allocations.

Some Optical Navigational Techniques

An important distinction has to be made between an optical system in a vehicle within the atmosphere and a space vehicle. For example, a star tracker in a typical vehicle which has most of its flight profile within the earth's atmosphere, usually has a narrow field of view intended to minimize sky brightness and background noise and consists of a telescope system rigidly pointed towards a given star and held in track mode by a servo motor. The sky brightness and background noise are not so serious when the vehicle is above the atmosphere and hence the optical field of view can be increased, giving the opportunity to observe many celestial bodies. Mixed with celestial bodies are man-made objects which, in many instances, reflect solar energy, appearing like stars. Wide angle optical navigation systems must, therefore, have the ability to discriminate between natural celestial bodies and man-made moving targets. A typical servo control system which would enforce the pointing to a specified star of a tracker in an atmospheric vehicle, would create angular momentum unbalance in an exo-atmospheric spacecraft, unless compensated for. The need for preserving angular momentum equilibrium or balanced torques is therefore essential in spacecraft.

Some of these conflicting requirements and properties of space navigation systems suggest two possible configurations, a wide-angle nonrotating system and a rotating track-while-scan system.

Nonrotating Sensor Concept: In principle, this method considers the acquisition and monitoring of an adequate image of the entire spherical field of view available to a space vehicle. A conceptual sketch describing this concept is shown in Fig. 6. Such a device, which may be called a "Fly's Eye Camera" because of its ability to look through a wide angle and track different objects independently, may conceivably be developed by a mosaic type or sensor array in which multiple fields of view may be overlapped to give a broad picture of the celestial sphere. From a knowledge of the solar system and the celestial sphere, which may be carried in its memory, the Fly's Eye Camera could provide many valuable navigational data without serious control system requirements. There is no doubt that the on-board computer will have to be sophisticated because of the many functions and transformations it has to perform.

Track-While-Scan (TWS) Concept: This concept is an extension of the method of self-contained navigation presented by Lillestrand and Carroll [2]. In principle, the TWS instrument observes a portion of the celestial sphere by a rotating telescope. The instantaneous portion of the celestial sphere under observation is defined by a slit or slits in the image plane of the telescope. Fig. 7 illustrates a belt-like projection of the celestial sphere observed by a single scanning slit. The corresponding object space image of the slit is shown superimposed on the celestial sphere.

The azimuth angle between any two stars in the field of view may be measured in two ways:

1) If the platform supporting the rotating telescope remains fixed in space, an angle encoder may be employed and the angle of rotation of the telescope measured at the instant of transit of each star.
2) Alternatively, if the rotation rate ω is a constant, the periodic nature of the observed star pattern will permit an accurate calibration of this rate. The difference in azimuth angle $(\theta_2-\theta_1)$ between any two stars may then be determined by measuring the time interval (t_2-t_1) between each star crossing the slit, since $(\theta_2-\theta_1)=\omega(t_2-t_1)$.

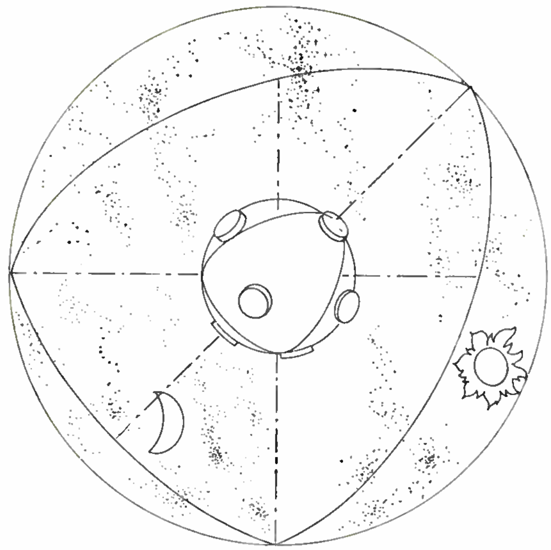

Fig. 6—Nonrotating tracking instrument.

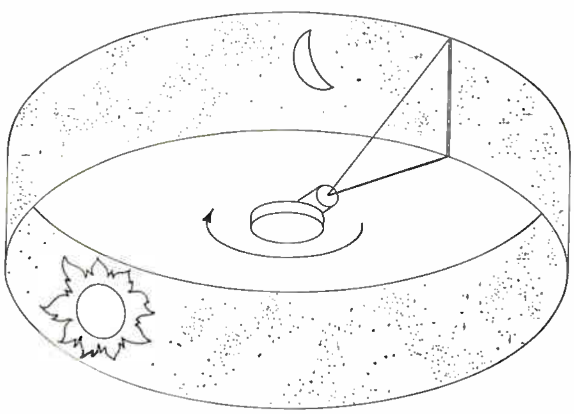

Fig. 7—Track-while-scan instrument.

The technique for precise measurement of azimuth angular separation of celestial bodies by means of a telescope rotating with a constant angular rate is similar to the well-known transit telescope. The aligned transit telescope is constrained so that its line of sight is always in the plane of the meridian. The constant angular rate, in the azimuth direction, is supplied by the angular rotation of the earth. During the manual operation of a transit telescope, the observer records the time at which each star crosses the instrument crosshair. In the TWS automatic instrument, the star transit across a narrow slit may be recorded as a photoelectric pulse from a photodetector placed behind the slit.

Advanced Concepts in Data-Processing Techniques

The successful deployment of self-contained navigation systems depends on successful development of reliable components of small size, weight and power allocations. The increased emphasis of accuracy and redundant logic, as well as explicit trajectory solution in completely self-contained systems, requires the use of a sophisticated, large-scale general-purpose data-processing machine. Some trends in data-processing computers may be pointed out.

Some factors which may be considered in optimizing the data processing are:

1) Equipment time sharing: The possibility of time sharing of an arithmetic module between two computational processes, where each process has a different time when peak load occurs.
2) Computer control: The problem may lend itself to unique addressing and instruction coding.
3) Input-Output: The realm of data conversion where perhaps the input-output unit can be greatly reduced. This appears particularly feasible if the system is self-contained. The problem then becomes one of designing the subsystems to operate using machine language inputs.

In addition to the factors listed above the design and development necessary to build a digital computer that will perform within high reliability standards, perform all desired functions with a speed and accuracy dictated by system specifications, and designed within critical weight and size limits, seems to center around the application of state-of-the-art considerations of packaging philosophy, electronic component microminiaturization construction, advanced circuit and logical design techniques, and a thorough testing and quality control program.

To obtain maximum packaging density a required amount of development must be expended in the area of efficient packaging of miniature and microminiature components. The state of the art in electronic packaging is changing at a rapid rate as shown in Fig. 8, which is a graphical representation of the variation of component packing density as a function of time. As indicated in Fig. 8, there are three methods of achieving microminiaturization of electronic equipment. All may be considered for application to space flight, and may be grouped as follows:

1) Single Dimension: This method uses thin films for resistors and capacitors and separate microcomponents for inductances and semiconductors. A single type of element (*i.e.*, resistor or capacitor) is deposited on each wafer. This method is currently in use and promises a density of up to 600,000 components per cubic foot.

2) Two Dimension: This method uses thin films for resistors and capacitors, as above, but combines them on a single wafer. The combining reduces external interconnections leading to an over-all increase in packing density. The disadvantage is that the yield goes down due to the multiple operations involved. When the problems are solved, packing densities of up to 2.5 million components per cubic foot can be realized.

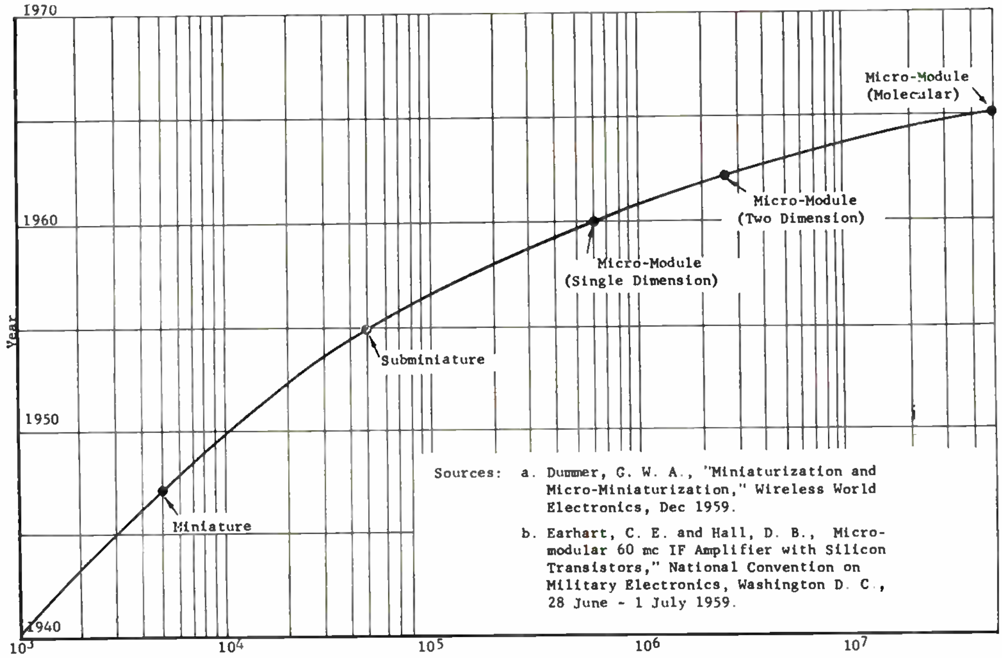

Fig. 8—Trend of packing density.

3) Molecular: In this method, resistors, capacitors, inductors, diodes, transistors, and other electronic devices are mounted together on one surface of a semiconductor wafer. Packing densities of from 20 to 100 million components per cubic foot are expected; however, major improvements in connectors, heat transfer methods, and intercommunication between circuits are required to fully utilize the high densities possible.

Advanced Concepts Using Optical Doppler Techniques and Lasers for Space Navigation

A comparison between radar and optical techniques for making velocity and distance measurements will soon convince the reader that the optical techniques offer higher accuracies, narrower beamwidths and all-round better performance than radar, especially in terms of size, weight and power requirements. A brief review is now presented of the use of optical Doppler techniques and lasers for space navigation.

Two papers by Franklin and Birx [8], [9] describe studies carried out for the USAF investigating the use of natural electromagnetic radiation for navigational purposes. The emphasis is on the measurement of velocity utilizing the Doppler phenomenon.

Franklin and Birx use the well-known fact that when there is relative motion between a source of radiation and an observer, the radiation observed is shifted an amount $\Delta\lambda$ which is proportional to the relative velocity according to the equation

$$\Delta\lambda = \lambda_1 - \lambda_2 = \frac{v\lambda_1}{c}$$

where

v = relative velocity of source with respect to observer
c = velocity of light
λ_1 = wavelength of radiation observed with no relative motion
λ_2 = wavelength observed with relative motion

from which one obtains the velocity equation

$$v = \frac{c(\lambda_1 - \lambda_2)}{\lambda_1}.$$

Franklin and Birx base their error analysis upon the velocity error equation

$$\delta v = \frac{2c\delta\lambda}{\lambda_1}$$

where $\delta\lambda$ = error in determination of wavelength. In their first paper [8] a method is described using a slit system constructed to allow the radiation from a spectral line to be split so that each half of the flux falls on a separate detector. The outputs of the two detectors would be balanced at zero velocity. Utilizing such a system, a limitation on accuracy of ± 60 ft/sec was the theoretical figure obtained. In their second paper [9], Franklin and Birx describe a method of computing the shift by comparing the spectral lines of the received radiation with a template consisting of a photographic negative of the spectral lines and measuring the displacement of the template necessary to return to a matched condition. The authors find that with such a system it should be possible to obtain sensitivities of from one to 10 m/sec but at the time of the writing of the paper, the work had not progressed far enough to provide evidence of this order of sensitivity.

It should be noted that all such methods of utilizing the Doppler phenomenon can give only the component of velocity in a radial direction from the source. Also, all measurements made thus far have been made with respect to the sun and great advancements in the state-of-the-art are required if radiation from other stellar bodies is to be used.

A paper by Norton and Wildey [10] is concerned with fundamental limitations to optical Doppler measurements for space navigation. The authors consider the result of various physical phenomena which produce asymmetric broadening of the spectral lines in the radiation from stellar bodies. The phenomena considered are: second-order Zeeman effect, quadratic Stark effect, pressure shift, sunspot effect, and variability of radius. Calculations by the authors using the sun as an example result in their concluding that the physical characteristics of stellar electromagnetic sources such as the sun vary in such a manner that a variability of approximately ± 200 ft/sec may be expected in the observer's measured optical Doppler velocity. Norton and Wildey express the opinion that it is this which imposes a fundamental limitation on the accuracy with which Doppler measurements may be made optically rather than the instrumentation.

One of the most interesting discussions on the determination of distance and velocity using optical maser principles is found in a paper by Ellis and Greenwood [11]. The particular features contributing to the advantageous application of optical masers to space navigation are:

1) The systems could be very small in size, and self contained,
2) Power requirements could be low even for long distances,
3) Velocity measurements will be very accurate.

The availability of the extraordinary degree of parallelism and the narrowness of frequency bandwidth achievable in the laser makes this instrument extremely noteworthy for space navigation applications. Another attractive feature of the laser is the extraordinary capacity of the laser receiver for discriminating against extraneous background light and to its extremely low internal noise level.

The determination of distance from a laser transmitter to some scattering object can be accomplished by standard methods similar to radar and sonar. Ellis and Greenwood present an example of a two-foot diameter transmitter and receiver optical maser consuming 66 watts of average power yielding an accuracy of one part in 100,000 for the measurement of distance between two spacecraft 160,000 km apart. The most serious disadvantage for many space applications is the requirement for transmitter and receiver beams to be trained in the same direction and its poor performance in the search mode.

Another interesting application of the laser is the high accuracy with which one can measure the altitude of a spacecraft above a very small spot on the surface of a planet. This is in contrast to the microwave situation where, because of unavoidable beamwidth, the measurement always constitutes an average of distances to a broad range of points below.

Ellis and Greenwood [10] extol the virtues of the laser as a Doppler velocity measuring device. They present an interesting example of a vehicle for soft lunar landing and point out that an accuracy of a tenth of one per cent in velocity is reasonable for lunar approach velocity of about 2300 knots at an altitude of about 1600 km above the moon's surface. Using a similar example for a planetary approach, they predict a self-contained system of about one cubic foot volume and about ten pounds weight.

The laser transmitter is now available; a space-worthy laser receiver is still not available. The future, however, holds promise for more advanced laser developments and hence their use in space navigation.

Advanced Concepts of Guidance Management

The majority of space boosters which are deployed for launching orbital payloads were developed originally for military missile applications. It is therefore quite common to see each stage of a multistage vehicle equipped with its own guidance and control system for thrust vectoring, booster control and engine cutoff. The payload seldom has a major part in the navigational functions of the individual stages of the booster which places the payload along its path. It seems possible that savings in weight, instrumentation costs, and ground-based equipment could be obtained by bringing the "payload into the picture," especially in advanced and future space missions for which both the payload and the boosters can be specially designed to fit each other's requirements. If one accepts the premise that future payloads will include the requirement of self-contained navigation, the final upper stage will have all the usual equipment, such as gyros, accelerometers, star and planet trackers, clocks, radio frequency equipment and a fairly large general purpose computer, necessary to guide the spacecraft during all phases of flight (Fig. 9). Such an integrated, self-contained system would seem very desirable for providing all the necessary navigation and guidance facilities for the boost phase, the orbital phase, midcourse, landing or return phase, etc. Thoughts such as these have been expressed by Cashmore [12].

A basic problem is created when the inertial sensors of the multistage system are located at a station or stations which are an appreciable distance from the center of gravity of the vehicle. During launch operations, the payload at the top of the booster does not experience the

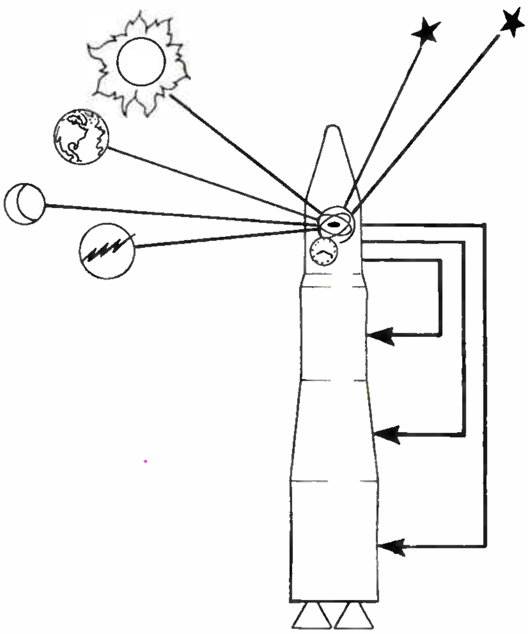

Fig. 9—Payload guidance management.

bending and c.g. separations and accelerations. This compensation or correction must be allowed for in the thrust-vector control and engine cutoff of the multi-stages. Secondly, the optical windows of the optical instrumentation contribute errors during launch and the tracking of celestial bodies is subject to refraction and shimmering until the vehicle approaches very high altitudes. Compensations for these errors will be necessary. Third, aborts on the launch pad are still better handled by ground crew than by the payload, and provisions for individual engine controls are necessary.

The future trend will, however, be an evolution of the guidance management concept by which the self-contained payload guidance and the ground-based command and control center jointly "manage" the guidance functions to achieve thrust-vector control and engine cutoff of the individual stages, as well as the navigation of the orbital spacecraft, all functions to be performed mostly by the use of and within the available instrumentation of the final upper stage itself.

Acknowledgment

A review paper such as the preceding necessarily reflects the concepts and creative efforts of many individuals, frequently informally transmitted and therefore difficult to acknowledge. Specifically cited, however, are the contributions of W. J. Reilly, Dr. J. Titus, G. D. Barnes, R. B. Freund, Dr. J. K. Robe, and R. C. Hakes.

ULTRASONICS

Organized with the assistance of the IRE Professional Group on Ultrasonics Engineering

Uses of Ultrasonics in Radio, Radar and Sonar Systems*

WARREN P. MASON†, FELLOW, IRE

Summary—A short historical review is given of the development of ultrasonics. Uses in the low-amplitude range are sonar systems, dispersive and nondispersive delay lines, ultrasonic inspectoscopes, and crystal and mechanical filters. In all of these applications, the very low internal friction of metals and fused silica provides very low losses, while the guided wave properties of various shaped transmission paths provide either dispersive or nondispersive transmission. The dispersive transmission is useful for FM radar systems which are not limited in power by breakdown of the system, while nondispersive delay lines have uses in MTI radar systems, in pulse decoding systems and in computers. The low dissipation and frequency stabilities inherent in quartz crystal vibrations have been used extensively in the production of very selective filters and in the control of oscillators. Ultrasonics and hypersonics (frequencies about 10^9 cycles) are useful tools for investigating liquid and solid-state reactions.

I. Introduction and Review of Uses of Ultrasonics

The introduction and development of ultrasonics spans a time of about 80 years. Ultrasonics (originally called supersonics, a name now used to describe speeds faster than sound) can be said to have started in 1883 with the Galton whistle. Capable of producing sound waves of a frequency higher than can be heard by humans, such whistles were used to demonstrate the reflection, refraction, interference and propagation of sound. A minor use was found in summoning dogs without alerting humans.

No further uses were found for ultrasonics until the advent of World War I, when an intensive program on submarine detection was carried out. Since sound waves are the only type of wave propagation that can detect submerged submarines, considerable effort was spent generating and detecting such waves. The most sucessful effort [1] was carried out for the French government under the direction of P. Langevin. Using a sandwich made of quartz crystals cemented to steel plates, a directive sound beam was obtained which could be reflected off sunken objects and results were obtained which compared with those achieved up to the beginning of World War II. While this effort came too late to be of use in World War I, it laid the foundation for the extensive applications in World War II for both detecting and destroying submarines (by ultrasonic homing torpedoes) which contributed materially to Allied victory.

Between the two wars, this principle was applied to ultrasonic fathometers which quickly and accurately measure the depth of the ocean. This technique has been used to map the ocean bottom and has located deep trenches, incipient underwater plateaus, islands and mountain ranges. The ultrasonic inspectoscope was an application of the same principle to the inspection of solid pieces for flaws, and for determining the thickness of materials such as boiler plates for which only one side is accessible. In this country the first publications and patents were those of Firestone [2]. Such methods are among the best for detecting small imperfections and cracks in metal castings, glasses and ceramics and in inspecting the quality of adhesive bonds in automobile tires and other products.

The advent of World War II stimulated not only ultrasonic research in the underwater sound or sonar field but also ultrasonic adjuncts to radar transmission. It was during this time that the liquid and solid ultrasonic delay lines were developed for use as timing devices, anti-jamming devices and moving target [3] indicator radar systems which accentuate the appearance of moving targets by minimizing the appearance of reflections due to stationary targets. In this use one frame containing all the reflections during one pulse period is stored in a delay line having a delay time equal to the period between successive pulses. These pulses are made to balance out the radar reflections coming back from the next pulse with the result that fixed targets are minimized but moving targets are not balanced out. Such delay lines have also been used in pulse decoding systems [4], and for information storage for computers [5]. Recently dispersive delay lines have become of interest [6] for high-power radar systems. In this use they convert a short high-power density amplitude modulated pulse into a long low-power density frequency modulated wave which does not overload the final amplifier stage. The reflected frequency modulated wave is converted back into a short amplitude modulated wave by sending it through a network having the reverse dispersion characteristic of the sending network. This restores the accuracy of the distance and direction determination.

The high Q (low dissipation) inherent in mechanical vibrations in solids has been used in obtaining very selective filters and in the control of oscillators. The first and by far the largest use in filter networks is the use of quartz crystals as impedance elements in electrical filters [7]. These are used on all of the channel filters of the long distance carrier systems, microwave systems and submarine cables of the Bell Telephone System to separate a given conversation from a group of twelve similar conversations in a channel bank. Recently, such crystals have been grown synthetically [8] from small scraps of quartz or even from sand. This process eliminates the variability of the source of supply and produces crystals of an economic size for cutting which are free from the usual defects of natural crystals. An even larger use for the high Q present in quartz crystals is in controlling the frequency of oscillators and time standards. During World War II, over 30,000,000 crystals were produced for this application. The present effort [9] is directed at improving the frequency stability and long time aging effect present in such crystals. While the final stability has been eclipsed by that obtainable in an atomic standard, quartz crystals are still the most used secondary standard and serve as the fly wheel even for atomic standards. Considerable effort [10] has also been expended in using the high Q present in metals and other solids in all-mechanical filters driven by electromechanical transducers for converting from electrical energy into mechanical energy and vice versa. This is discussed further in Section IV.

All these devices can be considered as low-power devices since they utilize the linear ranges of the transmission media. A number of high-power devices are in general use. These employ nonlinear effects in the transmission media to produce processing effects. These are discussed in a companion paper by F. Massa.

Ultrasonic waves have also proved to be a convenient method for investigating the effects of imperfections and solid-state motions on the properties [11] of materials used by the radio engineer. These ultrasonic and hypersonic waves have proved to be useful tools in investigating the fundamental properties of liquids and solids. In this use the ultrasonic waves produce liquid or solid-state motions which react back on the attenuation and velocity of waves traversing the medium. For example, in a ferromagnetic crystal the stress waves produce motions of the Bloch walls that divide adjacent ferromagnetic domains. This motion produces an extra strain component, on account of the change in the magnetostrictive expansion due to the motion of the domain walls, which lowers the effective elastic constant of a demagnetized sample. When this sample is completely magnetized, the domain walls disappear and the elastic modulus increases. This effect is known as the ΔE effect and its variation with frequency [12] is correlated with the distribution of domain sizes. The motion of the domain walls produce eddy currents which act as energy loss mechanisms and produce the micro-eddy current effect.

For associated, nonassociated and ploymer liquids and rubbers there are alternate positions of molecules or chains of polymer molecules which are occupied successively under the action of thermal oscillations. An ultrasonic wave can produce stresses that alternately make one or the other of the positions more probable. When the frequency of the ultrasonic wave coincides with the frequency for which thermal agitation causes the molecules to alternate their position, an attenuation peak known as a relaxation occurs. Ultrasonic waves have located isolated relaxations and groups of relaxations in liquids which give information on the types of motion taking place. In solids relaxations have been measured connected with thermal effects, domain and grain boundary effects, and the motions of dislocations.

Recently ultrasonic waves have contributed materially to a knowledge of the motion of electrons at cryogenic temperatures. At room temperatures the motion of the lattice caused by ultrasonic waves can communicate energy and momentum to the conduction electrons but since the mean free path of electrons in the lattice at room temperature is so small, most of the energy is given back to the lattice in the same phase and is not lost to the vibration. As the temperature is lowered, the mean free path gets very large and in pure materials may become considerably larger than the wavelength. Fig. 1 shows [13] the attenuation of longitudinal sound waves for two directions and two frequencies in a pure tin single crystal. When the mean free path is smaller than the acoustic wavelength, the damping is equivalent to a viscous effect (*i.e.*, transfer of momentum) and the attenuation increases proportional to the square of the frequency. On the other hand when the mean free path is greater than the acoustic wavelength, theory shows that the attenuation is proportional to the frequency. The dividing line appears to be about 8°K from Fig. 1. As the temperature drops below the superconducting temperature of 3.73°K for tin, the attenuation rapidly approaches zero. The form of the curve agrees with that predicted by the Bardeen-Cooper-Schrieffer theory of superconductivity. By putting on a magnetic field, the normal conductivity can be restored and the top curve of Fig. 1 shows the extension of the normal attenuation down to lower temperatures.

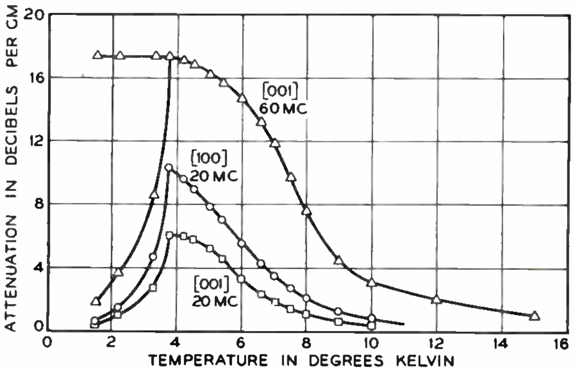

Fig. 1—Longitudinal wave attenuation for single crystal tin along the [001] and [100] axes.

Magnetic fields above the superconducting temperature have been used to delineate the shape of the Fermi surface, which is a constant energy surface which bounds the occupied states of electrons in momentum space. The electrical effects in a metal are primarily determined by the electrons of energy near the Fermi surface since these are the only ones free to move. For free electrons such surfaces are spherical in shape but in the band theory approximation, the Fermi surface for monovalent materials such as copper, gold and silver take the form [14] shown by the inside surface of Fig. 2. The outside surface is that for the Brillouin zone which delineates the surface in momentum space for which electrons suffer Bragg-type reflections. When the Fermi surface approaches the Brillouin zone a distortion of the spherical surface occurs as shown by Fig. 2. The effect of a magnetic field is to localize the electrons that can move onto a plane perpendicular to the magnetic field. It can be shown that the periodicity of the attenuation-H^{-1} curves can be related to the linear dimension of the Fermi surface perpendicular to the magnetic field and perpendicular in momentum space to the direction of wave propagation in real space. Measurements such as those shown [15] by Fig. 3 give details of the Fermi surface for different directions in momentum space.

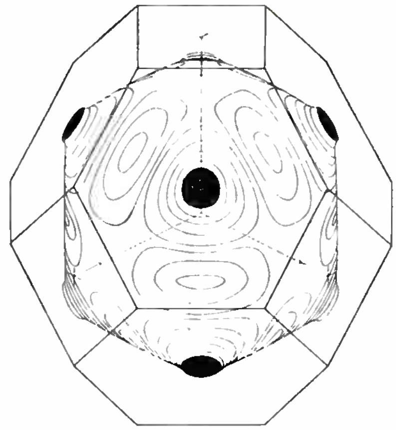

Fig. 2—Fermi surface and Brillouin zone for copper (after Pippard).

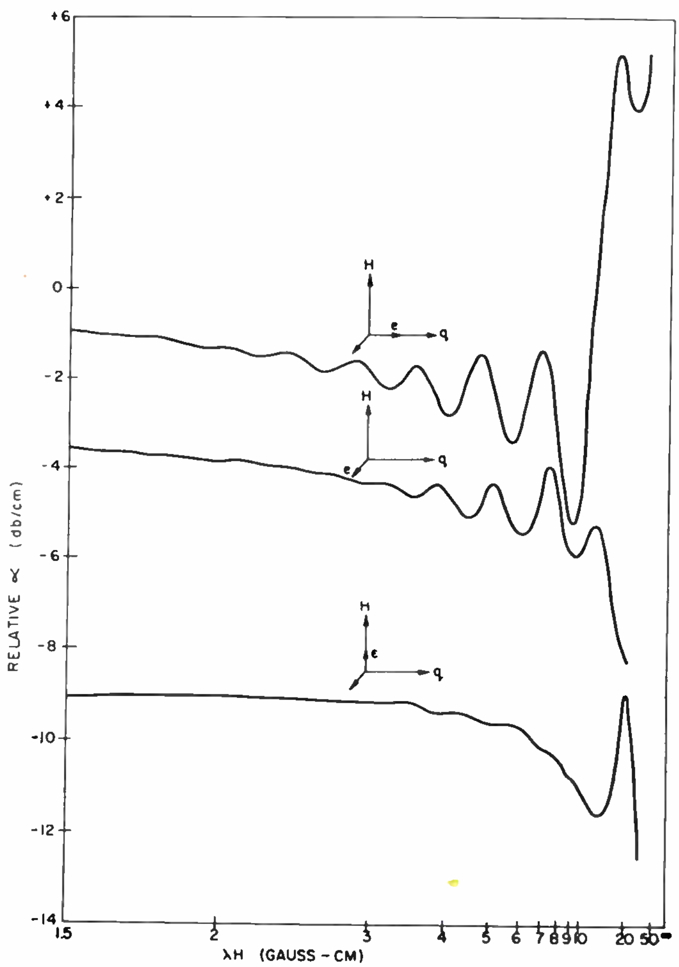

Fig. 3—Relative attenuation in pure single crystal copper as a function of the product of the wavelength times the magnetic field, for several orientations of the magnetic field and wave direction (after Morse and Gavenda).

Hypersonics has provided information on the conversion of sound waves to thermal energy which occurs in the form of quantized sound waves known as "Phonons." At low temperatures there are many fewer phonons and their mean free path and relaxation time τ between collisions becomes much larger. When the product of the angular frequency ω of acoustic waves propagating in the medium, and the relaxation time τ becomes greater than unity, the direct interchange of energy between acoustic waves and phonons gets much smaller and very little attenuation is experienced by the acoustic waves. Fig. 4 shows measurements due to Bömmel and Dransfeld [16] on the attenuation of shear waves in quartz for frequencies of 10^9 cycles and higher. Below about 15°K the attenuation becomes very small. This finding may have some practical uses in delay lines for storing large amounts of information since the bandwidth and hence the number of bits that can be stored at these frequencies can be very large for a given length. With the low attenuation possible at temperatures below 15°K, an enormous amount of information can be stored and retrieved at a subsequent time depending on the length of the rod.

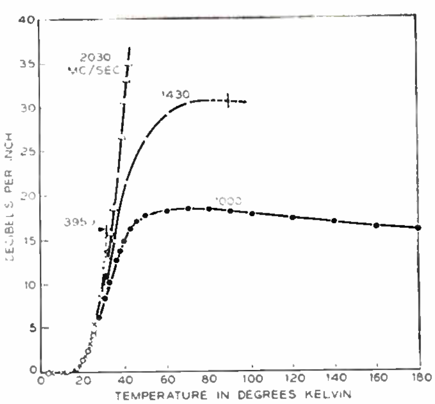

Fig. 4—Attenuation of shear waves in quartz at 1000 Mc (after Bömmel and Dransfeld).

II. Delay Lines

Section I gives a short summary of the various applications of ultrasonics. All of these probably affect the science of radio communication to some extent, but there are two applications very directly employed in radio, radar and sonar systems and these will be discussed in more detail in the last three sections. These applications are dispersive and nondispersive delay lines and ultrasonic mechanical filters. Neither of these types of transmission media can be connected with electrical circuits without the intermediary of an electromechanical transducer so that a short discussion of transducer properties is given. The properties of transducers are the determining factor in sonar systems.

There are of course all-electrical delay lines of the dispersive and nondispersive types but as the delays get larger and the frequency range covered becomes greater, the number of electrical elements becomes prohibitively large and it becomes cheaper and more satisfactory to resort to mechanical wave transmission. This follows because the velocity of transmission is only about 1 part in 10^5 as large as that for electrical waves in distributed conductors and because the Q (inverse of internal friction) is better for the best mechanical materials than for the best electrical lines in a comparable frequency range. The region for which it is better to shift from electical to mechanical probably is in the order of 10 μsec for bandwidths in excess of 1 Mc.

Delay lines initially used were usually of the water or mercury type but these types have mostly been replaced by solid delay lines. Such types are more compact, less subject to temperature changes and can stand considerably harder treatment. In the high-megacycle range solid lines are mostly constructed from strain-free fused silica, because this material has a very low attenuation and because sound scattering associated with a grain structure does not occur. According to the best measurements [17], the attenuation for longitudinal waves follows an equation of the form

$$\text{atten. (db per cm)} = 3 \times 10^{-4}F + 1.9 \times 10^{-5}F^n$$

where

$$n \doteq 2. \tag{1}$$

In this equation the attenuation is in db per cm and the frequency F in megacycles. For a delay of 1000 μsec which corresponds to a length of about 600 cm, the loss is about 11.5 db at 25 Mc. Shear wave losses have not been as carefully measured, but McSkimin finds that the Q in the low megacycle range is about the same as for longitudinal waves. The lower velocity (3.764×10^5 cm/sec compared to 5.968×10^5 cm/sec for longitudinal waves) gives a path length 63 per cent of that for longitudinal waves, but the loss is about the same.

Most of the fused silica delay lines are constructed in the form of many-sided polygons [18a] such as shown by Fig. 5, or wedges [18b]. In all of these space delay lines, shear waves are used because with the particle displacement parallel to the reflecting surface, only shear waves are reflected and at an angle of reflection equal to the angle of incidence. The dashed lines of Fig. 5 show the paths through the line from the transmitting crystal A to the receiving crystal J.

In these types of space lines, the beam spreads out as a function of distance and is much wider at the receiving crystal than at the transmitting crystal. Beyond the Fresnel region, which ends when the distance from the transducer d is

$$d > A^2/2\lambda, \tag{2}$$

where A is half the dimension of the crystal in a direction parallel to the principal face and λ the wavelength, the beam spreads out at a constant angle and

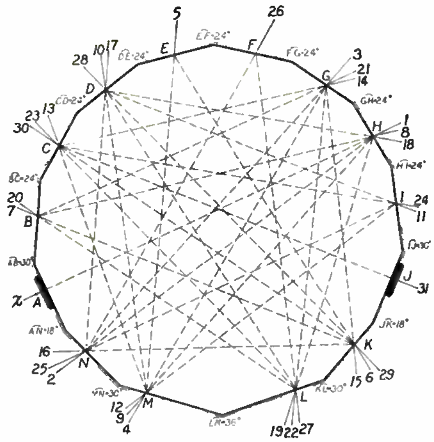

Fig. 5—Polygon shaped fused silica delay lines. Dashed lines show direction of wave propagation. Outside lines indicate damping regions to reduce spurious pulses (after Arenberg).

gives a loss in pressure approximately determined by the ratio

$$\frac{p}{p_0} = \frac{A^2}{d\lambda}. \tag{3}$$

The effect of this spreading is to produce unwanted reflections at times different from that for the main pulse. This can be minimized by putting absorbing material such as solder on the surfaces that are not required for the beam reflection.

The 15-sided polygon, which is used in most fused silica delay lines, proves to be almost an optimum compromise between maximum delay per unit area and maximum suppression of unwanted responses. With these type lines, center frequencies of 10 to 70 Mc, bandwidths up to about 50 per cent, losses of 40 to 70 db, suppression of unwanted reflections of from 30 to 40 db and delays up to 3500 μsec have been achieved with the largest fused silica pieces available.

The application of ceramic transducers [19a], [19b] to delay lines has resulted in the elimination of transducer loss since, as shown by Section IV, such transducers can be designed as band-pass filters with impedances which can be made to match the delay line. This has made possible a whole new field of delay line activity in producing short, compact low loss delay lines for pulse coding purposes [19b]. When thickness-shear ceramic transducers were developed [20], it became possible to operate a 700 μsec polygon line under matched termination conditions with a reduction in loss from 40 db to 20 db. The remaining loss is accounted for by absorption in the fused silica and by spreading losses.

The other type of line, that has been widely used, is the guided wave type such as the wire or strip lines. These types are useful not only for nondispersive lines but for dispersive lines as well [6]. Material such as 5052-H32 aluminum alloy has very low losses ($Q = 100,000$) while materials such as Ni-Span-C have a relatively low loss and a small change in velocity with temperature. Mathematical solutions for the propagation of longitudinal waves in rods were first given by L. Pochhammer and C. Chree [21a], but they were not studied extensively until the work of Bancroft [21b] and Hudson [21c]. The first systematic evaluation of all the modes in a wire or in a strip, including group velocity calculations, were made in References [6b] and [6c]. The first longitudinal mode in a wire has an inflection point, which leads to an approximately linear delay vs frequency characteristic. This is evident from the results of such a calculation [6b] as shown by Fig. 6. This figure shows the ratio of the phase velocity to the bar velocity $V_0(V_0 = \sqrt{Y_0/\rho})$, where Y_0 is the Young's Modulus and ρ the density, as a function of the diameter times the frequency divided by V_0. The result depends on the Poisson's ratio δ which is 0.33 for aluminum and 0.26 for Ni-Span-C. As can be seen, the ordinate should not exceed about 0.3 if a nondispersive transmission is desired. For frequencies of transmission up to a megacycle, the diameter should not exceed 0.15 cm. Wires of this type have been used in pulse decoding systems [4] and for information storage for computers [5]. On account of the small size, it is usually necessary to drive them by magnetostrictive means and loses of from 40 db to 50 db are common. Since such transducers cannot take all the energy out of the wave, it is generally necessary to terminate them in an extra length of highly damped material.

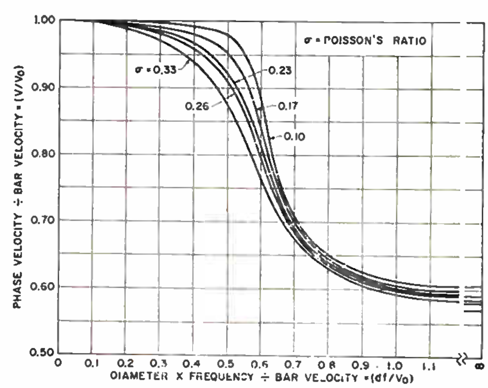

Fig. 6—Phase velocity as a function of the diameter frequency product for several values of Poisson's ratio (after May).

Magnetostrictive delay lines have the advantage that the delay can be made variable by changing the position of the transducers and it is fairly simple to obtain multiple outputs with different delays by incorporating more than two transducers. They are limited in frequency range by scattering by grains and surface imperfections.

Torsional waves can also be sent down wires and they have a mode which is nondispersive as long as the relation given by (4) is satisfied:

$$f < \frac{3}{4} \times \frac{5.136V}{2\pi a}, \tag{4}$$

where V is the torsional (shear) velocity of the wire and a the radius. Such torsional waves have been driven by two opposing longitudinal magnetostrictive wires [22a], by torsional barium titanate crystals [22b] and by the Wiedemann effect using [22c] a circumferential field in a magnetostrictive material to set up torsional oscillations. By sending a pulse of current down the magnetostrictive wire, combined with a preferred spacing of pick-up coils, it is possible [22d] to generate or decode a series of pulses.

Quite recently dispersive delay lines have come into considerable use [6] on FM radar systems. These are able to obtain power outputs over a good share of the repetition cycle, rather than just for the initial pulse. In principle, the action [6a] can be thought of as equivalent to dividing the width of the pulse frequency spectrum (equal approximately to $2/\tau$, where τ is the time of the sending pulse) up into a number of equal frequency ranges. If the dispersion is linear these ranges are then delayed by amounts which increase in equal increments for successive ranges with a total delay between the lowest and the highest frequency equal to the period of the radar repetition rate. In this way energy is being transmitted during the complete time interval. For the reflected radar pulse, the lowest frequencies return first and these are fed through a network which delays them most and the highest frequencies least. In this way the distance discrimination is restored. It can be shown [6a] that the discrimination factor D which in an amplitude modulation pulse system is defined as

$$D = T/\tau, \tag{5}$$

where T is the time between pulses and τ the time length of the pulse, becomes equal to, for a FM system,

$$D = (\delta_2 - \delta_1)(f_2 - f_1), \tag{6}$$

where $\delta_2 - \delta_1$ is the difference in delay between the lowest and highest frequency transmitted and $f_2 - f_1$ is the frequency range transmitted.

The dispersive properties of the wire or strip delay lines [6b–d] can be made use of in such systems. The phase velocity for a wire is shown by Fig. 6. The group delay is defined as

$$\delta = \frac{\partial B(\omega)}{\partial \omega}, \tag{7}$$

where $B(\omega)$ is the total phase shift and ω is 2π times the frequency f. Fig. 7 shows the delay as a function of frequency for the materials shown on Fig. 6. Similar delay curves [6c] are obtained for a flat strip driven by a longitudinal transducer. By mounting absorbing material along the thin edges, unwanted modes can be made as small as 55 db down with respect to the desired mode. When such lines are operated in the lower megacycle range a product of the time variation $(\delta_2 - \delta_1)$ times the bandwidth $f_2 - f_1$ of 100 has been achieved. It has been demonstrated that dispersive delay lines can replace the electrical version of the linear delay network containing hundreds of coils and capacitors and occupying 50 to 100 times the volume.

The nondispersive strip delay line of Meitzler [6d] using the shear mode has great potential for producing longer delays than possible with present fused silica delay line techniques while at the same time being very free of unwanted responses.

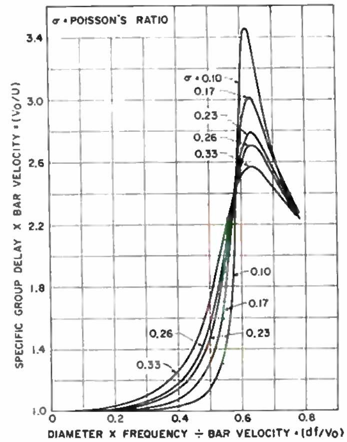

Fig. 7—Specific group delay as a function of the diameter-frequency product (after May).

III. Transducers and Resonators

All types of delay lines and indeed all electrical to mechanical ultrasonic devices require transducers to change electrical energy into ultrasonic energy and vice versa. There are two types of transducers in general use. These are the piezoelectric type (which includes a polarized electrostrictive material such as barium titanate as a special case) and magnetostrictive material of which the ferrites are the latest examples. The piezoelectric types obtain their conversion by producing a strain proportional to the applied field which reverses sign when the sign of the field reverses. Conversely, they produce an electric charge when they are strained. A magnetostrictive material has a strain which is proportional to the square or even power of the magnetic flux and it requires either a biasing field or a remanent polarization to produce a linear transducer.

The action of both types are well-known and this section is limited to discussing the condition for good efficiency of conversion and to giving the constants of the most used types of transducers. Equivalent circuits for transducers are useful for determining the efficiency and bandwidth possible for transforming electrical into mechanical energy and vice versa. While generalized circuits are available [23] for any terminating conditions, most of the transducers are of the half wavelength type which can be represented by the equivalent circuit of Fig. 8(a) for a piezoelectric type. For a polarized magnetostrictive transducer for which the eddy current loss is small (for example, for a ferrite) the circuit of Fig. 8(b)—which is the inverse of Fig. 8(a)—can represent

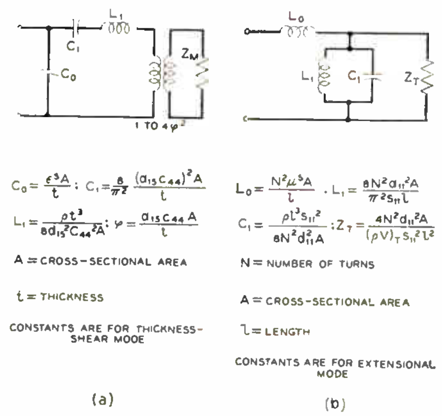

Fig. 8—Equivalent circuits for (a) piezoelectric driving crystal, (b) magnetostrictive transducer.

the relations. On account of the gyrator action of a magnetostricitive device [23], the mechanical elements, including the termination, have to be inverted to be used in this circuit.

The corresponding element values are given in terms of the fundamental data for longitudinal and shear vibrating quartz and four ceramics, the first three of which are widely used in transducers. These values are for low-amplitude motion. For larger amplitudes, changes [24] occur in some of the constants. (Table I)

The extensional modes have mostly been used for filters and underwater sound transducers, while the thickness shear and thickness longitudinal modes have been used for delay lines and oscillators.

For magnetostrictive material, the Piezoelectric Crystals Committee of the IRE has sponsored a "piezomagnetic" nomenclature which parallels the nomenclature of piezoelectric crystals. This nomenclature is followed in Table II, which lists several piezomagnetic materials. The MKS system is used throughout.

As an example of the use of such equivalent circuits, a fused silica delay line is considered. This is driven by a shear type piezoelectric ceramic. The widest band and the smallest loss result when the static capacitance C_0 is tuned by a series or shunt coil. The shunt coil results in the highest output impedance, which is usually preferred. All the elements are then shown by Fig. 9. This network has the configuration of a band-pass filter, which when properly terminated can transform electrical to mechanical energy without loss except for the usually small dissipation inherent in the elements. The design equations of such a network are

$$L_0 = \frac{(f_B - f_A)Z_0}{2\pi f_A f_B}, \qquad C_0 = \frac{1}{2\pi(f_B - f_A)Z_0},$$

$$L_1 = \frac{Z_0}{2\pi(f_B - f_A)}, \qquad C_1 = \frac{(f_B - f_A)}{2\pi f_A f_B Z_0}, \tag{8}$$

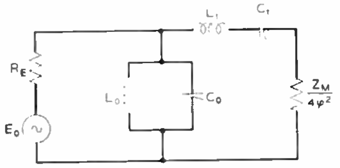

Fig. 9—Equivalent circuit for shear transducer driving a delay line.

where Z_0 is the image impedance at midband and f_A and f_B are the lower and upper cutoff frequencies when the transducer is considered as a band-pass filter. The bandwidth defined as $(f_B-f_A)/\sqrt{f_A f_B}$ is determined by the ratio of the shunt capacitance C_0 to the seies capacitance C_1. From (8) and Fig. 8(a)

$$\frac{f_B - f_A}{\sqrt{f_A f_B}} = \sqrt{\frac{C_1}{C_0}} = \frac{\sqrt{8}}{\pi} d_{15}\sqrt{\frac{c_{44}}{\epsilon^S}} = \frac{\sqrt{8}}{\pi}\frac{k}{\sqrt{1-k^2}}, \qquad (9)$$

where k, the electromechanical coupling factor for a shear crystal, is defined as

$$k = d_{15}\sqrt{\frac{c_{44}}{\epsilon^T}} = d_{15}\sqrt{\frac{c_{44}}{\epsilon^S}}(\sqrt{1-k^2}). \qquad (10)$$

For example for a shear wave transducer made from 80 per cent $BaTiO_3$, 12 per cent $PbTiO_3$, 8 per cent $CaTiO_3$, constructed as discussed by May [20], the fractional bandwidth ratio is 0.456. To get a 10-Mc bandwidth requires a mean frequency of 23 Mc. The other question of interest is how well the terminating load matches the transducer characteristic. Fused silica has a density ρ of 2.2×10^3 kg/M^3 and a shear velocity V_s of 3764 meters per second. The equivalent electrical termination is

$$R_E = \frac{R_M}{4\phi^2} = \frac{A\rho V_s}{4(d_{15}c_{44}A/t)^2} = \frac{\rho V_s t^2}{4(d_{15}c_{44})^2 A}, \qquad (11)$$

where t is the thickness of the transducer (1.3×10^{-4} meters) and A the area taken as 1 square cm (10^{-4} sq m). Inserting the numerical values from Table I, $R_E=5.66$ ohms. This should approximately match the design impedance of the transducer, which from (8) and Fig. 8(a) is

$$Z_0 = 2\pi(f_B - f_A)\rho_T t^3/8d_{15}^2 c_{44}^2 A = 15.2 \text{ ohms}. \qquad (12)$$

This provides a fair match over the band giving a slight rise in loss at the center.

Similar considerations apply to the design of other type transducers including those used for sonar. A recent paper [25a], describes a 200-inch diameter cylinder made by stacking up walls of barium titanate ceramic 12 inches long. This transducer is capable of radiating 2 Mw pulse power at 160 cps, at operating depths up to 10,000 feet. The lower frequency trend occurring since World War II makes use of the lower attenuation at low frequencies, and the greater freedom from the distorting effects of thermal gradients in the sea water media. The lower frequencies require much larger transducer sizes than were required for the kilocycle transmissions of World War II. The ferroelectric ceramics of Table I are one of the advances making such transducers possible. The low frequencies also improve the performance of magnetostrictive devices, and good efficiencies are found [25b] for flexural transducers employing nickel cobalt laminated structures.

IV. Filters and Oscillators Employing Mechanically Vibrating Elements

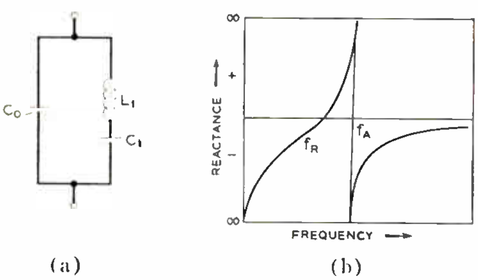
From the equivalent circuit of a half wave crystal on Fig. 8(a), it is seen that a crystal with a zero loading can be represented by a capacitance C_0 shunted by a tuned circuit having the element values shown by Fig. 10(a). The ratio between the shunt capacitance C_0 and the series capacitance C_1 is a function of the electromechanical coupling factor k. For the $-18.5°$ X-cut quartz which is largely used in crystal channel filters for separating one voice channel from another, this ratio is

$$\frac{C_0}{C_1} = \frac{\pi^2}{8}\,\frac{(1-k^2)}{k^2} = 139. \tag{13}$$

The impedance of a network of this type is shown by Fig. 10(b) and the separation between the resonance f_R and the antiresonance f_A is

$$\frac{f_A^2 - f_R^2}{f_R^2} = \frac{1}{r} \quad \text{or} \quad \frac{f_A - f_R}{f_R} \doteq \frac{1}{2r} = 0.0036. \tag{14}$$

The advantage of this type element over an equivalent coil and condenser is in the very high Q's possible in the motional arm (up to 20×10^6 at 100 kc if all the mounting loss is removed) and the low temperature coefficient of frequency inherent in most crystal cuts.



$$C_0 = \frac{\epsilon^S A}{l};\quad C_1 = \frac{8}{\pi^2}\,\frac{d_{21}^2 A}{s_{11}^E l};\quad L_1 = \frac{\rho l^3 s_{11}^{E^2}}{8 d_{21}^2 A}$$

$$\frac{C_0}{C_1} = \frac{\pi^2}{8}\,\frac{\epsilon^S s_{11}^E}{d_{21}} = \frac{\pi^2}{8}\,\frac{(1-k^2)}{k^2};\quad L_1C_1 = \frac{\rho s_{11}^E l^2}{\pi^2} = \frac{1}{\omega_R^2}$$

Fig. 10—Crystal resonator circuit and impedance characteristic.

Crystals alone are useful in narrow-band filters, but it can be shown that the bandwidth defined as in (9) cannot be larger than twice the value of (14). To get the wide bands necessary for voice communication, it was shown by the author [7], [26] that coils can be combined with crystals in lattice type filters. Fig. 11 shows a typical characteristic of a channel filter in a bank of 12 used in all the carrier, broad-band radio and submarine cable systems of the Bell System. With a source of supply guaranteed by synthetic quartz [8] and with the economics inherent in imperfection-free crystals of an economic size, there does not appear to be any present competitor likely to displace them.

Considerable work has been carried out in applying filters in the megacycle range. The principal difficulty is that at these frequencies it is necessary to use thickness modes of vibration of the crystal unit, and in these many spurious modes appear too near the desired mode to allow wide-band applications. Considerable theoretical effort [27a] has been applied to this problem and fairly close calculations have been made of the resonant frequency spectrum. On the experimental side, the spectrum [27b] of thickness AT shear vibrating crystals has been carefully measured. Contoured plates [28] and geometrical dispositions [29] of the driving plates have produced improvements. Fig. 12 shows a photograph of a contoured [28] fifth harmonic crystal mounted by rigid tabs to the side of the crystal. This crystal, which vibrates at 5.0 Mc, has a simple frequency spectrum, a Q consistent with quartz alone, and a very small aging rate.

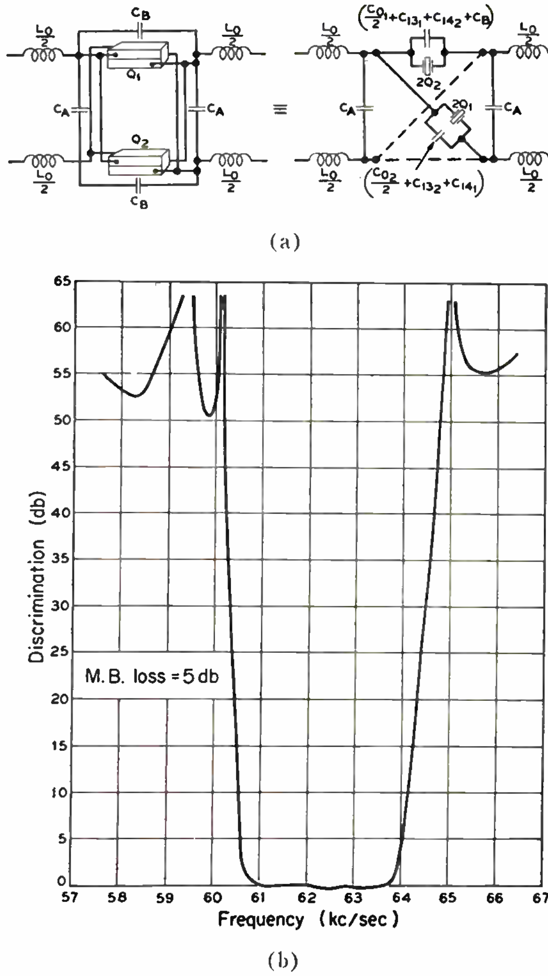


Fig. 11—Crystal channel filter. (a) Typical section showing use of divided plate crystals. (b) Attenuation characteristic for two sections of (a).

While such characteristics are consistent with good oscillator performance, it cannot be said that the resonator problem is completely solved. Research on oscillator crystals is directed toward mode studies, the effects of imperfections in the quartz on stability and aging, and on increasing the frequency range of crystal oscillators. The precision required has increased from 200

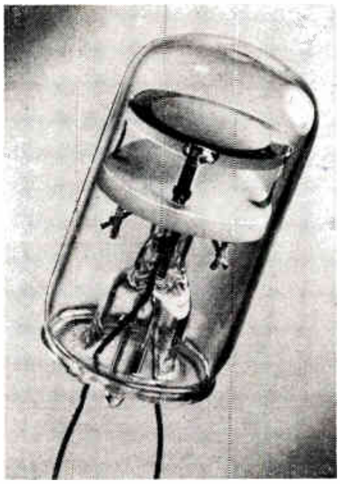

Fig. 12—Contoured fifth harmonic AT cut quartz crystal for use in frequency standards (after Warner).

parts in 10^6 during World War II to 20 parts in 10^6 at the present time. With the impending universal adoption of single-sideband communication, this tolerance [9] must be reduced by 2 orders more.

Another attack on the filter problem has been to use mechanical elements to produce the filtering, and transducers to couple the filter to the electrical circuit. Many types are possible [10], but the most widely used one appears to be the Collins mechanical band-pass filter whose constriction and performance are shown by Fig. 13. This usually works in the intermediate frequency range around 450 kc. Another type has recently been developed [30] which is capable of covering the frequency range from 10 kc to 60 kc with voice bands. Fig. 14 shows a typical characteristic. This filter, made of a low-temperature coefficient nickel iron composition, vibrates in a torsional mode. The side arms, which produce the filtering action, vibrate in flexural modes. The filter is driven by a transducer having 4 PZT ceramics on the two ends of the driving unit. These produce a second flexure having a node in the center, which is strongly coupled to the torsional filter. Such filters may be of interest for short haul carrier systems where the cost of modulating to higher frequencies would be prohibitive.

Ultrasonics in Industry*

FRANK MASSA†, FELLOW, IRE

Summary—**This paper presents a brief description of various successful industrial applications that have been made of ultrasonics. The applications are divided into three broad groups: low, medium, and high power. In the low-power group are included reduction of friction, inspection, remote control, flaw detection, and other types of gauging and nondestructive testing. The medium-power group includes ultrasonic machining, soldering, medical therapy, liquid level indicators, and similar types of depth gauges and instruments. The high-power group includes precision cleaning, emulsification, dispersion of metals, metallurgical, bacteriological, and other chemical and physical processing applications. It is only natural that the low- and medium-power applications received first commercial acceptance, while the high-power applications advanced more slowly awaiting the development of low-cost high-power ultrasonic transducers and low-cost ultrasonic power supplies. These latter requirements are at present reasonably well met, which means that great increases in industrial high-power ultrasonic applications can be expected in the immediate future.**

Introduction

Sound is a compressional wave in an elastic medium,[1] and because of its ease of propagation through liquids and solids, it is ideally suited for both examining and modifying the physical or chemical state of matter. Another property of sound is that it travels at a relatively slow speed (as compared with electromagnetic radiation), which makes it a useful tool for looking through solids and liquids in order to examine the medium for the presence of discontinuities, whether it be a submerged submarine or a hidden flaw inside a piece of steel.

One of the earliest developments in ultrasonics was the quartz sandwich transducer designed about 1920 for use as a navigational aid. In order to overcome the high-frequency limitations inherent in quartz, Langevin made up a quartz-steel sandwich consisting of several quartz plates cemented between two steel disks. This arrangement reduced the high resonant frequency of the quartz to the lower ultrasonic range and also provided a relatively large piston surface to achieve the desired radiation pattern.

During the latter part of the 1920's Wood and Loomis employed quartz crystal transducers to examine the effects of high-frequency ultransonic sound on the behavior of various liquids. Work in this field continued through the decade 1930 to 1940, during which time many investigators examined both chemical and physical changes in liquids caused by the introduction of ultrasonic energy. Because of the lack of suitable transducers and accurate instruments for the measurement of ultrasonic sound fields, the experiments were mostly qualitative in nature, and the reported results were primarily of academic interest.

During World War II, the tremendous success in enemy submarine warfare made it imperative that fundamental progress be made in underwater acoustics if this country were to survive. An intensive engineering development program initiated in 1940 produced in a few years a spectacular increase in fundamental knowledge in the design of underwater transducers capable of generating large amounts of ultrasonic power at any desired frequency. One of the most important factors contributing to this progress was the creation of standard hydrophones capable of measuring accurately underwater sound pressure over wide frequency ranges. Fig. 1(A) shows one of the earliest of these instruments that was developed during 1941 and employed Rochelle salt as the active element.[2] The inherent limitations of Rochelle salt, which restricted the range of application of this instrument, were overcome with the introduction of ammonium dihydrogen phosphate crystals which led to the improved measurement standard[3] shown in Fig. 1(B).

[3] F. Massa, U. S. Patent No. 2,613,261; October 7, 1952.

By 1950 a wealth of basic engineering information on ultrasonic transducer design had been accumulated, and accurate instruments for measuring ultrasonic sound were generally available. With these new tools, the early qualitative researches on the effects of ultrasonic sound on the properties of matter took on renewed practical engineering interest.

The purpose of this paper is to acquaint the reader with the large variety of important uses to which ultrasonics has been applied and to give a broad understanding of the basic principles that are employed in the various fields of application. For the ultrasonic engineer who is interested in the technical details of the properties of ultrasonic waves and in the design of apparatus for the generation and measurement of ultrasonic energy, an excellent classified bibliography of all the contemporary literature published during the past 30 years may be found in the Cumulative Indexes of the *Journal of the Acoustical Society of America*. Each of the three separate 10 year volumes list thousands of references conveniently classified under various headings including: Ultrasonics, Waves and Vibrations, and Underwater Sound. In the latest two Indexes are also included digests of several thousand acoustical patents issued during the past 20 years. This condensed material presents an excellent picture to the research engineer of all the contemporary work that has been carried on in ultrasonics and related fields.

Low-Power Applications

It is quite natural that the first practical applications of ultrasonics in industry were those requiring low-power levels. A very important industrial application is ultrasonic inspection, which makes use of the simple fact that the propagation of sound through a solid is distriburbed when there is a discontinuity in the material. The two most common principles employed in the design of ultrasonic inspection equipment are based either on the indication of a reduction in the transmitted sound due to the presence of a flaw, or on the reflected echo from the flaw which may be used to indicate its location.

A. *Continuous Automatic Inspection for Internal Flaws*

During 1943 one of the earliest continuous mass-production ultrasonic inspection systems was developed by the writer to solve a serious bottleneck that had developed in the inspection of sticks of solid fuel propellant. The rocket fuel consisted of rubber-like extrusions several feet long and a few inches in cross section, and the problem was to detect the presence of small air bubbles that would sometimes be trapped into the material during the manufacturing process. The presence of the included air could cause an explosion during the burning of the fuel, which would usually be fatal to the plane using the jet assist rockets. X-ray inspection was unsatisfactory not only because the process was too costly and time consuming, but because of a lack of sufficient contrast between an air bubble and the rocket fuel to give reliable indication on the X-ray film.

A satisfactory solution to the difficult testing problem was achieved by the simple ultrasonic test equipment illustrated in Fig. 2. A number of transducers, T1, T2, etc., are arranged to transmit sound of the appropriate frequency through various portions of the material, and another group, R1, R2, etc., are arranged to receive the transmitted signals. The output from each receiving transducer is recorded as a separate graph on a multichannel strip chart recorder, while the position of the paper chart is synchronized with that of the test specimen as it passes by the transducer array. If a flaw intercepts any region being scanned by the transducer pairs, the sound intensity through the material will be reduced and show up as a dip in the graphs being recorded on the moving chart.

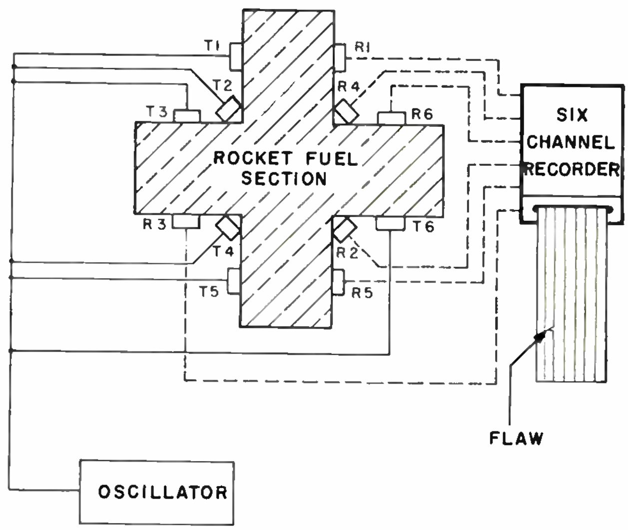

Fig. 2—Schematic sketch showing automatic ultrasonic inspection for hidden flaws in solid rocket fuel.

The system of ultrasonic scanning described above permitted the automatic recording of the homogeneity of large quantities of fuel sticks as they were continuously conveyed through the transducer array at the rate of 60 ft/minute. Air bubbles as small as $\frac{1}{16}$ inch diameter would produce a visible dip in the recorded charts. Hundreds of thousands of pieces were successfully inspected at negligible cost compared with the former less accurate and very expensive X-ray technique. Similar types of flaw-detection equipment have been developed and used for the continuous inspection of cemented or bonded joints and for inspecting for invisible discontinuities inside sheets such as are produced by foreign matter during the rolling of metals.

B. *Flaw Detection in Thick Materials*

The same principle employed in radar for locating airplanes by timing the arrival of a reflected pulse of energy has been successfully employed in the location of internal flaws in large metal parts by measuring the time of arrival of a reflected ultrasonic wave from the discontinuity. Firestone reduced this principle to practice about 1946;[4] it is now being widely used as an industrial inspection tool for examining the internal character of heavy metal parts better than can be accomplished by X-ray techniques. A schematic diagram of the ultrasonic flaw-detection system, which operates by timing the returned echo from a discontinuity in the material, is shown in Fig. 3. For a resolution of the order of $\frac{1}{8}$ inch in the location of the distance of the flaw below the surface, the echo time measurement has to be made in the order of 1 μsec which means that an ultrasonic transducer operating in the 5 to 10 megacycle range is required.

Referring to Fig. 3, a transducer is acoustically coupled by means of an oil film to a smooth prepared surface of the material under test while a pulse generator repetitively pulses the transducer at a rate of 60 cps. At the start of each pulse, a vertical deflection T_0 appears on the scope and, simultaneously, the horizontal time sweep is triggered in the oscillograph. The time base is adjusted such that the reflected echo from the opposite end of the specimen, T_1, fills the width of the tube. The pulses T_0 and T_1 appearing on the scope then represent the full height dimension of the specimen. As the transducer is moved over a region containing a flaw, an echo will be reflected from the flaw which will appear as T_2 on the scope. The relative position of T_2 along the base line will then represent the relative depth of the flaw inside the piece.

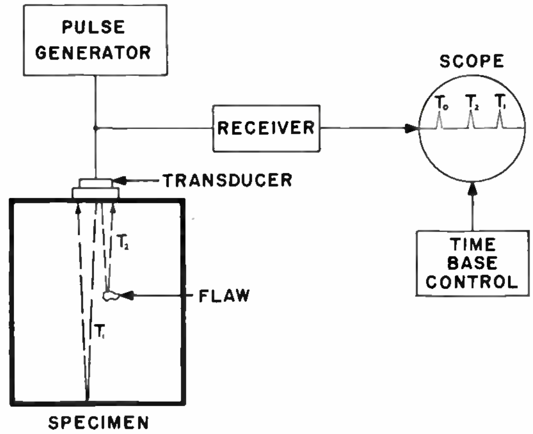

Fig. 3—Ultrasonic flaw detection by measuring reflected echo time.

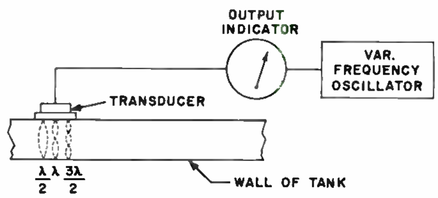

Fig. 4—Thickness measurement by ultrasonic resonance.

C. Thickness Gauging

The echo time principle for flaw detection may also be applied to the measurement of wall thickness where access is available from only one side such as in pipe lines and storage tanks. Ultrasonic gauging for these applications permits checking on internal corrosion without need for getting inside the pipe or tank. As might be inferred from the preceding section, it would be extremely difficult to measure echo time directly for gauging thin-walled materials because accurate time measurements of small fractions of a microsecond would be required.

For gauging thin-walled materials, a measurement of the thickness resonant frequency of the structure may be made, as illustrated in Fig. 4. A transducer is coupled to the outside wall of the material and is driven by a variable frequency oscillator. When the frequency supplied to the transducer corresponds with one-half wavelength of sound through the wall, the transducer will become effectively unloaded and the output meter will show an abrupt change in reading. A similar change will occur at multiples of the fundamental resonance, as illustrated by the standing waves $\lambda/2$, λ, and $3\lambda/2$, in Fig. 4. A necessary requirement in this method of thickness gauging is that the resonance frequency of the transducer be very much higher than the frequency corresponding to one-half wavelength in the thickness of the sheet.

[4] F. A. Firestone, "Supersonic reflectoscope, an instrument for inspecting the interior of solid parts by means of sound waves," *J. Acoust. Soc. Am.*, vol. 17, pp. 287–299; January, 1946.

D. Reduction of Friction

By injecting low-level ultrasonic energy into a material whose surface is in sliding contact with another, the coefficient of friction between the two bodies is very considerably reduced. Experimental work carried on by the author has shown reductions in the force required to move a heavy tool carriage over its polished guides by a factor of more than 10 to 1 in the presence of ultrasonics. In similar experiments in which paint was required to flow through a very thin slit, the injection of low-level ultrasonic energy into the nozzle maintained uniform flow of paint with slit openings as small as 0.001 inch, whereas without ultrasonics the slit had to be at least 0.007 inch to allow the paint to flow and then the flow would be intermittent due to clogging. For more detailed information concerning the equipment and its method of use, the reader may refer to U. S. Patents 2,738,173 and 2,746,813.

E. Remote Control Applications

One of the more recent large-scale applications for low-power ultrasonics is in the field of remote control. Hundreds of thousands of TV sets are being operated from across the room by means of a portable ultrasonic generator whose signal is picked up by a receiving transducer located at the set, which, in turn, actuates a relay to perform the required function. A similar application is for an automatic garage door opener which, in the simplest case, employs a transducer mounted on the front end of a car which sends out an ultrasonic signal on command to be picked up by a similar transducer located at the garage entrance, which actuates a relay to cause the door to open. Fig. 5 shows a photograph of inexpensive ultrasonic transducers as used in these applications.

Medium-Power Applications

A. Ultrasonic Machining

The fact that it is easily possible to ultrasonically vibrate the tip of a rod at amplitudes in the order of 100 g forms the basis for ultrasonic drilling. If a tool bit of any shape is vibrated at high frequencies and held with slight pressure against the surface of a hard brittle material, the tip will go through the material much like a vibrating air drill goes through a cement paving, except that at the ultrasonic frequencies, a polished finish is produced along the sides of the hole being formed. A fine abrasive mixed with a liquid to form a slurry is usually employed to achieve the best results.

A diagrammatic sketch of an ultrasonic drill is shown in Fig. 6 (next page). The transducer is fitted with a tapered tool post whose length is one-half wavelength of sound in the material at the frequency of operation. A tip of any desired shape is attached to the small end of the tool post and brought into contact with the work piece which is securely fastened to a table, as shown.

The arrangement illustrated in Fig. 6 has been used to "drill" any shaped hole through hard brittle materials that could not be otherwise machined. A similar type of ultrasonic tool has been used with the tool bit replaced by a die having an engraved face. By holding the vibrating die against the work piece, the imprint of the design is impressed into the hard material much as if a die were being pressed into the surface of wax.

B. Liquid Level Gauges

An accurate method of liquid level indication, which does not depend on the use of floats with their associated linkages and inaccuracies, makes use of the physical properties of sound-wave propagation through liquids. Since the speed of sound through a liquid is a fixed property of the liquid, it is possible to measure the transit time of a pulse of sound initiated from a transducer and passing through the height of the liquid in a tank, as illustrated in Fig. 7. A convenient and accurate manner for accomplishing the height reading is to choose a frequency such that the wavelength of the sound through the liquid corresponds to, say, 0.01 ft. An electronic counter in the timing circuit then merely counts the number of cycles of current passing through the transducer during the period from the start of the pulse until the reflected sound returns to the transducer after having travelled through the height of the liquid. The integrated number of cycles is a direct measure of the liquid height which can be directly displayed on an electronic counter in hundredths of a foot.

A basic requirement to the successful operation of the system is that the transducer have a very sharp beam angle and that it be free of significant secondary radiation at angles removed from its normal axis. A special transducer that achieves a 3° beam angle at 400 kc with radiation in secondary regions reduced by more than 30 db is shown in Fig. 8.

C. Medical Therapy and Diagnosis

It has long been realized that ultrasonic sound is easily conducted through body tissue and that strong localized heating may be produced by focusing the sound on discrete inner parts of the body. During the period immediately following World War II ultrasonic therapy was widely accepted among Western European countries. In West Germany alone several thousand ultrasonic therapeutic machines were in use, and reports on treatments in thousands of cases of numerous diseases indicated that a large majority were improved or completely healed. England and America remained skeptical over these early reports pending further medical research in this field and, therefore, ultrasonic therapy was more slowly accepted. At the present time there is renewed interest in this field, and it is noteworthy that President Kennedy was given ultrasonic treatment during his recent back illness.

In the diagnostic field, ultrasonics has been employed in locating brain tumors, kidney stones, and other "flaws" in the human body using techniques similar to those employed for flaw detection in metals.

D. Delay Lines

The physical principles and design technology of delay lines are covered in some detail in a companion article.[5]

E. Depth Indicators

Today tens of thousands of small boats are using ultrasonic depth indicators to give continuous information concerning the depth of water below the vessel. A typical low-cost depth sounder provides pulses of about 50 watts into a transducer which is usually mounted beneath the hull. The pulses are initiated by a contact switch synchronized with a rotating arm carrying a small neon bulb as the position of the bulb passes through zero. When the sound echo returns from the reflecting bottom the amplified received signal causes the neon bulb to flash. This process is repeated automatically several times per second so that the flashing bulb appears to remain at a fixed lighted position. A circular scale printed around the path of the rotating bulb is calibrated to show the depth of water in feet. This instrument will also show the presence of schools of fish, and it is so used as an aid in commercial fishing.

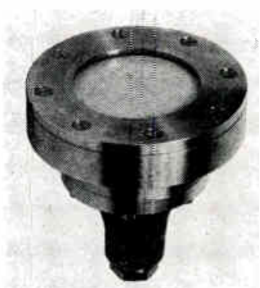

Fig. 8—Photograph of transducer for liquid level indicator (3° beam angle—negligible secondary lobes.)

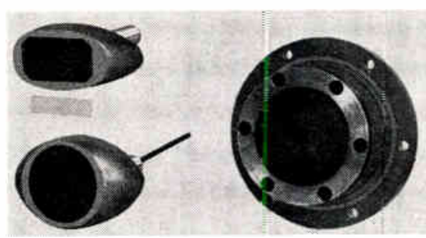

Fig. 9—Ultrasonic transducers for use in low-cost depth indicators.

Typical ultrasonic transducers designed for low-cost depth indicators are shown in Fig. 9. For deep-water navigational depth indicators, high-power equipment becomes necessary and larger transducers are required similar to those used in sonar systems.

High-Power Applications

A. Sonar

Sonar is to submarine detection and warfare what radar is to aircraft detection. In the field of high-power ultrasonic applications the greatest expenditures, reaching into the hundreds of millions of dollars, have been made in the development and production of sonar equipment. The successful development of the acoustically-guided torpedo during the latter stages of World War II probably saved us from the brink of disaster in which we were placed by the successful sinking of great numbers of our ships by enemy submarines. The vital needs of sonar in undersea warfare gave a tremendous impetus to the development of high-power ultrasonic transducers during the period of World War II.

We entered the war with inadequate sonar equipment. Two types of transducers were available: one used Rochelle salt with its inherent nonlinear characteristics and bad temperature stability, and the other used crude magnetostriction designs whose efficiencies were rarely higher than 10 per cent. These early transducers were generally piston-type radiators, one or two feet in diameter, operating at a kilowatt or two of power and were used as "searchlight" echo-ranging projectors covering about 10° in bearing at each position of search.

About 1942 ammonium dihydrogen phosphate crystals were made commercially available and removed all the limitations of Rochelle salt, resulting in the possibility of manufacturing high-efficiency, high-power transducers and extremely stable hydrophones. The searchlight-type sonar soon gave way to scanning sonar in which a high-intensity omnidirectional wafer-like beam of sound was sent out from a large cylindrical transducer, and the echo from a submarine would be received by an electronically-formed, rapidly-rotating beam. The scanning sonar transducer consists of a large number of vertical staves of elements arranged so that the outer radiating faces of the staves form a cylinder. When operated as a transmitter, all staves are connected in parallel and a high-intensity sound pulse of several wavelengths' duration is sent out in a 360° horizontal beam. Immediately after transmitting the pulse the transducer is connected as a receiver during which operation a group of staves are connected through time-delay networks such that the curvature of the stave fronts are effectively transformed in a plane surface, thereby creating a sharp horizontal beam for the receiving operation. The formed beam is electronically rotated at high speed by commutating the position of the lag line connections around the entire periphery of the transducer. The returning echo, whose pulse length is made longer than the scanning rate, is picked up by the rotating beam and the direction of arrival is indicated on a cathode-ray tube.

Scanning sonar transducers employing ADP crystals operate with powers of the order of 50 kw and have efficiencies of the order of 60 per cent. Improved magnetostriction transducers using staves made up of thin nickel laminations result in efficiencies of the order of 40 per cent. In applications requiring very accurate impedance and phase uniformity among individual staves (which are prerequisites for accurate beam information), ADP crystal has inherent advantages over the magnetostriction design. Recently, piezoelectric ceramics have become commercially available, and they are generally lower priced than either ADP or nickel. Barium titanate is the lowest cost and has found application in transducers where some degree of variation in impedance and sensitivity of the elements is permissible. Lead zirconate is the most recently available ceramic which has a much higher temperature stability than barium titanate and, therefore, permits higher power handling capacity. However, the new material still imposes a necessary variation in sensitivity and impedance among production elements.

Sonar transducers take dozens of forms depending on the particular application requirements. For a self-steering homing torpedo, for example, a multi-split-beam design is required to indicate whether the target is LEFT or RIGHT and UP or DOWN, so that automatic steering may be accomplished with the reception of each sonar signal. For underwater carrier telephony, an omnidirectional horizontal beam pattern is usually needed with a relatively small vertical beamwidth. Other transducers for special applications require special directional beam patterns. Today, transducers can be designed to deliver practically any amount of power at any desired frequency, and a wide choice of commercially available transducer materials permit the selection of the most economical design to meet the performance specifications.

B. Ultrasonic Cleaning

The basic advantages in the use of intense ultrasonic sound for thoroughly cleaning mechanical parts are well known.[6] However, premature attempts to market ultrasonic cleaning equipment with inadequate transducers and power supplies delayed general acceptance among the many potential industrial users of such equipment. Today, reliable high-power transducers may be produced, and economic power supplies can be built to permit large-scale installations for ultrasonic cleaning.

The chief merits of ultrasonic cleaning over the conventional methods are the great reduction of the cleaning time by the intense ultrasonic energy supplied to the cleaning liquid and the thoroughness of the cleaning. Under ultrasonic activation, the individual molecules of the cleaning liquid, vibrating at amplitudes corresponding to accelerations many times the value of gravity, literally bombard the microscopic foreign particles from the surface of the metal and allow a liquid film to get between the particles and the solid piece, thereby permitting all the microscopic deposit to be rinsed away by the cleaning liquid.

A striking example of the benefit of ultrasonic cleaning may be illustrated in an actual production application in which large aluminum plates had to be bonded with a high tensile strength joint. Using the best conventional degreasing and cleaning methods on the mechanical parts, the highest tensile strength realized at the bonded surface was 2500 psi under ideal controlled conditions. By introducing ultrasonic cleaning to the process before cementing the plates, the tensile strength of the bond was increased to over 6000 psi. A view of the cleaning tank and the plates being cleaned is shown in Fig. 10. This relatively small ultrasonic tank using 2 kw of driving power easily handled several hundred pieces per hour. To achieve the best results with ultrasonic cleaning, it is necessary that the acoustic power density at the surface of the transducer be in the range of about 10–50 watts per square inch, and that standing-wave regions in the cleaning solution be avoided by moving

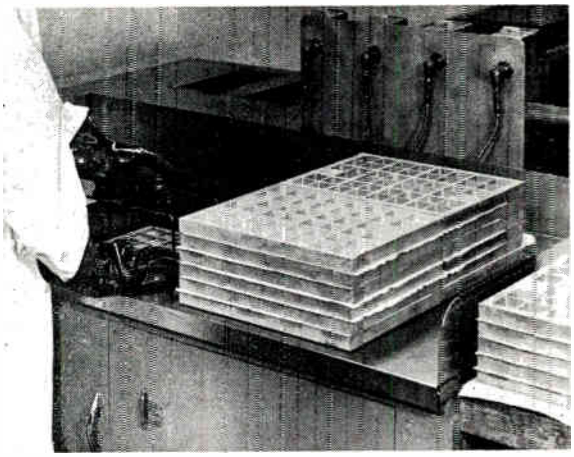

Fig. 10—Photograph of ultrasonic cleaning in production line.

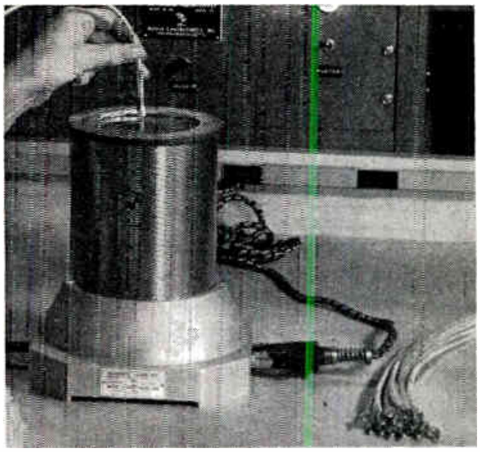

Fig. 11—Ultrasonic solder pot.

the parts relative to the position of the transducers.[7]

The spectacular advantages of ultrasonic cleaning extend into many related fields such as in the high-speed removal of heat treat scale from metals which can be accomplished in low-concentration pickling solutions operating at lower temperatures than is required by conventional methods. Another related application is micropolishing, which is accomplished by immersing the parts in an ultrasonic bath to which a fine abrasive is added. This method is particularly useful for polishing jewelry and precision parts of intricate shape where buffing methods are not feasible.

C. Metallurgical Applications

Ultrasonic energy has been employed to produce alloy-like mixtures of normally incompatible metals. For example, during the cooling of a molten mixture of iron and lead, the wide difference in melting points of the elements would result in a crude agglomeration of the lead-iron mixture. If the cooling takes place while the melt is subjected to intense ultrasonic activation, the two materials will solidify while they are held in a state of fine molecular dispersion, thereby producing a fine alloy-like mixture.

A similar application of ultrasonics has been used for the reduction of grain size in castings. By injecting intense ultrasonic energy into molten metals, it has been found possible to reduce the grain size of the solidified metal. Ultrasonics has also been effective in degassing molten metals, thereby producing denser castings.

The tinning or soldering of metals without the use of fluxes is made possible by simply dipping the metal parts into an ultrasonically-activated solder bath. The effect of the ultrasonic activation is to remove the oxide coating from the metal while it is submerged in the molten solder and immediately the metal becomes coated with the tinning solution. An additional beneficial effect of the ultrasonic activation is that the wetting action between the materials is increased and solder easily runs into tight crevices. By this procedure, dip soldering of printed circuits can be carried out without the fear of having "cold" solder joints and, also, because of the lack of necessity for using corrosive fluxes, fine wires may be ultrasonically soldered without fear of disintegrating the wire.

A commercial type of ultrasonic solder pot is shown in Fig. 11. In order to separate the ultrasonic transducer from the hot molten solder, a solid transmission line which is a multiple of one half the wavelength of sound in the material is used to transmit the sound energy from the transducer to the solder. The effectiveness of ultrasonic soldering is evidenced by the fact that a piece of untreated aluminum strip becomes brightly tinned by simply immersing the aluminum into the molten activated solder without the use of flux.

Ultrasonic equipment similar to that used for soldering applications can be used to improve the heat treatment of steel. For example, in the nitrogen hardening of stainless steels, a greater depth of penetration of hardening is achieved by ultrasonically activating the quenching bath.

D. Chemical Applications

The entire chemical industry will find the greatest variety of uses for ultrasonics. The terrific forces which are generated at the boundary region of two dissimilar materials when they are subjected to intense ultrasonic sound fields will cause such violent molecular activity that incompatible liquids such as mercury and water become emulsified. Solid metals immersed in ultrasonically-activated liquids may be broken down to become molecularly dispersed in the liquid. The tremendous increase in wetting action between materials in the presence of ultrasonic energy can be utilized for accelerating chemical changes or, in some cases, new chemical changes may take place that normally would not occur.

Fine-grained photographic emulsions have been produced ultrasonically much as fine-grained castings have been similarly produced. Artificially-produced colloidal-

[7] U. S. Patent No. 2,702,269; February 15, 1955.

like mixtures of metallic particles in liquids have been created by ultrasonic activation. High-frequency ultrasonic energy has successfully been used to control the molecular weight or viscosity of high polymers.

Electrodeposition of metals has been greatly influenced by ultrasonics. For example, it has been possible to chrome-plate titanium by ultrasonically activating the electrolyte. During electrolysis, the particles that pass from the anode to the cathode have been successfully broken down to finer size by subjecting the collecting cathode to ultrasonic vibration.

Future Industrial Applications

During the past decade a great many useful industrial applications for ultrasonics have been developed. In this same period, unfortunately, some equipment has been placed on the market that was not yet developed to operate reliably for the uses intended, which led to disappointing experiences in certain instances. On the other hand, there have been many successful pioneering industrial applications of ultrasonics that have become indispensible to the manufacturing processes in which they were used.

An important advancement of the past decade is the development of a variety of low-cost transducer materials that can be mass-produced in unlimited quantities to permit the economic production of reliable high-power transducers to fit practically any required application. Five primary materials are now available which will satisfy practically any industrial ultrasonic transducer requirement: quartz, ammonium dihydrogen phosphate crystals, magnetostrictive materials, polarized barium titanates, and polarized lead zirconates. Among these materials, quartz offers the greatest stability and uniformity, and its field of use is for such applications as frequency control, delay lines, and other high-frequency ultrasonic applications such as thickness gauges and flaw detection.

ADP crystal is stable and very uniform in its characteristics, and is primarily employed in the ultrasonic frequency range up to a few hundred kilocycles. Its greatest field of use is in applications requiring high precision such as in measurement standards and sonar applications requiring accurate beam-forming arrays. Magnetostrictive nickel and other alloys are useful for the lowest ultrasonic frequencies generally below 50 kc, and where extreme ruggedness is a major requirement. Of all the materials listed, only the magnetostrictive metals are free from tensile fractures under high imposed stress.

Polarized barium titanates are the lowest in cost among all the transducer materials, so it is natural to find it used where low cost is the predominant requirement in the design. Barium titanate loses some of its polarization and piezoelectric activity at temperatures above 175°F and it is also subject to deterioration with age. The most recently-developed material is the polarized lead titanate. These materials are fired ceramics similar to the barium titanates so that relatively low cost can be expected as more sources of supply become established. The lead zirconates are more stable than barium titanates and will operate at temperatures well beyond the boiling point of water. It seems very likely that the present increasing availability of lead zirconate as a source of low-cost high-power ultrasonic energy will enormously expand the uses of ultrasonics in industry. Sources of low-cost electrical power for operating high-power transducers as are now available with the new solid-state rectifiers and also with inexpensive rotating high-frequency alternators will also contribute to the widespread use of high-power ultrasonic equipment.

The greatest growth in industrial ultrasonics will undoubtedly be in the high-power field with large-scale industrial cleaning being perhaps the first big market. Up to the present time, high-power equipment operating from vacuum tube amplifiers has been too expensive to find widespread use. The availability of low-cost high-power ultrasonic equipment will also permit large-scale chemical and metallurigcal applications that heretofore were only of academic interest because of the prohibitive cost of the equipment.

In the low- and medium-power range, we shall see a greater acceptance of ultrasonic equipment in the medical field for both diagnostic and therapeutic applications. Continuing medical research with ultrasonics will find many ways to apply this equipment for the benefit of mankind. An indication of its increased acceptance by the medical profession is evidenced by the use of ultrasonic therapy by the President during his recent back difficulty. Many additional applications will be developed for new instrumentation and inspection techniques as well as in automatic and remote control systems in which controlled ultrasonic beams will efficiently and economically take over many menial chores now being performed by more laborious methods.

Present and Future Applications of Ultrasonics in Biomedicine*

WILLIAM J. FRY†, MEMBER, IRE

Summary—The current importance of ultrasonic energy for the investigation and modification of biological systems is reviewed and the immediately foreseeable potential apparent to the author is predicted. The uses of ultrasound in basic research studies of biological systems and medical applications are conveniently grouped into two major categories: passive uses, or those in which the acoustic field does not significantly modify either permanently or temporarily structure and/or function of the system, and active uses, or those in which modification of the system is the objective. Included within the first category are: absorption spectroscopy of solutions of macromolecular species, microscopy of cells and tissues, absorption characteristics of gross tissue, and visualization of soft tissue structure and its dynamics. The second category includes: the use of ultrasound in neuroanatomical and neurophysiological studies and the treatment of neurological disorders by the production of selective permanent or temporary changes in arrays of sites in the central nervous system, destruction of carcinogenic tissue, modification of endocrine glands, investigation of contractile and other properties of muscle, and the potentiation of ionizing radiation by simultaneous application of ultrasound. Applications of ultrasound in the biomedical field of a primarily technological nature are either mentioned only briefly or omitted entirely from the review.

The "socioeconomic" factors which determine the level of financial support, and thus the rate of scientific progress, for a field are also briefly mentioned.

INTRODUCTION

THE STUDY of the interactions of various forms of energy with a system furnishes information on its structure and dynamics. Appropriately controlled ultrasonic energy (arbitrarily defined as sound above 20-kc frequency) constitutes a tool of considerable power for the elucidation and modification of biological systems. This potential of ultrasound, for the investigation of biological material, has been glimpsed partially as a result of work already accomplished with the methodology and instrumentation that various investigators have developed under scantily supported research programs. This glimpse of the potential future is also indicated by ideas for immediate advances, a number of which are mentioned in this paper, but which are not active experimentally at the time of writing.

A review of this length cannot hope to be exhaustive and therefore some of the important work included under the title is either mentioned only briefly or in some cases entirely omitted. However, the specific directions of investigation discussed here include most of the major ones which appear fruitful to the author at the present time. These directions, both basic research (including animal and human) and technological applications (including medical therapy), are conveniently considered in two categories: 1) passive uses; that is, those employing acoustic field conditions which do not significantly modify either permanently or temporarily the biological system, and 2) active uses; that is, those employing acoustic field conditions which modify either permanently or temporarily the structure and/or dynamics of the biological system.

A paper of this type in which both past accomplishments in a field are scrutinized and future potential is predicted might well consider, in addition to the scientific and technological features of such endeavor, the associated "socioeconomic" factors. These latter are equal in importance to the former in determining the rate of progress that can be achieved in any discipline and their prominence in determining the present status of the field of ultrasound in biomedicine is strikingly apparent. Brief reference to these nontechnological factors is included here as a specific example of the way scientific progress in general is determined by the philosophy and/or modus operandi of an organization or social structure which provides the financial support for research.

I. PASSIVE USES OF ULTRASONIC FIELDS

Ultrasonic fields conditions, which do not disrupt or significantly modify biological systems, can be used to detect structure from microscopic to macroscopic levels and to elucidate function. Measurements of ultrasonic absorption and/or reflection characteristics usually constitute the basic information from which such knowledge is deduced. The study of biologically significant structure at the microscopic and submicroscopic levels is subdivided here into two categories: 1) ultrasonic absorption spectroscopy of solutions of biologically important macromolecular species, and 2) ultrasonic microscopy of cells and tissues. Similarly, the investigation of biological systems with passively employed ultrasound on the macro level is divided into two categories: 1) ultrasonic absorption characteristics of gross tissue, and 2) ultrasonic visualization of soft tissue structure and its movement. The present state of development in each of these subdivisions is considered briefly and future potential is indicated.

A. *Ultrasonic Absorption Spectroscopy*

From measurements of the ultrasonic absorption characteristics of macromolecular configurations and molecules of biological interest such as proteins, information on the states of aggregation and organization of these species in solutions and suspending media can

* Received by the IRE, September 5, 1961; revised manuscript received, November 8, 1961.

† Biophysical Research Lab., University of Illinois, Urbana, Ill., and Interscience Research Corp., Urbana, Ill.

be deduced. Work in this field is in the early stages and no *specific* mechanism to account for the major portion of the absorption has yet been formulated and verified. However, a phenomenological approach in which relaxation theory is applied to explain the frequency dependence of absorption of some of the materials on which data is available has received some attention. That the ultrasonic absorption coefficient might well constitute a sensitive indicator of configuration states of macromolecular species in solutions or embedding media is already suggested by the work of Schwan, Carstensen and collaborators. These investigators have reported the most precisely determined and comprehensive velocity and absorption results on erythrocytes in suspension, hemoglobin in solution, plasma, extracts from liver, etc., as a function of the concentration, temperature, and ionic content over the frequency range from 0.3 to 10 Mc [1], [2]. However, measurements over a considerably wider frequency range will probably be required before much information on structural features of biological macromolecular species in solutions and in cells can be deduced from such data.

The type of ultrasonic instrumentation employed in this work is illustrated in principle [3] in Fig. 1. The method makes possible the attainment of a high degree of accuracy in the measurement of absorption coefficients and velocity differences. The basic principle is the comparison of the acoustic properties of the medium of interest with those of water or other standard liquid. To achieve this, the sound tank is divided into two compartments by a diaphragm as illustrated. One compartment contains the standard solution, the other contains the medium. The ultrasonic transducers, which generate and detect the acoustic pulses, are moved by a precision sliding mechanism. Movement of this mechanism makes possible the substitution of any desired pathlength of the solution or suspension for an equal pathlength of the standard. Absorption coefficient values with an uncertainty as small as 0.002 cm^{-1} are computed from measurements of attenuation. By determining the phase of the signal at the receiver transducer with respect to the signal at the generator, it is possible to accurately measure acoustic velocity differences, and determinations to one part in 100,000 are reported.

The method just discussed for measuring absorption coefficients of biologically significant media is not useful if both the volume of material available and the magnitude of its absorption coefficient are small since the apparatus of Fig. 1 then requires a quantity of material of the order of 0.1 to 1 liter. When the volume of material available is small, for example, a few cubic millimeters, the thermocouple method illustrated in Fig. 2 can be used. This is an adaptation of the thermoelectric probe developed at this laboratory for measuring absorption coefficients of tissue and for determining acoustic field configurations [4]–[6]. From the recording of the transient rise in temperature of the medium surrounding the junction, following exposure to a pulse of ultrasound of rectangular envelope, it is possible to calculate the absorption coefficient of the embedding medium. This method, which requires that the absolute sound intensity and the heat capacity of the medium per unit volume be known to the same degree of accuracy as that desired in the absorption coefficient,

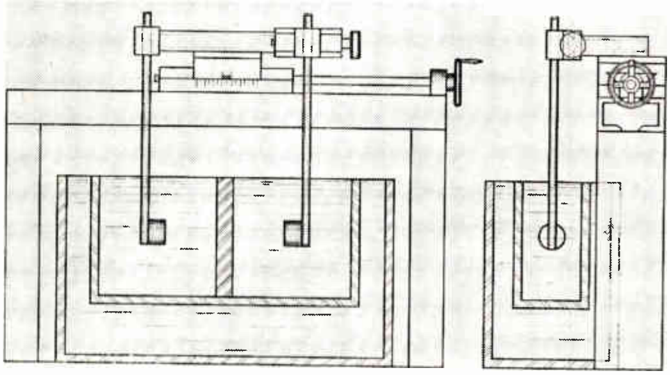

Fig. 1—Apparatus for precision measurement of ultrasonic absorption coefficients and velocity differences. Comparison of the acoustic properties of the medium of interest, which fills the left compartment of the sound tank, with a reference or standard liquid filling the right compartment of the tank, is achieved by this type of instrument. After choosing an appropriate spacing for the transmitter-receiver separation, the relative amplitude and phase of the received signal are determined as a function of the path length of the medium substituted for an equal path length of the standard by movement of the transmitter-receiver assembly relative to the two-compartment sound tank. The duration of the plane wave pulses and the dimensions of the tank are chosen so that reflection of ultrasonic energy from the tank walls does not interfere with the measurements.

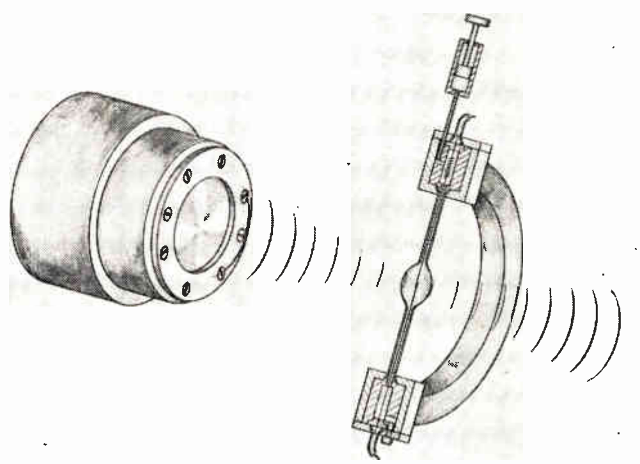

Fig. 2—Method of measuring the ultrasonic absorption coefficients of materials on samples as small as a few cubic millimeters. The material is supported in a tubular shaped container, formed of thin plastic sheet, in which a thermocouple is mounted in approximate coincidence with the long axis. The ultrasound pulses of rectangular envelope are focused in the volume of the medium surrounding the thermocouple junction and the voltage generated across the couple leads indicates the transient change in the temperature of the medium in the immediate neighborhood of the junction. From an analysis of the form of the temperature response, that part caused by absorption of the ultrasound in the body of the medium can be deduced, and from this and a knowledge of the heat capacity of the medium per unit volume and the absolute sound intensity, the acoustic absorption coefficient can be computed.

promises to be extremely useful in the further development of the field of ultrasonic absorption spectroscopy of solutions and suspensions of biological significance.

Absorption of ultrasound occurs in a *homogeneous* liquid when the changes in density are not in time phase with the changes in pressure. This type of behavior is produced by a variety of mechanisms classified into the two categories: viscosity or frictional lag and relaxation processes. The mechanism of the first category results from the fact that liquids exert resistance to shearing forces and for a Newtonian liquid this force is proportional to the velocity gradient and to the *constant* coefficient of shear viscosity. In non-Newtonian liquids the value of the viscosity coefficient depends upon the velocity gradient. The term "relaxation" process is used to include heat conduction, which is relatively unimportant for biological systems, and thermal and structural relaxation mechanisms [7]. Thermal relaxation results when the temperature of a fluid is changed due to the propagation of a sound wave, and the transfer of energy between external and internal degrees of freedom of components of the medium requires a time interval comparable to the period of the wave. The out-of-phase relations which result cause a conversion of acoustic into thermal energy. Structural relaxation results when a time interval comparable to the period of the sound wave is required for redistribution of the mutual orientation or degree of association of the components of the medium in response to the pressure changes produced by the sound field. Since configuration changes entail energy transfer, some acoustic energy is converted into heat when the rate of the redistribution process is too slow to follow the variations in pressure produced by the sound field without appreciable lag. If the equilibrium state of a chemical reaction is dependent to a sufficient degree upon the pressure of the reactants then acoustic absorption of the relaxation type takes place.

Absorption of ultrasound can occur as the result of relative motion between suspended structures and imbedding medium [8]–[11], *e.g.*, in cell suspensions or tissue. Such relative motion results since the densities of the suspended particles or their constituent parts are not, in general, equal to that of the suspending matrix. This relative motion gives rise to friction forces which cause absorption of acoustic energy.

Liquids can be subdivided into three classes on the basis of their ultrasonic absorption characteristics [12]–[14]. Members of the first group have ultrasonic absorption coefficient values close to those calculated on the basis of shear viscosity losses. Monatomic liquids such as mercury are in this group as well as some diatomic liquids such as oxygen and nitrogen. As far as is known at the present time, no biologically interesting materials are in this class. The second group is characterized by a positive temperature coefficient of absorption; that is, the magnitude of the absorption coefficient increases as the temperature increases and reaches values from three to four hundred times those calculated on the basis of a shear viscosity mechanism. Unassociated liquids such as benzine and carbon tetrachloride are in this group. The "excess" absorption of these liquids may be the result of a slow rate of exchange of energy between the external and internal degrees of freedom. The third group, the associated polyatomic liquids, exhibit a negative temperature coefficient of absorption. Liquids of this type include water and alcohols. The blood proteins exhibit such a negative temperature coefficient of absorption [15] but nerve tissue exhibits a positive temperature coefficient [7].

It is not possible in a review of this length to consider in any detail the methods of analysis leading to the identification and separation of shear viscosity mechanisms from relaxation processes and the identification of specific relaxation mechanisms and their characteristic frequency distributions. (See, for example, reference [7] for a discussion.)

The primitive state of knowledge of this field is apparent when it is compared with the present status of electromagnetic spectroscopy of atoms and molecules. In the ultrasonic case only a single molecular species—hemoglobin—has been studied in any detail and the underlying mechanism of absorption of not a single macromolecular structure has been worked out. When it is realized that classical electromagnetic spectroscopy (infrared, visible and X ray), which has yielded such a vast amount of information on the structure of molecules, atoms and crystals, can furnish little essential information on the macromolecular features of structures of interest here, and that electron microscopy is not readily adapted to the examination of solutions or suspensions, it is apparent that ultrasonic spectroscopy methods, in which the values of the absorption coefficient are critically dependent upon the macromolecular configurations in the embedding media, should receive major attention. It is emphasized here and it will be increasingly apparent from subsequent sections of this article that ultrasonic methods of the type described are particularly useful for the study and examination of structure on the biologically significant level.

B. Ultrasonic Microscopy of Cells and Tissues

Since different protein solutions and presumably other macromolecular species of biological significance are characterized by different values of the ultrasonic absorption coefficient [2], it is possible to develop an ultrasonic absorption microscope [7] to determine distributions of molecular species on an intracellular level. Since the mechanisms of absorption of ultrasonic and electromagnetic energy are completely different in general, components of cells and tissues would not exhibit the same differential absorption of these two forms of energy. Consequently, it is reasonable to expect to detect and visualize structures ultrasonically which are not seen by microscopes using visible light or electromagnetic energy in other portions of the spectrum and vice versa.

The principle of operation of one form of an ultrasonic absorption microscope is illustrated in Fig. 3. Acoustic waves are generated in a coupling medium by a piezoelectric element such as an X-cut quartz plate vibrating in thickness mode and this liquid conducts the sound to the specimen which is interposed between the source and a small thermoelectric probe or array of such probes. This array detects the acoustic energy transmitted through the portions of the specimen adjacent to the individual probes and thus an acoustic image of the structure can be reproduced by moving the specimen relative to the probe array [7], [16].

It should be noted here that this same device provides a method for measuring acoustic absorption coefficients of solutions or suspensions in the kilomegacycle frequency range. For this use the fluid medium, whose absorption coefficient is to be measured, fills the chamber and a single thermocouple probe is moved along the direction of propagation of the sound in the medium. The transient change in the temperature at the thermocouple junction, resulting from conversion of a fraction of the energy of the acoustic pulse into heat in the immediate neighborhood of the junction, measured as a function of the spacing distance between the source and probe, provides the necessary information to permit a calculation of the absorption coefficient of the medium. Work now in progress at this laboratory has shown that such a device can be used to measure absorption coefficients from the Mc frequency range into the kMc frequency range. At the present time it appears that an operating frequency spectrum of four orders of magnitude will be feasible.

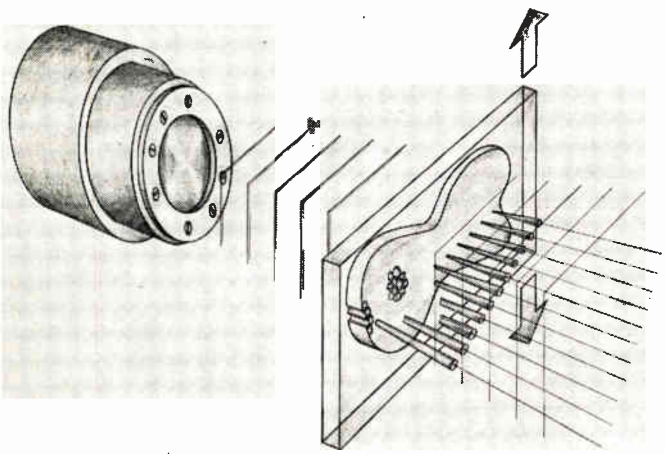

Fig. 3—Principle of operation of an ultrasonic microscope capable of resolving structure on an intracellular level. Plane pulsed waves of sound are generated by a piezoelectric plate element vibrating in thickness mode at any of a series of odd harmonics of the fundamental resonant frequency. After passing through the structure under examination, which is coupled in close proximity to the transducer element by a fluid medium, the acoustic energy passes into a medium imbedding an array of thermocouple junctions immediately adjacent to the specimen. Since differential absorption of the sound occurs in the specimen it is apparent that the temperature distribution defined by the different thermocouple outputs is a manifestation of structure in the specimen. By moving the specimen in its plane and in a direction at right angles to the direction determined by the linear array of junctions it is possible to obtain a two dimensional ultrasonic picture of microstructure of the specimen. The resolution of such a device is dependent on the size of the thermocouple junction, the thermal properties of the couple leads and of the imbedding medium, the ultrasonic pulse duration and intensity and the magnitude of differential absorption characteristic of the microstructural features.

Instruments designed on the basis of the principle illustrated in Fig. 3 have not yet been employed to examine or study the micro detail of cells or tissue structures since such devices are still in an early stage of development at this laboratory and much additional sophistication will be required before the microstructure of biologically interesting materials can be studied. However, a form of this device employing a single thermocouple junction is in use on the measurement of absorption coefficients of liquids from the low Mc into the kMc frequency range.

Calculations of the resolving power of an ultrasonic absorption microscope of the type discussed have been made [7], and it appears feasible on the basis of the analysis to expect a resolution of a few tenths of a micron at the higher operating frequencies. High resolving power requires operation in the kMc frequency range, not because of wavelength limitations, but rather because its attainment requires the use of short pulse lengths to minimize the effects of thermal conduction. The use of increasingly shorter pulse lengths requires increasingly higher ultrasonic absorption coefficient values in order to achieve a sufficient temperature change to be detectable, and since the absorption coefficient per unit pathlength increases with the frequency it is necessary to operate in the UHF range.

It should be noted here that an ultrasonic microscope based on lenses or reflector focusing principles would not be practical at the frequencies necessary to obtain high resolution since the acoustic absorption coefficient values per unit pathlength at these frequencies in liquid media are too high for the pathlengths which would be required in such designs.

Ultrasound employed in the manner indicated in this section would appear to have considerable potential for the examination and elucidation of biological structure on a microscopic level. It not only constitutes a new way of detecting structural features but it is also well suited for the examination of tissue or cells *in vivo*.

C. Ultrasonic Absorption Characteristics of Tissue

The absorption and the propagation characteristics of tissue for ultrasound must be determined to provide information basic to the utilization of this form of energy for: examination of the gross anatomy and normal dynamics of organs *in vivo*, diagnosis of malfunction and pathological states, modification or destruction of internal structure without incising of the intervening tissue in animals and humans. Quantitative information is essential for a basic understanding of the manner in which proteins and other macromolecular species contribute to the absorption in tissue and for an understanding of absorption mechanisms related to tissue structure as contrasted with that resulting from processes occurring on the "molecular" level.

As will be indicated in Section I-D of this paper, the ultrasonic visualization of soft tissue structure offers enormous potential for the examination of the anatomy of intact organisms and the associated dynamics but the acoustic propagation characteristics of such tissue must be understood in order to achieve the potential. In addition, the entire field concerned with the modification of tissue structure, reviewed in Section II, is dependent upon an accurate knowledge of the propagation characteristics of ultrasound in tissue. Both velocity [17] and absorption characteristics [18], [19] must be known.

In view of the incompleteness of the acoustic propagation data [20] in this field it is apparent that much experimental work and theoretical analysis must be accomplished before the absorption characteristics of a variety of tissue structures in the ultrasonic frequency range are both known and understood [8], [9], [11], [21]. A recent example of the type of data and analysis required for a basic understanding of absorption mechanisms in tissue in the megacycle frequency range is that reported from this laboratory on the absorption in lung [22].

Not only is it essential that the acoustic propagation characteristics of normal tissue be measured and understood but it is also necessary that the characteristics for pathological tissue be determined. This latter is particularly important if ultrasound is to be useful passively for diagnostic purposes.

D. *Ultrasonic Visualization of Soft Tissue Structure*

Nearly all soft tissue components possess essentially the same X-ray density, and therefore structural features of soft tissue cannot be visualized directly by using this radiation. By contrast, since soft tissue structure is not acoustically homogeneous (slight differences in acoustical impedance are present), small fractions of the ultrasonic energy incident on interfaces within or between such tissues are reflected. Since under the ultrasonic irradiation conditions required, no deleterious effects are produced in tissue, this form of energy provides a method of visualizing tissue structures (both normal and pathological) in three dimensions [23], [24]. In addition, their dynamic characteristics can be studied; for example, it is possible to observe the movements of major blood vessels and characteristics of heart motion [25]–[29]. Ultrasonic visualization methods have been applied in ophthalmology [30], and tumor localization and diagnosis have received the attention of a number of investigators [31]–[33].

The wavelength of the radiation determines the resolution which is obtainable and since the velocity of sound in soft tissue is close to that of water it is necessary to operate at frequencies of 1 Mc and above if resolution of the order of a millimeter is desired. At these frequencies the absorption per centimeter of tissue path is relatively high so that the received acoustic energy reflected from interfaces at different tissue depths is considerably affected in magnitude by this factor. By the use of focused beams and short pulse lengths it is possible to obtain resolution in both azimuth and range.

The instrumentation required for visual presentation of the reflected ultrasonic signals as a reconstruction of the tissue structure and for detection and processing the signals for the presentation system is quite sophisticated. It is necessary because of the tremendous range of amplitudes of the returning reflected signals to design the system with gain compensation. Since the orientation of the reflecting interface with respect to the direction of the incident beam is important in determining the direction of the reflected acoustic energy, and consequently the amount of energy which is returned to the receiving transducer, it is necessary to view each site in the structure from a number of different directions. The importance of this is apparent when it is observed that, for example, an angular shift from normal incidence of 10° can cause a reduction of the amplitude of the received signal by a factor of 100. Compound scanning techniques thus improve the picture detail and eliminate artifacts (see, for example, reference [7] for further details).

The ultrasonic method of soft tissue structure visualization just described—that is, one depending upon existing small differences in the acoustic impedance at tissue interfaces to provide reflected energy—although furnishing a tremendous amount of information not obtainable previously, does not permit the visualization of all tissue structures of interest. In addition, increased contrast between structures now detectable is extremely desirable in many cases. A considerable advance in these two directions can be expected by a new ultrasonic visualization method recently proposed and evaluated analytically by the author. The advantages offered by the new method can be illustrated by the following specific comparison. Present ultrasonic visualization methods do not detect boundaries between any internal brain structures since the acoustic impedance differences are not of sufficient magnitude to provide detectable amounts of reflected energy. However, it is presently possible to detect the ventricular system since the impedance difference between brain tissue and cerebrospinal fluid is sufficiently great to provide the necessary reflection. Since the study and modification of brain structure and function requires the placement of beams of radiation, electrodes, cannulae, etc., at specified sites in particular structures it is extremely important to have a system which permits visualization of all major brain structures (that is the boundaries between the major gray and white matter masses). This can be achieved and presently undetectable structural details in other tissues and organs of the body can be visualized by designing an instrument to induce temporary impedance differences at tissue interfaces. Such impedance changes can be induced at interfaces where the ultrasonic absorption coefficient changes in value; for example, in the brain the white matter exhibits an ultrasonic absorption coefficient approximately 1½ to 2 times that characteristic of gray matter.

The basic principle underlying the method proposed by the author is illustrated in Fig. 4. Two pulsed properly synchronized scanning beams of ultrasound are employed, one (the modifier) of relatively long pulse duration and the other (the analyzer) consisting of a series of pulses short compared to the first. These sound beams are, in general, of different frequencies. The long-pulse focused beam or modifier is used to produce in a relatively small volume of tissue (the site within the specimen receiving immediate attention) transient changes in temperature by conversion of acoustic energy into heat. In the boundary regions between tissue structures characterized by different values of the ultrasonic absorption coefficient transient steep gradients of temperature would thus be produced. Since the velocity of sound is temperature dependent corresponding gradients in the acoustic velocity would thus exist temporarily in these boundary regions. The second focused beam, the analyzer, would then be partially reflected from regions exhibiting such gradients. Calculations demonstrate that sufficient acoustic energy can be reflected when temperature differences which would not produce damage to the tissue are employed. This new method will achieve not only visualization of structures which are undetectable by instruments employing the present methodology, but will also permit increased contrast to be achieved between structures detectable with the present equipment, but for which improved contrast would be extremely advantageous. The new method is well suited to the centering of attention on chosen small volumes of tissue to provide enhancement of echoes from this region compared to those from surrounding or embedding structure. This is achieved since the temperature gradients which either induce or increase acoustic impedance differences at boundaries are of appropriate magnitude only in the region of the focus of the modifying beam. Thus, three major advantages over present methods of ultrasonic visualization of soft tissue structure are provided: visualization of structures not now detectable, increased contrast between presently detectable structures, and relative suppression of reflected energy from embedding and intervening tissue.

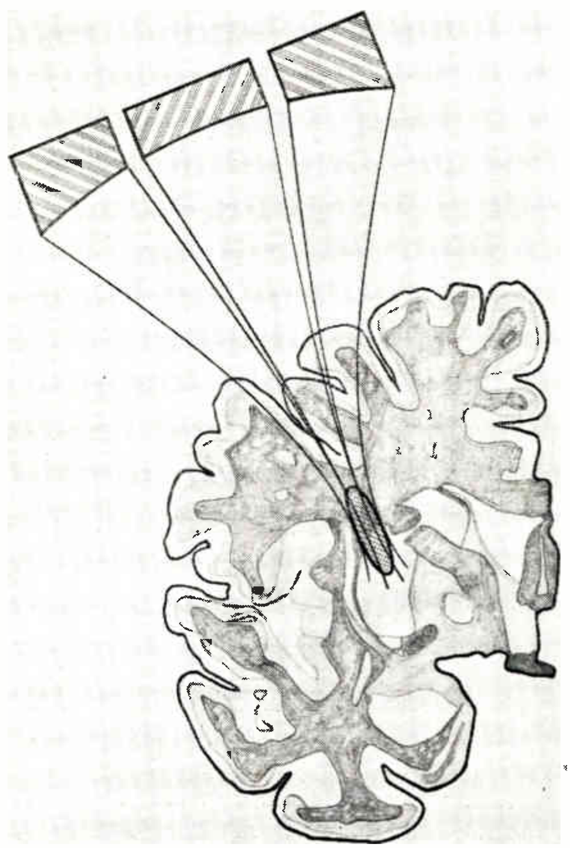

Fig. 4—Schematic diagram of ultrasonic method of visualizing soft tissue structure by employing one focused and pulsed beam of sound (included within the two concentric cones which surround the inner beam illustrated in the diagram) to induce temperature gradients of small nondamaging amplitude at tissue interfaces (brain, gray-white matter interface in the figure) and other structural features at which changes in acoustic absorption occurs. Since the velocity of sound is temperature dependent acoustic velocity gradients are thus induced in the regions of structural change. These gradients are then detected and their geometric positions determined by a second pulsed and focused ultrasonic beam (included within the innermost cone of the diagram) appropriately synchronized with the first. Both the temperature modifying and the examining beams are moved to scan the specimen. The duration of the pulse length of the former is relatively long (0.1 to 1 sec) in order to induce velocity gradients of appropriate amplitude without the use of extremely high ultrasonic intensities and the pulse length of the latter is very short (1 μsec) in order to provide appropriate resolution (0.1 to 1 mm).

The potential of ultrasound for examination of tissue is apparent when it is observed that the present widespread use of X rays in diagnosis is based on the visualization of a much more restricted range of structure than that which will be possible with instruments based on ultrasonic methods. The implications can again be emphasized by reference to the neurological field. No present method can achieve visualization of internal brain structures (nuclei and fiber tracts) and a variety of landmarking methods have been devised to provide systems of reference which at best furnish meager information. The direct visualization of all major brain structures, which the new ultrasonic method outlined briefly here is expected to provide, now appears to be within our grasp.

II. Active Uses of Ultrasound

Modification of structure and/or function at deep sites in tissue both for basic research on experimental animals [34]–[36] and humans [37], [38] and for routine treatment of disorders in medical therapy can be achieved with ultrasound. By focusing it is possible to produce changes at any desired depth without damage to intervening tissue and by appropriate control of the irradiation parameters selective action on components of tissue structure can be accomplished [34], [39]–[46]. Either permanent or temporary [34], [47] changes can be produced as desired. The central nervous system has been the object of the most intensive study using precisely controlled intense ultrasound and the present status of this area of activity will be briefly reviewed and future potential indicated.

A. Central Nervous System

In the central nervous system the selectivity that can be realized at the present time by employing ultrasonic field parameters corresponding to pressure amplitudes of 5 to 50 atmospheres and appropriate durations of exposure constitutes an extremely powerful tool for investigation of normal structure and function. By moving the focused beam about with an appropriate precision positioning system changes in regions of arbitrary sizes, shapes and orientations can be produced in deep sites without damaging intervening tissue. Microscopic studies of irradiated tissue show that blood vessels are the part of the brain most resistant to the action of the sound and also demonstrate that it is possible to interrupt selectively the neural components of white matter (the regions which contain only nerve fibers) without damaging gray matter (the regions containing the nerve cell bodies) subjected to the same irradiation conditions. No evidence of long term cumulative action comparable to that produced by ionizing radiation and ionizing particles exists.

The minimum size region that can be affected is determined by the volume of the focal region and this is, in turn, dependent upon the wavelength of the sound. At 1 Mc the wavelength in brain tissue is $1\frac{1}{2}$ mm and therefore the minimum size tissue volume that can be affected in easily reproducible fashion in homogeneous tissue is a few cubic millimeters. At higher frequencies changes can readily be restricted to smaller volumes of tissue if so desired. For example, at 4 Mc the tissue volume affected for a single exposure position can be as small as a few hundredths of a cubic millimeter. However, it is not possible to decrease the wavelength indefinitely, by increasing the operating frequency, to affect smaller and smaller tissue volumes in depth because as the frequency increases the absorption per unit path length also increases—linearly in the range of interest (at 1 Mc the pressure absorption coefficient is 0.1 cm^{-1}).

The procedure employed at the present time for the irradiation of brain structures requires that a portion of the skull be removed since bone has a much higher absorption coefficient [19] than soft tissue and, therefore, if left in place, thermal damage to underlying tissue would occur as the result of heat conduction from the irradiated bone. In addition, the irregularities of skull thickness and orientation would modify the beam shape and reduce the accuracy of positioning the focus. When the new ultrasonic visualization method discussed in the previous section is in operation, it may be feasible to develop instrumentation to eliminate the present requirement of bone removal since it will then be possible to view directly the focus of the ultrasonic beam, used for modification or disruption of neural structure, in the specific sites to be affected. The attainment of such a goal must however await the development of very elaborate instrumentation. Obviously all possible effort should be bent toward this objective since its realization would make the precision modification of brain structure for the treatment of a variety of neurological and other disorders in the human extremely simple to achieve in practice since no preliminary or auxiliary procedures such as the present surgical and ventriculographic preparations would be required.

Much work has been carried out on experimental animals to investigate the types of tissue changes which are produced (see references listed in the introduction to this section) and as a result ultrasonic methods are currently being employed at this laboratory in fundamental research studies of a neuroanatomical and behavioral nature. Anatomical investigations [35] heretofore not feasible are now possible since changes can be confined to selected volumes of tissue without *any* damage to other structures. When the desired "lesion" is achieved there is no ambiguity regarding interpretation of results such as ordinarily arises because of damage to other tissue. Fig. 5 illustrates in cross-section lesion arrays of various configurations in cat brains produced by focused ultrasound.

The advantages for neurophysiological and behavioral studies of the ultrasonic method of producing *permanent* changes in brain structures are similar to those for neuroanatomical investigations; that is, the production of selective lesions of desired sizes and shapes in combinations of structures without damage to other regions.

The extensive work carried out on experimental animals provides the basis for employing ultrasonic methods to study and modify the symptoms of human neurological disorders and a variety of such disorders has received the attention of the author and collaborators up to the present time [34], [37], [38]. These include: the tremor and rigidity of Parkinson's disease; involuntary movements of cerebral palsied individuals; intention tremors and nonpatterned movements; intractable pain, hyperesthesias and dysesthesias following cerebral vascular accidents; and phantom images and pain in amputees. The symptoms indicated can be affected by modifying various brain structures and the ultrasonic work already accomplished has provided much new information on the identification of specific structure subserving the underlying mechanisms. The flexibility and absence of stress during irradiation of the awake human patient makes possible the subtle and consistent step-wise modification of the neurological status as determined by continuous interview and examination during the procedure.

The instrumentation necessary for attaining the flexibility, reproducibility and accuracy for producing *permanent* changes at desired arrays of sites in the hu-

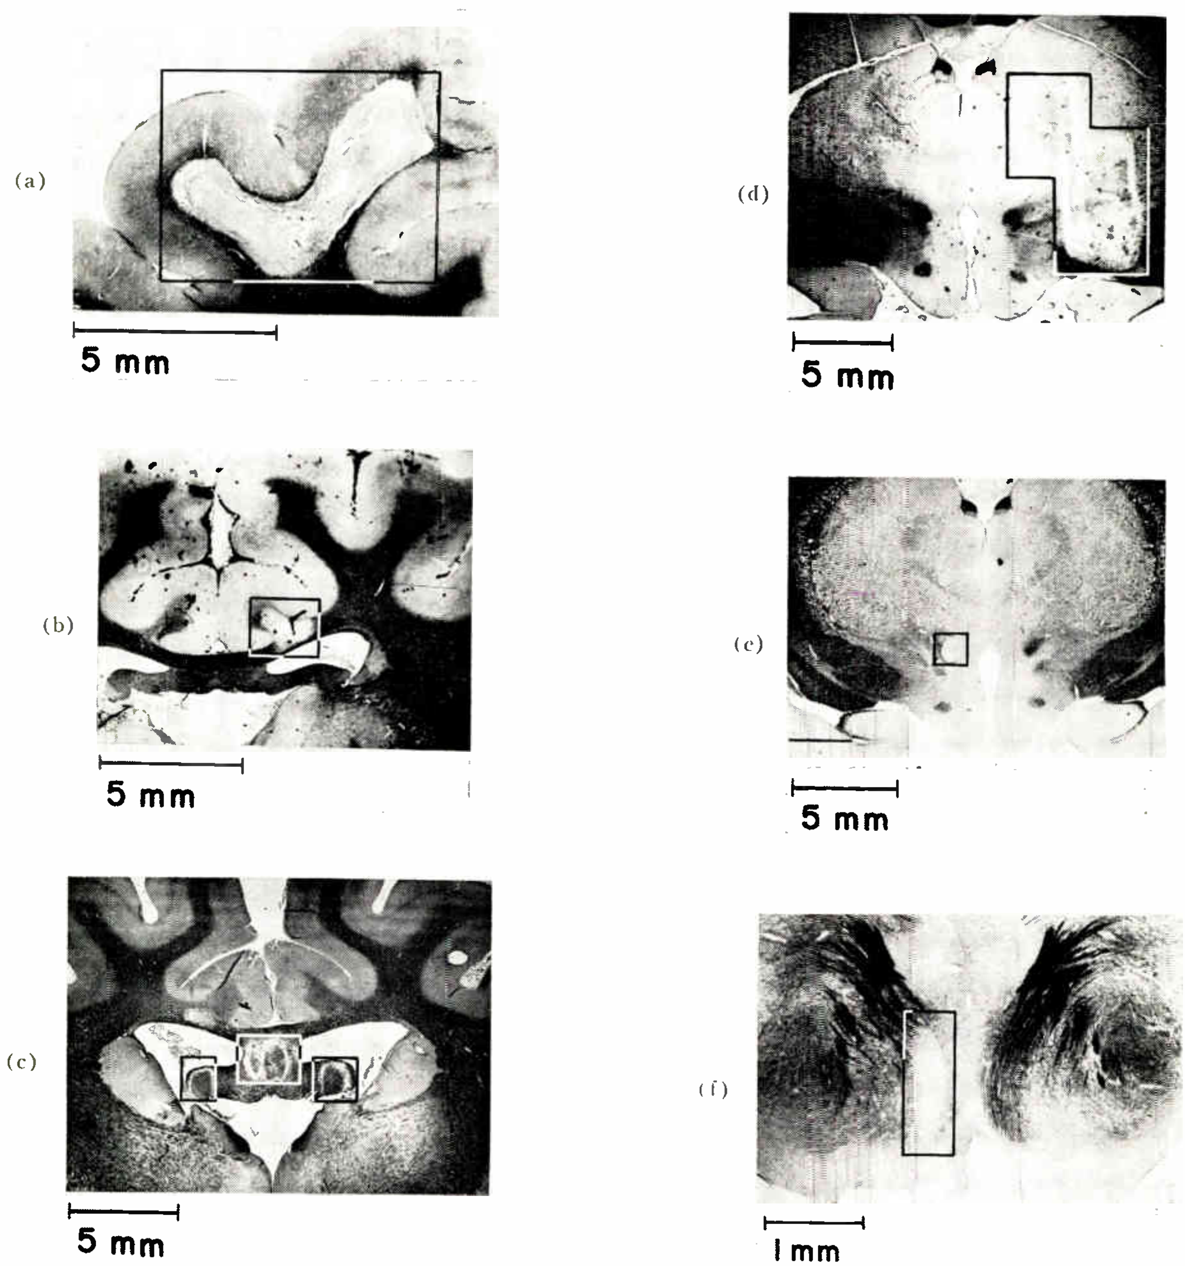

Fig. 5—Stained tissue sections of cat brain showing various shaped ultrasonic lesions in a variety of structures. The white matter or nerve fiber tract regions are stained dark and the gray matter or nerve cell body regions are relatively unstained. (a) Lesion in the subcortical white matter with no invasion of the immediately adjacent cortical gray matter. The brain cross section shown exhibits the maximum dimensions of the lesion. Its extent perpendicular to the cross-section is small, It was produced by moving the focus (1 Mc sound) in the plane of the section with a 1 mm spacing between adjacent sites. (b) Lesion placed to interrupt longitudinally running fibers—the cingulum running perpendicular to the plane of the section—in the white matter of the cingulate gyrus. The lesion was produced by placing the focus at an array of sites spaced 0.2 mm apart, 4 Mc sound. (c) Three lesions in the subcallosal fornix. The longitudinally running fibers are interrupted in the lateral half of the structure bilaterally and the fibers in the medial portion of the structure in the plane of the section are destroyed. No damage was produced in the corpus callosum and underlying thalamic structures: 0.2 mm spacing between adjacent sites of the array, 4 Mc sound. (d) Two thin rectangular sheet lesions in the thalamus and subthalamus. These lesions are thin in the direction perpendicular to the section shown, 4 Mc sound used. (e) Interruption of the mammillothalamic tract: 0.2 mm spacing, 4 Mc sound. (f) Lesion in the medial part of the medial mammillary body. The lesion extends throughout the length of this structure, *i.e.*, for 1½ mm in the direction perpendicular to the section shown. The lesion is shown in cross section: 0.2 mm spacing, 4 Mc sound.

man brain is quite elaborate and not inexpensive. The apparatus presently employed, which is illustrated in Fig. 6, includes: a stereotaxic head holder incorporating X-ray equipment; ultrasonic focusing transducers; a positioning system for placing the focus of the beam at desired predetermined arrays of sites; electronic equipment for supplying the necessary electric excitation to the transducers and for accurately controlling the sound level and duration of exposure; calibration instrumentation for precisely determining acoustic field configurations and for measuring absolute sound levels; and auxiliary equipment for control of factors such as coupling liquid temperatures [34], [36], [48].

Intense ultrasound can also be used to produce temporary, that is, reversible changes in the central nervous system. This is demonstrated by results obtained on the visual system of the cat [34], [47]. For example, when an eye of the animal is subjected to flashes of light or if the optic nerve is stimulated electrically, electrical events occur in regions of the brain concerned with the receipt and processing of incoming visual information. The pattern and complexity of these electrical events in the visual cortex are dependent upon a number of factors and various components of the evoked response can be identified depending upon the level and type of anesthesia, the temporal sequence of exciting stimuli, the temperature of the brain, etc. When the focus of the sound beam is placed in structures (*e.g.*, lateral geniculate nucleus) concerned with the processing and transfer of information and an appropriate set of irradiation parameters are employed, it is possible to produce changes in the magnitudes and latencies of the components of the potentials evoked in the visual cortex. A focused sound beam employed in this fashion constitutes an analyzer for the complex circuitry of the brain. That is, nerve pathways and centers over which information is transmitted and processed can be located and studied by observing the temporary changes induced by focused ultrasound in, for example, electrical responses manifested in brain structures following stimuli of various types and configurations.

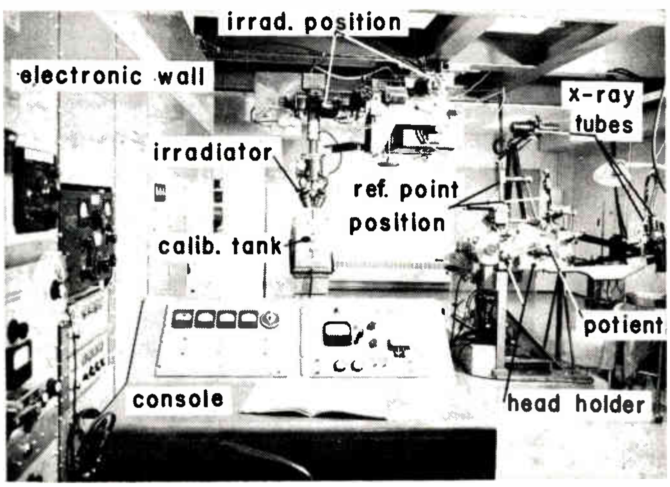

Fig. 6—View of the irradiation room for modifying brain structures in the human. An awake comfortably positioned patient is shown with head supported in the holder by four stainless steel rods whose rounded tips engage hemispherical indentations in the outer table of the skull. The tips of these rods can be accurately repositioned in space by the micrometer adjustments provided on the supporting posts in order to permit a number of irradiation procedures if desired without the necessity of determining the coordinates of the internal landmarks more than once. The three X-ray tubes and cross hair positioning system employed in the coordinate determination of landmarks are shown mounted on the head holder. The four beam irradiator, which has provided the focused intense ultrasound for the human work accomplished up to the present, is in position over the calibration tank. It swings into place over the head of the patient after a hopper which supports the coupling liquid is positioned over and engaged in water tight connection with the patient's scalp. The placement of the focus of the ultrasound in the sites of the array of positions to be modified in the brain is accomplished by the overhead structure. Since the scalp is intact during irradiation (an appropriate portion of the skull bone is removed at an earlier procedure) there is no necessity for sterile procedure once the small scalp incisions at the sites where the supporting rods engage the skull are sealed. The electronic instrumentation is mounted on the panels on the left wall and in the control console in the foreground.

From the work that has been accomplished it is apparent that three-dimensional mapping of brain function of a type and scope heretofore completely unattainable will be possible by moving appropriately controlled focused beams of ultrasound through brain structures and observing resultant changes. Some of these possibilities are apparent when one considers that the resolution obtainable with ultrasonic methods can make a moving sound focus the equivalent of 10,000 to 100,000 electrodes capable of disturbing in controlled temporal sequences threshold relations of neural events in essentially any combination of structures in a single brain. Such methods will be extremely useful both in fundamental research studies on experimental animals and on humans and in human therapy. In the latter application it will not be necessary, for example, to destroy any brain structure to locate regions involved in specific malfunction or pathological behavior.

If will be possible to investigate relations between complex behavior and brain mechanisms with some hope of obtaining a basic understanding of the operation of the maze of inter-connections and inter-relations which exist. However, to bring such a program to fruition, major developments in instrumentation must be forthcoming. The instrumentation which is required (at an estimated cost of several million dollars for a single installation) will include: data storage equipment; data analyzers, programming apparatus, presentation systems for results of data analysis; anatomical and functional presentation systems; a multiplicity of focusing transducers; positioning systems; ultrasonic visualization instrumentation; and a variety of types of control equipment.

The study and correction of malfunctions of the human brain—the most complex mechanism yet identified by man—would appear to warrant the development and use of instrumentation which is at least comparable in sophistication to that currently in use in investigations of the "physical" world. We have a long way to go but it is to be hoped that support for such activity can be obtained so that the major contributions promised by new methodology, for example the ultrasonic procedures indicated herein, are forthcoming.

B. Other Structures

High-level ultrasound can be used to modify tissue other than that of the central nervous system but other structures have not received comparable attention. The application of intense ultrasound to the treatment of soft tissue tumors has been reported [49], [50]. An unfocused beam of large cross-sectional area (50 cm^2) and intensity levels up to 500 w/cm^2 were used to modify and destroy malignant tissue. The treatment of deep tumors by high intensity ultrasound will require the development of focusing transducers capable of irradiating relatively large volumes of tissue simultaneously. This is necessary in order to confine the duration of the procedure to practical time limits. The "effective" sizes of the foci employed for the current work on the central nervous system are much too small (0.1 to 10 mm^3) for treating large tissue masses (1 to 10 cm^3). The development of focusing transducers with focal regions large in cross sectional area uniform, within a few per cent, in acoustic field parameters presents difficulties. Some headway on the development of appropriate focusing systems using modified cylindrical lenses has been achieved at this laboratory [51], [52].

It should be noted here that work accomplished during the 1940's on the use of relatively low intensity ultrasound to modify tumors with enhancement reported in some cases and suppression in others does not constitute an appropriate basis on which to judge the possible applicability of high-level ultrasound for the favorable modification of carcinogenic tissue. This view is reasonable since desirable effects may only be achieved above certain threshold levels, as has been demonstrated in the case of the central nervous system. Investigations into the possible production of selective changes in carcinogenic cells, that is, for example, the possible action of high-level ultrasound to *selectively* destroy such material when embedded in normal cellular masses is extremely desirable and should receive major attention in the immediate future.

The endocrine status of both experimental animals and humans has been modified by irradiation of the pituitary in work accomplished by the author and collaborators [53], [54]. This work has application not only to the study of normal endocrine balance but also to the modification of endocrine function in, for example, patients with endocrine tumors—metastasizing breast tumors [54]. From the work accomplished it is apparent that the endocrine state of an organism can be drastically modified by hypophyseal irradiation with ultrasound and made to undergo a series of changes with various recovery rates either to pre-irradiation or altered endocrine status. The histological work of this laboratory [53] indicates that it may be possible to alter the ratios of the gland cellular populations of the pituitary and thus the interesting possibility of redesigning the hypophysis by the application of controlled dosages of ultrasound is suggested. If this can be achieved it will constitute a powerful procedure for the study and modification of endocrine physiology.

Another type of tissue, which has been the object of basic investigative work employing ultrasound in attempts to obtain fundamental information, is muscle [55]–[58]. Such work continues and it is hoped that increased knowledge of muscle structure and its relationship to the contractile and electrical characteristics of the tissue will be forthcoming.

The action of ultrasound on cells and tissues other than those already mentioned has received the attention of various investigators. For examples of work reported within the last ten years see [59] through [61] for liver, skin and some embryonic tissues and reference [62] for a specific plant tissue.

Before concluding this section it is of interest to call attention to another intriguing use of ultrasound in the study of biological systems, that is, in combination with ionizing radiation. An extremely small amount of work has been accomplished in this direction and it has been shown that X-ray dosages necessary to irreversibly destroy some types of tumor tissue can be reduced by a factor of two or more by simultaneous irradiation with relatively low-intensity ultrasound [63], [64]. The mechanism of such action should receive attention and studies must be extended to the use of high-level ultrasound in combination with ionizing radiation.

III. Technological Applications

It has not been the intention of this review of the present status and future potential of ultrasound in biomedicine to consider various developments of a strictly technological nature. A number of these, both apparatus and nonresearch applications, have already been developed and more are expected in the future including equipment for use in basic research and for medical technology. Present examples of equipment development include: ultrasonic apparatus which produces cavitation to disrupt cells and tissues in order to free intracellular contents in a form unaffected by chemical agents, equipment for separation of layers of tissue by the use of ultrasonically induced cavitation [65] and ultrasonic blood flowmeters [66], [67]. In medical therapy the use of ultrasound at low level as a diathermy procedure might well be classified as technological in character [68], [69]. These few examples serve to indicate the range of developments that have been thus far conceived and applied. It is, of course, practically impossible to predict at any one time the specific apparatuses which will be invented for future use in research and technology. However, it does appear possible to predict investigative directions which will produce fruitful research and to indicate new fields of applications which can be expected to arise therefrom. Such has been the theme of this paper.

Concluding Statement

It is apparent from the basic research work in progress and accomplished and current applications that precisely controlled ultrasound constitutes an extremely powerful tool for the investigation and modification of structure and function in biological systems. This form of energy is particularly useful for perturbing or disrupting structure on the micro-level characteristic of biological organization. Although some of the results already achieved are rather exciting when compared with past capabilities, it is apparent that the field is in a primitive state compared to the future potential. Although it is possible at the present time to outline at least some of this extensive potential for basic biological and biomedical investigations and medical technology, its rate of attainment is determined to a major extent by the economic status of the field as decided by agencies which provide the financial support. It is to be hoped that the "socioeconomic" status of this field will soon change to permit the necessary increased support to be provided so that a major fraction of the potential now visualized is realized within this decade. A support level at least two orders of magnitude greater than that currently available to the field will be necessary in order to achieve the indicated research objectives and initiate the consequent applications during this period of time. Application of the results of the basic research in routine medical practice will require additional funds both for the acquisition of appropriate sophisticated instrumentation and the training of individuals to utilize it.

VEHICULAR COMMUNICATIONS

Organized with the assistance of the IRE Professional Group on Vehicular Communications

The History of Land-Mobile Radio Communications*

DANIEL E. NOBLE†, FELLOW, IRE

Summary—**This paper on land-mobile radio communications was prepared for the noncommunications and nonmobile radio specialist. The early pioneering work of the police is covered, and after a brief statement about the early use of mobile transmitters, the Connecticut State Police two-way FM system is described. From the introduction of FM into the Connecticut system to the present, engineering efforts have been directed toward the improvement of selectivity, the elimination of spurious responses and spurious radiation of the equipment, and in general, toward technical improvements which would make possible both an increase in spectrum utilization and an increase in channel loading. In the more recent embodiments of equipments, transistors have been used for the power supply, for audio amplifiers, and for complete receiver circuit design. While the use of single-side-band modulation and the general characteristics of random-access systems are under investigation, advantages have not been disclosed which would justify a switch from FM to some other modulation system. The efficiency of frequency utilization must be increased, and any system which offers a substantial improvement over FM will be given careful attention.**

Land Vehicular Communications

THE EARLY history of land-mobile radio communications is a history of police pioneering. The police of the U. S. have always been identified with the innovators in the communications field. As early as 1877, the Albany, N. Y., Police Department installed five telephones in the Mayor's office, connected to the precinct police stations; this was only two years after Alexander Graham Bell developed the telephone. In 1880 the Chicago Police Department installed the first police call box on the street, and three years later the Detroit, Mich. Police Department installed one police telephone, at a time when there were only seven telephones in the entire city.

In the radio field, spark transmitters were used by the New York Harbor Police in 1916 to communicate with their boats and other boats in the harbor. The Pennsylvania State Police installed point-to-point radio telegraph between headquarters and posts on 250 kc, back in 1923.

Just for a bit of perspective, remember that in 1904 Indianapolis was the automobile manufacturing center of the world, with Stutz, Marmon, Cole, National, and Dusenberg in the area, and it was during this year that the Indianapolis Police replaced the horse-drawn paddy-wagons and automobiles. The police began to use their first motorcycles in 1909, and in 1917 the Detroit Police began using automobiles with two men per car parked at police telephone booths along the streets. They did not patrol, but stayed in the booth between calls. A telephone in each booth supplied communications; a potbellied stove in one room, the coal bin in another, took care of the winter temperatures.

To a man of vision, the need for direct communication with moving police automobiles was clear. That man of vision, who refused to accept repeated failures in his attempts to establish practical radio communications with moving police cars, was Commissioner William P. Rutledge, of the Detroit Police Department. In 1921, only four years after the city pioneered the use of automobiles for police work, Commissioner Rutledge purchased a Western Electric 1-A, 500-w broadcast transmitter and installed it in police headquarters. This was before the days of crystal control, and the

unit was a self-excited oscillator-modulator combination with two WE-212D's as oscillators, and another pair for modulators, and with a 1500-v motor generator for the power supply. For a period of six years, Commissioner Rutledge and his organization tried to develop a practical system to provide satisfactory voice communications to the moving cars. Their point of failure was the receivers. They could not build receivers which would work reliably in the police cars. Both voice and radio telegraph were tried, but the basic problem of receiver instability and lack of sensitivity limited the coverage. With each new year they found new approaches, but all were failures. The accumulation of frustration became so strong that, in 1927, the station was shut down and the radio room was locked up. During the six-year period, they had also battled a merry-go-round of license changes. When the station was first opened on May 23, 1921, it operated under the amateur license W8BNE, working on 200 m. But on August 16 of the same year, the license was changed to experimental W8XAB and the wavelength changed to 375 m. In 1922 another change put it on a provisional limited commercial license KOP on 360 m, which was changed in 1923 to 286 m, again in 1924 to a Class-A broadcast station on 277.8 m, and back again in 1926 to a limited commercial license WCK on 144.8 m. Even then the peregrinations were not complete. Later in 1926 the station was moved back to 200 m with a Class-A broadcast license; it was changed again in 1927 to a limited commercial grant for Station WCK on 144.8 m. According to one of the rulings in 1922, the Detroit Station KOP was required to provide broadcast entertainment during regular hours, with the police calls interspersed as required. Finding suitable performers for the broadcast programs was difficult, and the police band was given a notable workout.

Although Commissioner Rutledge closed down the radio station in 1927, he did not give up. He was convinced that the modern automobile had given the criminal an advantage in speed that could not be overcome by the use of police cars controlled by telephone. The prohibition era of crime flourished in the nation, and big city bootleg gangs were in ruthless control; slayings and corruption paced a nationwide major increase in crimes of all types. With the automobile, the criminal could strike hard and speed away with little chance of interference from the police cars awaiting calls at the telephone police booths. Patrolling without communications was a futile exercise. Commissioner Rutledge was desperate when he closed the radio room in 1927, but he did not give up.

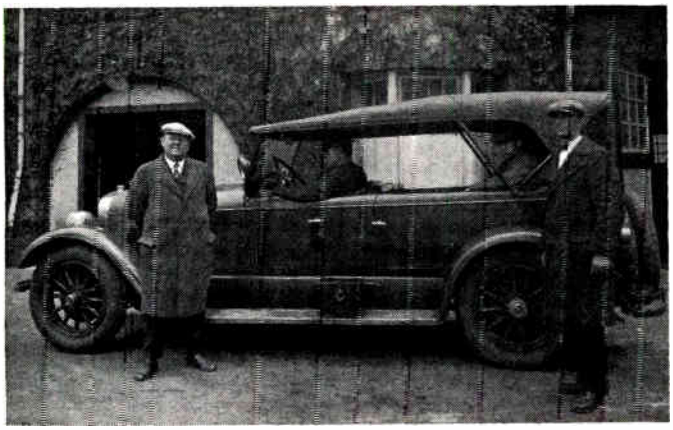
Remember that 1927 was still the early days of radio. Most home radios used B and C batteries for power and A batteries for storage, and even the car broadcast radio did not make its appearance until 1930. Short-wave radio was still 200 m, so Commissioner Rutledge was pressing the state of the art with his proposed police system on 144.8 m.

During the summer of 1927, Robert L. Batts, a young student from Purdue University, was working at a radio parts store in downtown Detroit. He developed quite a following of do-it-yourself customers who were purchasing kits to build radio sets. One of his customers was a young Detroit motorcycle policeman, named Kenneth Cox, and he and Bob Batts frequently discussed the possibility of making a radio receiver work in a police car. Batts had been using a superheterodyne receiver with a loop in a Dodge truck for tracking radio interference. To him the problem of car reception seemed simple. In the fall, when Batts went back to Purdue, he and Cox continued to communicate by mail, and Batts sent along suggestions and sketches for the construction of a police radio receiver. Late that fall, Cox went to Commissioner Rutledge and told him he could make a radio work in a police car. He had built a breadboard model thoroughly cushioned with foam rubber, and he deliberately dropped the receiver on the floor in Rutledge's office to show how rugged it was. It still worked. Cox received the assignment from Commissioner Rutledge to develop the receiver and he began a campaign immediately to entice Batts back to Detroit.

After some jousting with the Federal Radio Commission, a new construction permit was granted on February 4, 1928, to move the equipment to Belle Isle for operation on 144.8 m, and later on 94 m for the starting of new tests. Perhaps we should describe this 94-m assignment as the UHM of the early radio days.

Batts was finally prevailed upon to return to Detroit as a patrolman (that was the only way Commissioner Rutledge could pay him), to start work on the development of the new receivers. Bernard Fitzgerald and Walter Vogeler were given the job of rebuilding the Western Electric 1-A transmitter from a self-excited unit to a crystal-controlled MOPA, and Batts started on the new receiver design. The new receiver consisted of three stages of tuned RF, using the newly-available screen grid type-322, a 200-A detector, a 201-A first audio amplifier, and a 112-A output tube. Copper shielding compartments in the RF and detector sections, with locked-tuning capacitor adjustments, contributed to the electrical and mechanical stability. Heavy duty 135-volt B-batteries were used, and a 6-volt storage battery mounted on a running board provided the A-power. The A-battery drain was 1.1 amperes, and it was necessary to switch the storage batteries every four days.

Station W8FS first went on the air April 7, 1928, transmitting to a new receiver in cruiser No. 5 (Fig. 1) —and it worked! The receiver stayed tuned and reception was satisfactory all over the city. After nearly seven years of persistent effort, Commissioner Rutledge's dream had come true, and the improved communications system soon proved its value for the apprehension of criminals. The radio-equipped cruisers caught hold-up men, car thieves, and burglars, sometimes seconds after the call was reported to the dispatchers at police



(a)

headquarters. At times, the car was just around the corner or almost in front of the place from which the call originated. With this initial success to spur him on, Batts carried on an extensive program of field testing and built new and improved receivers to equip the entire fleet of police cars.

The pioneering of this early police radio system was truly the beginning of the land-mobile radio communications industry. The Detroit Police Radio System drew world-wide publicity, and visitors arrived from all over the world to inspect the system. Other city police departments planned radio systems, and like Detroit, they were forced to build their own receivers. In September, 1929, the Cleveland Police Department was the second system to go on the air with a few cars. Batts, who had moved on to Indianapolis in October, 1929, put that city police department on the air on December 24 of the same year.

There were other firsts. The pioneering record would not be complete without a brief mention of the first freight train installation. Arthur Batcheler, Supervisor of Radio for the Department of Commerce Radio Division, took part in a test demonstration April 23, 1928 on a New York Central freight train. A train consisting of a locomotive, 125 freight cars and 2 cabooses, was equipped with an experimental General Electric 50-watt radiotelephone installation to furnish communication between locomotive and caboose, or between either locomotive or caboose and the signal towers which the train passed en route. Batcheler reported, in a letter to the Department of Commerce, "The demonstration was a most successful one and communication was carried on continuously over the entire route." He also stated, "The Federal Radio Commission no doubt will have to provide channels for operation of this service, which, in the future, is destined to come into general use." For the freight train applications the problems of cost, installation, and maintenance outweighed urgency, and the work was dropped. For the police use of radiotelephone, urgency was the paramount consideration, and the number of installations increased rapidly.

The pioneering work of the Detroit City Police had broken through the barrier to successful radio communications to the police cars. Equivalent systems were established in many cities. The State Police became interested also, and on May 17, 1930, the Federal Radio Commission granted the State of Michigan the license for 5000 w on 1642-kc daytime and 1000 w at night. The Michigan State Police Station was on the air by October, 1930.

As soon as the use of broadcast transmission to police cars became routine, it became apparent that there was an urgent need for acknowledgment and talk-back. Lt. Vincent Doyle, the radio man for the Bayonne, N. J., Police Department, decided to do something about the two-way communications matter; in March, 1933, he was on the air with the first two-way police radio system, using REL AM equipment on 33.1 Mc. Four police cars were equipped. The units used superregenerative receivers and noncrystal-controlled MOPA transmitters with a pair of 210's in the final. The stations were operated on the temporary experimental license W2XCJ.

Bob Batts had not lost his pioneering spirit. In 1933 he had the Indianapolis Police Radio Division on the air with a 200-w base station and two 20-w mobile two-way units. The mobile transmitter units were high powered compared to the ones used in the initial installations in other parts of the country. Batts teamed his 20-w transmitters with 6-tube VHF AM superhets of good sensitivity, with 6-v tubes. The base station was equipped with a 100-foot antenna, and very reliable two-way communications were established despite the fact that quartz crystals were not available for either the transmitter or the receiver control. The lack of crystals and the high battery drain discouraged a further expansion of the system, even though the test results were excellent. The Indianapolis Police Department also pioneered the installation of superheterodyne receivers on police motorcycles. In 1931 there were thirty-two solo motorcycles in the Indianapolis Police Department equipped with AM superheterodyne receivers operating on 2442 kc, using P. R. Mallory vibrator power supplies. Although a few commercial receivers were available, the equipment used until 1935 in nearly all of the police radio systems was of the do-it-yourself variety—and excellent equipment it was, too, for the state of the art. Late in 1931 the Bosch Corporation offered the first commercial compact superheterodyne receiver with a separate dynamotor power supply, which eliminated the B batteries. The Sparton Company in Michigan offered receivers for a brief period. The introduction of the Mallory vibrator power supply in 1931 was an important step forward, with a resulting decrease in operating costs and an increase in reliability. RCA and GE entered the mobile radio field in 1936, with F. M. Link following, and Motorola began selling police radio receivers in 1937. As a result of hearings held in 1936, the Federal Communications Commission issued Order No. 19, dated October 13, 1937, which allocated twenty-nine VHF channels to police departments in the band 30.58 to 39.9 Mc. This order was a milestone in the development of two-way VHF police communications. The use of crystal control for both transmitters and receivers became universal, and in 1938 the FCC established the maximum allowable frequency tolerance of 0.05 per cent on frequencies above 30,000 kc.

Interest in two-way communications spread to the power companies, and in 1938 George Underhill established a system for the Central Hudson Gas and Electric Company of Poughkeepsie, N. Y. Earl Glatzel established the second system a few months later for Detroit Edison. In 1939 the FCC defined police communications as emergency service and recognized the power utilities with provisions for special emergency licenses. By then, a number of commercial brands of equipment were available, with RCA, F. M. Link, GE, and Motorola as the leaders.

Two-way VHF communications were standard for city installations, but state police were still operating on one-way broadcast systems. It remained for Colonel Edward J. Hickey, Commissioner of the Connecticut State Police, to establish the first two-way state police system in the country, and it was the privilege of the author of this paper to pioneer the system as the first police FM installation. The success of the Connecticut system started the nationwide switch from AM to FM.

The details of the Connecticut State Police FM radio system design may be found in the November and December, 1940, issues of *Electronics*. The shift from AM to FM was a radical step, but the use of FM, or more properly PM (phase modulation), in the Connecticut system only partially accounted for the success of the system. In nearly all city two-way AM installations, the base station transmitters and receivers were located at the most convenient spot, which was usually the City Hall or some other police-controlled facility. An ambient noise level at the base station receiver sometimes reached several microvolts, and only strong signals from the mobile transmitters could get through. For the Connecticut system, each tentative base station location was checked for noise level, and a test run was made with a mobile unit maintaining communications with a temporary base station installation. The optimum location was picked for both low noise level and high elevation, and telephone wire connections were provided to control the station from the barracks radio dispatch office.

It would be obvious to any engineer that the best place for the mobile antenna would be in the middle of the rooftop of the automobile, and so, to gain maximum communications range, this was the location selected. Tapered steel-tubing fishing rods were purchased and mounted on a spring held in place by a molded collar. Coaxial cable connected the antenna to the transmitter and receiver in the car trunk. This combination of the selection of low-noise and high-elevation base station locations, and the use of efficient mobile antenna installations assured the success of the system. While good coverage would probably have been achieved with AM, the unique capture effect of FM made it possible for ten individual police-troop base stations to operate simultaneously on the same frequency assignments without significant interference. Two frequencies were used, 39,400 kc for the base station transmitter and 39,180 kc for the mobile transmitters. The use of two frequencies was a unique approach, designed to make it unnecessary for the low-powered mobile transmitters to compete with the adjacent area 250-w base stations transmitting from high antennas. To provide car-to-car communications, provisions were made for switching extra crystals into the mobile transmitters for operation on the base station frequency. Since there was only a difference of 220 kc, the switch could be made without retuning the transmitter and with only a nominal loss of power. As a practical matter, it was found that the adjacent base stations could go on the air simultaneously, and each base station would capture its own mobile stations. Where there were exceptions to this rule in the case of a preferred transmission path existing between the mobile unit and the opposing station, it was only necessary for the mobile unit to move along slowly and stop on the peak of the standing wave to capture the desired station. In general, it may be said that each base station operated as an independent system; but that every base station was capable of communicating with every other base station, and of taking over communications with the patrol cars in an adjacent area when a base station failure occurred. This two-frequency, three-way design provided flexibility for state-wide communications with generous factors of safety and with a minimum of equipment complexity. An alternate system using individual frequencies for each area either would have eliminated interarea communications, making it impossible for a car to switch from one base station to another as it traveled across the state, or would have made it necessary to equip each car and base station with complex multichannel equipment.

The major virtue of the use of phase modulation in the Connecticut system was not the wideband FM noise-reducing characteristic which is usually identified with the FM broadcast service. The virtues of FM noise reduction are realized only when the signal exceeds the noise level, but in the mobile communications systems, the chief noise and the most serious noise limitation are produced by the radiating automobile ignition systems. The ignition-pulse interference nearly always exceeded the signal level and, at times, pulses would reach peak values several hundred times greater than the level of the desired signal. Each pulse would take over the limiter temporarily and, in effect, would gate the receiver for the duration of the pulse. This was an inherent brute-force pulse noise suppressor, and it outperformed the pulse noise gates sometimes used in AM receivers. In fairness, it should be stated that there existed one AM pulse noise suppressor system which followed the envelope of the received modulated wave and cut the pulse at the instantaneous amplitude of the associated wave. With this envelope-following pulse clipper, an AM receiver offered competition for FM in the one category of ignition noise suppression. There were, however, other important attributes of the FM system which combined to outclass the general performance of AM for mobile communications. It was often necessary to maintain communications with very weak signals. With the AM system, the moving car passing through the standing waves would produce a flutter of modulation as the signal dipped from a usable level to an unusable level. It seemed impracticable to design the AM receiver with time constants necessary to control the distortion caused by the rapid changes in the radio and the subsequent audio signal levels. With FM the audio volume was not a function of the signal level, and as a result the standing-wave modulation produced some noise flutter as the signal dipped below the reception level, but the standing-wave modulation would yield readable signals where communication was lost in an equivalent AM system. The sensitivity of an FM receiver could also be maintained at a very high level with generous factors of safety to compensate for tube aging and for circuit detuning. With a limiter functioning normally at $\frac{1}{4}$ v, it was possible to design a receiver which would amplify the front-end ambient noise to 15 or 20 v at the limiter. Tube aging and circuit detuning could reduce this limiter voltage substantially with no apparent effect upon the reception performance. Perhaps the final point of advantage of FM over AM was the superior squelch system. The AM squelch consisted of a simple gate which would be opened when the received signal was strong enough to trip the blocking voltage on the grid of the audio amplifier. Unfortunately, the receiver did not recognize the difference between noise energy and carrier energy, so that a strong noise would also open the squelch. The police officer in the car would understandably adjust the squelch so that the noise would not open it, and as a result the sensitivity of the receiver would become the rather low sensitivity of the squelch control. The FM equipment employed in the Connecticut State Police system was manufactured by the F. M. Link Company and was, in general, an adaptation of high-quality AM standard units but with the necessary change-over to FM to provide increased gain with an effective limiter and a frequency detector, but the squelch system used was the same as that employed in the AM equipment.

When the first Motorola FM mobile communications equipment was designed, a new squelch system was introduced, which became the standard of the FM industry. This circuit, which became known as the "differential squelch," balanced the voltage change produced by the characteristic FM noise reduction in the presence of a carrier, against the voltage resulting from the rectification of received noise. With this arrangement, the squelch would open with a very-low-level signal (0.15 μv) when there was little noise present, but as the noise increased, the signal level required to open the squelch also increased. The system was so balanced that the loudspeaker would always be activated at a signal-to-noise ratio so low that the voice was unreadable. With this squelch system, noise bursts would close, rather than open, the squelch gate, and the sensitivity of the receiver was no longer limited by the sensitivity of the squelch. A further receiver design refinement substantially increased the effective sensitivity of the receiver by decreasing the inherent first mixer noise. The final receiver design could provide excellent communications in low-noise areas with a signal input voltage of less than $\frac{1}{2}$ μv. A signal generator input to the receiver of 0.4 μv would produce a 20-db receiver noise reduction. The receiver squelch system, the high sensitivity, and the reserve gain were the keys to the extended range and the reliability of performance made possible when the equipment was used in systems with the base stations installed at high-elevation and low-noise-level locations.

The mobile transmitter designs were straightforward, with a crystal oscillator feeding a modulator, which, in turn, activated two quadruplers, a doubler, and a final amplifier. Perhaps it should be noted that, with the PM transmitter using the same power amplifier tube as that used for AM, the average power could be increased to a value approximating the peak power of the AM output, or to maximum tube rating. The 20- to 25-w AM transmitter became a 35–40 w FM transmitter, with an 807 tube in the final amplifier. Two tubes in the final amplifier and an increased power supply provided a 50- to 60-w output with no modulator change.

The first FM two-way mobile communications installations were characterized by exceptional reliability of communications and exceptional range of communications as compared to the usual AM installations.

In the early days of FM equipment design, the receiver selectivity was wide open, with an IF selectivity 50 kc wide, 6 db down, and 200 kc wide, 60 db down. The receiver's spurious and image responses were only 40 or 50 db down. The deviation of the transmitter was uncontrolled, with a modulation sensitivity varying all the way from 18 kc to 45 kc for the same signal input. The final test for modulation was a voice test with a microphone, and the deviation was not measured. The spurious radiation of the transmitters was practically uncontrolled, with substantial spurs radiating interference. These faults, however, were important only in a crowded spectrum and they did not limit or interfere with the performance of isolated systems. In 1940 there were only a few thousand transmitters on the air, and interference was not a major factor, but by 1948 the number had grown to 86,000 transmitters, with a leap to 695,000 in 1958, and the number projected for 1963 is 1,390,000 transmitters. The technical history of mobile communications equipment design since 1940 is a history of development to improve the efficiency of spectrum utilization.

While the police pioneered the development of the first practical mobile communications system, the engineers of the radio communications industry carried out a continuous program of refining the equipment design to increase the spectrum loading. As spectrum crowding developed, bringing with it the inevitable interference problem, the needed reduction of transmitter spurious radiation, the reduction of receiver spurious responses, and a substantial improvement in receiver selectivity followed rapidly. Additional refinements reduced the transmitter noise, introduced instantaneous deviation control, and provided receiver design to minimize desensitizing and intermodulation interference. Without going into laborious detail, a look at the specifications for modern "transistorized" units will partially define the progress which has been made.

General

Two-Way Mobile Radio Station: single case ($3\frac{1}{4} \times 13\frac{3}{8} \times 17\frac{1}{2}$ inches; 29 pounds).

Transmitter

Power Supply: Transistor oscillator type "dc transformer."

Power Output: RF 30 or 50 w, 40 Mc; 25 w, 160 Mc.

Transmitter Spurious: More than 85 db below carrier.

Frequency Stability: ± 0.0005 per cent of assigned frequency. $-30°C$ to $+60°C$ with $+25°C$ reference.

Modulation: As specified, ± 5 or ± 15 kc for 100 per cent at 1000 cps.

Circuits and Multipliers: Phase modulator and deviation control; doubler; tripler; doubler-driver; power amplifier.

FM Noise: -50 db below ± 3.3-kc deviation at 1000 cps.

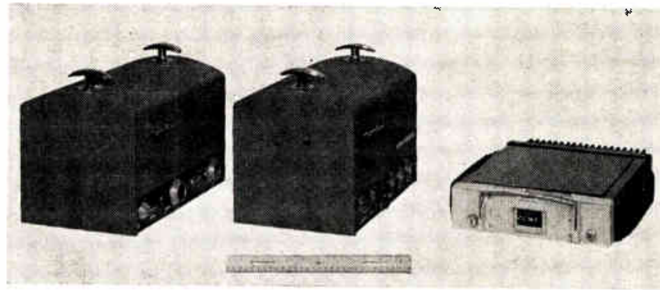

Fig. 2—1940 separate FM transmitter and receiver "breadloaf" packages compared to the 1961 single-packaged transmitter-receiver with transistor-type receiver.

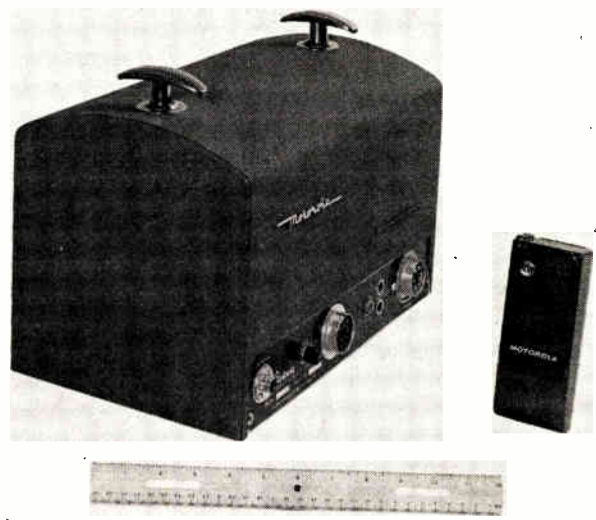

Fig. 3—1940 receiver compared with the equivalent 1961 transistor-type receiver, which is complete with speaker and battery supply.

Fig. 4—Quarter-wave cavity selector used for base station control of intermodulation and desensitizing in the 160-Mc band.

Receiver

Selectivity: -100 db at ± 15 or ± 32 kc, as specified.
Channel Spacing: Designed for original 40- or 60-kc spacing and, for split channels: 20, 30, 40, or 60 kc.
Sensitivity: Depends upon frequency, etc. 0.3 μv to 0.6 μv for 20-db quieting with 50 ohms of RF input impedance.
Stability: ± 0.0005 per cent of reference over temperature range -30 to $+60°$C.
Squelch: Noise compensated. Threshold sensitivity, 0.15 to 0.25 μv. Also tone-coded squelch available.
Audio Output: 5-w to 3-ohm load.

Of all the problems which have limited spectrum loading, desensitizing and intermodulation have been the two most difficult to control. The design of 455-kc IF selectivity providing 100-db protection at the edge of the channel was readily accomplished, but desensitizing and intermodulation are related to receiver front-end RF rather than IF selectivity. A mobile unit parked in the shadow of an opposing or undesired station may attempt to receive a 1-μv signal from its parent base station. Since the opposing station, which may be on a frequency several channels removed from the desired channel, can pass signals through the acceptance band of the RF section of the mobile receiver, this high signal level can blank out the desired 1-μv signal from the distant station even though the nearby station cannot be heard because of the tight IF selectivity. In a somewhat similar pattern, two nearby transmitters, radiating strong signals on, for example, the second and third channels removed from the referenced desired signal, can mix in the front end of the receiver to generate a mixing product directly on the frequency of the desired signal, and strong enough to wipe out the desired distant station signal. The only immediately apparent solution to such interference problems is RF selectivity comparable to that obtained in the IF section of the receiver, but of course, at 50, 100, and 450 Mc, this is completely beyond the art. By stressing the linearity of the RF amplifier circuit design and by resorting to multicircuit high-Q front-end filter stages, the engineers have provided a modest 65- to 70-db protection.

Particular cases of interbase-station interference problems were solved by the use of very-high-Q quarter-wave cavities. Obviously, such cavities were too large for mobile station use and even this radical approach failed to provide the 100- to 150-db adjacent-channel protection necessary for adequate spectrum loading. While the use of cavities in the receiver base station front-end design did not offer complete solutions, it did increase the efficiency of spectrum utilization and solved many specific problems which developed as new systems were added in crowded areas. Fortunately, the recent introduction of the varactor and its promised application to the up-converter and down-converter circuits offers a potential solution to both desensitizing and intermodulation, with the expectation that the needed 100- to 150-db protection may be achieved in the future.

Spectrum loading for maximum utilization is a three-dimensional problem involving frequency, space, and time. Frequency division has been the traditional approach to radio spectrum utilization. The available channels may be increased by narrowing each channel so that radio systems are operating with less frequency separation. The original FCC rule making established 40-kc bandwidths for the 25- to 50-Mc band, 60-kc bandwidths for the 148- to 162-Mc band, and 100-kc bandwidths for the 450- to 470-Mc region. Subsequent channel splitting changed these bandwidths to 20 kc, 30 kc, and 50 kc, respectively. With the development of intermodulation and desensitizing protection of 100 db, or greater, channel splitting to 15 kc for the 160-Mc band, and 25 kc for the 450-Mc band, may be expected to provide additional spectrum loading.

As the bandwidths are narrowed, the automobile ignition-pulse-noise interference in the lower bands becomes a limiting factor for systems range. The inherent pulse-noise suppression characteristics of FM receivers employing 40-kc and 60-kc bandwidths made the use of additional pulse-noise receiver gates unnecessary, but with the split channels, especially in the 25- to 50-Mc band, the range of communications is decreased by the ignition noise and the effectiveness of a system can be restored only by the use of a self-gating pulse-noise suppressor. These pulse suppression systems are beginning to be used in industry, and a typical application may be found in the Motorola low-band transistor receivers which utilize the following straightforward design: While the pulse is delayed by a line section in the front end of the receiver, a parallel circuit amplifies and shapes the pulse for use as a gating signal which temporarily blanks the receiver input at the instant of the arrival of the opposite-number delayed pulse. Since we are dealing with pulse durations of a few microseconds, the receiver gate may be closed for the duration of the pulse without destroying the intelligibility of the voice transmission. In actual tests, with weak signals and with strong high-repetition rate ignition-pulse noises completely destroying the intelligility of reception, the activation of the pulse-gating system reduced the noise to such a degree that voice intelligibility was restored. It may be said in general that the increase of spectrum loading by splitting channels to narrower bandwidths results in a degradation of the signal-to-noise ratios of the operating systems. The use of effective pulse-noise-gating circuitry becomes necessary to substantially restore both the range and the quality of reception.

While the development of the land-mobile communications systems has been almost wholly concerned with the use of FM or PM, tests have been carried out to explore the potential of both single-sideband and random-access systems for this service. There are two major disadvantages to the use of single-sideband in mobile applications:

1) The complete suppression of the carrier is not at present practicable because of the problem of generating restored carrier in the receiver within the tolerance requirements for low-speech distortion. The necessary maintenance of the locally generated carrier at ±30 c at 150 Mc would demand design tolerances which, at the very least, are beyond the economic tolerance of the industry.
2) Single-sideband reception cannot tolerate ignition pulse-noise interference. The range and performance of ordinary single-sideband systems in comparison to ordinary FM systems is inferior to the point of unacceptability without the use of some form of single-sideband pulse-noise suppression.

Obviously, both objections may be limited by the extension of the art. The vestigial carrier can be transmitted with the sideband to synchronize the local receiver carrier generator. It is also possible to establish community carrier-frequency reference transmitters which would be used to provide the synchronizing frequency for the restoration of the carrier in all receiver systems operating in the area.

The ignition-noise problem is a temporary problem, since a normal development of the automobile may be expected to eliminate such noise-making transmitters; but in the meantime, it is feasible to equip single-sideband receivers with pulse-noise suppressors which will bring them into performance competition with FM receivers.

There seems to be no information about the equivalent of the flutter noise (standing-wave modulation effect) as applied to single-sideband systems.

One significant advantage of the use of single sideband transmission should be stressed. It should be obvious that, because of the reduced average power transmitted, potentially interfering intermodulation products will be greatly reduced.

So far, there has been no strong trend in the mobile industry to move toward single sideband, because the equipment is, in general, more costly, more critical in terms of adjustment and maintenance, and without substantial advantages within the present art for either improved performance or for increased channel loading. This is not the final word, however, and the pressure for radio spectrum space may eventually force the development of systems which may be operated without interference and with no more than 5-kc channel spacing. It should be noted in passing that the generation of many single-sideband channels properly coordinated can be accomplished at a given base station; but by the very nature of the mobile station, each car installation must be regarded as a separate and isolated system, thus limiting the use of such multiplexing to the fixed stations.

While the single-sideband approach to increased channel loading will be scrutinized constantly by the mobile radio industry, a second approach of interest is the wide-band time-sharing system sometimes referred to as the "random-access" system. At present, the application of the random-access discreet address system seems to have more potential interest for military communications than for use as a substitute for the FM police and industry communications systems. In the random-access approach, each transmitter sends short pulses which carry both the voice and the essential coding. Simultaneous conversations in the same spectrum band are possible because each transmitter has a relatively low-duty cycle transmitting the short pulses, and different transmitters share time on the same channel. Since the transmitters are not synchronized, there will be occasional coincidence of pulses. To minimize the resulting interference, the pulses from each transmitter are coded to particular receivers, so a receiver recognizes only the pulses addressed to it. The coding, or addressing, is accomplished by using redundant transmission, with each single transmitting pulse replaced by several pulses which carry the same modulation, but which are transmitted on several carrier frequencies and/or in different time slots. A receiver may have a fixed address, and a transmitter may have a variable code so that it can change the address to reach different receivers. The required bandwidth for a single RF channel is somewhere between 1 and 10 Mc, depending upon how many simultaneous talkers are to be accommodated in a given communication system. The maximum permissible number of simultaneous messages per Mc depends upon the selected modulating and addressing scheme, and on the geographical distribution of the stations. Several simultaneous messages per Mc may be possible. In a wide band-system, three or four hundred stations might find it possible to operate simultaneously, providing instant communication to associated addressee mobile units. The random-access approach substitutes time division for frequency slicing. Since we are now reaching frequency division limits which make it difficult to achieve improved efficiency through the use of further frequency slicing, the potential for increasing efficiency of spectrum utilization offered by other systems approaches must be thoroughly explored. It is too early to evaluate the competitive significance of random access and other similar time division systems for industrial and special mobile service applications, but the use of such systems would seem to be limited to special operational requirements of the type encountered in military operation.

In the frequency, time, and space dimensions of radio spectrum communications loading, there is the time factor which involves the time on the air for any transmitter as a factor independent of any modulation system used. The taxi radio dispatch service has succeeded in maintaining high-channel loading by operating systems which share time on the same channel. It is probable that the effectiveness of channel time-sharing could be greatly increased by the use of automatic selection and lock-out techniques to insure the protection of the station using the air. Either carrier control or wire line interconnections could be used, with proper monitoring by a computer memory and logic system to provide for an equitable distribution of time on the channel for the sharing systems.

The third dimensional factor, space, is concerned with a balance of many elements associated with the problem of geographical separation as a means for allowing channel assignment duplication without interference. It is obvious that elevation, antenna height, radiated power, tropospheric and ionospheric transmission, and FM capture-effect are all pertinent to the influence of space upon channel loading. Of the factors mentioned above, the FM capture effect has contributed the greatest positive force for permitting channel duplicate assignments with a reasonable geographical separation between systems. Unfortunately, the FM capture effect is reduced as the channel width is decreased; and while there is a gain in the total number of channels available for assignment, there is a loss in the number of duplicate installations for a given area because of the necessity for increasing the geographical spacing between systems operating on the same channel. Until adequate protection is provided against intermodulation and desensitizing, the splitting of channels may not add as many interference-free systems as might be possible with the wider bandwidth assignment in areas where modest geographical separations permit same-channel operation.

The single-sideband system does not provide a capture effect, but where the carrier is eliminated, the radiated energy follows the random surges of energy radiation which is characteristic of voice communications, and the average interfering power radiated is low. It would be expected that compared to the equivalent performance of a pair of FM systems, single-sideband systems operating on the same channels would cause less intelligibility-destroying interference. Every proposed new system of modulation displays both advantages and disadvantages. Until there is some *substantial* advantage in the use of the frequency, time, and space dimensions for one mobile radio modulation system over all others, there is very little incentive for changing the present FM pattern of systems design.

The change from AM to FM did not alter the physical characteristics of mobile equipment significantly. The transmitter was still a combination of frequency multipliers and a power amplifier, with the phase modulator substituted for the amplitude modulator. The receiver became a double-conversion superheterodyne with RF and IF amplification, but with the addition of limiters and a frequency detector which differentiated it from the AM unit. The first major construction change came with the adoption of the single-chassis construction for both transmitter and receiver, as opposed to the earlier approach where the transmitters and receivers were separate units. The single chassis reduced the size of the equipment, but perhaps the real advantage was the reduction in manufacturing costs.

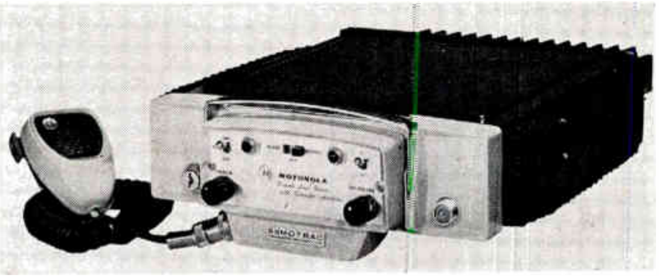

Fig. 5—The 1961 mobile FM station with transistorized receiver and power supply.

The most radical change in equipment construction came with the application of the transistors and solid-state diodes. The first application of transistors provided a power amplifier for the receiver output to increase the audio level. High audio level in police cars is particularly desirable because of the necessity for overriding the wind noise produced at the time of a high speed chase.

The second solid-state application was the use of transistors in a power supply oscillator circuit to step up the 6- and 12-v battery supplies to the high voltages required for receiver and transmitter operation. Both the transmitter power amplifiers and the transistor power supplies proved to be more reliable than the tube, vibrator, and motor generator equivalents. Size, weight, heat, and cost reduction were additional bonuses realized as a result of this application of solid-state devices. The present trend is toward the greater use of transistors in all mobile and portable equipment. There has been a complete change to transistors for both receivers and transmitters used in some portable applications. For the mobile units, the change-over has provided complete receivers with transistors and with no tubes, but the lack of high-power transistors for VHF amplification has limited the application to transmitter design. The use of transistors in the receiver has made additional reduction in the equipment, heat, size, and weight possible. Reports from the field, concerning the maintenance of new equipment built with transistors, show a substantial improvement in reliability over the record established with tube apparatus. The trend toward the utilization of transistors in equipment design will continue, and transistors will be applied to transmitter construction as soon as transistors with the needed high-power output characteristics become available.

The common carrier land-mobile radio service, pioneered by AT&T in 1946 with the St. Louis installation, has always used selective calling, which has also been available for use in the private systems. While the squelch provides protection against noise, it does not provide protection against unwanted carriers on the same frequency. Although selective calling would provide such protection, it also tends to slow down the operational response characteristics of the system, and for this reason, many systems owners have rejected selective calling. In operations where speed is less important, the use of selective calling has been discouraged by the substantial additional cost of the required accessory equipment. A compromise approach has been the use of selective squelch or tone-operated squelch. When the selective squelch system is used, the base station is equipped with a coded tone, usually operating at a subaudible level for the system, and the squelch systems in all of the associated mobile units will open only when activated by the base-station coded tone. The system requires that squelch code tones be allocated to avoid duplication in any given area. In the taxi service particularly, the use of coded squelch has been found to eliminate a high percentage of the unwanted and unrelated voice communications from other systems operating on the same channel. The coded squelch is a means for increasing the practicability of channel time-sharing.

While this paper has been primarily concerned with the pioneering work of the police and with the technological history of the land-mobile radio telephone systems development, the story would not be complete without some mention of the rule-making established by the Federal Radio Commission and, later, by the FCC, and of the qualification of new users and the growth of the land-mobile radio communication industry. The first rules in the format as we know them today (Part 10—Emergency Radio Service, and Part 11—Miscellaneous Radio Services) were adopted October 3, 1933, by the Federal Radio Commission. The FCC was established in 1934. The definitive standards for FM in the land-mobile services were not adopted by the FCC until it implemented the Atlantic City International Treaty of 1947, which was ratified by the U. S. on June 18, 1948. These technical standards were the same as those incorporated in our present-day rules up to the time of the split-channel rule-making proceedings of 1958. The 1948 rule-making established the land-mobile services on a fully licensed basis, extended the qualifications for licenses to many new users, and in general, established the foundation upon which the modern mobile communications industry has grown. From the original tentative allocation of frequencies for special emergency service, formal licensing has been extended to include, in addition to the public safety radio services, such services as land transportation, industrial radio, common carrier, and citizens band.

The continuing substantial expansion of land-mobile radio communications is inevitable. The EIA report on, "Private Land Mobile Systems in the United States," June 5, 1961, predicts that there will be 1,390,000 transmitters in service in 1963; 2,650,000 in 1968, and 5,000,000 in 1978. Both increased spectrum allocations and the use of new spectrum-stretching techniques must be adopted if growth is to be accommodated without an associated rise of interference to intolerable levels. Fortunately, the mobile radio engineers will have problems to keep them busy until 2012 A.D.

Future Developments in Vehicular Communications*

AUSTIN BAILEY†, FELLOW, IRE

Summary—**Starting from current trends in the field of land mobile radio-telephone services, primarily in the United States of America, forecasts of development over the next ten to twenty years have been made. It is estimated that by 1970 there will be two and a half million mobile telephones in the United States and over thirteen million by 1980. There is a discussion of the interrelated political, economic and engineering factors which will affect the future of vehicular communications. To meet user needs, coordinated broad-band systems are predicted for use cooperatively and on a common carrier basis with great efficiency of spectrum utilization. Currently, a broad-band system of 1000 channels could be accommodated in about 75 Mc of contiguous frequency spectrum in the lower part of the UHF band. It is conceivable that within the next two decades many more channels could be accommodated in a given bandwidth. Reducing the cost of mobile telephones is both necessary and capable of attainment. Pocket-size for a mobile telephone is indicated as probable during this period. New features for user convenience and better systems performance, such as full-duplex operation, push buttons for signaling, improved frequency stability, automatic channel selection and mobile station identification are predicted in coordinated systems within the next twenty years.**

Introduction

VEHICULAR communications include signaling and talking to or from vehicles which move on land, swim in water, or fly through the air and even in outer space. The only available means for connecting with vehicles is radio. If vehicular communications are to develop and expand, adequate provision in the limited spectrum available for all communication purposes will have to be made. It seems self evident that those regions in the radio spectrum best suited to vehicular communications and presently employed for other kinds of services soon will have to be made available to meet the demand of a people who are more and more a mobile population.

A discussion of the future of vehicular communications might properly include all the many ways of transmitting information and the adaptation of these ways to all kinds of vehicles. By far the largest number of mobile communications, however, are by telephone with and between vehicles traveling on land. Therefore, the scope of this paper will be limited to a discussion of telephone communication with land vehicles.

Looking toward what is yet to come always requires a glance backward to obtain perspective. We are living quite literally in the presence of an explosion of knowledge. It seems prudent to consider in this paper only those future developments which may be expected in the next ten to twenty years.

* Received by the IRE, June 26, 1961.

" . . . what's past is prologue;"

Public safety agencies were the first to find a real need to communicate with land vehicles. At first the communications were sent only one way. As the technology advanced and the use of somewhat higher frequencies became feasible, radio transmitters began to be installed in automobiles. The first two-way mobile telephone system for a police department was placed in service about the middle of 1933. By the end of that decade there were about 10,000 radio transmitters in police cars—all of which employed amplitude modulation.

About the middle of the 1930's, Edwin H. Armstrong made a discovery which was destined to change completely the techniques employed for land mobile radiotelephony. Although first applied to entertainment broadcasting, the impact of frequency modulation has been even greater in land mobile services. At the beginning of 1940, the Federal Communications Commission announced that it would accept applications for use of FM in services other than broadcasting. This was the beginning of a new era in land mobile communications. So valuable was FM in this type of service that within the period of only six years, substantially all transmitters were FM. FM not only reduces noise but helps reduce co-channel interference, signal flutter and variable intelligibility within the coverage area.

Beginning in 1945, with about 18,000 land mobile transmitters in service in the United States, the number has almost tripled every five years. Statistics from France indicate that the number in service there is doubling about every five years. Along with this phenomenal growth there have been advances in techniques resulting in lower costs, increased reliability, decreased weight and size, and generally improved attractiveness. But there have been few changes in the type of communications in the last decade from the standpoint of the user. Whether he is telephoning on a private system or employing the service furnished by a common carrier, this service is still largely one of dispatchers or land telephone subscribers talking to people in cars and trucks whenever these people happen to be in the right vehicles and within range of an associated base station. While it is true that technical advances have resulted in more satisfaction to the user because of reduced maintenance, lower battery drain and less channel sharing as a result of split-channel operation, something more than this is needed to make the service as convenient and valuable as is desirable. This will be discussed later.

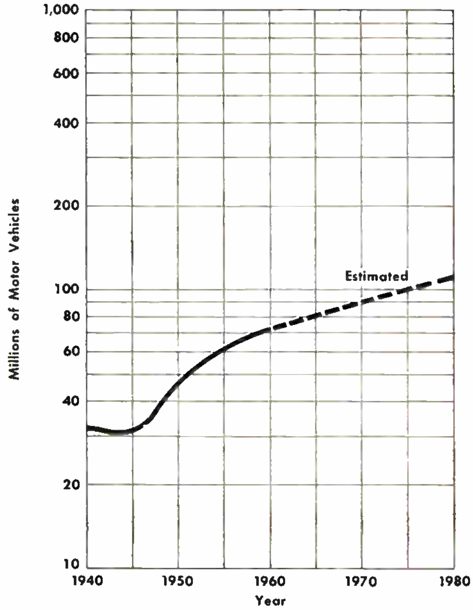

Fig. 1—Millions of motor vehicles registered in the United States based on Automotive Manufacturers Association data and the projection to 1970 made by General Motors Corporation.

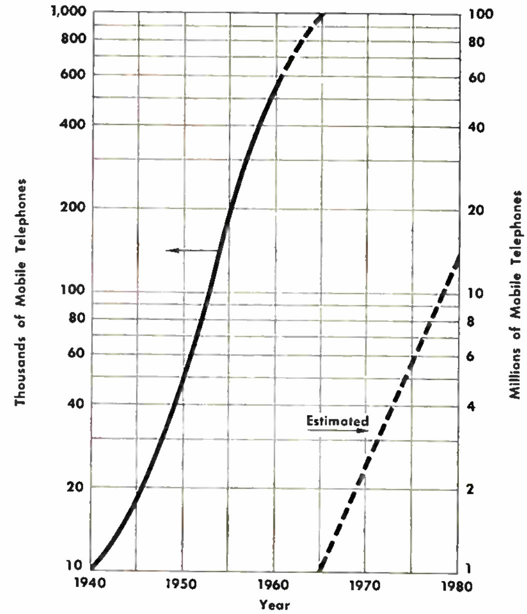

Fig. 2—Thousands of mobile telephones in the United States based on FCC annual reports and EIA projections to 1970.

" . . . what to come, is your and my discharge."

What kind of a world will it be in the next ten to twenty years? The world population at present is multiplying about four times in every 100 years. In the United States the rate, including immigration, is even greater—about fourfold every 70 years. The 1960 census in the United States counted some 179,323,175 people. The U. S. Census Bureau estimates that this figure will be about 203,000,000 in ten years and by 1980 about 231,000,000. Along with such a growth rate has come a substantial decentralization of industry and a redistribution of urban population into suburban and country areas. This is possible today because of the extensive communications network now available. The trend will certainly continue and means of communication will have to keep pace with the times.

Another change in the pattern of living in the United States is that individuals are increasingly on the move. This is apparent in the growth of annual passenger miles by public transportation and in the increase in the number of vehicles registered in the United States each year. Both of these are increasing at a rate greater than the rate of population increase. Fig. 1 shows the present growth rate in the number of vehicles registered in the United States to be about fourfold in forty years. However, it is estimated that this rate of growth will not continue but will gradually decrease in the next two decades. In Fig. 1 it is estimated that the total number of vehicles registered in 1970 will be about 90 million and in 1980 about 102 million. Logarithmic presentation is used because the slope of the curve indicates a growth rate independent of the numerical value of the ordinate. (Fig. 2 is on the same scale.)

With population, extra-urban development, mobility of individuals, the convenience of communications and the number of motor vehicles all increasing at astounding rates, what will be the growth in the number of land mobile telephones in use in the United States at the end of the next ten and twenty years? The answer to this question depends also on many political, economic and technical factors, and all of these factors are interrelated. Currently, in this country there are about 70,000,000 land telephones and only about 700,000 mobile telephones. It is estimated that by 1970 there will be about 2,500,000 mobile telephones in use and by 1980 over 13,000,000. Fig. 2 shows an estimate of the growth in the number of mobile radio transmitters used in the land mobile services.

Political Considerations

Nature has provided a limited frequency spectrum suitable for mobile services. Because this limited space is one of the natural resources, it is and should be controlled by government. There has to be a proper balance between the values of various services in the assignment of this frequency space. Furthermore, each service must be efficient in its use of frequency space.

There are a number of ways in which better use could be made of the frequency space available. Sharing, both geographically and on a time basis, is employed somewhat in services with similar characteristics such as those in the various categories of land mobile services. In the frequency range above 50 Mc a great deal more could be done.

Already there is substantial geographical sharing in the 150-Mc band; probably the greatest application of this has been in the common carrier services. To the extent that it proves useful, it is to be expected that computers will be used to determine the geographical distribution of frequency assignments. Data on the interference range of existing stations will be stored in the memory of these computers and new systems will be engineered in on the basis of noninterference with existing systems.

Time-sharing is already in use to a limited extent among those stations in the same classes of service where the time-value of information is not too critical. There is no doubt but that more of this is possible. However, a great deal will be accomplished when the load factors of different types of services are taken into account. As an example of this, many of the land mobile services which are employed primarily for commercial purposes have load factors with high peaks during certain hours of the business day and very small demand during the evening and night periods. On the other hand, the audiences for broadcasting and television are smaller during the business day and much greater during the evening hours. It seems self evident that in the not too distant future there will be time-sharing of frequencies by different classes of services.

Engineers have accomplished much to alleviate the regulatory problems. In the mobile services, improvement in techniques have already enabled channel assignments to be placed more closely together. In the 30- to 50-Mc region, channel spacings in the United States have been reduced from 40 to 20 kc. In the 150- to 160-Mc range, channel spacings are currently 30 kc in the same geographical area and 15 kc in adjacent areas. The region between 450 and 470 Mc has also been reduced to 50-kc spacing, and a further split to 25 kc is proposed.

The consensus of engineering opinion at this time is that little more can be accomplished in the way of channel splitting in this general frequency region with the present individual channeling plan. The most promising solution is the general use of broad-band systems. With such systems, a plurality of voice communication channels from a common base station is possible with freedom from the coordination problems present with large numbers of individual channels. Accordingly, they would probably be operated by common carriers for service to many categories of users. A broad-band system which has been proposed and awaits only governmental approval contemplates up to 1000 channels, in up to about 75 Mc of frequency spectrum in the lower part of the UHF band. This system gives each call access to a group of these channels, and this greatly improves the efficiency with which channels are utilized. This *group operation factor*, or the gain in message handling capacity obtained by having access to a group of channels rather than to only a single channel, depends on a number of variables such as calling rate, holding time and the allowable average delay or permissible probability of delay. It can amount to a fourfold increase where access is provided to somewhere in the order of 5 to 10 channels. Probably, the broad-band system will embody access to a larger number of channels for greater efficiency.

To obtain even greater channel utilization for mobile telephone frequencies in densely built-up metropolitan areas, a cellular plan for broad-band systems has been proposed. This plan contemplates the use of a considerable number of low-power base stations with quite limited coverage from each. By this arrangement it would be possible to utilize the same frequency assignment simultaneously for several conversations in the metropolitan area. Of course, to make this plan effective electronic switching associated with memory circuits will be essential to maintain continuity of the telephone connection while a conversation is in progress.

Early construction of and experience with the proposed broad-band systems, together with advancements in several phases of the art over the next two decades, could lead to further improved spectrum utilization. It is possible to envision a 4-Mc band of spectrum providing about 250 two-way telephone circuits which, with utilization of the group operation factor, might give service equivalent to that of more than 1000 individual channels today.

As a further step in making greater message-carrying capacity available, digitized voice transmission, or some other new and better method of transmitting the intelligence in speech on a reduced bandwidth, may come into general use. Such a new development might result in a further increase in channel availability of over tenfold.

Economic Considerations

The mobile telephone user needs an equipment which is not only low in first cost but also one that will require low maintenance. Transistorization may lead to units with these characteristics in a few years. However, low cost and low maintenance are not the only features needed. Attention will be directed later to other changes from present practice to improve system operation or to increase the user's convenience. All of these improvements will require extensive development work in this mobile radio field.

Development costs are bound, in one way or another, to become a part of the price of the equipment. Only if good mobile telephone equipment can be manufactured in sufficient quantity will the price be low. Automated manufacturing methods tend to reduce the cost of fabrication, but the tooling expense is considerable. Tooling costs for automatic production prove in only when the quantity to be produced is relatively large. Both the development and manufacturing costs, on which so much of the price to the user depends, will be reduced only if there is assurance that a market exists for the product.

At present, installation costs for mobile telephones in cars are material. They add to what the user must pay to get a telephone in his vehicle. There are two approaches to the reduction of this item of expense. The first approach will most certainly be factory installation of the mobile telephone as an accessory in the motor vehicles. This alone would reduce the installation cost to about a tenth of the present figure. There seems to be no valid reason why this should not be done now in fleets of cars for private systems and in automobiles for users having a need for telephone service through the common carriers.

The other approach one may estimate will probably materialize in the period between 1970 and 1980. With subminiaturization, the mobile telephone may become more an item of apparel than an automotive accessory. However, motor vehicles may well be factory equipped with standardized arrangements to carry the mobile telephone when it is to be used in an automobile. A radiotelephone *holster* will provide connection to the car battery and connection to an antenna installed on the automobile. Moreover, it may provide additional features.

From the point of view of economics, mobile telephones will have to be removed from the class of luxury items and become commonplace tools of industry. Certainly, the user will be willing to pay more for access to mobile communication facilities than to fixed ones, but how much more? That all depends on the value the potential user places on the mobility factor in communications. Proportionately more people will prove interested in mobile telephones as the costs trend toward those of telephones in fixed locations. However, it is likewise a proven fact that more people will want mobile telephones as convenience in the use of such facilities approaches the convenience of telephones at fixed locations.

Engineering Considerations

Recent advances in solid-state physics and all the variety of diodes, transistors, thin metallic films, new magnetic materials, new dielectric compounds, unheard of semiconductors and *molecular circuitry* are but the harbingers of the developments to be expected over the next two decades. This must be well understood in considering future developments in the engineering of mobile radiotelephones because the changes from present practices and techniques will be almost revolutionary.

Coordinated Broad-Band Systems

As previously mentioned, coordinated broad-band systems are the best hope for the spectrum development essential to satisfying the growing demand for mobile telephones for both cooperative and common carrier uses. Engineering studies have shown this in a most convincing manner. Not only is a coordinated system the logical way to share equitably the suitable RF space, but it seems to be the only way to obtain more mobile telephone channels with less interference and lower cost to the user. Moreover, most of the complexity required, including multiple receiver locations, will be in the shared base station facilities, and thus the costs would be divided among the users.

It must be appreciated that the development of the coordinated broad-band systems with the efficiency of spectrum utilization envisioned in the section on "Political Considerations" will not come into being all at once but will evolve from extensive development. To be sure, when first used, the efficiency of spectrum utilization may be only a small number of times greater than split channels can give but they have far greater ultimate capacity.

Without further consideration of the engineering aspects of coordinated broad-band systems or the base stations used therein, some of the features that may be developed for mobile equipments operating as a part of such systems can be outlined.

Size Reduction

Over the past two decades there has been a substantial reduction in the size of mobile telephone equipments. The past history and the trend of the future is shown in Fig. 3. In the photograph of Fig. 4 this trend is further illustrated by comparison of a two-unit equipment of only a few years ago with a current single-unit equipment which is transistorized in part. Unfortunately, the price of transistors has also increased the cost of mobile telephones, but this situation is only temporary. Transistors are being produced in ever-increasing quantities with improved quality at lower cost. In a few years, as the methods for manufacturing are improved, the cost of transistorized equipment may be expected to be less than that of equipment employing vacuum tubes.

Some transistors are now being produced in quantity occupying a volume of only 4×10^{-11} cubic inches, and this is probably not as small as they can be. However, reduction in size of the equipment has not been accomplished solely as a result of the smaller size of transistors. The efficiency of transistors has also made it possible to reduce the size of the equipment and still obtain adequate heat dissipation. This problem of heat dissipation will probably set the lower limit on the size of mobile telephones but current practices in engineering design are a long way from that limit.

It is estimated that the micromodular approach to the problem of size will result in a 100 to 1 reduction over present-day components. Reduction by a factor of five might result from the use of thin films deposited on substrates to form the necessary electric circuits. It has been predicted that this will probably be in use by 1970. This seems not to be the limit in size reduction, since it is known that integrated circuits on common semiconductor substrates will yield a further 4 to 1 decrease in size. Two-stage amplifiers have already been demonstrated which have a volume no more than three ten-thousandths of a cubic inch. Moreover, it has been claimed that the unconventional electrical principles of

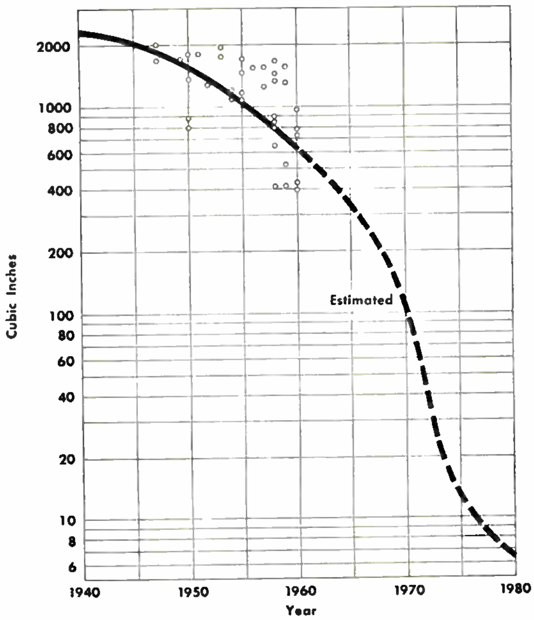

Fig. 3—Volume in cubic inches of two-way mobile radio telephone equipment—10–30 watts RF output—from data furnished by General Electric Company.

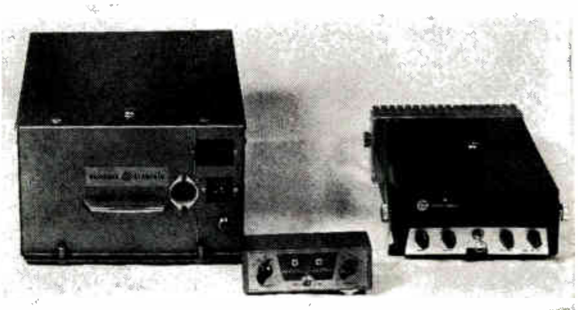

Fig. 4—General Electric Company mobile telephone equipments showing size reduction between 1950 and 1960.

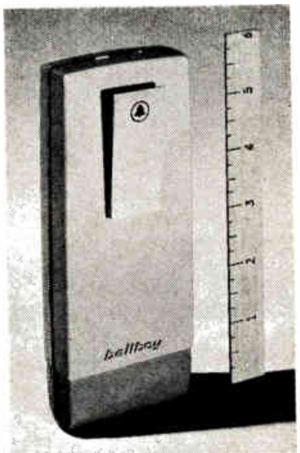

Fig. 5—Bell System's "Bellboy"—a 152- to 162-Mc radio receiver for adjacent channel operation with selective signaling and self-contained rechargeable battery.

molecular circuitry will make possible a reduction in equipment volume to one ten-thousandth of the size currently used for mobile telephone equipment. Obviously not all of these reductions will be needed to obtain in a package of about 6.5 cubic inches the equipment now contained in about 650 cubic inches.

Pocket-carried radio receivers with about 7 cubic inches volume, including batteries, are available now from several suppliers. These are employed in certain paging services. Radio transmitters with lower power and limited range of about this same size are likewise on the market. Illustrated in Fig. 5 is a selective signaling receiver which operates in the 152- to 162-Mc frequency range. This may be thought of as a mobile telephone bell. All of these devices perform but one of the several functions needed in the mobile telephone of the future. It seems quite reasonable to expect that before 1980 all of the functions then required for a two-way mobile telephone can be provided in a unit no larger than one of the paging receivers.

One thing not covered by the foregoing discussion of size nor illustrated by Figs. 3 or 4, is the power supply necessary to run the equipment. Some way must be found to reduce the size of the power supply. While the use of transistors has already done much to reduce the power requirement of mobile telephones, there is a limit when consideration is given to the RF power that must be generated and radiated. It is expected that significant advances will be made in the power supply field by 1970. A simple alternative would be a large reduction in mobile transmitter power with a correspondingly large increase in the number of radio receivers associated with each base station transmitter. Such proliferation of radio receiving locations may be found to be economically feasible in any event.

Duplex Operation

Most mobile telephone systems today are operated on a push-to-talk basis. The common carriers, however, are using push-to-talk in the vehicle only. Where the general public, such as passengers on railroad trains, has access to the telephone in the vehicle, and separate transmit and receive frequencies are employed, no push-button is involved.

Push-to-talk operation requires some experience in proper coordination between hand and voice. There are available today arrangements which permit operation of the mobile units without using manual switching. It seems likely that soon push-buttons will be outmoded, except for car-to-car communications or single frequency operation.

Mobile Frequency Control

Single-sideband operation, with its accompanying efficiency of spectrum utilization in coordinated broadband systems, requires a higher order of frequency stability than currently in use. In such systems there are numerous ways this might be accomplished. An innovation which may be introduced is that all radio frequencies needed in the mobile set will be derived from control frequencies sent out from the base station transmitter. By this means all of the frequencies in the coordinated system might be held within a tolerance two orders of magnitude better than present practice. This can be done without costly equipment in the vehicle.

The techniques, to provide much better frequency stability at the base station, are available at the present time. Application of these techniques will increase the base station cost, but again this incremental increase on a system basis is divided among the large number of mobile units served by the system. It seems likely that control of mobile station frequencies from the associated base station will come into extensive use even before the change is made to single-sideband operation. Simple cost considerations indicate that this will be the case.

Signaling and Switching

A definite trend in mobile equipment today is toward the inclusion of some kind of selective calling. The very nature of radio makes a mobile telephone a party-line telephone, and it is desirable in nearly all cases to communicate with but one party at a time. Common carrier systems have used selective signaling since the very beginning.

The selective signaling apparatus in the mobile unit will be used also to switch the mobile equipment automatically to some designated channel in the group which, at that time, is not being employed for communication. Moreover, this same apparatus also will function automatically to send its identifying signal back on the designated channel. Arrangements to do this have been demonstrated but are not yet in commercial use even on the few channels now available. It seems likely that the value of automatic channel selection and mobile station identification will make them practically essential on coordinated systems.

One of the features essential to economy in common carrier systems will be selective signaling in both directions on substantially all calls. Several installations of such *two-way dialing* systems have already been made and are in successful operation.

In the next several years there will be further development in the signaling arrangements used for selective calling, station identification, automatic channel selection and two-way dialing. The use of push buttons in the vehicle instead of the conventional telephone dial is indicated. User demand for convenience in operation will be the controlling factor.

A new signaling system could retain the desirable characteristics of frequency shift keying so essential to reliability but eliminate the undesirably slow speed of a dial-pulse system. It may be essentially a start-stop system, possibly employing a four-unit code. The code signal for a single digit should be sent in about a tenth of a second; just a little faster than the time required for a person to push successive buttons in a group to send a sequence of digits. Either electronic or mechanical means may be used, but the apparatus would differ materially from that now in mobile telephone service.

Conclusions

There exists, most certainly, a need for great expansion in vehicular communications over the next two decades. Large-scale production of equipment for this expansion would tend to reduce costs. Technological advances are providing new tools with which to go further in the directions indicated by current trends. Adequate spectrum space to support this expansion must be assured, however, if the need is to be met.

Acknowledgment

The author wishes to express his appreciation for the information and assistance he has received from J. A. Anderson, General Motors AC Spark Plug Division, J. E. Dingman, AT&T Company, Admiral F. R. Furth, IT&T Corporation, H. Van Aken, General Electric, and from their associates in each of these companies. Particular thanks are due R. P. Gifford, GE Company and J. W. Stubner, AT&T Company, for their valuable help during the preparation of this paper.

Contributors

M. Donald Adcock (SM'56) was born in Tolladega, Ala., on August 16, 1921. He received the A.B. degree in physics from Howard College, Birmingham, Ala. He also studied radar at Massachusetts Institute of Technology and Harvard University, Cambridge. in 1944.

In 1942, he joined M.I.T.'s Radiation Laboratory, under Dr. L. C. Van Atta, where he designed, supervised, and operated the first primary-pattern apparatus which was the forerunner of many such equipments; he assisted in the development of the original ground-based microwave fire-control antenna and worked on the first cut paraboloid antenna design. In 1944 he joined the Navy as a Radar Officer; upon his release he worked for the Antenna Research Branch, Naval Research Laboratory, Washington, D. C. There he developed broadband antennas, and did research with Dr. A. E. Marston on helical radiators. In 1951 he was employed by Hughes Aircraft Company, Culver City, Calif., where he was Head of the Microwave Laboratory. He is responsible for many antenna developments, such as two-dimensional slot arrays, low-frequency very-large antenna systems, and reconnaissance antennas. He was co-founder of American Systems, Inc., Inglewood, Calif., where he heads the Electromagnetic Systems Division.

❖

Samuel N. Alexander (A'44–M'55–SM'55–F'56) was born in Wharton, Tex., on February 22, 1910. He received both the A.B. degree in physics and the B.S. degree in electrical engineering, in 1931, from the University of Oklahoma Norman, and was awarded a Tau Beta Pi Fellowship for graduate studies. In 1933 he received the M.S. degree in electrical engineering from the Massachusetts Institute of Technology, Cambridge, where he continued his doctoral studies under a Coffin Foundation Research Fellowship, in 1934.

From 1935 to 1940 he worked as a Laboratory Engineer for the Simplex Wire and Cable Company, Cambridge, and during 1939 and 1940 was a Research Assistant at M.I.T. From 1940 until 1943, he was a Physicist with the Navy Department working on electronic instrumentation and from 1943 to 1946 was Senior Project Engineer with Bendix Aviation Corporation, Towson, Md., working on development of military telemetering equipment. In 1946 he joined the staff of the National Bureau of Standards, Washington, D. C. As Chief of the Electronic Computers Laboratory he was engaged in the development of digital computer technology and had over-all supervision of the design and construction of SEAC and DYSEAC. Since 1954 he has been Chief of the Data-Processing Systems Division of NBS. This activity grew out of the earlier computer development program and now includes the application of digital techniques to data processing and information storage and retrieval and the application of combined analog and digital techniques to automatic instrumentation and dynamic control systems.

Mr. Alexander is a member of the AIEE, ACM, American Physical Society, American Documentation Institute and Washington Academy of Sciences. He is also a member of Phi Beta Kappa, Sigma Xi, Tau Beta Pi and Sigma Tau. In 1956 he received a silver medal from the Royal Academy of Engineering Science, Stockholm, Sweden.

❖

Edward W. Allen, Jr. (M'44–F'53) was born in Portsmouth, Va., on February 14, 1903. He received the E.E. degree from the University of Virginia, Charlottesville, in 1925, and the L.L.B. degree from George Washington, University, Washington, D. C., in 1933.

He joined the Federal Communications Commission, Washington, D. C., in 1935. He became Chief of the Technical Research Division in 1946, and since 1951 has been Chief Engineer of the FCC. He has been active in the development of technical standards and radio allocations throughout his association with the FCC.

Mr. Allen, a member of the Electrical Standards Board of the American Standards Association, has participated in electrical coordination work for many years. He is also a member of the U. S. National Committees of URSI and the International Electrotechnical Commission. He is a member of the Executive Committee of the International Radio Consultative Committee (CCIR) of the International Telecommunications Union (ITU) and has served as a delegate to seven meetings of the Union, at two of them as Delegation Chairman. He has been a member of the IRE Wave Propagation Committee since 1949, and received the IRE Harry Diamond Award, in 1958. He is a member of Tau Beta Pi and of Phi Alpha Delta.

Gene M. Amdahl (A'53–M'57) was born in Flandreau, S. Dak., on November 16, 1922. He received the B.S. degree in physics from South Dakota State College, Brookings, in 1946, and the M.S. and Ph.D. degrees in physics from the University of Wisconsin, Madison, in 1949 and 1952, respectively.

From 1952 to 1956 he was associated with the IBM Development Laboratory, Poughkeepsie, N. Y., where he was Project Engineer and Systems Designer of the IBM 704, 709 and Stretch computers. From 1956 to 1960 he worked at the Thompson Ramo Wooldridge Corporation and at Aeronutronic Systems, Inc., where he held the position of Manager of Data Processing Engineering. In 1960 he rejoined IBM in Research, Yorktown Heights, N. Y., where he held the position of Director of Experimental Machines, and is now the Advanced Systems Design Manager in the Data Systems Division, Poughkeepsie, N. Y.

Mr. Amdahl is a member of the American Physical Society.

❖

Morton M. Astrahan (S'45–A'50–M'51–SM'57) was born in Chicago, Ill., on December 5, 1924. He received the B.S.E.E. degree from Northwestern University, Evanston, Ill., in 1945, the M.S.E.E. degree from the California Institute of Technology, Pasadena, in 1946, and the Ph.D. degree from Northwestern. in 1949.

He joined the IBM Corporation, Endicott, N. Y., in 1949. In 1951 and 1952 he participated in the planning and logical design of the 701 Computer at Poughkeepsie, N. Y. From 1953 to 1955 he was in charge of the IBM Systems Planning on the AN/FSQ-7 Computer for the SAGE Air Defense System. He also directed input-output development and prototype testing for the AN/FSQ-7. In 1956, he moved to the San Jose Research Laboratory of IBM, Calif. He was Manager of systems research and responsible for applications and specifications of experimental research devices for future data-processing systems, 1956 to 1958. In 1959 he joined the San Jose Laboratory of the newly formed IBM Advanced Systems Development Division. He is currently Assistant Manager of a systems development project.

Dr. Astrahan was the first Chairman of the IRE Professional Group on Electronic Computers, in 1952 and 1953. He was Chairman of the National Joint Computer Committee, from 1956 to 1958, and Chairman of the NJCC delegation visiting computers in the USSR, in 1959. He is currently Chairman of the Finance Committee for the American Federation of Information Processing Societies. He is a member of the AIEE, Eta Kappa Nu, Tau Beta Pi, and Sigma Xi.

❖

Stephen S. Attwood (SM'44–F'61) was born in Cleveland, Ohio, on May 29, 1897. He received the B.S.E. degree in mechanical engineering, in 1918, and the M.S. degree in electrical engineering, in 1923, both from The University of Michigan, Ann Arbor.

During the years 1918 to 1919 he served as Ensign, U.S.N.R., aboard naval vessels with the responsibility of Assistant Engineer Officer. The year 1919 was devoted to construction work for the Packard Motor Car Company. He returned to The University of Michigan in 1920 as Instructor in Electrical Engineering, and was promoted through the grades to Professor, in 1937. He was a member of the U. S. Government Mission to England on Radio Wave Propagation in late 1943. From 1944 to 1945 he was Director of the Wave Propagation Group, at Columbia University, New York, N. Y., for the Office of Scientific Research and Development. In 1953, at The University of Michigan, he was named Chairman of the Electrical Engineering Department, and in 1958 he was appointed Dean of the College of Engineering.

Mr. Attwood is a member of Tau Beta Pi, Sigma Xi, Eta Kappa Nu, and is a Fellow of the AIEE.

❖

William S. Bachman (S'32–A'36–M'45–SM'54–F'56) was born in Williamsport, Pa., on October 29, 1908. He received an E.E. degree from Cornell University, Ithaca, N. Y., in 1932.

From 1934 to 1946 he was associated with the General Electric Company, as Engineer in the Radio Receiver Engineering Department, having made contributions to the development and design of loudspeakers, radio and phonograph combinations, and phonograph pickups. Among his developments, the most familiar is the G.E. variable reluctance pickup. In 1946 he joined Columbia Records, Inc., as Director of Engineering and Research, and in this capacity, contributed to the development and production engineering of Lp records, the heated stylus disk recording technique, viscous damped reproducer arms and program controlled automatic groove-spacing equipment.

Mr. Bachman has been active on numerous industrial committees and is a Past Chairman of the Technical Committee of the Record Industry Association of America. He has served for many years on the Board of Editors of the IRE. He was granted the Audio Engineering Society Berliner Award for outstanding developments in disk recording and reproduction. He is a Fellow of the Audio Engineering Society.

❖

Austin Bailey (A'22–M'25–F'36–L) was born in Lawrence, Kan., on June 9, 1893. He received the A.B. degree from the University of Kansas, Lawrence, in 1915, and the Ph.D. degree from Cornell University, Ithaca, N. Y., in 1920.

In 1918 he was made a Second Lieutenant of the U. S. Army Signal Corps. After his university work and following military service, he was first employed as Superintendent of the Apparatus Division, Corning Glass Works, Corning, N. Y., and then became Assistant Professor of Physics at the University of Kansas. In June, 1922, he accepted a position with the American Telephone and Telegraph Company, New York, N. Y., where he worked on radio engineering problems, retiring from the Bell System as Mobile Radio Engineer on June 30, 1958. Since then he has been an independent Engineering Consultant.

Dr. Bailey is a member of Sigma Xi, Alpha Chi Sigma, and a Fellow of AIEE.

❖

Ralph R. Batcher (J'16–A'18–M'22–SM'43–F'50) was born in Dysart, Iowa, on June 7, 1897. He received the B.S. degree in electrical engineering from Iowa State College, Ames, in 1920.

While a radio amateur (starting in 1909), he organized in 1915 an early broadcasting service in the middle west which sent daily weather and crop reports from station 9YI. During World War I, he became a Radio Inspector at the Port of New York, and also taught at the Marconi Institute and Signal Corps classes at the College of the City of New York. In 1920 he became a Circuit Designer Engineer on machine switching systems at the Western Electric Company, New York, N. Y. In 1924 he joined A. H. Grebe and Company, L. I., N. Y., as receiver Designer and a Consultant to their broadcasting stations WAHG, WBOQ and WABC.

While there he invented the SLF variable condenser.

In 1928 he helped organize and was an officer of the Decatur Manufacturing Company, Brooklyn, N. Y., manufacturers of radio speakers. In 1935 he joined the Allen D. Cardwell Company, Brooklyn, as a Consultant, and later became Director of Engineering until 1944, when he became Consultant on the publications of the Caldwell-Clement Corporation, New York, N. Y., on the magazines *Electronic Industries, Electronic Instrumentation* and *Tele-tech.* While at Cardwell, he developed a number of printed circuit applications and the use of plated circuits for electronic assemblies. He also designed a completely automatic production calibrator for military frequency meters that "read" the dials at more than 100 readings per minute and printed the calibration books automatically. This calibrator saved many hundred man-years of calibrator's time during the production interval.

In 1950 he became Chief Engineer of the RETMA (now Electronic Industries Association), where he handled their Data Bureau in charge of tube registrations and more than one hundred technical committees dealing with system and product standardization work. He was a Consultant to the Joint Electron Tube Engineering Council (JETEC), and a Consultant to the Department of Defense Advisory Group on Reliable Electronic Equipment (AGREE). At present he provides a consulting service to manufacturers on product design and production problems, and automatic control.

Mr. Batcher is a Fellow of the Radio Club of America and a member of Tau Beta Pi, and a registered professional engineer in the state of New York. He was Chairman of the Board of Directors of the 1954 National Electronics Conference. From 1954 to 1957 he served as Chairman of the IRE Professional Group on Production Techniques. He has been active on many IRE committees, including the Annual Review Committee (Chairman, 1949–1954), Public Relations (Chairman, 1950–1951), Board of Editors, Meetings and Papers, Standards, Symbols, and Television. From 1951–1952 he served as IRE representative to the ASA Sectional Committee (C16) on Radio (Secretary, 1952).

❖

Max C. Batsel (A'21–F'27) was born in Fulton, Ky., on June 16, 1894. He received the B.M.E. degree from the University of Kentucky, Lexington, in 1915.

He then immediately joined the Western Electric Company, Hawthorne Works, Chicago, Ill., as a Student Engineer. Upon completing this course of training, he joined the staff of the Bureau of Standards, Washington, D. C. He was commissioned as Second Lieutenant in the Signal Corps during

World War I and assigned to the Radio Development Section. In 1920 Mr. Batsel resigned from the Signal Corps and joined the Westinghouse Electric and Manufacturing Company, where he participated in the design of the first receivers specifically designed for receiving broadcasted programs in 1921. The Radio Department was established in 1922, and he was appointed Section Engineer responsible for broadcast receiver development and design. In 1928 the responsibilities of the section were increased to include the development and design of sound motion-picture equipment, both 16 and 35 mm.

In 1929 he was appointed Chief Engineer of the RCA Photophone Division, a separate RCA Subsidiary Company with headquarters in New York City and a branch office in London, England. In 1932 the Photophone Company was merged with the RCA Manufacturing Company in Camden, N. J., and Mr. Batsel was appointed Manager of the Sound Section of the Engineering Division. The engineering and manufacturing operations of the Sound Division were moved to Indianapolis, Ind., in 1941, and he became Chief Engineer of the Indianapolis Plant. He served in this capacity until recalled to Camden to assume the duties of Chief Engineer of the Engineering Products Department of which the Sound Division became a Section. In 1955 he was appointed Chief Engineer of the Defense Electronic Products. At present he is retired and acting as Consultant.

Mr. Batsel is a Fellow of the Society of Motion Picture and Television Engineers, and a member of the American Society of Naval Engineers and of Tau Beta Pi. He received the Modern Pioneers Award given by the National Association of Manufacturers in 1940.

❖

Benjamin B. Bauer (S'37–A'39–SM'44–F'53) was born in Odessa, Russia, on June 26, 1913. He received the B.S. degree in industrial electrical engineering from Pratt Institute, New York, N. Y., in 1932, and the E.E. degree from the University of Cincinnati, Ohio, in 1937.

In 1936 he joined Shure Brothers, Inc., Chicago, Ill., manufacturers of microphones and electronic components; he became Chief Engineer, in 1940, and Vice President, in 1950, and continued in this capacity until 1957 when he was appointed Head of Audio and Acoustics at CBS Laboratories, Stamford, Conn. In 1958 he became Vice President of CBS Laboratories taking charge of the Acoustics, Magnetics, and Instrumentation Research Departments. During this time he was responsible for the development of a great many electroacoustical instruments such as microphones, disk recording and reproducing transducers, and magnetic recording devices. He has over thirty patents in these fields and has frequently been concerned with the task of carrying various products through research, design and into the production engineering phases.

Mr. Bauer is a member of Eta Kappa Nu, Tau Beta Pi, and Sigma Xi, and a Fellow of the Acoustical Society of America and the Audio Engineering Society. He recently received the Eta Kappa Nu Award of Merit.

❖

Arnold H. Beck (S'36–A'39–M'55–F'59) was born in Norfolk, England, on August 7, 1916. He was educated at Gresham's School, Holt, and at University College, London, where he received a B.S. degree in engineering, in 1937.

After two years work on electronic navigation with Henry Hughes & Sons, he was seconded to the Admiralty Signal establishment until the end of World War II. In 1947 he joined Standard Telephones & Cables to establish the valve laboratory then located at Enfield. He worked on a broad range of valves and gas tubes for communication systems at S.T.L. In 1958 he joined the academic staff of Cambridge University where he is a Lecturer in Electrical Engineering.

Mr. Beck is an associate member of the IEE, and the author of three books on electronics: "Velocity Modulated Thermionic Tubes," "Thermionic Valves" and "Space-Charge Waves."

❖

Vitold Belevitch (SM'54–F'61) was born in Helsinki, Finland, on March 2, 1921. He received the E.E. and M.E. degrees, in 1942, and the D.Sc. degree, in 1945, all from the University of Louvain, Belgium.

From 1942 to 1957 he was in the Wire Transmission Department of Bell Telephone Mfg. Cy., Antwerp, Belgium.

At present he is Director of the Comite d'Etude et d'Exploitation des Calculateurs Electroniques, Brussels, Belgium, and a Professor at the University of Louvain.

Dr. Belevitch is the author of two books on network theory (in French) and of numerous articles.

Leo L. Beranek (S'36–A'41–SM–45–F'52) was born in Solon, Iowa, on September 15, 1914. He received the B.A. degree from Cornell College, Mt. Vernon, Iowa, in 1936, the M.S. and Sc.D. degrees in applied physics from Harvard University, Cambridge, Mass., in 1940, and the D.Sc. (Hon.) degree from Cornell College, in 1946.

At Harvard he was an Instructor from 1940–1941, Assistant Professor from 1941–1943, Director of Research on Sound Control from 1940–1943, and Director of the Electro-Acoustics and Systems Research Laboratories from 1943–1946. At the Massachusetts Institute of Technology, Cambridge, he was Associate Professor of Communication Engineering from 1947–1959, Technical Director of the Acoustics Laboratory from 1947–1953, and has been a Lecturer since 1959.

Dr. Beranek is Chairman of the Acoustical Standards Board of the American Standards Association and a Fellow of the American Physical Society, the Acoustical Society of America, the American Academy of Arts and Sciences, the AAAS, and the Audio Engineering Society.

❖

Harold H. Beverage (A'15–M'26–F'28–L) was born in North Haven, Me., on October 14, 1893. He received the B.S. degree in electrical engineering in 1915, and the honorary degree of Doctor of Engineering, in 1938, both from the University of Maine, Orono.

He was associated with Dr. E. F. W. Alexanderson of the General Electric Company in 1916, specializing in the development of receiving systems. He developed the wave antenna in collaboration with C. W. Rice and E. W. Kellogg. In 1920 he was transferred to the Radio Corporation of America, and continued to specialize in the development of receiving systems for VLF and HF transoceanic communication, at Riverhead, N. Y. He collaborated with H. O. Peterson and J. B. Moore in the development of the space diversity receiving system for high frequencies. He became Chief Research Engineer for RCA Communications, Inc., in 1929, and was appointed Vice President in Charge of Research and Development in 1940. When the Communications Research Laboratory became part of RCA Laboratories in 1942, he was appointed Director of Radio Research. He retired in 1958, and is presently a Consultant on Communications to the Radio Corporation of America.

Mr. Beverage is a Fellow of the AIEE

and the AAAS. He has received many honors, including the IRE Morris Liebmann Memorial Prize, 1923; the IRE Medal of Honor, 1945; the IRE PGCS Achievement Award, 1958; the AIEE Lamme Medal, 1957; the Signal Corps Certificate of Appreciation, 1944; and the Presidential Certificate of Merit, 1948.

❖

Frank J. Bingley (A'34–M'36–SM'43–F'50) was born in Bedford, England, on November 13, 1906. He received the B.Sc. degrees in mathematics and physics (both with honors), in 1926 and 1927, respectively, from the University of London, England.

Since then he has been continuously associated with television. He was employed by the Baird Television Company of London, in 1927 and was in charge of their New York Laboratories for two years. In 1931 he joined the Philco Corporation of Philadelphia, Pa., where he has been associated with the development of transmitting and receiving equipment. as well as with television-systems engineering. He has worked extensively in recent years in the field of color television, and is currently in charge of a program of industrial and military television equipment design.

Mr. Bingley is a member of the Franklin Institute, has served on many industry committees concerned with the development of television standards, and is the recipient of the 1956 Zworykin Television Award of the Institute for his work in colorimetry.

❖

Henry P. Birmingham (M'53–SM'56) was born in Newburgh, N. Y., on March 17, 1920. He received the Ed.B. degree from Rhode Island College, Providence, in 1942, and did further study at the University of Pennsylvania, Philadelphia, and the American University, Washington, D. C.

He served in the U. S. Air Force as an Instructor in Radar Maintenance and as a classification specialist during World War II. He later joined the staff of Brown University, Providence, as a Research Psychophysiologist under NDRC. He joined the U. S. Naval Research Laboratory in 1945, where he is presently Head of the Engineering Psychology Branch in the Applications Research Division.

He organized the IRE PGHFE and served as Chairman during the first year of its existence. He received the Naval Ordnance Development Award for work in fire control, and the Meritorious Civilian Service Award for work in the development of man-machine control system theory.

Mr. Birmingham is a member of the Aerospace Medical Association, the Human Factors Society, and the Eastern Psychological Association.

❖

Henry G. Booker (SM'45–F'53) was born in Barking, Essex, England, on December 14, 1910. He became a naturalized American Citizen, in 1952. He received the B.A. degree, in 1933, specializing in pure and applied mathematics, and the Ph.D. degree, in 1936, specializing in ionospheric physics, both from Cambridge University, England.

In 1935 he became a faculty member of Christ's College, Cambridge, England, in which capacity he conducted research in radio wave propagation and taught applied mathematics and theoretical physics. From 1937 to 1938 he was a Visiting Scientist at the Department of Terrestrial Magnetism of the Carnegie Institute, Washington, D. C. At this time he evolved the theory of propagation of radio waves through a stratified doubly-refracting ionosphere, demonstrating the twisted unsymmetrical paths followed by wave packets. During World War II he was in charge of theoretical research at the Radar Research Establishment of the Royal Air Force, Malvern, England; here, he was involved in the development of new ideas in antennas and propagation. He holds patents on the resonant slot and cosecant antennas, and has conducted radio meteorological investigations. After the war he returned to Cambridge, where he lectured in applied mathematics and conducted ionospheric research. In 1948 he became a Professor of Electrical Engineering at Cornell University, Ithaca, N. Y., where he is now the Director of the School of Electrical Engineering; he is also a member of the faculties of physics and engineering physics. In 1959 he became Associate Director of Cornell's Center for Radiophysics and Space Research.

Dr. Booker is the recipient of the Smith Prize, three Premiums of the Institute of Electrical Engineers (London), and a Guggenheim Fellowship, in 1954, to conduct research on the theory of radio reflections from aurorae and to visit various European scientific institutions. He has been the Chairman of two International Commissions of the International Scientific Radio Union. He is a Fellow of the Royal Meteorological Society and is a member of the American Geophysical Union, the American Astronomical Society, the American Meteorological Society, the AIEE, and the American Association of Physics Teachers. In 1960 he was elected to the National Academy of Sciences.

❖

Virgil E. Bottom (M'47–SM'60) was born in Douglass, Kan., on January 6, 1911. He received the A.B. degree from Friends University, Wichita, Kan., in 1931, the M.S. degree from The University of Michigan, Ann Arbor, in 1938 and the Ph.D. degree from Purdue University, Lafayette, Ind., in 1949.

He was Professor of Physics at three institutions, Friends University, Colorado State University, and McMurry College, Abilene, Tex. During the years 1943 to 1945 he was employed by the Signal Corps, first in OCSIGO, Crystal Section, Washington, D. C., and later at SCEL, Fort Monmouth, N. J. From 1953 to 1958 he was employed by the Semiconductor Products Division of Motorola, Inc., Phoenix, Ariz., where he was engaged in the development of semiconductor devices. From 1948 to 1953 he was a member of the subpanel on Frequency Control Devices of the Research and Development Board, Department of Defense, Washington, D. C. He is presently Professor of Physics at McMurry College.

Dr. Bottom is a member of the American Physical Society, the American Association of Physics Teachers, Sigma Xi, Sigma Pi Sigma and a Fellow of the Texas Academy of Science.

❖

James T. Brothers (A'29–SM'45–F'59) was born in New York, N. Y. on April 30, 1908. He attended the Washington Square College of New York University, and did graduate work at Columbia University, New York, N. Y., the City College of New York, and the University of Detroit, Mich.

From 1926 to 1927 he worked on component research and development at the Polymet Manufacturing Company, New York, N. Y. In 1927 he was employed by Pilot Radio Company, Brooklyn, N. Y. He was with the A. H. Grebe Company, Richmond Hill, N. Y., in 1928, working on ac tubes and receivers, and he also worked as a Consultant on sound on film recording, and on electronic equipment for medical purposes. In that same year he returned to the Pilot Radio and Tube Corporation, where he worked on vacuum tube and component design, sound systems, aircraft, automobile, and home entertainment radio and television transmitters and receivers. From 1930 to 1933 he was a Consultant to licensees on receiver circuitry, tube design, measureurement techniques and evaluation at the RCA Patent Department, New York, N. Y. Since 1933 he has been employed by the Philco Corporation, Philadelphia, Pa., as a Consultant on component and tube design, evaluation and application, circuitry and measurement techniques. He is now in charge of standards and technical liaison at Philco.

Mr. Brothers has been a member of numerous government and industrial committees, Chairman of the Advisory Group on Electronic Parts Working Group on Capacitors, of the Research and Development Board Subpanel on Electro-Mechanical Devices, and of the Electronic Industries Association Safety Committee. He is also a member of the Philadelphia District Council of the American Society for Testing Materials, Chief Technical Advisor and Delegate to the International Electrotechnical Commission Technical Committee No. 12.

❖

Christopher Buff (A'45–M'48–SM'55) was born in Camden, N. J., on January 6, 1917. He took engineering courses at Union Junior College, Cranford, N. J., and at Hofstra College, Hempstead, N. Y.

From 1941 to 1946 he was employed in various engineering capacities by Press Wireless Inc., New York, N. Y., and was instrumental in the development of some of the early FSK equipment. In 1946 he joined Mackay Radio and Telegraph Company, New York, N. Y., as an Engineer engaged in the development of HF communications equipment. Subsequently he was active in systems engineering for the company, making several trips abroad. He has also participated in the work of CCITT study groups at Geneva. He is now Chief Engineer of the parent company, American Cable and Radio Corporation, New York, N. Y. He has been an active licensed radio amateur since 1931.

❖

Charles R. Burrows (A'24–M'38–SM43'–F'43) was born in Detroit, Mich., on June 21, 1902. He received the B.S.E. in electrical engineering and the professional degree of E.E. from The University of Michigan, Ann Arbor, in 1924 and 1935, respectively. He received the A.M. and Ph.D. degrees in physics from Columbia University, New York, N. Y., in 1927 and 1938, respectively.

From 1924 to 1945 he was a member of the technical staff of the Bell Telephone Laboratories working in the research department, specializing in radio wave propagation. He participated in the transatlantic experiments both on long and short waves,

being responsible for the analysis of the latter. He supervised early ultra-short wave propagation experiments which uncovered many of the laws of ultra-short wave propagation. Just prior to the war he worked on the proximity fuse. Early in the war he contributed to the development of radar. Later, as Chairman of the Committee on Propagation of NDRC, he was responsible for all the propagation research affecting the war effort. At the end of the war he accepted the appointment as Professor of Electrical Engineering and Director of the School of Electrical Engineering at Cornell University, Ithaca, N. Y., where he developed research in radio astronomy, radio wave propagation, the ionosphere and vacuum tubes. He is currently Vice President of Engineering and Research at Datronics Engineers, Inc., Bethesda, Md.

Dr. Burrows has been active in URSI, having served many years on the U. S. National Committee as Vice Chairman and Chairman; he was head of the U. S. delegation to the 10th General Assembly of URSI in Sydney, Australia, in 1952. From 1948–1954 he served as International President of Commission II on Tropospheric Propagation. From 1946–1954 he was President of the Joint Commission on Radio-Meteorology of the International Council of Scientific Unions.

Dr. Burrows has received the Presidential Certificate of Merit; and a certificate as a Distinguished Alumnus of the College of Engineering at The University of Michigan. He is a Fellow of the AIEE, and the APS, and a member of the American Geophysical Union, American Astronomical Society, American Rocket Society, Sigma Xi, Tau Beta Pi and Eta Kappa Nu.

❖

Marvin Camras (S'41–A'42–SM'48–F'52) was born in Chicago, Ill., on January 1, 1916. He received the B.S.E.E. degree from the Armour Institute of Technology, Chicago, in 1940, and the M.S. degree from the Illinois Insitute of Technology, Chicago, in 1942.

Since 1940 he has been a staff member of the Armour Research Foundation, Chicago, where he has been concerned with research in the Electronics Division on such projects as remote control, high-speed photography, magnetostriction oscillators, and static electricity.

He has contributed developments which are used in modern magnetic tape and wire recorders, including high-frequency bias, improved recording heads, wire and tape materials, magnetic sound for motion pictures, multitrack tape machines, and binaural sound reproduction.

Mr. Camras is a member of the Acoustical Society of America, AIEE, SMPTE, AAAS, Eta Kappa Nu, Tau Beta Pi, and Sigma Xi. He is presently Editor of the IRE TRANSACTIONS ON AUDIO, and received the John Scott Medal, in 1955, for his work in magnetic recording.

❖

Philip S. Carter (S'48–A'50–M'56), 1896–1961 was born in Glastonbury, Conn., on July 22. He received the A.B. degree in mechanical engineering from Stanford University, Calif., in 1918.

He was employed by the General Electric Company in Dr. E. F. W. Alexanderson's radio laboratory, and was associated with H. H. Beverage in the early experiments leading to the development of the wave antenna. In 1920 he transferred to the Radio Corporation of America and assisted in the design of the VLF antennas at Rocky Point, N. Y. In 1925 he joined the Transmission Laboratory at Rocky Point, where in association with C. W. Hansell and N. E. Lindenblad, he pioneered in the development of long-wire types of antennas for high frequencies. In 1942 the Rocky Point Laboratory became a branch of RCA Laboratories. For over 40 years, he was active in the development of antennas and well known as an antenna expert.

❖

Sheldon S. L. Chang (SM'53–F'61) was born in China, on January 20, 1920. He attended Yenching University, Peking, National Southwest Associated University, Kunming, and Tsinghua University, in Kunming, and received the B.S. and M.S. degrees in physics in 1942 and 1944, respectively. He won a scholarship by competitive examination for studying electrical communication at Purdue University, Lafayette, Ind., in 1945, and received the Ph.D. from Purdue, in 1947.

He was an Instructor at Purdue, from 1947 to 1948, and Research and Development Engineer with Robbins and Myers, Inc., Springfield, Ohio, from 1948 to 1952. He joined the faculty of New York University, in 1952 and is presently a Professor of Electrical Engineering.

Dr. Chang is a member of AIEE, ASEE, the American Physical Society, Eta Kappa Nu, Sigma Xi and Tau Beta Pi.

Colin Cherry was born in St. Albans, England, on June 23, 1914. He received the B.Sc. degree, in 1936, from the University of London, and the M.Sc. and the D.Sc. degrees from London University, in 1940 and 1942.

During World War II he was with the British Telecommunications Research Establishment doing research on radar and in this area was mainly concerned with flying trials. Since 1949 he has been on the faculty of the Electrical Engineering Department of the Imperial College of Science and Technology of London University, England. In 1958 he was appointed a Professor in that University.

Prof. Cherry is a member of the Institution of Electrical Engineers, London.

❖

Harold Chestnut (SM'57) was born in New York, N. Y., on November 25, 1917. He received the B.S.E.E. and the M.S.E.E. degrees from the Massachusetts Institute of Technology, Cambridge, in 1939 and 1940, respectively.

He has been with the General Electric Company since 1940, when he joined the Test Course. In 1942 he supervised the G.E. Electrical B Advanced Engineering Program. Upon completion of this program in 1943, he joined the Aeronautics and Ordnance Systems Division. From 1943 to 1956 he had assignments in AOS in Systems Development, Advanced Development, Guided Missiles, and Marine Systems sections. In 1954 he was appointed Ordnance Engineer, and in 1955, Project Engineer F-104. Since 1956 he has been Control Systems Engineer in the General Engineering Laboratory of General Electric, Schenectady, N. Y.

Mr. Chestnut has been Guest Instructor in the Extension Division of Union College, Schenectady, a member of the Research and Development Board Committees, Chairman of the AIEE Feedback Control Systems Subcommittee on Component Specifications, Vice Chairman of the North American Control Council, first President of the International Federation of Automatic Control, and Chairman of the AACC Control Advisory Committee. He is currently President of the AACC.

❖

Lan Jen Chu (A'39–VA'39–SM'48–F'52) was born in Hweiying, Kiangsu, China, on August 24, 1913. He received the B.S. degree

in electrical power from Chiao Tung University, Shanghai, China, and the S.M. and the Sc.D. degrees in electrical engineering from the Massachusetts Institute of Technology, Cambridge, in 1935 and 1938, respectively.

He served as a Consultant to the Radiation Laboratory and the Radio Research Laboratory, Harvard University, Cambridge, Mass., from 1942 to 1945, on various electromagnetic problems. He joined the staff of the Radiation Laboratory, M.I.T., in 1942 and during the last years of the war he supervised research and design of many special antennas for radar and communication applications. In 1945 he served as an Expert Consultant to the Secretary of War and was sent to China to head the Advisory Specialist Group to the U. S. Armed Forces in China. He is now Professor of Electrical Engineering at M.I.T. and a staff member of the Research Laboratory of Electronics.

Dr. Chu is a Fellow of the American Physical Society and the Academia Sinica, and a member of Sigma Xi.

❖

James D. Cobine (A'34–SM'44–F'57) was born in Oklahoma City, Okla., on May 10, 1905. He received the B.S.E.E. degree from the University of Wisconsin, Madison, in 1931, and the M.S.E.E. degree from the California Institute of Technology, Pasadena, in 1932. From the latter school he also received the Ph.D. degree in electrical engineering and physics, in 1934.

From 1933 to 1934 he was an Assistant at the California Institute of Technology, and from 1934 to 1935 he was a Graduate Assistant at the Harvard University Graduate School of Engineering, Cambridge, Mass. He remained at Harvard as Instructor, 1935 to 1938, Faculty Instructor, 1938 to 1941, and Assistant Professor, 1941 to 1945. From 1943 to 1945 he was Group Leader of the Harvard Radio Research Laboratory (OSRD). In 1945 he became a Physicist for the General Electric Research Laboratory where he is presently working. He was a member of the Advisory Board of the Research Council of Rutgers University, 1950 to 1959. His field of specialization is electrical discharges in gases, high current arcs and noise in gas discharges.

Dr. Cobine is a Fellow of the American Physical Society and a member of AIEE, NSPE, ASEE, AAAS, Sigma Xi, Tau Beta Pi and Eta Kappa Nu. He has received the Army-Navy Certificate of Appreciation.

Ivan S. Coggeshall (A'26–M'29–F'42–L) was born in Newport, R. I., on September 30, 1896. He was President of the IRE in 1951, and Director, 1941–1944, and 1951–1953. An early wireless amateur, he joined Western Union, New York, N. Y., in 1917. He retired in 1959 as Assistant Vice-President, International Communications.

His activity in the IRE and the AIEE spans 30 years; he is a Fellow in and contributor of papers to both. He wrote the article "Radiotelegraphy" in *Encyclopaedia Britannica*, and the chapter "Wire Telegraphy" in the *Radio Engineering Handbook*. He holds the honorary degree of Doctor of Engineering from Worcester Polytechnic Institute, Mass., which he attended from 1914 to 1917. He retired as Commander, U. S. Naval Reserve, after service in both World Wars. He is now of the Headquarters Staff, AIEE, and a member of IRE's History Committee.

❖

Paul D. Coleman (A'45–M'55) was born in Stoystown, Pa., on June 4, 1918. He received the B.A. degree from Susquehanna University, Selinsgrove, Pa., in 1940, the M.S. degree in physics from Pennsylvania State University, University Park, in 1942, and the Ph.D. degree in physics from the Massachusetts Institute of Technology, Cambridge, in 1951.

He was employed as a Physicist with the U. S. Signal Corps, Dayton, Ohio, and subsequently with the U. S. Air Force at Wright Air Development Center, Dayton, from 1942 to 1946. During this period he worked on electromagnetic theory, and received the AAF Meritorious Civilian Award, in 1946, for his contribution to aircraft antenna theory. From 1946 to 1951 he was a Physicist with the U. S. Air Force Cambridge Air Research Center, Bedford, Mass., and later a Research Associate in Physics at the Research Laboratory of Electronics, M.I.T., where he was concerned with the generation of submillimeter waves.

In 1951 he became an Associate Professor of Electrical Engineering at the University of Illinois, Urbana, where he established the Ultramicrowave Group in the Electrical Engineering Research Laboratory. He is presently a Professor on the graduate electrical engineering staff, teaching and directing research on submillimeter wave generation, detection, and propagation.

Dr. Coleman is Chairman of the Board of Technological Counselors of FXR, Inc., Woodside, N. Y. He is a member of Sigma Xi, the American Physical Society, and Pi Mu Epsilon.

Edmund Harry Cooke-Yarborough (M'45) was born at the village of Campsall near Doncaster, Yorkshire, England, on December 25, 1918. He was educated at Canford School and at Christ Church, Oxford, where he received the M.A. degree in physics, in 1944.

In 1940 he joined the Telecommunications Research Establishment at Dundee, and moved with the Establishment, first to Swanage and then to Malvern, where he worked on airborne radar and radar countermeasures during the war and on weapon guidance and nuclear instrumentation after the war. In 1949 he joined the Electronics Division of the Atomic Energy Research Establishment at Harwell, and became Head of the Electronics Division in 1957.

Mr. Cooke-Yarborough is a member of the IEE and a Fellow of the Institute of Physics.

❖

Stanley F. Danko (M'46) was born in New York, N. Y., on January 6, 1916. He received the B.S. degree in electrical engineering from Cooper Union, New York, N. Y., in 1937, and pursued graduate studies in UHF techniques at the Moore School of Electrical Engineering, University of Pennsylvania, Philadelphia, and at Rutgers University, New Brunswick, N. J.

He was employed in the U. S. Army Signal Corps Inspection Laboratory in Philadelphia for the period 1940–1946, joining the U. S. Army Signal Research and Development Laboratory at Fort Monmouth, N. J., in 1946. He has been associated with the electronic component development activities at the Signal Research and Development Laboratory, specializing in the development of coaxial cables, RF connectors, inductive components and miniaturization techniques, including printed circuits and packaging of electronic assemblies. He was a principal in the establishment of the dip-soldered printed wiring process (Auto-Sembly) in use today. In 1957 he received a Department of the Army Award for his miniaturization contributions. He is currently Chief of the Electronic Parts and Assemblies Branch of the Electronic Components Department of the U. S. Army Signal Research and Development Laboratory.

Mr. Danko is Secretary of the Professional Group on Military Electronics, an Associate Member of the Working Group on Planning and Requirements of the Advisory Group on Electron Devices, and a registered professional engineer in Pennsylvania.

Paul S. Darnell (SM'52–F'61) was born in Philadelphia, Pa., on November 14, 1901. He received the B.S. degree in electrical engineering from the University of Pennsylvania, Philadelphia, in 1922, and the M.A. degree from Columbia University, New York, N. Y., in 1925.

In 1922 he joined the Engineering Department of The Western Electric Company, New York, N. Y., which became the Bell Telephone Laboratories in 1925. From that time until 1960 he worked principally in development and design of electronic component parts and devices for both the Bell System and military applications. He was appointed Director of Transmission Apparatus Development in 1953, and in 1960 he became Director of Military Reliability Engineering. He has served on many industrial and government committees. During 1958–1960 he chaired the Ad Hoc Study Group on Parts Specification Management for Reliability, sponsored by the Department of Defense.

❖

Edward E. David, Jr. (A'48–M'56–SM'58) was born in Wilmington, N. C., on January 25, 1925. He received the B.E.E. degree from the Georgia Institute of Technology, Atlanta, in 1945, and the Sc.D. degree from Massachusetts Institute of Technology, Cambridge, in 1950.

During the years 1945 to 1950 he was a Research Assistant at the M.I.T. Research Laboratory of Electronics, Cambridge, working with microwave vacuum tubes and noise theory. He joined the Bell Telephone Laboratories, Murray Hill, N. J., in the Fall of 1950 and was concerned with communication acoustics and underwater sound. He is presently Director of Visual and Acoustics Research and is concerned with the perception and coding of sensory information and with human information processing.

Mr. David was selected by Eta Kappa Nu as one of the country's Outstanding Young Engineers in 1954. In 1958 he received the George W. McCarty Award from the Georgia Institute of Technology as the outstanding young alumnus of the year. He is the author of two books on the physics and physiology of speech communication: "Man's World of Sound," and "Waves and the Ear." He contributed a chapter entitled "Phasing of R-F signals," in "Crossed-Field Microwave Devices." He is a Fellow of the Acoustical Society of America, and a member of Eta Kappa Nu and Sigma Xi.

Glenn L. Dimmick was born in Macon, Mo., on December 7, 1905. He received the B.S.E.E. degree from the University of Missouri, Columbia, in 1928.

Upon graduation he joined General Electric Company as an Engineer on talking motion-picture equipment. In 1930 he was transferred to the RCA Victor Plant in Camden, N. J., as a Development Engineer in the field of sound recording. During the 20 years from 1928 to 1948 he was active in the fields of sound recording, infrared, telephony, monochrome and color television, and high-vacuum evaporation. This work resulted in improved photographic recording methods, optics for sound recording, infrared detection, television, sound powered telephones, recording galvanometers, and magnetic recording devices. In 1948 he was made a Group Manager, and in 1953 he became Section Manager of the Optics, Sound and Special Engineering Section of RCA, working on television and other electronic equipment. Early in 1955 he was appointed Manager of the General Engineering Development Section of Defense Electronic Products; in 1956 he was made Chief Development Engineer, General Engineering Development Section; and in 1957 he became Chief Development Engineer of the Special Systems and Development Department. He is presently on the staff of the Chief Engineer of the Surface Communications Division, Defense Electronic Products.

Mr. Dimmick is a Fellow of the Society of Motion Picture and Television Engineers. His awards include the SMPTE Progress Medal Award in 1941, the RCA Victor Award of Merit in 1949, the Award of Merit for outstanding achievement presented by the Academy of Motion Pictures and Sciences in 1952, and the Missouri Honor Award for Distinguished Service in Engineering in 1954.

❖

Harold E. Dinger (A'27–M'43–SM'43–F'58) was born in Barberton, Ohio, on May 7, 1905. He attended the University of Akron, Ohio, and the University of Maryland, College Park.

From 1929 to 1939 he was Chief Instructor at the McKim Technical Institute, Akron, Ohio, and during 1939 and 1940 was Transmitter Engineer for the Ohio Broadcasting Company. Since 1940 he has been with the U. S. Naval Research Laboratory, Washington, D. C., specializing in radio propagation and radio interference studies.

Mr. Dinger received the Navy's Meritorious Civilian Service Award in 1947 and has received certificates of commendation from the Department of State, the ASA and the RDB. He has been a U. S. delegate to meetings of the IEC and CISPR in Lucerne (1947), Paris (1950), and Philadelphia (1961); the URSI in Sydney (1952), Boulder (1957), and London (1960); and the CCIR in London (1953), Warsaw (1956), Geneva (1958), and Los Angeles (1959). He is a member of the U. S. Executive Committee, CCIR, the U. S. National Committee, URSI, and is a Past Chairman of URSI Commission IV. He is a member of the RESA and AFCEA, and a Fellow of the AIEE, and AAAS. He is Chairman of the IRE-PGRFI for the term 1961–1962.

❖

Robert D. Elbourn (S'40–A'41–M'48) was born in Indianapolis, Ind., on October 5, 1919. He received the B.S.E.E. degree, in 1940, and the M.S.E.E., in 1949, from Purdue University, Lafayette, Ind. In 1940 and 1941 he worked on magnetic recording and electronic instrumentation for C. G. Conn, Ltd. in Elkhart, Ind. From 1941 to 1947 his work in the U. S. Naval Ordnance Laboratory, Washington, D. C., was chiefly concerned with the development of mines and torpedoes, with about one year devoted to the design of an electronic digital computer. In 1947 he became a member of the professional staff of the Electronic Computers Section of the National Bureau of Standards, Boulder, Colo., which became the Data Processing Systems Division, in 1954. Here he continued work on digital magnetic recording, participated in the design of SEAC (Standards Eastern Automatic Computer) and was engaged in research and development for improving circuits and components for high-speed electronic digital computers. He became Chief of the Components and Techniques Section, in October, 1954, and has been supervising research on information retrieval techniques and the design and development of advanced computer components and circuitry.

Mr. Elbourn is a member of the AIEE, American Physical Society, Association for Computing Machinery, Association for Symbolic Logic, Philosophical Society of Washington and the Washington Academy of Sciences. He is also a member of Tau Beta Pi and Eta Kappa Nu.

❖

L. Essen was born in Nottingham, England, on September 6, 1908. He received the B.Sc. degree from Nottingham University, in 1928. Later he earned the London Ph.D. and D.Sc. degrees for published work.

After some post-graduate work on the diffusion of electrons in gases, he joined the National Physical Laboratory, Teddington, Middlesex, England, in 1929 and is now a Deputy Chief Scientific Officer there. He was awarded the Vernon Boys Prize for his work on the velocity of light, the Tompion Gold Medal of the Worshipful Company of Clockmakers for his work on quartz clocks, and the Popov Gold Medal for his work on atomic clocks.

Dr. Essen is a Fellow of the Royal Society of London.

❖

Ronald M. Foster (SM'53–F'54) was born in New York, N. Y., on October 3, 1896. He received the S.B. degree (*summa cum laude*) from Harvard University, Cambridge, Mass., in 1917, and the Sc.D. degree (honorary) from Fairleigh Dickinson University, Rutherford, N. J., in 1960.

He was an Instructor in Mathematics at Harvard University from 1921 to 1922. He joined the research and development department of the American Telephone and Telegraph Company (1921 to 1934), where he developed the Foster Reactence Theorem, published in 1924. This work represented the first major break-through in the synthesis of electrical networks. In 1934 he joined the Bell Telephone Laboratories. He remained there until 1943 when he became Head of the Mathematics Department at the Polytechnic Institute of Brooklyn, N. Y.

He has done notable work on the mathematical basis of antenna arrays, ground return circuits and network theory. In addition to his work on the Foster Reactance Theorem, he is co-author (with Dr. G. A. Campbell) of the Campbell-Foster Tables, and the author of "Fourier Integrals for Practical Application." He resigned his position as Department Head in June, 1961 but continues to teach. He is currently on a year's leave of absence from his teaching duties.

Dr. Foster is a member of Phi Beta Kappa, Sigma Xi, the London Mathematical Society, the Edinburgh Mathematical Society, and a Fellow of the AAAS.

❖

William J. Fry (A'42–M'55) was born in Johnstown, Pa., on April 14, 1918. He received the B.S. and M.S. degrees from Pennsylvania State University, University Park, in 1940 and 1941, respectively.

From 1939 to 1941 he was a Graduate

Assistant in Physics at Penn. State, and from 1941 to 1946 he was a Research Physicist at the Naval Research Laboratory, Washington, D. C. Since 1946 he has been with the University of Illinois, Urbana, first as a Research Assistant Professor, and since 1954 as Research Professor and Head of the Biophysical Research Laboratory, which he established at the University. Included in his personal research are contributions to the following fields: quantitative neuroanatomy, analysis of cardiovascular systems, physical mechanism of the action of ultrasound on biological systems, ultrasonic human neurosurgery, mechanism of acoustical adsorption in tissue, vision mechanisms, reversible changes in the central nervous system produced by ultrasound, design of ultrasonic transducers, and ultrasonic interferometry.

Prof. Fry is a Fellow of the Acoustical Society of America, and a member of the American Physiological Society, the American Academy of Neurology, American Mathematical Society, Mathematical Association of America, Society for General Systems Theory, American Institute of Physics, American Institute of Ultrasonics in Medicine, the Biophysical Society, and Sigma Xi.

❖

Herman Garlan (M'46) was born in New York, N. Y., on December 5, 1907. He received the B.S. degree from the College of the City of New York, in 1929, and the E.E. degree from Columbia University, New York, in 1936.

He has been with the Federal Communications Commission since 1940, starting as a Field Engineer at the Chicago office, where he was concerned with radio station inspections and enforcement matters. In 1945 he was transferred to Washington, D. C., where he worked on regulatory matters dealing with the land mobile communications services, including station licensing, frequency allocations, promulgation of technical standards, and other rule-making activities. He transferred to the Office of the Chief Engineer in 1953, assigned to coordinate and unify the technical standards in the FCC rules. Since 1954 he has been Chief of the RF Devices Branch in the Office of the Chief Engineer where he is responsible for all aspects of the regulatory program in Parts 15 and 18 of the FCC Rules which regulate interference from nonlicensed devices such as diathermy, industrial RF heating equipment, receiver radiation, and other low-power devices.

Mr. Garlan is a member of Tau Beta Pi and Sigma Xi. He has been a member of the Administrative Committee of PGRFI since 1960. He was Vice Chairman of the 2nd and 3rd National Symposia on RFI. He was a member of the U. S. delegation to the 1958 (The Hague, Netherlands) and 1961 (Philadelphia, Pa.) Plenary Sessions of CISPR—the Special International Committee on Radio Interference.

❖

Peter C. Goldmark (A'36–M'38–F'42) was born in Budapest, Hungary, on December 2, 1906. He studied at the Universities of Berlin, Germany, and Vienna, Austria, receiving the Ph.D., in physics from the latter.

In 1936 he joined the Columbia Broadcasting System, Inc., as Chief Television Engineer, later becoming Director of the Research and Development Division. The first practical color television system was developed under his direction in the CBS Laboratories, and on August 27, 1940, the first color broadcast in history was made from the CBS television transmitter in New York. During the war CBS Laboratories were responsible for many military developments in the field of electronic countermeasures and reconnaissance, under his supervision. After the war the long-playing record was developed by Dr. Goldmark and his associates at CBS Laboratories. In 1954 he became President of CBS Laboratories and Vice President of CBS, Inc. He is also a Visiting Professor for Medical Electronics, University of Pennsylvania Medical School, Philadelphia.

Dr. Goldmark is a Fellow of the AIEE, the SMPTE, the Audio Engineering Society, and the British Television Society. In 1945 he was awarded the Television Broadcasters Association Medal for his color television pioneering work. He is the only member of the IRE to hold both the Morris Liebman Memorial Prize (1946), and the Vladimir K. Zworykin Television Prize (1961). In 1960 he received the Achievement Award from the IRE Professional Group on Audio.

❖

John N. Grace (S'51–A'52–M'54) was born in Pittsburgh, Pa., on May 27, 1924. He studied electrical engineering at Carnegie Institute of Technology, Pittsburgh, and received the D.Sc. degree in 1951. Since finishing graduate school he has been employed at Westinghouse Bettis Atomic Power Laboratory, Pittsburgh. He started in Instrumentation and Control and became Supervisor of Reactor Plant Kinetics. In 1955 he became Manager of the Advanced Development Reactor Section and in 1957 was assigned responsibility for S1W, S2W, S3W and S4W Physics. He later was responsible for Physics and Kinetics in the Natural Circulation Reactor Project and presently is Manager of Physics and Kinetics on the Destroyer Project.

Dr. Grace is a member of the American Nuclear Society and AIEE.

❖

Alfred R. Gray (A'27–VA'39–SM'56–F'61) was born in Farmington, N. H., on March 12, 1906. From 1924 to 1948 he studied courses at university extensions; from 1950 to 1960 he attended Massachusetts Institute of Technology, Capital Radio Engineering Institute, and the University of California, for advanced study.

He is President and Chief Engineer of Astronics Reliability, Inc., and Executive Vice President and General Manager of Astronics of Florida, both in Orlando, Fla. He has been an active member of the IRE Professional Group on Production Techniques, now Product Engineering and Production. He was Editor of this Group's TRANSACTIONS from 1954 to 1960. He is presently Chairman of the Administrative Committee. During 1960–1961 he also was Chairman of the Orlando Section of the IRE.

Mr. Gray is a Fellow of the Radio Club of America.

❖

Elliot L. Gruenberg (A'43–SM'50) was born in New York, N. Y., on March 16, 1918. He received the B.E.E. degree from the College of the City of New York, in 1938.

His first work was with the U. S. Army Signal Corps, as Junior Engineer inspecting radio and navigation systems such as instrument landing localizers. In 1944 he joined the Technical Devices Corporation, Roseland, N. J., as Quality Control Engineer. From 1947 to 1951 he was Senior Engineer with the J. H. Bunnell Co., Brooklyn, N. Y., working on the design of military radio receiving and transmitting equipment.

From 1951 to 1958 he was with the W. L. Maxson Corporation. As Manager of Staff Engineering, he directed activity in radar systems, ECM, ECCM, telemetry, and navigation applied to defense and control systems. In 1958 he joined the Federal Systems Division of the IBM Corporation, where he has been Technical Leader on advanced defense concepts studies concerned with ballistic missile defense. He has contributed to studies in radar, communications, and telemetry for space tracking and surveillance, missile defense and control, intelligence, and air traffic control. He is presently Manager of the Space Communications Department of the Communications Systems Center, Rockville, Md.

Mr. Gruenberg holds patents on classified electronic devices and radar systems improvements. He is co-inventor of the FASTAR system. He is presently serving as Editor-in-Chief of the "Handbook on Telemetry and Remote Control," McGraw-Hill Book Company, Inc., New York, N. Y.

❖

Ernst A. Guillemin (A-41–SM'48–F'49) was born in Milwaukee, Wis., on May 8, 1898. He received the B.S. degree in electrical engineering from the University of Wisconsin, Madison, in 1922, and the S.M. degree in electrical engineering from the Massachusetts Institute of Technology, Cambridge, in 1924. He was awarded the 1924 Saltonstall Traveling Fellowship for study at the University of Munich, Germany, where he received the Ph.D. degree in 1926.

He returned to M.I.T. as an Instructor in 1926, became an Assistant Professor in 1928, Associate Professor in 1936, and Professor of Electrical Communications in 1944.

He was appointed Consultant to the Microwave Committee of the National Defense Research Committee, in 1940. In this capacity, approximately half of his time was devoted to consultation with various groups in the Radiation Laboratory, M.I.T., on a large variety of problems dealing with the design of electrical networks for special applications. One of the results was development of a network for production of radar pulses. In 1941 he also took over the administrative responsibilities of the Communications Option, Department of Electrical Engineering, at M.I.T. In 1960 he was appointed Webster Professor of Electrical Engineering, the chair which he now holds.

In 1948 Dr. Guillemin was awarded the President's Certificate of Merit for his outstanding wartime contributions and in 1960 he was awarded the IRE medal of honor. He is a Fellow of the AIEE and the American Academy of Arts and Sciences, and a member of the American Society for Engineering Education.

Raymond F. Guy (A'25–M'31–F'39) was born in Hartford, Conn., on July 4, 1899. He is an engineering graduate of Pratt Institute, New York, N. Y.

After 42 years with NBC-RCA, New York, N. Y., he retired to enter the field of engineering consultation and representation in AM, FM, TV, and international broadcasting, with headquarters in Haworth, N. J. During the past year he has been Consulting Engineer to the United States Operations Missions in Saigon and Rabat.

Mr. Guy was President of the Institute of Radio Engineers in 1950, the Broadcast Pioneers in 1956, the De Forest Pioneers in 1958 and the Veteran Wireless Operators Association in 1960. He is Secretary of the Broadcast Pioneers, Chairman of the Engineering Subcommittee of the Voice of America, a member of its Industry Advisory Committee, and a Science Consultant for the Agency. He is a Fellow of the AIEE and the Radio Club of America. He was awarded the Marconi Gold Medal by the VWOA, a special plaque and citation by the Broadcast Pioneers, the 1961 Annual Engineering Achievement Award by the National Association of Broadcasters, and was cited by the Radio and Television Executives Society for having the longest continuous experience in broadcasting of any person in the world. For many years he was Chairman of the Engineering Committee of the TV Broadcasters Association and the Engineering Advisory Committee of the NAB. He is Chairman of the IRE Professional Group on Broadcasting.

❖

Raymond A. Heising (A'20–F'23–L) was born in Albert Lea, Minn., on August 10, 1888. He received the E.E. degree from the University of North Dakota, Grand Forks, in 1912, the M.S. degree from the University of Wisconsin, Madison, in 1914, and the honorary D.Sc. degree from the University of North Dakota, in 1947.

He entered the Research Department of the Western Electric Company, New York, N. Y., in 1914 and was one of four men assigned to initiate research in radio. He conducted the first Bell System laboratory work on multiplex carrier on wires. He designed and constructed the first Bell System radio transmitters at Montauk, N. Y., and Washington, D. C., from these, radio telephonic demonstrations were made in April and September, 1915, respectively; the latter involved transcontinental and transoceanic demonstrations. He was responsible for the development of the first practical radio telephone transmitters, which took the form of radio telephone sets for aircraft and naval ships. He independently discovered the *E* and *F* layers and their movements by "radar" type pulse technique. Since retiring from the Bell Telephone Laboratories in 1953, he has been active as a Consulting Engineer.

Dr. Heising received the Morris Liebmann Memorial Prize in 1921 and the Founders Medal in 1957. He has served on many IRE Committees and was President of the IRE in 1939. He promoted the division of work between the Executive Committee and the Board of Directors in 1942. His latest contribution to the IRE was the devising of the Professional Group System.

❖

Keith Henney (A'18–M'26–SM'43–F'43) was born in McComb, Ohio, on October 28, 1896. He received the B.A. degree from Western Reserve University, Cleveland, Ohio, in 1921, and the M.A. degree from Harvard University, Cambridge, Mass., in 1925.

In 1912 he had his first experience with radio via a crystal detector and a two-slide tuner. He had his first experience in publishing in Marion, Ohio, where he was a cub reporter on the anti-Harding daily paper. His radio experience continued by means of rotary spark gaps, Thordarson 1-kw transformers, and glass plate condensers in his amateur station 8ZD. He is still a radio amateur, operating W1QGU in New Hampshire and K2BH in New York.

In 1923 he joined the technical staff of the Western Electric Company. The next five years were spent developing a radio laboratory for Doubleday Doran & Company, publishers of *Radio Broadcast*. In 1929 his first book, "Principles of Radio" was published. It is now in its sixth edition. He became Associate Editor of *Electronics* upon its founding by the McGraw-Hill Book Company, Inc., New York, N. Y., in 1930. He became Managing Editor in 1934; Editor-in-Chief in 1935; Consulting Editor in 1946, and Editor of *Nucleonics* in 1947. He retired from McGraw-Hill, in 1961.

Mr. Henney edited the "Radio Engineering Handbook" (1933) now in its fifth edition; published "Electron Tubes in Industry" (1934) and "Color Photography for the Amateur" (1938), and was co-editor of the "Handbook of Photography" (1939). He is a member of the Harvard Club of New York City, a Fellow and Past President of the Radio Club of America, and an Associate of the Photographic Society of America. He was a Director of the IRE from 1945 to 1948. He was awarded a plaque at the 1944 Rochester Fall Meeting for "His many years of unselfish service to the radio and electronic industries through the technical press."

Karl G. Hernqvist (SM'60) was born in Boras, Sweden, on September 19, 1922. He received the E.E. and the Licentiate of Technology degrees from the Royal Institute of Technology, Stockholm, Sweden, in 1945 and 1951, respectively, and the Ph.D. degree from the same institution, in 1959.

He was an Assistant Engineer in the Royal Swedish Air Force during 1945 and 1946, where he worked in the fields of radar and microwave instrumentation. From 1946 to 1952 he was concerned with microwave measurements and electron tube research with the Research Institute of National Defense, Stockholm. During 1948 and 1949 he was a trainee under the sponsorship of the American-Scandinavian Foundation at RCA Laboratories, Princeton, N. J., where he performed research on high-density electron guns. He has been a member of the technical staff of the Electronic Research Laboratory at RCA Laboratories since 1952, where he has specialized in the gaseous electronics field. During the past several years he has headed a group working on thermionic converters.

Dr. Hernqvist is a member of the American Physical Society and Sigma Xi.

❖

Edward W. Herold (A'30–M'38–SM'43–F'48) was born in New York, N. Y., on October 15, 1907. He received the B.Sc. degree in physics from the University of Virginia, Charlottesville, in 1930, the M.Sc. degree from the Polytechnic Institute of Brooklyn, N. Y., in 1942, and an honorary D.Sc. degree, also from the Polytechnic Institute of Brooklyn, in 1961.

From 1924 to 1926 he worked at Bell Telephone Laboratories, and from 1927 to 1929 with E. T. Cunningham, Inc. He was with RCA at Harrison, N. J., from 1930 to 1942, and from 1942 to 1959 at RCA Laboratories, Princeton, N. J., where he became Director of the Electronic Research Laboratory. In 1959 he joined Varian Associates, Palo Alto, Calif., as Vice President of Research. He has made his career in research and development, specializing in electron tubes, semiconductor physics and devices, signal-to-noise problems, and plasma physics.

Dr. Herold is a member of Phi Beta Kappa and Sigma Xi, and has been active in IRE affairs, including membership on the Board of Directors, from 1956 to 1958.

❖

Julia F. Herrick (M'46) was born in North St. Paul, Minn., on September 14, 1893. She received the B.A. and M.A. degrees from the

University of Minnesota, Minneapolis, in 1915 and 1919, respectively. After several years of high school and college teaching, she returned to the University of Minnesota where she received the Ph.D. degree in biophysics, in 1931.

She was appointed a member of the staff of the Mayo Clinic and Mayo Foundation, Rochester, Minn., as a Consultant in Biophysics at the Institute of Experimental Medicine in 1936. She became an Assistant Professor of Physiology at the Mayo Foundation in 1938, an Associate Professor in 1945, and Professor in 1958. Her designation was later changed to Professor of Biophysics.

Her studies of blood flow in various mammalian blood vessels have resulted in some modifications in the Rein thermostromuhr which extended the use of this instrument to the measurement of the flow of blood under more normal conditions.

In 1942, at the request of the War Department, Dr. Herrick joined the Signal Corps Engineering Laboratories, Fort Monmouth, N. J., where her work was concerned largely with radio direction-finding. Returning to the Mayo Foundation in 1946, her research activities were devoted to the biologic effects of microwaves and ultrasound, physiologic thermometry, and the circulation of the blood. In 1959 she joined the Cardiovascular Laboratory, Department of Medicine, University of Wisconsin, Madison, as a Research Associate, and since 1960, she has been a Senior Scientist at the Vista Laboratory, California Institute of Technology, Pasadena.

Dr. Herrick has worked extensively on the development of an ultrasonic flowmeter, and with the assistance of electronic engineers and physicists, a first model of the flowmeter has been constructed. The instrument is presently being used for measuring the velocity of blood outside the natural circulation in the body; further development is necessary for measurements in the living body.

Dr. Herrick is a Fellow of the New York Academy of Sciences, and a member of the American Physiological Society, the American Physical Society, AAAS, Sigma Xi, Phi Beta Kappa, Alpha Gamma Delta, and Mortar Board. She has been chairman of the IRE Professional Groups on Medical Electronics and Ultrasonics Engineering, and is former Editor of IRE TRANSACTIONS ON MEDICAL ELECTRONICS.

❖

Ralph E. Hiatt (M'47–SM'58) was born in Portland, Ind., on April 12, 1910. He received the B.A. degree in physics from Indiana Central College, Indianapolis, in 1932, and the M.A. degree in physics from Indiana University, Bloomington, in 1939. He later took several graduate courses in mathematics

at Boston University, Mass.

He taught mathematics and science in Indiana public schools until 1942. From 1942 to 1945 he was employed by the Radiation Laboratory, Massachusetts Institute of Technology, Cambridge. As a Staff Member in the Radiation Laboratory Antenna Group, he worked on microwave radar antennas; he organized the Ipswich Antenna Test Station and was Chief of this installation in 1944 and 1945. He joined the Air Force Cambridge Research Center in 1945 and was Chief of the Ground Antenna Section until 1956. From 1956 until 1958 he was Chief of the Antenna Laboratory (later the Electromagnetic Radiation Laboratory). In 1958 he joined the Radiation Laboratory of The University of Michigan, Ann Arbor, as Associate Head of the laboratory and he organized an experimental group in the laboratory. He became Head of the Radiation Laboratory in 1961. He is currently engaged in work on radar scattering, in antenna research, and in experimental plasma studies.

Mr. Hiatt is a member of the American Physical Society, of Sigma Xi, and the American Institute of Physics. He was President of the AFCRC Branch of the Research Society of America in 1957–1958, and is listed in *American Men of Science*.

❖

John K. Hilliard (A'25–M'29–SM'43–F'52) was born in Wyndmere, N. Dak., on October 22, 1901. He received the B.S. degree in physics from Hamline University, St. Paul, Minn., in 1925, and did graduate work in electrical engineering at the University of Minnesota, Minneapolis. He received the D.Sc. degree in engineering from Hollywood University, Calif., in 1951.

He was with the Metro Goldwyn Mayer Studios, Culver City, Calif., for 14 years, where he was engaged in the development of recording and reproducing film and tape equipment, as well as designing microphones and loudspeakers for theaters. He worked then at the Radiation Laboratory of the Massachusetts Institute of Technology, Cambridge, as Project Engineer. For the past 17 years he has been with the Altec Lansing Corporation, Anaheim, Calif., where he is concerned with transducers and communication equipment. His present position is Vice President and Director of the Ling-Altec Research Division.

Dr. Hilliard is a Fellow of the Acoustical Society of America, the Audio Society, SMPTE, and is a member of AIEE, Eta Kappa Nu, the Institute of Environmental Engineers, and of the Armed Forces Committee on Hearing Bioacoustics. He is Acoustic Consultant to the Brain Institute, UCLA Medical School.

❖

Albert S. Hoagland (S'50–A'54–SM'57) was born in Berkeley, Calif., on September 13, 1926. He received the B.S. degree, in 1947, the M.S. degree, in 1948, and the Ph.D. degree, in 1954, all in electrical engineering, from the University of California at Berkeley.

He was Project Engineer on the California Digital Computer Program from 1948 to 1950. From 1954 to 1956, he was a Consultant for IBM, San Jose, and Assistant Professor at the University of California, teaching senior and graduate courses in switching theory and computers. He joined the staff of the IBM Research Laboratory, San Jose, Calif., in 1956, where he was a Senior Engineer in charge of advanced mass memory development. In 1959 he was appointed Manager of the Engineering Sciences Department. During 1960 he was on special assignment to the random access memory product development group in San Jose and is now a Systems Manager in the Advanced Systems Development Division.

Dr. Hoagland is a member of AIEE, Phi Beta Kappa, Sigma Xi, Eta Kappa Nu, and Tau Beta Pi. He is a registered professional engineer in the state of California.

❖

Conrad H. Hoeppner (SM'47–F'58) was born in Spooner, Wis., on March 12, 1918. He received the B.S.E.E. degree, in 1939, and M.S.E.E. degree, in 1940, both from the University of Wisconsin, Madison. He did graduate work at the Massachusetts Institute of Technology, Cambridge, and received the professional E.E. degree, in 1947, from the University of Wisconsin.

Thereafter, he was employed by the U. S. Naval Research Laboratories, Washington, D. C.; he was Director of the Electronics Laboratory, Glenn L. Martin Co., Baltimore, Md.; Director of the Engineering Products Department, Raytheon Manufacturing Company, Waltham, Mass.; Vice President and Director of General Electronic Laboratories, Manager of the Electronics Division of the W. L. Maxson Corporation, New York, N. Y.; Manager of the Development Division, Stavid Engineering

Plainfield, N. J., and Chief Scientist and Director of Research at Radiation, Inc., Melbourne, Fla. He is presently President of the Electronetics Corporation, Melbourne, Fla.

Mr. Hoeppner is a member of Sigma Xi, Pi Mu Epsilon, Phi Kappa Phi, Phi Eta Sigma, and Eta Kappa Nu, and is a Fellow of Tau Beta Pi and the Wisconsin Alumni Research Institute. He also served with the Research and Development Board of the Department of Defense and he holds over forty patents.

❖

Linwood S. Howeth, Captain, USN (Ret.), was born in Hurlock, Md., on February 19, 1902. He was appointed Ensign, U. S. Navy, in 1925, and received the B.S. degree from the United States Naval Academy, Annapolis, Md.

Prior to World War II he served in various assignments, afloat and ashore, most of which were in the field of communications. During World War II his major assignment was in communications in the Pacific Theater. Following the war he served in various communications billets in the Office of the Chief of Naval Operations, Washington, D. C. In 1952 he became Deputy Director, Naval Communications, Washington, D. C. He retired from that assignment in 1955. Since retiring he has devoted the major portion of his time to the preparation of "A History of Communication-Electronics in the United States Navy," which is to be published in the near future.

❖

Edward C. Jordan (S'36–A'39–SM'45–F'53) was born in Edmonton, Alberta, Canada, on December 31, 1910. He received the B.Sc. degree, in 1934, and the M.Sc. degree, in 1936, both in electrical engineering, and both from the University of Alberta, Edmonton, and, in 1940, he received the Ph.D. degree from Ohio State University, Columbus.

He was Control Operator at radio station CKUA for seven years, 1928 to 1935, Electrical Engineer for International Nickel Company for 2 years, 1935 to 1937 and since 1940 he has taught electrical engineering at Worcester Polytechnic Institute, Mass., Ohio State University and the University of Illinois, Urbana. At the latter two universities he supervised research on antennas and radio direction finding. Presently he is Professor and Head of the Department of Electrical Engineering at the University of Illinois.

Dr. Jordan is author or co-author of four books on antennas and wave propagation, and radio and electronics. He is a member of the USA National Committee of URSI and Past-Chairman of Commission VI on Radio Waves and Circuits. He is Past Chairman of the IRE Professional Group on Antennas and Propagation.

❖

John E. Karlin (M'56) was born in Johannesburg, Transvaal, South Africa, on February 28, 1918. He received the B.A. and M.A. degrees from Capetown University, in 1938 and 1939, respectively, and the Ph.D. degree from the University of Chicago, Ill., in 1942. His formal education emphasized both electrical engineering and experimental psychology.

From 1942 to 1945 he was engaged in military communications research at Harvard University's Psycho-Acoustic Laboratory, Cambridge, Mass. In 1945 he joined the technical staff of Bell Telephone Laboratories, Murray Hill, N. J. to study psychophysical problems concerned with transmission. Since 1952 he has been Head of the Human Factors Research Department studying communication properties of man from the viewpoint of man-machine coupling in communication systems.

Dr. Karlin is a member of the Acoustical Society of America and the American Psychological Association.

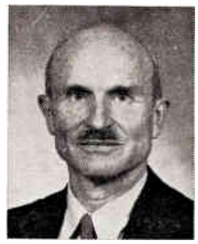
❖

Arthur C. Keller A'36–VA'39–SM'51–F'61) was born in New York, N. Y., on August 18, 1901. He received the B.S. degree, in 1923, from Cooper Union, New York, N. Y., the M.S. degree, in 1925, from Yale University, New Haven, Conn., and did graduate work at Columbia University, New York, N. Y., from 1925–1929.

He is at present Director of Switching Apparatus Development at Bell Telephone Laboratories Inc., New York, N. Y. Previously he was Director of Component Development and Director of Switching Systems Development. His interests have been in the fields of electromechanical devices, sound recording and reproducing equipment, sonar, switching apparatus, electronic heating, sputtering equipment and complete telephone systems. For contributions in World War II he received two U. S. Navy citations for his work in sonar systems and devices. At present he is a Consultant for the Department of Defense (Research and Engineering) and the Chairman of a Working Group.

Mr. Keller is a member of the AIEE, American Physical Society, Acoustical Society of America, SMPTE, Yale Engineering Association and Society for Experimental Stress Analysis, and is a licensed professional engineer in New York State. He is listed in "American Men of Science," "Who's Who in the East," "Who's Who in Engineering," etc.

❖



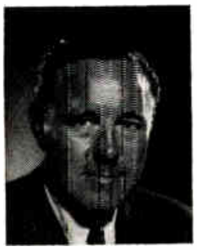
Ronold W. P. King (A'30–SM'43–F'53) was born in Williamstown, Mass., on September 19, 1905. He received the A.B. degree, in 1927, and the S.M. degree, in 1929, both from the University of Rochester, N. Y., where he majored in physics. He was awarded the Ph.D. degree by the University of Wisconsin, Madison, in 1932, after having done graduate work at the University of Munich, Germany, and Cornell University, Ithaca, N. Y.

He served as Teaching and Research Assistant at the University of Wisconsin in 1932–1934 and as Instructor and Assistant Professor of Physics at Lafayette College, Easton, Pa., in 1934–1937. The year 1937–1938 he spent in Germany as a Guggenheim Fellow. In 1938 he joined the faculty of Harvard University, Cambridge, Mass., where he advanced to the rank of Professor in 1946. He is now Gordon McKay Professor of Applied Physics at Harvard University. In 1958 he studied and traveled abroad as a Guggenheim Fellow. His research has been primarily in the field of antennas, transmission lines, and microwave circuits.

Dr. King is a Fellow of the American Physical Society and the American Academy of Arts and Sciences, a corresponding member of the Bavarian Academy of Sciences, and a member of the American Association of University Professors and the AAAS. He is also a member of Phi Beta Kappa and Sigma Xi.

❖

Winston E. Kock (S'45–F'52) was born in Cincinnati, Ohio, on December 5, 1909. He received the E.E. degree and the M.S. degree from the University of Cincinnati, in 1932 and 1933, respectively, and the



Ph.D. degree in physics from the University of Berlin, Germany, in 1934. He was a Teaching Fellow at the University of Cincinnati from 1934 to 1935, attended the Institute for Advanced Study, Princeton, N. J., from 1935 to 1936, and was a Fellow of the Indian Institute of Science at Bangalore, in 1936.

In 1936 he became Research Engineer and later Director of Electronic Research at the Baldwin Piano Company. In 1942 he joined the Radio Research Department of the Bell Telephone Laboratories, where he conducted research on microwave antennas. He was appointed Director of Acoustics Research in 1951, in which capacity he directed the research on the Navy Jezebel-Caesar project, and in 1956, he became Director of Audio and Video Systems Research. He joined the Systems Division of the Bendix Corporation, Ann Arbor, Mich., as Chief Scientist in late 1956, and became Director and General Manager of the Research Laboratories Division, Southfield, Mich., in January, 1958.

In 1958 Dr. Kock received the award of Outstanding Young Electrical Engineer from Eta Kappa Nu, and in 1952 he was awarded the honorary degree of Doctor of Science by the University of Cincinnati. He is a Fellow of the American Physical Society and the Acoustical Society of America, and a member of Tau Beta Pi, Eta Kappa Nu, and Sigma Xi. He is also a member of the Governing Board of the American Institute of Physics and the Board of Directors of Eta Kappa Nu.

❖

Granino A. Korn was born in Berlin, Germany, in 1922. He received the B.S. degree in physics and mathematics, from Brown University, Providence, R. I., in 1942, and the M.A. and Ph.D. degrees in physics from Columbia University, New York, N. Y., and Brown, in 1943 and 1948, respectively.

After wartime service in the U. S. Navy, he was successively a Project Engineer with Sperry Gyroscope, Great Neck, N. Y., Head of the Analysis Group at Curtiss-Wright, Columbus, Ohio, a Staff Engineer with Lockheed Aircraft Company, Burbank, Calif., and a Consultant under his own name. Since 1957 he has been a Professor of Electrical Engineering at the University of Arizona, Tucson, where he teaches courses on electronic computers and communications theory.

Dr. Korn is a member of Sigma Xi and Simulation Councils, Inc.

Ezra S. Krendel (SM'58) was born in New York, N. Y., on March 5, 1925. He received the B.S. degree from Brooklyn College, N. Y., in 1945, the S.M. degree in physics from the Massachusetts Institute of Technology, Cambridge, in 1947, and the M.A. degree in social relations from Harvard University, Cambridge, Mass., in 1949.

He has been with the Franklin Institute Laboratories, Philadelphia, Pa., since 1949, and presently he is the Manager of the Engineering Psychology Laboratory. His professional experience has included diverse operation research and human factor studies including human dynamics, EEG analysis, visual research, human mechanical power, communications and information flow in large man-machine systems, and the detailed analysis of many weapon systems. With D. T. McRuer, he was awarded The Franklin Institute's Louis E. Levy Medal for a quantitative engineering description of human dynamic behavior (1960).

Mr. Krendel is a member of the American Psychological Association, Operations Research Society of America, the Ergonomics Research Society, the Committee E-18 of the ASTM, and the IRE-PGHFE Administrative Committee.

❖

Benjamin Lax was born in Hungary, on December 29, 1915, and came to the U. S. in August, 1926. He ceived the B.S. degree in mechanical engineering, in 1941, from Cooper Union, New York, N. Y., and the Ph.D. degree in physics, in 1949, from the Massachusetts Institute of Technology, Cambridge.

After entering the U. S. Army in 1942, he went through OCS, and then through radar school at Harvard University, Cambridge, Mass., and the Massachusetts Institute of Technology, Cambridge. He was a Radar Officer assigned to M.I.T. Radiation Laboratory from 1944 to 1946, when he became a Consultant for Sylvania Electric Company. From 1949 to 1951 he carried out research in microwave gas discharge for the Geophysical Directorate of Cambridge Research Center. In November, 1951 he joined the Solid State Group at Lincoln Laboratory, where he became head of the Ferrites Group, in 1953, and of the Solid State Group, in 1955. In 1957 he became Associate Head of the Communications Division at Lincoln, in charge of solid-state physics in several laboratory groups, and was appointed Head of the Solid State Division when it was established, in 1958. He has also been appointed Director of the new M.I.T. National Magnet Laboratory, as of July, 1960.

Dr. Lax received the 1960 Oliver E. Buckley Prize from the American Physical Society for his fundamental contributions to microwave and infrared spectroscopy of semiconductors. He is a Fellow of the American Physical Society, and has been a member of the Executive Committee of the Solid-State Division for the American Physical Society. He is a member of Sigma Xi, of the Advisory Panel for Solid-State Science of the AF Office of Scientific Research, and of the Advisory Committee of the National Bureau of Standards. He was Associate Editor of the *Journal of Applied Physics* from 1957 to 1959, and is at present Associate Editor of the *Physical Review* and of the *Microwave Journal*.

❖

Arthur W. Lo (S'43–A'50–SM'56) was born in Shanghai, China, on May 21, 1916. He received the B.S. degree in physics from Yenching University, China, in 1938, the M.A. degree in physics from Oberlin College, Ohio, in 1946, and the Ph.D. degree in electrical engineering from the University of Illinois, Urbana, in 1949.

He taught physics and electronics in several colleges before joining the Radio Corporation of America, in 1951. At RCA Laboratories he developed a number of basic techniques on using solid-state devices for logic and memory. He was in charge of a switching research group responsible for developing various basic millimicrosecond switching techniques using parametric phase-locked oscillators and tunnel diodes, and for developing a unified view on digital components and circuits. He joined the International Business Machines Corporation, Poughkeepsie, N. Y., in 1960, and served as Manager, Advanced Technical Development, in the Data Systems Division. He is presently in charge of Exploratory Digital Technology in the Components Division.

In his field of work Dr. Lo has contributed a number of technical papers and lectures, and U. S. and foreign patents. He has also co-authored a textbook, "Transistor Electronics." He is a member of Sigma Xi.

❖

Harold W. Lord was born in Eureka, Calif., on August 20, 1905. He received the B.S. degree in electrical engineering, in 1926, from the California Institute of Technology, Pasadena.

Since 1926 he has been employed in several Engineering Departments and Laboratories of the General Electric Company doing research and advanced development work in various fields of electronic and magnetic circuitry and combinations thereof, including radar pulse modulators, television sweep circuits, magnetic amplifiers, broad-band transformers, ballasts for arc discharge devices and high-speed transient studies of arc ignition. For the invention of thyratron synchronous timing circuits for resistance welders, he received the Coffin Award in 1933. He is presently in the Applied Physics Section of the General Electric Research Laboratories, Schenectady, N. Y., and is also a Consultant to the U. S. Department of Defense.

Mr. Lord is a Fellow of the AIEE.

❖

Lee B. Lusted (A'45–SM'53–F'59) was born in Mason City, Iowa, on May 22, 1922. He received the B.A. degree from Cornell College, Mount Vernon, Iowa, in 1943, with a major in mathematics and physics.

Following graduation he joined the Radio Research Laboratory, Harvard University, Cambridge, Mass., as a Special Research Fellow to work on radar countermeasures. In 1944, at the request of General Eisenhower, he went to the European Theatre of Operations as a member of the Petticoat Mission to supervise the installation of countermeasures equipment on ships of the British Home Fleet prior to D-Day.

Following World War II he entered the Harvard Medical School and received the M.D. degree, in 1950. He took specialty training in radiology at the University of California, San Francisco, where he was Assistant Professor of Radiology until 1956, when he joined the Diagnostic X-ray Department at the National Institutes of Health. At the present time he is Professor of Biomedical Engineering and Associate Professor of Radiology at the University of Rochester, N. Y.

He was Chairman of IRE-PGME, in 1956–1957, and he has been Editor of the IRE Transactions on Bio-Medical Electronics, since 1959. In 1960 and 1961 he was a United States representative on the Council of the International Federation for Medical Electronics and is now a member of the Executive Committee. He is Chairman of the National Institutes of Health Advisory Committee on Computers in Research and a member of the National Academy of Sciences-National Research Council Committee on the Use of Electronic Computers in the Life Sciences.

Dr. Lusted is a Fellow of the New York Academy of Sciences and the AAAS. He is a Diplomate of the American Board of Radiology and a member of the American Roentgen Ray Society, the Radiological Society of North America and Sigma Xi.

R. Stuart Mackay (SM'56) was born in San Francisco, Calif., on January 3, 1924. He received the B.A. and Ph.D. degrees in physics from the University of California at Berkeley, in 1944 and 1952, respectively.

He was a Teaching Assistant in both physics and electrical engineering at the University of California from 1944 to 1949. He was responsible for the University's first electron microscope, 1946–1951. From 1949 to 1957, he was Lecturer and then Assistant Professor of Electrical Engineering. During this period he organized some of the first courses in electronic pulse techniques and in electron microscopy. At the University of California Medical Center, San Francisco, he organized and was Director of the Research and Development Laboratory, from 1954 to 1958. He was also Lecturer in Biophysics and Associate Research Biophysicist, from 1954 to 1957. In the summer of 1956 he was a Deputy Project Officer at the AEC tests in the Marshall Islands.

During 1957–1958, he was a Guggenheim Fellow at the Karolinska Institute, Stockholm, Sweden, where later he was Visiting Associate Professor of Medical Physics in the summer of 1959. From 1958 to 1960 he was Associate Clinical Professor of Experimental Radiology and Associate Research Physicist in the Radiology Department of the UC Medical Center. From 1960 to 1961 he was Visiting Professor of Biophysics at the University of Cairo, Egypt, and also Fulbright Lecturer. He is presently Associate Clinical Professor of Optometry and Associate Research Biophysicist at University of California at Berkeley.

Dr. Mackay is a member of the Mine Advisory Committee of the National Research Council of the National Academy of Sciences, and of Phi Beta Kappa, Sigma Xi, and Pi Mu Epsilon. He is former Vice Chairman of the IRE Professional Group on Bio-Medical Electronics.

❖

Laurence A. Manning (S'43–A'45–SM'55) was born in Palo Alto, Calif., on April 28, 1923. He received the A.B. degree in electrical engineering from Stanford University, Calif., in 1944, and the M.Sc. and Ph.D. degrees, in 1948 and 1949, respectively.

He joined the war-time Radio Research Laboratory at Harvard University, Cambridge, Mass., as a Special Research Associate. He is now a Professor of Electrical Engineering at Stanford. His principal interests are in the fields of ionospheric radio propagation and engineering education.

Dr. Manning is a member of Sigma Xi, Phi Beta Kappa, the American Geophysical Union, the American Meteorological Society, and the U.S.A. National Committee of the International Scientific Radio Union.

❖

Jesse Marsten (M'25–SM'43–F'57) was born in Hungary, on January 1, 1897. He received the B.S. degree, in 1917, from the College of the City of New York, N. Y.

From 1917 to 1919 he was an Assistant Engineer at the Marconi Wireless Telegraph Company of America, Aldene, N. J. He then joined the Radio Corporation of America, New York, N. Y., as a Broadcast Transmission Engineer. He was Chief Engineer at the Freed-Eisemann Radio Corporation, Brooklyn, N. Y., during the years 1925 to 1930. In 1930 he joined the International Resistance Company, Philadelphia, Pa., where he was Vice President and then Senior Vice President. He retired from this firm in 1961, but continues to serve as a Consultant.

❖

Warren P. Mason (A'36–F'41) was born in Colorado Springs, Colo., on September 28, 1900. He received the B.S.E.E. degree from the University of Kansas, Lawrence, in 1921, and the M.S. and Ph.D. degrees from Columbia University, New York, N. Y., in 1924 and 1928, respectively.

He has been principally engaged in investigating the properties of solids. He has also studied wear, fatigue in metals, and the joining of materials in solderless wrapped connections and thermocompression bonds. He is in charge of the Applied Mechanics Research group of the Bell Telephone Laboratories, Murray Hill, N. J.

Dr. Mason is a Fellow of the American Physical Society and of the Acoustical Society of America. He is a member of the Rheological Society and of Sigma Xi and Tau Beta Pi.

❖

Frank Massa (A'30–VA'39–M'55–F'59) was born in Boston, Mass., on April 10, 1906. He received both the B.S. degree in electrical engineering and the M.Sc. degree from the Massachusetts Institute of Technology, Cambridge, in 1927 and 1928, respectively. From 1927 to 1928, he was a Swope Fellow at M.I.T.

From 1928 to 1940 he was employed by the Victor Talking Machine Company, Camden, N. J., where he did pioneering work in electroacoustics, including the creation of earliest acoustic test procedures and the initial basic development of many types of microphones, loudspeakers, phonograph pickups, etc., widely used in radio, phonograph and sound-motion-picture reproduction. He was associated with the Brush Development Company, Cleveland, Ohio, from 1940 to 1945, where he was Director of Acoustical Engineering in charge of basic research and development of sonar transducers. He was personally responsible for the development of more than fifty new underwater transducers used during World War II in connection with anti-submarine warfare and acoustic mine equipments. During the years 1945 to 1958 he was President and Director of Engineering at Massa Laboratories, Inc., Hingham, Mass. There he supervised the development of numerous electroacoustic products and instruments, including sonar transducers for use in acoustically guided torpedoes, acoustic mines, antisubmarine warfare applications, and other electroacoustic products for industrial applications. In 1958 he became President of the Massa Division, Cohu Electronics, Inc., Hingham, Mass., which is continuing the work of Massa Laboratories. He is also Vice President and Director of Cohu Electronics, Inc. During World War II, he served under U. S. Navy auspices on several scientific committees dealing with undersea warfare, hydrophonic standardization, calibration of hydrophones, underwater sound measurements, etc. He also served on numerous committees of the American Standards Association and the Acoustical Society of America where he dealt with problems in electroacoustics.

Mr. Massa is a Fellow of the Acoustical Society of America, and a member of AIP. He is the author of textbooks, papers, and patents mostly dealing with electroacoustics.

❖

John G. Mavroides was born in Ipswich, Mass., on December 29, 1922. He received the B.S. degree in electrical engineering from Tufts University, Medford, Mass., in 1944, and the M. S. and Ph.D. degrees in physics, in 1951 and 1953, respectively, from Brown University, Providence, R. I. While at Brown, he was Research Assistant in Ultrasonics, in 1950 to 1951, and R. G. D. Richardson Fellow, in 1951 to 1952.

In 1944 he was commissioned an Aviation Officer in the U. S. Naval Reserve. After attending the Navy Electronics and Radar Schools at Bowdoin College, Brunswick, Me., and the Massachusetts Institute of Technology, Cambridge, he served in the Pacific Theatre as a Technical and Tactical Radar Officer. In 1946 he joined the Transducer Group of the U. S. Navy Underwater Sound Laboratory, New London, Conn., where he was engaged in the research, design and development of solid-state sonic and ultrasonic electromechanical devices for underwater communications and sonar.

Since 1952 he has been a member of the staff of M.I.T. Lincoln Laboratory, Lexington, where he has been concerned with various phases of solid-state research, including semiconductor devices and the investigation of the electronic band structure of solids employing galvanomagnetic, magnetoacoustic resonance and infrared magnetospectroscopy techniques. At present he is leader of the Solid-State Spectroscopy Group.

Dr. Mavroides is a member of the American Physical Society, Tau Beta Pi, and Sigma Xi.

❖

Eleanor M. McElwee (M'51–SM'53) was born in New York, N. Y., on May 15, 1924. She received the B.A. degree in english and mathematics from Ladycliff College, Highland Falls, N. Y., in 1944. She has also taken courses at the Cooper Union Evening School of Engineering and at the Technical Publications Center of Fordham University.

She worked for the Western Electric Company, N. Y., from 1944 to 1947, as an Assistant Engineer of manufacture, and for the Sylvania Product Development Laboratories from 1947 to 1951, first as an Engineering Analyst and then as a Technical Editor. Since 1951 she has been an Engineer in the Commercial Engineering activity of the RCA Electron Tube Division, Harrison, N. J.

Miss McElwee has had several papers published in Sylvania and RCA company magazines and in various IRE publications. She has also taught courses in writing and editing at RCA and at Fordham University. She was the organizer of the IRE Professional Group on Engineering Writing and Speech and has served as Secretary since its inception. She is also a member of the Professional Groups on Education and Engineering Management.

❖

Brockway McMillan (SM'54–F'62) was born in Minneapolis, Minn., on March 30, 1915. He received the B.S. and Ph.D. degrees in mathematics from the Massachusetts Institute of Technology, Cambridge, in 1936 and 1939, respectively.

Prior to going on active duty with the Navy in 1943, he was an Instructor at M.I.T., and a Procter Fellow and H. B. Fine Instructor at Princeton University, N. J. During his tour with the Navy, he served at the U. S. Naval Proving Ground, Dahlgren, Va., and at the Los Alamos Laboratory, N. Mex. In 1946 he joined Bell Telephone Laboratories, Murray Hill, N. J., as a Research Mathematician; in 1955 he became Assistant Director of Systems Engineering, and in 1959 he was named Director of Military Research.

Dr. McMillan has served as occasional Consultant to a number of offices in the Department of Defense, to the Office of Defense Mobilization, to the Weapons Systems Evaluation Group, and with the Office of the President's Special Assistant for Science and Technology. In June, 1961, he was sworn in as Assistant Secretary of the Air Force for Research and Development.

Dr. McMillan is a member of the Society for Industrial and Applied Mathematics (of which he is a Past President), the American Mathematical Society, Mathematical Association of America, Institute of Mathematical Statistics, Operations Research Society, and the AAAS.

❖

Duane T. McRuer (S'47–A'50–SM'54) was born in Bakersfield, Calif., on October 25, 1925. He received the B.S. and M.S.E.E. degrees from the California Institute of Technology, Pasadena, in 1945 and 1948.

Since 1957 he has been President of Systems Technology, Inc., Inglewood, Calif. His previous associations have been with Northrop Aircraft, from 1948 to 1954, and with Control Specialists, Inc., from 1954 to 1957. Professionally, he has covered most aspects of control systems engineering with particular emphasis on the development and design of manual and automatic guidance and flight control systems. With E. S. Krendel, he was awarded, in 1960, the Franklin Institute's Levy Medal for work on the description of human dynamic behavior.

Mr. McRuer is a member of SAE Committee A-18 (Aerospace Vehicle Flight Control, and the IRE-PGHFE Administrative Committee. He is an Associate Fellow of the Institute of Aeronautical Sciences, a senior member of the American Astronomical Society, and a member of the American Rocket Society, the American Physical Society, and the AIEE.

Stewart E. Miller (M'46–SM'53–F'58) was born in Milwaukee, Wis., on September 1, 1918. He received the S.B. and S.M. degrees in electrical engineering from Massachusetts Institute of Technology, Cambridge, in 1941.

Since 1941 he has been employed by the Bell Telephone Laboratories, Red Bank, N. J., and has been concerned with coaxial transmission system development, radar system development, and microwave communication research. At present he is Director of Guided Wave Systems Research. He has served the U. S. Air Force in several advisory capacities.

Mr. Miller is a member of Eta Kappa Nu and Tau Beta Pi and is an associate of Sigma Xi.

❖

Captain Alton B. Moody was born in Thatcher, Ariz., on July 28, 1911. He was graduated from the U.S. Naval Academy, in 1935, and is an experienced air and sea navigator.

He has taught navigation at the Naval Academy, and has written or edited several widely-used books and a number of articles on navigation. He was chairman of a group that in 1961 conducted a long-range scientific study of navigation for NATO. He has received the Thurlow Award for the outstanding contribution to the science of navigation, and other recognitions. In February, 1962 he became Chief, Navigational Systems of the National Aeronautics and Space Administration.

Captain Moody is Past President of the Institute of Navigation and a member of the Board of Governors of the American Polar Society, the New York Academy of Sciences, the AAAS, and the Scientific Research Society of America.

❖

George A. Morton (A'39–SM'46–F'51) was born in New Hartford, N. Y., on March 24, 1903. He received the B.S. degree in electrical engineering, in 1926, the M.S. degree in electrical engineering, in 1928, and the Ph.D. degree in physics, in 1932, all from Massachusetts Institute of Technology, Cambridge.

He was a Research Associate and Instructor at M.I.T., from 1927 to 1933. He joined the Research Laboratory of RCA Manufacturing Company, Camden, N. J., in 1933, as a Research Engineer. He was transferred to RCA Laboratories, Princeton, N. J., in 1941, as a Research Section Head and in 1954 became Associate Director of the Physical and Chemical Research Laboratory. He is now Director of the Conversion Devices Laboratory, Electron Tube Division, RCA Laboratories, Princeton.

During World War II Dr. Morton was a Section Member, National Defense Research, and a member of the AAF Advisory Board, NDRC, RDB Panel IR. He received the IEE Overseas Premium Award and Air Force, Navy, and Army Certificates for War Research. He is the co-author of "Television" (1940, 1954), "Electron Optics and the Electron Microscope" (1945). He is a Fellow of the American Physical Society and a member of Sigma Xi, the AIEE, and the AAAS.

❖

Daniel E. Noble (A'25–SM'44–F'47) was born in Naugatuck, Conn., on October 4, 1901. He received the B.S. degree, in 1929, from Connecticut State College (now the University of Connecticut), Storrs. His Connecticut training was supplemented by graduate work at the Massachusetts Institute of Technology, Cambridge, and by summer work at Harvard University, Cambridge, Mass.

Over a period of seventeen years, he combined the teaching of mathematics and electrical engineering at the University of Connecticut with consulting work and radio and electronic experimentation. He joined Motorola, Inc., in 1940, as Director of Research. Before leaving the University of Connecticut, he pioneered FM radio broadcast and mobile radio development work and, as Consultant to the Connecticut State Police, he was responsible for the design and development of the first statewide two-way mobile radio communications state police system and the first FM system. With Motorola, he advanced over the years from Director of Research to General Manager of the Communications and Electronics Division, to Vice President and Director, and finally, to his present position as Director and Executive Vice President in charge of the three Motorola Divisions dealing with communications, semiconductor, and military electronics products. While Manager of the Communications Division of Motorola, he directed the development of equipment improvements which paced the universal change-over of land-mobile radio systems from AM to FM. He particularly emphasized engineering effort directed to the solution of the problems related to the need for substantial increases in the efficiency of spectrum utilization.

With the announcement of the invention of the junction transistor, his interest turned to the semiconductor and solid-state electronics fields as the most promising areas for corporate expansion. He initiated programs of transistor circuitry research and transistor applications in the Communications and Military Electronics Divisions, and established the Corporate Semiconductor Research Organization, which was later expanded into the Motorola Semiconductor Products Division. He also organized the Solid-State Electronics Department. This new department extended the research into the areas of specialized solid-state devices, integrated circuits, and informational processing and controls. He planned that this department should also serve as the point of dissemination for new solid-state techniques for use in the development of new products and product improvement in all other corporate divisions. He has been particularly active in the organization and coordination of corporate research and development programs concerned with both thin film and morphological, or molecular, integrated circuits. His experience and interests have included not only research and development, which he characterizes as major problems of selection and emphasis, but also the over-all responsibility for the design, mass production, sales, service, and customer relations associated with a complex industrial electronics manufacturing operation.

He has served either as chairman or as a member of many industrial and professional, technical and advisory committees, including the Radio Technical Planning Board (Chairman of Panel 13), and the National Color Television Systems Committee. He holds three patents on electronic devices, including the basic FM squelch patent.

Mr. Noble is a member of the Board of Directors of the Arizona State University Foundation, Chairman of the Foundation Advisory Committee on Engineering and Science Education, and a member of the Army Scientific Advisory Panel. He received the honorary D.Sc. degree from Arizona State College, Tempe, in 1957.

❖

Kenneth A. Norton (A'29–M'38–SM'43–F'43) was born in Rockwell City, Iowa, on February 27, 1907. He received the B.S. degree in physics from the University of Chicago, Ill., in 1928, and continued his studies at Columbia University, New York, N. Y., from 1930 to 1931.

During 1929 he was with the Western Electric Company, Chicago, Ill. From 1929 to 1934 he was in the radio section of the National Bureau of Standards, Washington, D. C. He then joined the technical information section of the Federal Communications Commission, Washington, D. C. from 1934

to 1942, and was responsible for a technical study of clear-channel broadcasting and the initial technical studies leading to the allocation of frequencies to television broadcasting. He was Assistant Director of the operational research group and a Consultant on radio propagation in the Office of the Chief Signal Officer, Washington, D. C., from 1942 to 1943 and from 1944 to 1946. He also served as a radio and tactical countermeasures analyst in the operational research section of the Eighth Air Force in England, 1943 to 1944. Since 1946 he has been in the Central Radio Propagation Laboratory of the National Bureau of Standards where he organized and was Chief of the Frequency Utilization Research Section. At present he is Chief of the Radio Propagation Engineering Division, Boulder, Colo., and is currently concerned with radio guidance systems for missiles and satellites, long-range radio communications systems involving transmission via satellites, tropospheric scatter and propagation at very low frequencies.

He has been a delegate to several international radio conferences, including the Provisional Frequency Board, Geneva, Switzerland, 1948, and the High-Frequency Broadcasting Conference, Mexico City, 1948. He was Vice Chairman of the United States delegation to the 1950 meetings of Television Study Group 11 of the International Radio Consultative Committee (CCIR) in the United States, France, The Netherlands, and the United Kingdom. He was a United States delegate to the Interim Study Group Meetings of the CCIR, Geneva, 1958, and to the IXth Plenary Assembly of the CCIR, Los Angeles, Calif. He was also a delegate to the XIth and XIIIth General Assemblies of the International Scientific Radio Union (URSI), The Hague, The Netherlands, 1954, and London, England, 1960, respectively, as well as Chairman of the Local Arrangements Committee for the XIIth General Assembly, Boulder, Colo., 1957.

Mr. Norton was awarded the Stuart Ballantine medal by the Franklin Institute, for his work on radio propagation and FM and television frequency allocations. In 1960 he received the IRE Harry Diamond Memorial Award, the highest award offered to a government employee in the field of radio and electronics. He was cited for "contributions to the understanding of radio wave propagation." In 1962 he received the Exceptional Service Award of the U. S. Department of Commerce for "outstanding contributions and leadership in the field of radio propagation research." He is a Fellow of the American Physical Society, AAAS, AIEE, and a member of the Scientific Research Society of America, the American Geophysical Union, the American Mathematical Society, the Institute of Mathematical Statistics, and the American Statistical Association.

James D. O'Connell (SM'53–F'57), Lieutenant General, USA (Ret.), was born in Chicago, Ill., on September 25, 1899. He received the B.S. degree, in 1922, from the United States Military Academy, West Point, N. Y. Prior to World War II he served in a variety of troop assignments and commands overseas and in the United States. During this period he attended the Signal School, Northwestern University, Evanston, Ill., Sheffield Scientific School, Yale University, New Haven, Conn. (where he received the M.S. degree in communications engineering); and the Command General Staff School.

During the war he served in Washington, in the North African theater and later in the European theater. Following the war, he served as Commanding Officer, Signal Corps Engineering Laboratories; Signal Officer, Eighth U. S. Army in Japan; Signal Officer, Second U. S. Army; Deputy Chief Signal Officer and Chief Signal Officer, U. S. Army. He holds both foreign and U. S. Army decorations, including the Distinguished Service Medal. He retired in May, 1959, and later that year became a Vice President of General Telephone, and Electronics Laboratories.

General O'Connell is a member of the Joint Technical Advisory Committee of the IRE-EIA, and Chairman, JTAC Ad Hoc Committee 60.2 Space Communications.

❖

B. M. Oliver (S'40–A'40–M'46–SM'53–F'54) was born in Santa Cruz, Calif., on May 27, 1916. He received the B.A. degree in electrical engineering from Stanford University, Calif., in 1935, and the M.S. degree from the California Institute of Technology, Pasadena, in 1936. Following a year of study in Germany under an exchange scholarship, he returned to the California Institute of Technology where he received the Ph.D. degree, in 1940.

From 1939 to 1952 he was employed at the Bell Telephone Laboratories, Murray Hill, N. J., in television research and radar development. He is now Vice President in Charge of Research and Development at the Hewlett-Packard Company, Palo Alto, Calif.

Dr. Oliver is a member of the American Astronautical Society.

❖

Harry F. Olson (A'37–VA'39–SM'48–F'49) was born in Mt. Pleasant, Iowa, on December 28, 1902. He received the B.E.

degree, in 1924, the M.S. degree, in 1925, the Ph.D. degree, in 1928, and the professional E.E. degree, in 1932, all from the University of Iowa, Iowa City. He received the honorary degree of D.Sc., in 1959, from Iowa Wesleyan, Mt. Pleasant.

In 1928 he joined the Radio Corporation of America, and worked in several of their divisions until 1941, when he joined the RCA Laboratories, Princeton, N. J. He is presently the Director of the Acoustical and Electromechanical Laboratory of the RCA Laboratories. From 1939 to 1943 he was a Lecturer in Acoustical Engineering at Columbia University, New York, N. Y.

For his contributions to the field of audio engineering, he received the Modern Pioneer Award of the National Association of Manufacturers, in 1940, the John H. Potts Medal of the Audio Engineering Society, in 1952, the Samuel Warner Medal of the Society of Motion Picture and Television Engineers, in 1955, the John Scott Medal of the City of Philadelphia, in 1956, and the Achievement Award of the IRE Professional Group on Audio, in 1956. In 1959 he was honored by election to the National Academy of Sciences.

Dr. Olson is a Fellow of the American Physical Society, the Acoustical Society of America, the Audio Engineering Society, and SMPTE, and a member of Tau Beta Pi and Sigma Xi. He was President of the Acoustical Society of America, in 1952, and is currently President of the Audio Engineering Society. He has served as Chairman of the Professional Group on Audio (1957–1958), Director of the IRE (1959–1960), and on numerous IRE committees.

❖

Clure H. Owen (A'32–VA'39–M'55) was born in Aldrich, Mo., on June 5, 1904. He received the B.S. and M.S. degrees in electrical engineering from the Georgia Institute of Technology, Atlanta, in 1930 and 1936.

From 1927 to 1931 he worked as a Radio Operator at Broadcast Station WSB, Atlanta. He served as Radio Inspector and Radio Engineer with the Federal Communications Commission in Atlanta and Washington, 1931 to 1935. Since 1945 he has been with the American Broadcasting Company, New York, N. Y., as Allocations Engineer and Business Manager of the Engineering Department.

Mr. Owen was on the Administrative Committee of the IRE Professional Group on Broadcasting from its inception until 1960, and was its Chairman in 1958 and 1959.

Alvin L. Pachynski (SM'59), Major General, USAF (Ret.), was born in Chicago, Ill., on October 10, 1904. In 1927 he was appointed Second Lieutenant, Signal Corps, and received the B.S. degree from the United States Military Academy, West Point, N. Y. In 1928 he received the M.S. degree from Yale University, New Haven, Conn.

There followed 12 years of experience in Army communications, primarily in the engineering of fixed radio stations. In 1940 he was assigned to Air Force staff and command positions in which he was variously responsible for the organization, planning, operation, programming and research and development of communications-electronics systems; these culminated with his appointment in 1953 and 1956, respectively, as Air Force Deputy Director and Director of Communications-Electronics. He retired in 1958, and at present is a Consultant.

Major General Pachynski is an honorary Life Member and a National Director of AFCEA.

❖

Robert M. Page (SM'45–F'47) was born in St. Paul, Minn., on June 2, 1903. He received the B.S. degree in physics from Hamline University, St. Paul, in 1927, the M.S. degree in physics from George Washington University, Washington, D. C., in 1932, and was awarded an Honorary Doctor of Science degree by Hamline University, in 1943.

Since 1927 he has been at the Naval Research Laboratory, Washington, D. C., where his work has been precision instrumentation in the field of electronics. In 1934 he completed the first pulse radar in the world for detection of aircraft, for which he received the U. S. Navy Distinguished Civilian Service Award, the Presidential Certificate of Merit, an IRE Fellowship, the Harry Diamond Memorial Award of IRE, and the Stuart Ballantine Medal of the Franklin Institute. In recognition of technical and scientific achievement in research and development for the United States Navy, he has been given the Captain Robert Dexter Conrad Award. In March of 1960 he was presented with the President's Award for Distinguished Federal Civilian Service. He is now Director of Research at the U. S. Naval Research Laboratory.

Mr. Page is a Fellow of the AAAS and the American Scientific Affiliation. He is a member of the Washington Academy of Sciences, the Scientific Research Society of America, and the Armed Forces Electronics and Communications Association.

George W. Patterson (J'31–A'49–SM'54–F'59) was born in Rochester, N. Y., on May 6, 1912. He received the B.S.E.E. degree from the University of Vermont, Burlington, in 1934, the M.A. degree in physics from Columbia University, New York, N. Y., in 1936, and the Ph.D. degree in mathematics from the University of Pennsylvania, Philadelphia, in 1958.

After teaching in public schools (1935–1937), he joined the staff of the National Bureau of Standards, initially on the staff of WWV, 1938 to 1939, and later on the Bat-Pelican project, 1953 to 1956. He received the Naval Ordnance Development Award for distinguished civilian service from the U. S. Navy for his contribution to this pioneer guided missile development. In 1946 he joined the staff of the Moore School of Electrical Engineering of the University of Pennsylvania, where he designed the logic for the EDVAC arithmetic circuits and coordinated the logic design for the entire machine. From 1950 to 1955 he was with the Research Center of the Burroughs Corporation, Paoli, Pa., after which he rejoined the faculty of the Moore School. Currently he is Associate Professor and Section Head for systems logic research there.

In addition to teaching and directing research on switching theory, Prof. Patterson has been active in computer standardization, having been a member of the Electronic Computers Committee since 1949, and currently Vice Chairman. He was also a member of the ACM committee that wrote the first programming glossary, and a member of the ASA Y32-14 task group that developed standards for computer logic symbols. He is now a member of ASA sectional committee X3 on data-processing systems. He is also a member of the American Mathematical Society, the Franklin Institute, Phi Beta Kappa, Sigma Xi, and a Fellow of the AAAS.

❖

Richard L. Petritz (A'54–M'60–SM'62) was born in Rockford, Ill., on October 24, 1922. He received the B.S. and M.S. degrees in electrical engineering, in 1946 and 1947, respectively, and the Ph.D. degree in physics, in 1950, all from Northwestern University, Evanston, Ill.

While completing his graduate studies at Northwestern University where he was a Walter P. Murphy Fellow, from January, 1948 to June, 1949, he held various positions in the fields of physics, electronics and nuclear weapons. From 1950 to 1954 he was a member of the Physics Department of the Catholic University of America, Washington, D. C. Prior to joining Texas Instruments, Incorporated, Dallas, Tex., in 1958, he was Chief of the Semiconductor Research Branch at the U. S. Naval Ordnance Laboratory, White Oak, Md. At present he is Director of the Semiconductor Research Laboratory, Corporate Research and Engineering at Texas Instruments.

Dr. Petritz received the IRE Browder J. Thompson Memorial Prize, in March, 1954, and the U. S. Navy honored him with the Meritorious Civilian Service Award in December, 1954. He is a member of the American Association of Physics Teachers, the American Association of University Professors, the American Physical Society, Eta Kappa Nu, Sigma Xi, Tau Beta Pi, Triangle Fraternity, the Washington Philosophical Society, and a Fellow of the Texas Academy of Science.

❖

John R. Pierce (S'35–A'38–SM'46–F'48) was born in Des Moines, Iowa, on March 27, 1910. He received the B.S. degree, in 1933, and the Ph.D. degree, in 1936, from the California Institute of Technology, Pasadena, and went to the Bell Telephone Laboratories the same year.

From 1936 to 1955 he worked on high-frequency electron tubes, and particularly on traveling-wave tubes. He became Director of Electronics Research in 1952 and is now Executive Director, Research—Communications Principles Division, a field including research in radio, television, electronics, acoustics and vision, mathematics, and group behavior. The Bell Laboratories' work on Project Echo has been carried out in his department.

In 1948 he received the IRE Fellow Award for his "many contributions to the theory and design of vacuum tubes." He was the recipient of the Eta Kappa Nu Outstanding Young Electrical Engineer Award for 1942 and the IRE Morris Liebmann Memorial Prize for 1947. He was Editor of the PROCEEDINGS OF THE IRE 1954–1955. In 1960 he received the Stuart Ballantine Medal.

He is the author of "The Theory and Design of Electron Beams," "Traveling-Wave Tubes," "Electrons, Waves and Messages," "Man's World of Sound" (with E. E. David, Jr.), and "Symbols, Signals and Noise," and in addition has written many popular science articles for various magazines.

Dr. Pierce is a Fellow of the American Physical Society, the Acoustical Society of America, and the British Interplanetary Society, and a member of the National Academy of Sciences.

Leon Podolsky (A'30–M'46–SM'53–F'57) was born in Philadelphia, Pa., on November 3, 1910. He received the E.E. degree from the Drexel Institute of Technology, Philadelphia, in 1934, and he did graduate work in medical physics at Temple University Medical School, Philadelphia, from 1934 to 1937.

His entire career in the electronics industry has been associated with components. He has acted as a Consultant to the Armed Forces and has been chairman of numerous military-industry task forces in the electronic components field, including D.O.D. AGREE Task Force V. He is Chairman of the EIA Component Parts Panel, Chairman of ASA Committee C83, and Chief Technical Advisor on Electronic Components to the U. S. National Committee of the International Electrotechnical Commission. As the Chief U. S. Delegate on Electronic Components, he attended meetings of the International Electrotechnical Commission in Europe and Asia for the years 1952 to 1960. Presently, he is Technical Assistant to the President of the Sprague Electric Company, North Adams, Mass.

Mr. Podolsky is a Fellow of the AIEE and is a registered professional engineer in the states of Massachusetts and New York. He has received numerous government and industry awards for outstanding service and was the recipient of the IRE-EIA Fall Meeting Award in 1957.

❖

Insley B. Pyne (S'49–A'50–M'55) was born in New York, N. Y., on July 26, 1919. He received the A.B. degree in physics and the M.S.E. degree in electrical engineering, both from Princeton University, N. J., in 1948 and 1950, respectively.

From 1951 to 1961 he served on the faculty of the Electrical Engineering Department at Princeton, first as Instructor (1951 to 1952) and later as Assistant Professor (1952 to 1961). In 1961 he joined the staff of the Princeton Computer Center. His work has been in the field of analog and digital computers, and switching theory.

Mr. Pyne is a member of the AIEE and Sigma Xi.

❖

John R. Ragazzini (A'41–M'46–SM'52–F'55) was born in New York, N. Y., on January 3, 1912. He received the B.S. and E.E. degrees from the College of the City of New York, in 1932 and 1933, respectively, and the A.M. and Ph.D. degrees from Columbia University, New York, N. Y., in 1938 and 1941, respectively.

He began his teaching career in the School of Technology at C.C.N.Y., later going to Columbia University where until recently he was Professor of Electrical Engineering and Chairman of that department. In July, 1958, he left Columbia University to become Dean of the College of Engineering at New York University. He directed research at Columbia University during World War II in the area of fire and bombing control by means of electronic simulators. This work led to many of the early developments in electronic analog computers and simulators. His later research work was in the field of control systems and, more specifically, in sampled-data control systems. He has been a Consultant in the fields of computers, control and guidance systems for a number of industrial organizations.

Dr. Ragazzini is a member of Phi Beta Kappa, Tau Beta Pi, Sigma Xi, and Eta Kappa Nu.

❖

Edward G. Ramberg (M'53–SM'53–F'55) was born in Florence, Italy, on June 14, 1907. He attended Reed College, Portland, Ore., and received the B.A. degree from Cornell University, Ithaca, N. Y., in 1928, and the Ph.D. degree in theoretical physics from the University of Munich, Germany, in 1932.

He joined the Electronic Research Laboratory of the RCA Manufacturing Company, Camden, N. J., as a Junior Engineer, in 1935, and was transferred to the RCA Laboratories at the David Sarnoff Research Center, Princeton, N. J., in 1942. Except for three interruptions—in Civilian Public Service, 1943 to 1945, as Visiting Professor at the University of Munich, in 1949, and as Fulbright Lecturer at the Technische Hochschule, Darmstadt, Germany, 1960 to 1961, —he has worked since then as a Research Physicist at the RCA Laboratories in the fields of electron microscopy, electron optics and optics relating to television, theory of thermoelectric refrigeration, and other problems in electron physics.

Dr. Ramberg is a Fellow of the American Physical Society and a member of the Electron Microscope Society of America, the American Association of Physics Teachers, the AAAS, Sigma Xi, and Phi Kappa Phi. In 1959, he was named a Fellow of the Technical Staff of RCA Laboratories.

❖

Simon Ramo was born in Salt Lake City, Utah, in May, 1913. He received the B.S. degree in electrical engineering from the University of Utah, Salt Lake City, in 1933, and the Ph.D. degree in electrical engineering and physics from the California Institute of Technology, Pasadena, in 1936.

At this time he joined General Electric's research staff where his work was in the areas of microwaves, electron optics and other phases of physics and engineering. From 1946 to 1953 he was with the Hughes Aircraft Company, Culver City, Calif., where he first held the positions of Director of Research, Electronics Department, and Director of Guided Missile Research and Development and later the position of Vice President and Director of Operations. He was Executive Vice President of The Ramo-Wooldridge Corporation (which he and Dr. Wooldridge founded in September, 1953) prior to the merger of that Corporation with Thompson Products, Inc. At present, he is Vice Chairman of the Board and Director of Thompson Ramo Wooldridge, Inc., Los Angeles, Calif.

He is a Regents' Lecturer in Engineering at the University of California and a Research Associate at the California Institute of Technology. He was also the W. Rupert Turnbull Lecturer, in 1956, and the Steinmetz Memorial Lecturer, in 1959. He received the honorary degree of Doctor of Engineering, in 1960, from Case Institute of Technology, Cleveland, Ohio, and, in 1961, from the University of Utah.

Dr. Ramo is a Fellow of the AIEE, the American Physical Society, the American Rocket Society, and the Institute of Aeronautical Sciences. He was a recipient of the Eta Kappa Nu Honorable Mention Award, 1941; the IRE Electronic Achievement Award of the Pacific Region, 1953; the Raymond E. Hackett Award, 1955; and the Arnold Air Society Paul T. Johns Trophy, 1961.

❖

Oscar Reed, Jr., (S'39–A'41–SM'47) was born in Washington, D. C., on April 2, 1917. He received the B.E.E. degree from the Catholic University of America, Washington, D. C., in 1939.

He then joined

the firm of Jansky & Bailey, Washington, D. C., where he is presently a Consulting Radio Engineer. He has specialized in broadcast-engineering allocating developments, practice before the FCC, and broadcast-station design and evaluation work.

Mr. Reed is a past member and former Chairman of the Professional Group on Broadcasting, and currently serves as Chairman of the AIEE Technical Committee on Broadcasting. In 1949 and 1950 he represented the U. S. Government as an industry advisor to the North American Regional Broadcast Conference, Montreal, Canada, and Washington, D. C. He is a registered professional engineer in the state of Maryland and in the District of Columbia.

❖

Walther Richter (SM'44–F'53) was born in Heidelberg, Germany, on May 17, 1900. He obtained the B.S. degree in electrical engineering at the Institute of Technology in Karlsruhe, Germany.

He joined the Engineering Department of the A. O. Smith Corporation, in 1925, where he became Director of Electrical Engineering and Research, in 1930. From 1939 to 1943, he engaged in private consulting practice. From 1943 to 1951, he was associated with the Engineering Development Department of the Allis-Chalmers Manufacturing Company, Milwaukee, Wis., where he was in charge of the electronics laboratory of this department. In 1951 he returned to consulting. He is now a Consultant in Electronics to the staffs of the Research Center of the Outboard Marine Corporation, the Electrical Research Laboratory of the A. O. Smith Corporation, and the Development Department of Cutler-Hammer, Inc., Milwaukee, Wis. He taught courses in industrial electronics from 1935 to 1950 in evening sessions at the University of Wisconsin, and from 1954 to 1960 at Marquette University, Milwauee.

Mr. Richter is a Fellow of the AIEE.

❖

Preston Robinson (M'54) was born in Boston, Mass., on June 30, 1902. He received the S.B. degree, in 1922, and the S.M. degree in chemical engineering, in 1923, both from the Massachusetts Institute of Technology, Cambridge. He received the Ph.D. degree in physical chemistry from the University of California at Berkeley, in 1925.

From 1923 to 1925 he was a Teaching Fellow in Chemistry at the University of California, and the following four years he was a Research Metallurgist at Guggenheim Brothers Laboratories, New York, N. Y. Since 1929 he has been with the Sprague Electric Company, North Adams, Mass., first as Director of Research and Engineering, and since 1953 as Consultant. His recent assignments have been as Consultant to the Department of Defense in the capacity of Chairman of the Working Group on Electronic Materials, and Consultant to the Materials Advisory Board of the National Academy of Sciences.

Dr. Robinson is a member of the American Chemical Society, the American Physical Society, Sigma Xi, and several other technical societies.

❖

John D. Ryder (A'29–SM'45–F'52) was born in Columbus, Ohio, on May 8, 1907. He received the B.E.E. degree, in 1928, and the M.S. degree, in 1929, both from the Ohio State University, Columbus, and the Ph.D. degree in electrical engineering, in 1924, from Iowa State University, Ames.

From 1929 to 1931 he was with the General Electric Company, Schenectady, N. Y., in vacuum and gas tube development. In 1931 he joined the Bailey Meter Company, Cleveland, Ohio, as Supervisor of the Electrical and Electronic Section of the Research Laboratory. In 1941 he was appointed Assistant Professor of Electrical Engineering at Iowa State College, was made Professor, in 1944, and in 1947 assumed the position of Assistant Director of the Iowa Engineering Experiment Station. In September, 1949 he became Head of the Department of Electrical Engineering at the University of Illinois, Urbana, and in July, 1954 became Dean of the College of Engineering at Michigan State University, East Lansing.

He was President of the NEC, 1953, President of the IRE, 1955, and President of Eta Kappa Nu, 1956 to 1957, and also served on the Boards of Directors of these organizations. He was the Editor of the IRE, in 1958 and 1959, and a member of the Army Scientific Advisory Panel, 1957 to 1959. He has served since 1957 on the Signal Corps Research and Development Advisory Board, and since 1955 as Advisor to the National Research Council for the Office of Ordnance Research.

Dean Ryder is a Fellow of the AIEE and the AAAS, and a member of Tau Beta Pi, Eta Kappa Nu, Phi Kappa Phi, Sigma Xi, and Pi Mu Epsilon.

❖

Clifford M. Ryerson (SM'55) was born in Brooklyn, N. Y., on September 23, 1915. He received the B.S. degree in physics from Stetson University, De Land, Fla., in 1937,

and the M.S. degree in electronics from Duke University, Durham, N. C., in 1938.

Later, on the technical staff at Duke, he managed three cosmic-ray expeditions, and then won a Meritorious Civilian Service Award for a war-time instrumentation program for the Navy. In 1946 he organized and managed the Applied Physics Branch of the Naval Gun Factory, Washington D. C. In 1951 he became a system designer, and soon advanced to Project Manager of the RCA Moorestown Plant. Expanding his earlier work on product reliability, he then advanced to the main Camden Plant, where he developed the RCA Reliability Engineering Program. He then expanded this effort into a broad program of control for product assurance, which included the management and integration of all control specialties, such as reliability maintainability, value engineering, quality assurance and system effectiveness. He is currently concerned with making consulting and technical audit service in this field available to all industry and to the government. At present he is Vice President of the EL-TEK Divisions of EL-TRONICS, Hawthorne, Calif.

Mr. Ryerson is a registered professional engineer, a senior member of the American Society for Quality Control, an official of the National Reliability Symposia, the organizing chairman of the National Reliability Training Course, and a participant in many military-industry programs, such as AGREE, BIMRAB, PSMR, etc.

❖

Peter C. Sandretto (A'30–M'40–SM'43–F'54) was born in Pont Canavese, Italy, on April 14, 1907. He received the B.S. and E.E. degrees from Purdue University, Lafayette, Ind., in 1930 and 1938, respectively. He also graduated from the Army's Command and Staff School, and performed graduate work at Northwestern University, Evanston, Ill.

He began his more than 30-year association with aeronautical electronics, in 1930, as a member of the technical staff of Bell Telephone Laboratories, where he was engaged in the design of some of the first radio equipment for commercial transports. From 1932 to 1942, while Head of the Communications Laboratory of United Air Lines Transport Corp., he participated in the early air traffic control efforts.

During World War II, he served with the United States Air Force as Assistant Chief of the Radar Division, Headquarters, Army Air Force; as U. S. Signal Liaison Officer in the Air Ministry, London, England; as Chief of the Electronics Test Section, Air Proving Ground Command, Eglin, Fla.; and as Chief of the Electronics Division, Army Air Force's Pacific Ocean Areas, where his staff section was responsible for the establishment of the Air Force's traffic control system for the Twentieth Air Force. He holds the rank of Brigadier General in the U. S. Air Force Reserve.

In 1946 he joined the International Telephone and Telegraph Corporation's Aviation Department and attended many meetings of the International Civil Aviation Organizations, which were concerned with air navigation and traffic control facilities. He has served on committees of the Radio Technical Commission for Aeronautics since its inception and was a member of Special Committee 31 which established the common system for air navigation and traffic control. He became Technical Director and Vice President of IT&T Laboratories, in 1954 and 1956, respectively, and is presently Deputy Executive of IT&T's U. S. Defense Group, Nutley, N. J. He has written and lectured extensively in many parts of the world on the subject of air navigation and traffic control, and, as a consequence, has become internationally recognized for his work in this field. In 1958 he was Honorary (Keynote) speaker at the Ausschuss für Funkortung in Berlin. He is the author of "Principles of Aeronautical Radio Engineering," first published in 1942, and "Electronic Navigation Engineering."

Mr. Sandretto is a member of Eta Kappa Nu and the Institute of Navigation, and an associate member of the IEE.

❖

K. N. Satyendra (SM'61) was born in Mysore, India, on May 19, 1924. He received the B.Sc. (Hons.) degree in physics from the University of Mysore, India, in 1943 and the E.E. degree from the Indian Institute of Science, in 1946. He was awarded gold medals for outstanding work at these two institutions. He received the M.S. and Ph.D. degrees from Illinois Institute of Technology, Chicago, Ill., in 1948 and 1954, respectively.

From 1948 to 1954 he served as an Assistant Professor of Electrical Engineering at Illinois Institute of Technology. During the next six years he was associated with the Westinghouse Electric Corporation, where he was engaged in advanced research and development programs pertaining to fire control systems, air-to-air and air-to-surface missile guidance, radar and infrared detection and space weapon systems. In 1959 he joined Nortronics, Palos Verdes Estates, Calif., where he presently serves as Director of Research; he is responsible for advanced research in various aspects of space electronics. Currently he is very active in the space programs of both NASA and the USAF. He has also been a regular lecturer at UCLA on graduate courses on infrared, space optics, etc.

Dr. Satyendra is a Fellow of the British Interplanetary Society and a member of the American Rocket Society, American Astronautical Society, Institute of Aerospace Sciences, AIEE, Sigma Xi, Tau Beta Pi, and Eta Kappa Nu.

❖

Kurt Schlesinger (A'41–SM'51–F'54) was born in Berlin, Germany, on April 20, 1906. He received the Dipl.-Ing. and Doctor of Engineering degrees, in 1928 and 1929, from the Technical University of Berlin.

From 1941 to 1944 he was with RCA Laboratories, Purdue University, Lafayette, Ind., and from 1944 through 1947, he was Consulting Engineer in Color Television for CBS, New York, N. Y. He was Head of a TV Research Department at Motorola, Inc., Chicago, Ill., from 1947 to 1958. In 1958 he joined the General Electric Company as a Consulting Engineer to the Cathode Ray Tube Department, Syracuse, N. Y.

Dr. Schlesinger has numerous U. S. Patents and has written over 30 technical articles. He has served on NTSC committees charged with studies of dot-interlace and color. He is a contributor to the "Handbook of Television Engineering," edited by Don Fink and published by McGraw-Hill Book Company. In 1957 he was Visiting Lecturer at Northwestern University, Evanston, Ill.

He is a member of the Television Society of London and the Research Society of America.

❖

Mortimer A. Schultz (SM'48) was born in Portland, Me., on March 21, 1918. He received the B.S. degree in electrical engineering from the Massachusetts Institute of Technology, Cambridge, in 1939.

From 1939 to 1945 he worked at the Westhinghouse Industrial Electronics Division, Baltimore, Md., where he was engaged in television and low-frequency radar projects. After a year at Photoswitch, Inc., Cambridge, Mass., as a Project Engineer for military radar attachments, he returned to Westinghouse Research Laboratories, as Section Manager in charge of radar, sonar, and industrial control. With the start of the nuclear submarine project, he transferred to the Westinghouse Bettis Field, Pittsburgh, Pa., where he was engaged in the development of the instrumentation and control system for the *Nautilus*. In 1955 he was on loan to the Sherwood fusion project at Princeton, N. J., and on his return to Pittsburgh was responsible for the design and operation of the Westinghouse Testing Reactor. In March, 1961 he opened his own nuclear consulting offices in Pittsburgh.

Mr. Schultz is a member of the American Nuclear Society and the AIEE.

❖

Oliver G. Selfridge was born in London, England, on May 10, 1926. He attended the Massachusetts Institute of Technology, Cambridge, from 1942 to 1950, receiving the S.B. degree, in 1945.

He worked for two years at the Signal Corps Laboratories, Fort Monmouth, N. J. Since 1952 he has been with the M.I.T. Lincoln Laboratory, Lexington, Mass., where he is a member of Division V, Information Processing. For the past few years he has been working on pattern recognition and other areas in artificial intelligence.

❖

Robert Serrell (A'35–SM'44) was born near Lyon, France, on October 16, 1904. He was a radio amateur in France in the twenties. He received the E.E. degree from the Institut Normal Electrotechnique, Paris, in 1926.

He was a Design Engineer at General Electric, Schenectady, N. Y., and at RCA, Camden, N. J., from 1927 to 1935. He was engaged in television engineering at RCA in Camden from 1935 to 1940, and was in charge of television transmitter development with the Columbia Broadcasting System in New York, in 1940 and 1941. He was Group Leader and Consulting Engineer at the Radio Research Laboratory of Harvard University, Cambridge, Mass., from 1942 to 1945, and in charge of television operations at CBS, 1944 to 1947. From 1947 to 1953 he was engaged in research in applied mathematics and in electronic computer theory at the Princeton Laboratories of RCA. He was Head of the RCA Computation Laboratory Princeton, N. J., from 1953 to 1957. Since September, 1957, he has been a Consultant engaged in the design of special-purpose electronic computers and data-processing machines and in the development of mathematical inference techniques. He is also a Research Associate of Haskins Laboratories, New York, N. Y.

Mr. Serrell is a Past Chairman of the IRE Electronic Computers Committee; a member of Sigma Xi, the Association for Computing Machinery (past Council member), the American Mathematical Society and the New York Academy of Sciences.

Ralph M. Showers (S'39–A'42–M'47–SM'55) was born in Plainfield, N. J., on August 7, 1918. He received the B.S.E.E. degree, in 1939, the M.S.E.E. degree, in 1941, and the Ph.D. degree, in 1950, all from the University of Pennsylvania, Philadelphia.

He is Professor of Electrical Engineering and Section Head of Communications Research in The Moore School of Electrical Engineering, University of Pennsylvania. He is also an Instructor of graduate courses in physical electronics, electronic circuits, communications systems, and of a seminar in operations research and systems engineering.

Dr. Showers was Chief U. S. delegate to the CISPR Conference (International Special Committee on Radio Interference) at The Hague, in 1958. He has been national Chairman of IRE-PGRFI, in 1960–1961, and is at present Chairman of the Philadelphia Section of IRE. He is Chairman of the American Standards Association C63 Ad Hoc Committee for the 1961 CISPR Conference.

Dr. Showers is a member of the AIEE, the American Standards Association, the Operations Research Society of America and Sigma Xi.

❖

Keeve M. Siegel (SM'57) was born in New York, N. Y., on January 9, 1923. He received the B.S. and M.S. degrees in physics from Rensselaer Polytechnic Institute, Troy, N. Y., in 1948 and 1950, respectively.

He has served with The University of Michigan, Ann Arbor, since 1948, first as a Research Associate, then as a Research Engineer. He became Head of the Upper Atmosphere Physics Section, in 1949 and Head of the Theory and Analysis Department, in 1952. Since 1957 he has been Head of the University's Radiation Laboratory and Professor of Electrical Engineering. His work at The University of Michigan has been in the fields of electromagnetic theory (*e.g.*, scattering and diffraction), high-altitude research and work in thermodynamics and hydrodynamics (*e.g.*, incompressible ideal subsonic flow), and passage of plane waves of sound in air. In 1961, he was appointed President and Director of the Ann Arbor Division of the Conductron.

Prof. Siegel is a member of the American Physical Society, American Institute of Physics, American Mathematical Society, and Sigma Xi. He is an Associate Fellow of the Institute of Aeronautical Sciences, a member of the USAF Scientific Advisory Board, and Consultant to the Advanced Research Projects Agency and several major corporations. He is a member of the Editorial Boards of the *Journal of Research of the National Bureau of Standards* and the *Journal of Mathematical Physics.* He is a member of Commission VI of URSI. He is listed in *Who's Who in America, American Men of Science. Who's Who in World Aviation,* and *World Directory of Mathematicians.*

❖

Samuel Silver (M'46–SM'50–F'54) was born in Philadelphia, Pa., on February 25, 1915. He received the B.A. and M.A. degrees in physics, in 1935 and 1937, respectively, from Temple University, Philadelphia, and the Ph.D. degree in physics, in 1940, from the Massachusetts Institute of Technology, Cambridge.

Following one year as a Postdoctoral Research Assistant in the Mendenhall Laboratory of Physics at Ohio State University, Columbus, he joined the faculty of the University of Oklahoma, Norman, where, as Instructor and Assistant Professor of Physics, he served until 1943. During that period he conducted research on molecular structures. He then joined the Radiation Laboratory at M.I.T. as a staff member in the Antenna Group where he carried on research on theory of microwave antennas and networks.

He joined the newly-formed Antenna Research Branch of the Naval Research Laboratory, Washington, D. C., in 1946, as head of a basic research group. He came to the Department of Electrical Engineering of the University of California at Berkeley, in 1947 and was made Professor of Electrical Engineering, in 1950 and subsequently Professor of Engineering Science. He spent the year 1953–54 at the Royal Technical University of Denmark and the Cavendish Laboratory, Cambridge University, under a Guggenheim Fellowship. In 1956 he was appointed Director of the Electronics Research Laboratory of the Electrical Engineering Department. He developed the research program on microwave antennas and applied electromagnetic theory and related areas of microwave electronics. He is currently directly engaged in upper atmosphere studies and solar phenomena in the microwave region. He was awarded a Guggenheim Fellowship for 1960–1961 for research in upper atmospheric physics. He was appointed Director of the Space Sciences Laboratory of the University of California on January 1, 1960.

Dr. Silver was Chairman of the International Commission VI (Radio Waves and Circuits), 1953–1960, and is currently Secretary of the USA National Committee of URSI. He is a Fellow of the American Physical Society and a member of the American Geophysical Society, the New York Academy of Sciences, and Sigma Xi.

❖

Donald B. Sinclair (J'30–A'33–M'38–SM'43–F'43) was born in Winnipeg, Manitoba, Canada, on May 23, 1910. He received the S.B., S.M., and Sc.D. degrees from the Massachusetts Institute of Technology, Cambridge, in 1931, 1932 and 1935, respectively.

Since 1936 he has been employed by the General Radio Company, West Concord, Mass. He has held the positions of Assistant Chief Engineer, Chief Engineer, Vice President and Director, and in 1960 he was appointed Executive Vice President and Technical Director. During World War II he was in charge of search-receiver work for radar countermeasures at the Radio Research Laboratory of Harvard University, Cambridge, Mass., and he was a member of the National Defense Research Committee on guided missiles. In 1943 he went to North Africa with the first Ferret plane, which was sent to the European theater of operations. For his work on countermeasures and guided missiles he received the President's Certificate of Merit in 1948. From 1954 to 1958 he was a member of the Technical Advisory Panel on Electronics of the Department of Defense, and he is presently serving as Consultant to the Defense Department.

Dr. Sinclair is a Fellow of the AIEE, and a member of Sigma Xi, Eta Kappa Nu, the AAAS, the American Physical Society and the National Association of Manufacturers Research Committee. He was President of the IRE in 1952 and has also served as Treasurer and Vice President. At various times he has been on the Executive Committee and on the Board of Directors.

❖

S. Fred Singer was born in Vienna, Austria, on September 27, 1924. He received the B.E.E. degree from Ohio State University, Columbus, in 1943, and the A.M. and Ph.D. degrees from Princeton University, N. J., in 1944 and 1948, respectively.

After service in the U. S. Navy from 1944 to 1946, he joined the Applied Physics Laboratory of The Johns Hopkins University, Silver Spring, Md. There he was a member of one of the earliest high altitude research groups using rockets. He and his collaborators discovered the electrojet current flowing in the equatorial ionosphere. From 1950 to 1952 he was Scientific Liaison Officer, Office of Naval Research, at the U. S. Embassy, London. In 1953 he joined the University of Maryland, College Park, where he is Professor of Physics, and Director of the experimental and theoretical programs of the Space Research Group. He has been intensely interested in and has published many original papers on satellites and their scientific applications.

Dr. Singer is a member of Commission IV of the International Scientific Radio Union, Director of the American Astronautical Society and a Fellow of numerous scientific societies in the U. S. and abroad.

❖

Hector R. Skifter (A'31–M'36–SM'43–F'51) was born in Austin, Minn., on March 4, 1901. He received the B.A. degree from St. Olaf College, Northfield, Minn., in 1922, and an Honorary D.Sc. degree, in 1945, also from St. Olaf College.

From 1922 to 1929 he was an Instructor in Physics and Mathematics at St. Olaf College. He was Chief Engineer of the Western Radio Company, St. Paul, Minn., from 1929 to 1932. During the years 1932 to 1942 he was a Consulting Radio Engineer, and from 1934 to 1942 he was Technical Supervisor of the National Battery Broadcasting Company, St. Paul. He was Associate Director of the Airborne Instruments Laboratory (AIL) of the Columbia University Division of War Research under a contract with the Office of Scientific Research and Development (OSRD), from 1942 to 1945. He was responsible for the development of the airborne magnetometer for submarine detection and the development of electronic countermeasures against German guided missiles. In August, 1945 when the OSRD contract was terminated, AIL was incorporated as an independent laboratory with Dr. Skifter as President. In June, 1958 he was elected to a Vice Presidency of Cutler-Hammer, when AIL merged with Cutler-Hammer.

In 1957, he served the Department of Defense as a part-time Consultant. In February, 1959, he took a leave of absence from his position as President of Airborne Instruments Laboratory to accept the full-time position of Assistant Director of Defense Research and Engineering. During his period of office he was responsible for technical evaluation and integration of defense weapons systems, planning and supervising the development of new and improved systems and their control environment, including anti-aircraft and anti-missile missiles and interceptor aircraft. As part of his duties he served as Chairman of the Ballistic Missile Defense Steering Group, spearheaded the installation of the BMEWS (Ballistic Missile Early Warning System) program, and coordinated the planning for the development of the NIKE-ZEUS and the ARPA DEFENDER programs. He served as a member of the Department of Defense Panel for the evaluation program of the BOMARC Weapon System and was the Chairman of the U. S. Delegation to the Tripartite Conference (United States, United Kingdom, and Canada) Technical Subgroup on Defense Against Ballistic Missiles. In April, 1960, he resigned from his position with the Department of Defense and rejoined AIL as President.

Dr. Skifter is a Vice-President and a Director of Cutler-Hammer, Inc., Chairman of the Board of Directors of the Research Analysis Corporation, and a Director of the American Research and Development Corporation and of Rabinow Engineering Company. He was formerly a member of the Board of Directors of Intercontinental Electronics Corporation and Cramer Controls Inc. He was also a member of the Gaither Security Resources Panel of the President's Science Advisory Committee. He is also Consultant to the President's Science Advisory Committee, Executive Office of the President, and a member of the Army Scientific Advisory Panel, the New York State Scientific Advisory Council and the Advisory Committee, Department of Ordnance, U. S. Army.

Dr. Skifter is a member of the Cosmos Club, the Wings Club, and the University Clubs of Washington and Milwaukee. He is a Director of Nassau Hospital, N. Y., a Trustee of Hofstra College, and a Director of the Long Island Fund.

❖

David Slepian (A'52–M'57–SM'60–F'62) was born in Pittsburgh, Pa., on June 30, 1923. He attended The University of Michigan, Ann Arbor, from 1941 to 1943, at which time he entered the U. S. Army and served in the Signal Corps until 1946. From 1946 to 1949 he attended Harvard University, Cambridge, Mass., where he received the M.A. degree, in 1947, and the Ph.D. degree in physics, in 1949. He spent the academic year 1949–1950 at the University of Cambridge, England, and at the Sorbonne, Paris, as a Parker Fellow in physics from Harvard.

In 1950 he joined the Bell Telephone Laboratories, Murray Hill, N. J., as a Research Mathematician and has remained in this position since. His interests here have been in communication theory and applied mathematics, especially applications of probability theory. During the academic year 1958–1959 he was a Visiting McKay Professor of Electrical Engineering at the University of California at Berkeley.

Dr. Slepian is a member of AAAS, the American Mathematical Society, Institute of Mathematical Statistics, Society for Industrial and Applied Mathematics, Commission VI of URSI, and Sigma Xi. He served on the Administrative Committee of PGIT from 1958–1960 and is presently on the Council of SIAM.

❖

George C. Southworth (M'26–F'41–L) was born in Little Cooley, Pa., on August 24, 1890. He received the B.S. degree from Grove City College, Pa., in 1914, and did graduate work both at Columbia University, New York, N. Y., and Yale University, New Haven, Conn., where he received the Doctorate degree, in 1923.

Prior to World War I he began experimental work at Grove City College, Pa., and during the war continued with research work at the National Bureau of Standards and at Yale University. Since 1923 he has been with the Bell System, where he has been associated with the transoceanic radio telephony and later with the early development of microwave techniques.

For his work in waveguides, he received the Morris N. Liebmann Prize of the IRE, in 1938 and the Stuart Ballantine Medal of the Franklin Institute, in 1947; for his work on microwave radiation from the sun, he received the Louis Levy Medal of the Franklin Institute, in 1946.

Dr. Southworth is a Fellow of the American Physical Society and the AAAS.

❖

Karl R. Spangenberg (A'34–SM'45–F'49) was born in Cleveland, Ohio, on April 9, 1910. He received the B.S. degree and the M.S. degree in electrical engineering from the Case Institute of Technology, Cleveland, in 1932 and 1933, respectively, and the Ph.D. degree from Ohio State University, Columbus, in 1937.

For some twenty years he has been on the staff of the Electrical Engineering Department of Stanford University, Calif. This period has been punctuated by technical work in the European Theater during World War II, a period as Head of the Electronics Division of the Office of Naval Research, 1948 to 1949, and a period as Head of the Electronic Engineering Department of the Instituto Technologica de Aeronautica in the state of Sao Paulo, Brazil, 1952 to 1954. During the past several years he has been a Consultant on engineering, management, and education, to various companies, mostly in the San Francisco Bay Area.

Mr. Spangenberg is the author of "Vacuum Tubes" and "Fundamentals of Electron Devices." He is a member of the American Physical Society.

❖

Malcolm L. Stitch (SM'58) was born in Elizabeth, N. J., on April 23, 1923. He received the B.A. degree in French and the B.S. degree in physics from the Southern Methodist University, Dallas, Tex., both in 1947, and the Ph.D. degree in physics from Columbia University, New York, N. Y., in 1953.

From 1949 to 1951 he was an Instructor in Physics at Sarah Lawrence College, Bronxville, N. Y., and the following year at Cooper Union College of Engineering, New York, N. Y. From 1953 to 1956 he was a Research Physicist at Varian Associates, Palo Alto, Calif., and since 1956 he has been with the Hughes Aircraft Company, Culver City, Calif., where he is currently Manager of Laser Development in the Radar and Missile Electronics Laboratory.

He designed the first high-temperature microwave spectrometer and with colleagues examined the microwave spectra of the alkali halides in the neighborhood of 1000°C. He also led the effort to exploit the systems application of lasers by being responsible for the design of the COLIDAR (COherent LIght Detecting And Ranging) ranging system at Hughes. He has also made contributions to the fields of frequency control of microwave tubes, maser theory and technology, atomic clocks, and quantum electronics.

Dr. Stitch is a member of the Physical Society, the AAAS, American Association of Physics Teachers, Physical Society of Japan, the New York Academy of Sciences, and Sigma Xi.

❖

Ernst Stuhlinger was born in Niederrimbach, Germany, on December 19, 1913. He received his Doctorate in Physics at the University of Tuebingen, Germany, in 1936.

He was appointed Assistant Professor of the Physics Department of the Berlin Institute of Technology and was a member of the faculty there from 1936 to 1941. He worked closely with Dr. Hans Geiger, developer of the Geiger counter, for seven years. From 1939 to 1941, he was a member of a research group conducting studies in nuclear physics. In the Spring of 1943, he joined the Rocket Development Center at Peenemuende, Germany, which was under the technical

supervision of Dr. Wernher von Braun, presently Director of George C. Marshall Space Flight Center, Huntsville, Ala. At Peenemuende, Dr. Stuhlinger carried on research in connection with the development of guidance and control systems for the V-2 guided missile. Dr. Stuhlinger, who became an American citizen on April 14, 1955, came to the United States in 1946 under the auspices of the Ordnance Corps, U. S. Army. He conducted research and development work with guided missiles at Ft. Bliss, Tex., and assisted in high altitude research firings of captured V-2's at White Sands Proving Ground, N. Mex. From 1956 until July 1, 1960, he was Director of the Research Projects Laboratory, Army Ballistic Missile Agency, U. S. Army Ordnance Missile Command at Redstone Arsenal, Huntsville, Ala. He is now the Director, Research Projects Division of the George C. Marshall Space Flight Center.

Dr. Stuhlinger, who has gained recognition for his feasibility and design studies of electrical propulsion systems for space ships, was awarded the American Rocket Society's Propulsion Award on December 7, 1960. He is a member of a number of professional societies including the ARS, AAS, and the International Astronautical Academy.

❖

William O. Swinyard (A'37–M'39–SM'43–F'45) was born in Logan, Utah, on July 17, 1904. He received the B.S. degree in mathematics and physics from Utah State University, Logan, in 1917, and has done graduate work at Columbia University, New York, N. Y., and Northwestern University, Evanston, Ill.

In 1930 he joined the Hazeltine Corporation, Bayside, N. Y.; in 1937 he was transferred to Chicago, Ill. He has been Chief Engineer of Hazeltine Research, Inc., since 1942, and Vice President and Director, since 1958. He is one of the founders of the National Electronics Conference, and has served the NEC as President and Chairman of the Board.

Mr. Swinyard is a Fellow of the Radio Club of America and the AAAS, a professional member of Eta Kappa Nu; and Past President of the Chicago Radio Engineers Club. He is a registered professional engineer in the state of Illinois, and a member of the National Society of Professional Engineers and the Illinois Society of Professional Engineers.

❖

Samuel A. Talbot (SM'61) was born in Holderness, N. H., on April 19, 1903. He received the A.B. degree, in 1925, from Cornell University, Ithaca, N. Y., the M.S. degree, in 1931, from Trinity College, Hartford, Conn., and the M.A. and the Ph.D. degrees in physics from Harvard University, Cambridge, Mass., in 1932 and 1938, respectively.

He was a Master at the Loomis School, Windsor, Conn., from 1927 to 1930, and an Instructor and Tutor in Physics at Harvard, from 1930 to 1935. In that year he joined the staff of the Department of Ophthalmology, The Johns Hopkins University, Baltimore, Md., working on physiological optics; he was appointed Associate Professor of Medicine (biophysics) in 1946. From 1942 to 1944 he worked for the Office of Science Research and Development. His main fields of interest are electro- and ballistocardiography, circulatory biophysics, cardiovascular sound, and biophysical methods and measurements. He is currently director of the P.H.S. Training Program in Bio-Medical Engineering at The Johns Hopkins Medical School.

Dr. Talbot is a member of the Physiological Society, the Optical Society, the Society of Experimental Biology, the American Heart Association, the Hospital Physicists Society, the Biophysical Society (Secretary), and the Visual Neurophysiology Society.

❖

Frederick E. Terman (A'25–F'37) was born in English, Ind., on June 7, 1900. He received the B.A. degree in chemical engineering, in 1920, and the E.E. degree, in 1922, both from Stanford University, Calif., and the D.Sc. degree in electrical engineering from the Massachusetts Institute of Technology, Cambridge, in 1924.

He has served on the faculty of Stanford University since his appointment as an Instructor in Electrical Engineering in 1925. In 1937 he became Professor and Head of the Electrical Engineering Department; in 1945 he was appointed Dean of the School of Engineering, and in 1955 became Provost, and since 1958 has been Vice President and Provost of Stanford.

On leave during World War II, he organized and directed the Radio Research Laboratory set up at Harvard University by the Office of Scientific Research and Development. The laboratory was the chief United States agency developing radar countermeasures.

In 1946 he was decorated by the British government, and in 1948 received the United States' highest civilian award, the Medal of Merit. Harvard University, the University of British Columbia, and Syracuse University have awarded him honorary doctoral degrees.

A Past President of the IRE, Dr. Terman received the Institute's Medal of Honor, in 1950. He is also a member of the AIEE, the American Physical Society, and the ASEE, and, in 1946, was elected to the National Academy of Sciences.

❖

George R. Town (A'37–SM'44–F'50) was born in Poultney, Vt., on May 26, 1905. He received the E.E. and the D.Engr. degrees from Rensselaer Polytechnic Institute, Troy, N. Y., in 1926 and 1929, respectively.

From 1929 to 1933 he did research at the Leeds and Northrup Company, Philadelphia, Pa. From 1933 to 1936 he taught at Rensselaer. In 1936 he joined the Stromberg-Carlson Company, Rochester, N. Y., where he remained until 1949; during the last five years of this time, he was Manager of Engineering and Research.

In 1949 he came to Iowa State University, Ames, as Associate Director of the Engineering Experiment Station and Professor of Electrical Engineering. For 20 months, in 1957 and 1958, he was on leave of absence from Iowa State University serving as Executive Director of the Television Allocations Study Organization, Washington, D. C. In 1959 he was named Dean of the College of Engineering at Iowa State University.

Dr. Town is a fellow of the AIEE and a member of ASEE, NSPE, Tau Beta Pi, Sigma Xi, Eta Kappa Nu and Phi Kappa Phi.

❖

John G. Truxal (S'47–A'48–SM'54–F'59) was born in Lancaster, Pa., on February 19, 1924. He received the B.A. degree from Dartmouth College, Hanover, N. H., in 1944, and the D.Sc. degree from Massachusetts Institute of Technology, Cambridge, in 1950.

He taught at Purdue University, Lafayette, Ind., and then at the Polytechnic Institute of Brooklyn, N. Y., where he has been Head of the Electrical Engineering Department, and is currently Vice President for educational development.

Dr. Truxal is Chairman of the American Automatic Control Council Theory Committee and Past Chairman of the IRE Professional Group on Education. He is a member of the Administrative Committee of PGAC and PGE, and a member of the IRE Editorial Board.

❖

Lester C. Van Atta (M'42–SM'43–F'52) was born in Portland, Ore., on April 18, 1905. He received the B.A. degree in physics from Reed College, Portland, in 1927, and the Ph.D. degree from Washington University, St. Louis, Mo., in 1931.

He served in the Physics Department of Princeton University, N. J., from 1931 to 1932, in the Physics Department of the Massachusetts Institute of Technology, Cambridge, from 1932 to 1940, and in the M.I.T. Radiation Laboratory as Head of the Antenna Group from 1940 to 1945. From 1945 to 1950 he was Head of the Antenna Research Branch of the Naval Research Laboratory, Washington, D. C. Since 1950 he has been at Hughes Aircraft Company, Culver City, Calif., originally as Head of the Microwave Laboratory, then as Associate Director of the Research Laboratories, and later as Director of Technical Information and Education. From May, 1960 to June, 1961, he was on professional leave from Hughes as Special Assistant for Arms Control to the Director of Defense, Research and Engineering, Office of the Secretary of Defense, Washington, D. C. In July, 1961 he returned to Hughes Aircraft Company as Technical Director of the Hughes Research Laboratories.

Since 1940 he has been active in military research and development at the M.I.T. Radiation Laboratory, the Naval Research Laboratory, and Hughes Aircraft Company. In addition, he served on the Research and Development Board as Chairman of the Panel on Antennas and Propagation from 1946 to 1949. More recently, he participated in a series of WSEG studies of continental air defense from 1956 to 1958, a series of PISGAH and other research and development conferences for the Army from 1957 to 1959, two ARGUS studies at Lawrence Radiation Laboratory, Livermore, Calif., from 1948 to 1959, and on the Gaither Committee in 1959.

At Hughes Aircraft Company he directed such systems studies as the Hemispherical Scan System for the Navy and the ICBM Passive Defense System for the Air Force, both systems based on electronic beam-scanning techniques. In connection with his responsibility for education at Hughes, he was active in the creation of the Southern California Industry-Education Council, and served as its Vice President during 1959–1960. His technical fields of specialization have included high resistors, electron scattering in gases, high-voltage and high-vacuum engineering, production and scattering of hard X rays, nuclear reactions by bombardment, microwave antennas and microwave components and systems.

Dr. Van Atta is a Fellow of the American Physical Society and has been active in the Research Society of America and the International Scientific Radio Union, especially Commission VI. He has been very active in the IRE, including chairmanship of the Antenna and Waveguide Technical Committee, the PGAP, and the Los Angeles Section. He is presently serving on the Board of Directors of the IRE. He is a member of the AAAS, the American Association of Physics Teachers, and the American Geophysical Union.

❖

Joseph H. Vogelman (M'46–SM'49–F'59) was born in New York, N. Y., on August 18, 1920. He received the B.S. degree, in 1940, from the College of the City of New York, and the M.S. and Ph.D. degrees, in 1948 and 1957, respectively, from the Polytechnic Institute of Brooklyn, N. Y., both in electrical engineering.

In 1945 after several years at the Signal Corps Radar Laboratory at Fort Hancock and Belmar, N. J., he joined the staff of the Watson Laboratories, Red Bank, N. J., where he served as Chief of the Development Branch until 1951, responsible for research and development of test equipment and microwave components and techniques. In 1951 he moved to the Rome Air Development Center, Griffiss Air Force Base, N. Y. From 1951 to 1953 he was Chief Scientist in the General Engineering Laboratory and Consultant on UHF and SHF theory and techniques to the U. S. Air Force. He was Chief of the Electronic Warfare Laboratory, directing all research and development in ground-based electronic warfare for the USAF, 1953 to 1956. From 1956 through June, 1959, he was Technical Director of the Communications Directorate with responsibility for the Air Force research and development effort in ground-based and ground-to-air communications. He is now Vice President of Research, Development and Engineering, Capehart Corporation, Richmond Hill, N. Y.

Dr. Vogelman is a Fellow of the AAAS and a member of Eta Kappa Nu, Sigma Xi, the AIEE, and the Armed Forces Communications and Electronics Association.

Willis H. Ware (A'43–SM'49–F'62) was born in Atlantic City, N. J., on August 31, 1920. He received the B.S. degree from the University of Pennsylvania, Philadelphia, in 1941, and, as a Tau Beta Pi Fellow, the S.M. degree from the Massachusetts Institute of Technology, Cambridge, in 1942, both in electrical engineering, and the Ph.D. degree, in 1951, from Princeton University, N. J.

From 1942 to 1946 he was employed by the Hazeltine Electronics Corporation, Little Neck, N. Y., where he did research and development in radar and IFF. In 1946 he became one of the original members of the staff of the Electronic Computer Project at the Institute for Advanced Study, Princeton, N. J., where he worked on the design and development of the large-scale general-purpose electronic digital computer, which later was to set the pattern for the construction of several other "Princeton-class" machines. In 1952 he joined The RAND Corporation, Santa Monica, Calif., where presently he is the Associate Head of the Computer Sciences Department, concerned principally with the development of large machines and their application to military and scientific problems.

Dr. Ware is a member of the ACM, the AAAS, Tau Beta Pi, Sigma Xi, Eta Kappa Nu, Pi Mu Epsilon, and Sigma Tau. He has been very active in the PGEC, having served as Chairman, in 1958–1959. He has been a member of the IRE Technical Committee 8 on Computers since 1951, and has served as IRE representative to the National Joint Computer Committee (1959 to 1961). In 1958 he served as Chairman of the Western Joint Computer Conference. In 1959 he was a member of an eight-man delegation of American scientists who visited the U.S.S.R. to discuss computers and related matters. In 1961 he was elected first Chairman of the American Federation of Information Processing Societies. He received the Achievement Award of the Los Angeles Section of the IRE in 1957.

❖

Ernst Weber (M'41–SM'43—F'51) was born in Vienna, Austria, on September 6, 1901. He received the Ph.D. degree, in 1926, from the University of Vienna, having studied philosophy, physics, and mathematics, and the D.Sc. degree, in 1927, from the Technical University of Vienna, having studied engineering, particularly field theory as applied to machinery.

After working as Research Engineer for the Austrian Siemens-Schuckert Company, he was transferred to the company's Berlin office, in 1929, and was also appointed Lecturer at the Technical University of Berlin. In 1930 he became Visiting Professor at the Polytechnic Institute of Brooklyn, N. Y.; the next year he was named a permanent Research Professor of Electrical Engineering in charge of graduate study. From 1942 to 1945 he was Professor of Graduate Electrical Engineering and Head of graduate study and research in that field. Under his direction the graduate enrollment increased from less than 200 to over 900 students.

Early in World War II he organized a microwave research group which developed the precision microwave attenuator, sorely needed for the accurate calibration of radar. In recognition of the contributions of the research group, he was awarded the Presidential Certificate of Merit. Out of this wartime research grew the Microwave Research Institute, which expends each year more than $1,000,000 on research projects for the military services, and the Polytechnic Research and Development Company, which was then owned by the Polytechnic Institute of Brooklyn.

In 1945 he was appointed Head of the Department of Electrical Engineering, and Director of the Microwave Research Institute. When a vice presidency for research was created by the Polytechnic Institute of Brooklyn in 1957, he was named to the position; following the death of the Institute's president, in June, 1957, he became Acting President and then President. He also served as President of the Polytechnic Research and Development Company until its sale in 1959. In January, 1959, he was elected President of the IRE.

A pioneer in the high-frequency electronic research, he holds more than 50 American, Canadian, and British patents in the field of microwave techniques. His published works include many scientific papers on electromagnetic fields, linear and nonlinear circuits, and microwave measurements. He has contributed to several books, and published "Mapping of Fields" and "Linear Transient Analysis." In 1959 he was appointed to the Army Scientific Advisory Panel by the Secretary of the Army.

Dr. Weber is a Fellow of the AIEE and the American Physical Society.

❖

Vernon I. Weihe (SM'45–F'58) was born in Louisville, Ky., on March 3, 1909. He received the B.S.E.E. degree from the Speed Scientific School of the University of Louisville, in 1931, and did graduate work at the University of Louisville and the University of Cincinnati, Ohio.

He has been engaged in air navigation, communications, and traffic control development since 1935. During World War II, as Chief Engineer of the Communications and Navigation Laboratory at Wright Field, Dayton, Ohio, he had cognizance over the development and procurement of many types of communication, navigation, and specialized equipments used during the war. Since 1946 he has been concerned with air navigation and traffic-control systems planning as a member of the Air Transport Association, as a Development Engineer, and currently as Director of Advanced Systems Planning for General Precision, Inc., Washington, D. C.

Mr. Weihe is a member of the Institute of Aeronautical Sciences, and a Past President of the Institute of Navigation.

❖

James O. Weldon (A'26–SM'46–F'54) was born in Canton, Mo., on March 15, 1905.

He was first engaged in radio engineering in 1927. From 1933 to 1952 he was a Consulting Engineer and manufacturer of transmitting equipment. He was appointed Chief Engineer of the Bureau of Communication Facilities, Overseas Branch, Office of War Information in August, 1942, and a few months later became Chief of that Bureau. He organized Continental Electronics Manufacturing Company, Dallas, Tex., in 1946. As President and Director of Engineering, he has closely directed the engineering design and development of most of Continental's high-power transmitters which are now in use by the Army, Navy, Air Force, the Bureau of Standards and the Voice of America.

❖

John W. Wentworth (S'48–A'50–M'55) was born in Greenville, Me., on November 3, 1925. He received the B.S.E.E. degree from the University of Maine, Orono, in 1949.

He then joined RCA and spent several years doing design and development work on broadcast studio equipment for color television. During this period, he also organized and taught a course in color television engineering, which later resulted in the publication of a textbook on the same subject. From 1954 to 1959 he served as the Manager of a group of design engineers engaged in projects related to television studio equipment. Since July, 1959 he has been engaged in the field of educational electronics, and in his present capacity of Manager, Educational Electronics, Broadcast and Television Division, RCA, Camden, N. J., he is in charge of a service which coordinates many of RCA's activities in the educational field.

Mr. Wentworth is a member of SMPTE, Tau Beta Pi, Phi Kappa Phi, and Sigma Xi.

Harold A. Wheeler (A'27–M'28–F'35) was born in St. Paul, Minn., on May 10, 1903. He received the B.S. degree in physics, in 1925, from George Washington University, Washington, D. C., and continued post-graduate studies until 1928 at The Johns Hopkins University, Baltimore, Md.

He was employed by the Hazeltine Corporation, Little Neck, N. Y., from 1924 to 1946, advancing to Vice-President and Chief Consulting Engineer. In 1959, he resumed some activity with this company as a Vice-President and a Director. Since 1947 his principal occupation has been as President of Wheeler Laboratories, Inc., Great Neck, N. Y., now a subsidiary of Hazeltine Corporation. In this capacity he is directing their Great Neck and Smithtown Laboratories, specializing in microwaves and antennas.

Mr. Wheeler has served the IRE in such positions as Director (1934, 1940 to 1945) and Chairman of the Standards Committee; he has contributed many papers to IRE periodicals and received the Morris N. Liebmann Memorial Prize from IRE, in 1940. He is a Fellow of AIEE and Radio Club of America, an Associate Member of IEE (British), and a member of Sigma Xi and Tau Beta Pi.

❖

William C. White (A'15–M'25–F'40) was born in Brooklyn, N. Y., on March 24, 1890. He received the E.E. degree from Columbia University, New York, N. Y., in 1912.

He entered the General Electric Research Laboratory in the summer of 1912 as an Assistant to Dr. Irving Langmuir during the years of pioneer development of the high vacuum tube. When this research reached the commercial stage, he was appointed engineer in charge of a development and design section for their manufacturer. Shortly before retirement in 1955, he returned to the Research Laboratory at the General Electric Company.

Mr. White served on the Board of Directors of the IRE, 1943 to 1947, and as its Treasurer during 1946.

❖

Laurens E. Whittemore (A'16–M'25–F'27) was born in Topeka, Kan., on August 20, 1892. He graduated from Washburn College, Topeka, in 1914, and received the M.A. degree from the University of Kansas, Lawrence, in 1915, where his major was physics.

After three years of graduate study and teaching at the University of Kansas, he was employed in the Radio Laboratory of the National Bureau of Standards, Washington, D.C., from 1917 to 1923. In 1924 he became a member of the staff of the U.S. Department of Commerce and served as Secretary of the Interdepartment Radio Advisory Committee. He was Assistant Secretary or Secretary of the four annual National Radio Conferences called by the Secretary of Commerce, Herbert Hoover, 1922–1925.

From 1925 to 1957 he was a member of the headquarters staff of the American Telephone and Telegraph Company, New York, N. Y., where he was concerned with, among other things, relations with Federal regulatory agencies. He attended a number of International Radio and Communication Conferences either on behalf of the U. S. Government or the American Telephone and Telegraph Company, and was Secretary of the International Radio Conference, Washington, D. C., in 1927.

Mr. Whittemore was Vice-President of the IRE, in 1928, and a member of the Board of Directors, from 1926 to 1929 and from 1935 to 1937. He has held assignments on a number of IRE Committees, including the Standardization Committee of which he was Chairman, from 1926 to 1929, and the Annual Review Committee of which he was Chairman, from 1940 to 1949. He served on the Board of Editors, from 1929 to 1953. He is a member of Sigma Xi.

❖

Lofti A. Zadeh (S'45–A'47–M'50–SM'56–F'58) was born in Baku, Russia, on February 4, 1921. He attended the American College, Teheran, Iran, and received the B.S.E.E. degree from the University of Teheran, in 1942. He came to the U. S. in 1944 and entered the Massachusetts Institute of Technology, Cambridge, where he received the M.S. degree, in 1946.

He joined the staff of Columbia University, New York, N. Y., as an Instructor in Electrical Engineering and received the Ph.D. degree, in 1949. He was promoted to Assistant Professor in 1950, Associate Professor in 1953, and full Professor in 1957. In 1956 he was a member of the Institute for Advanced Study, Princeton, N. J. At present, he is Professor of Electrical Engineering at the University of California at Berkeley.

He has published papers on the subjects of time-varying networks, optimal filters, and nonlinear systems, with emphasis on the general principles underlying the transformation of signals and the characterization of input-output relationships. His main interest at present is in system theory and sequential control processes.

Prof. Zadeh is Chairman of U. S. Commission VI of the International Scientific Radio Union (URSI), and a member of the AIEE, the American Mathematical Society, the American Physical Society, the Institute of Mathematical Statistics, the ACM, the Society for Industrial and Applied Mathematics, Tau Beta Pi, Eta Kappa Nu, and Sigma Xi.

VSWR measurements of extreme precision

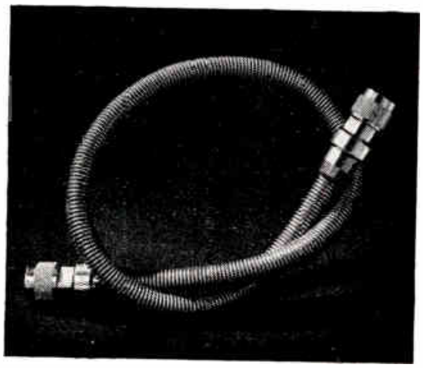
FXR's Model B813T VSWR Amplifier is a fully transistorized portable standing-wave amplifier with a full-scale maximum error at 5 db of ±0.05 db. We think it's the most accurate on the market.

The unit is designed for use on battery power for applications in the field where power is not available or in the laboratory where line noise might cause inaccuracies in measurement. Where power is available, however, the unit can be operated from the line in the normal manner.

Calibrated range of the B813T is 75 db. Normal, expanded and compressed meter scales are provided and can be used interchangeably without the need for readjustment of the gain control. The unit has special circuitry for bolometer protection and a meter display for bolometer resistance checking and current adjustment.

Other features of the B813T include controls and circuitry for selective meter damping, bandwidth selection and frequency peaking, range selection in 5-db steps, battery voltage checking and self-contained charging. Price: $285.00.

Need a high temperature cable for nuclear application?



. AMPHENOL ultra-high temperature flexible rf cable is capable of continuous operation at 1000°F with short excursions to higher temperatures.

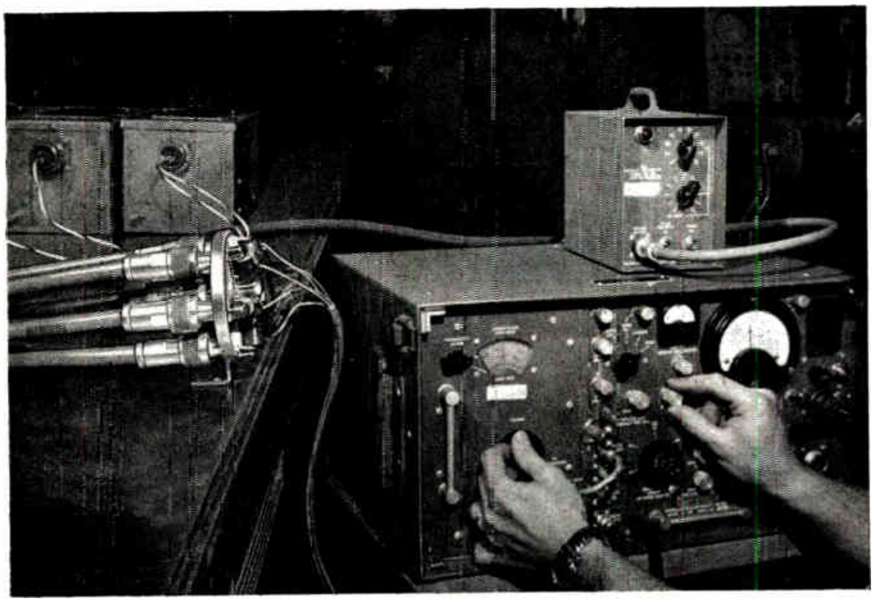
Application engineered for aircraft and missile temperature environments, the cable is a completely sealed rf transmission system consisting of inner and outer conductors separated by a dielectric of modified semi-solid silica.

Over all is a protective-sealed metallic-convoluted jacket. Cable ends are terminated at the factory with hermetically sealed 1000°F Series N plugs. System is resistant to nuclear radiation and is ideal for reactor use.

DATA

Altitude Insensitive-Moisture Resistant	Capacitance: 30.0 f/ft.
Resistant to Shock and Vibration	Velocity of Propagation: 69.0%
Resistant to Nuclear Radiation	Voltage Breakdown: 3500 Volts RMS
Connectors: Series N Plugs	Maximum Operating Voltage: 1000 VRMS
Impedance: 50 Ohms	Weight: Cable, 17½ lbs pr 100 ft.
	Connectors, 2½ ounces each

1000°F flexible rf cable is available in standard lengths up to 200 feet. Part number is 777-502. Specify length desired in order or quotation request. Length is measured from connector mating end to connector mating end.



FXR coax switch cuts Norden Laboratory test time

Norden, a division of United Aircraft Corporation, operates an environmental test laboratory at its Norwalk, Conn., plant.

Faced with an ever-increasing number of systems requiring noise and interference tests under military specifications, Norden engineers asked FXR to design a 50-ohm resistor-terminated coaxial switch that would have identical electrical characteristics through each of six outputs. Now, to check different channels, instead of disconnecting and connecting cable, Norden engineers just flick a small knob. All unused channels are grounded through 50-ohm terminations, with no significant crosstalk to interfere with the measurements being recorded.

The result is a faster, more convenient test procedure. If you're running noise tests under MIL-I 6181B, 6181D, 26600 or 19610 you'll find that this new coaxial switch will save hours of tedious work.

Maybe you have some other unusual rf switching problem. Why not ask us about it?

How to reduce your cable inventory

Most people we know cut up the cable they purchase, then put connectors on each end.

Why not let us make your cable assemblies? As the only major manufacturer of coaxial cable and coaxial connectors, FXR can probably save you money. We can certainly save you time.

How? Well, for one thing, you don't have to inventory so much cable or so many connectors. You don't have to set up production facilities for making these cable assemblies. And, you don't have to worry about quality control. We can produce sophisticated electrical assemblies to your rigid specifications. We have the people, facilities, and know-how to guarantee quality.

FXR manufactures Amphenol coaxial cable, Amphenol and "ipc" coaxial connectors and DK coaxial switches. Together, they constitute the industry's broadest line of coaxial components. Why not let us put them together for you?

The RF Products and Microwave Division Amphenol-Borg Electronics Corporation; 33 East Franklin Street, Danbury, Connecticut.

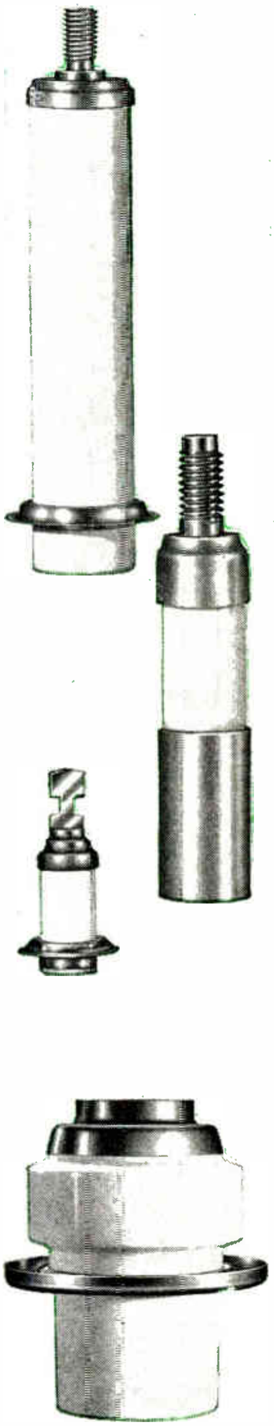
IMMEDIATE DELIVERY

of ALITE®

STANDARD HIGH ALUMINA BUSHINGS

In Over 100 Types and Sizes



More than 100 sizes of standard Alite high voltage terminals, feed-throughs, cable end seals and high amperage bushings are stocked for immediate, "off-the-shelf" delivery to simplify design problems, save time and help reduce costs.

One of these standard Alite high alumina ceramic-to-metal hermetic seals may be just the answer to your problems of reliability and maintenance where service conditions are extremely severe or critical.

- Alite hermetic seals — tested for vacuum-tightness with a high sensitivity helium mass spectrometer — are adaptable to virtually any assembly procedure, such as welding, brazing or soldering.
- Alite's mechanical strength and thermal-shock properties far exceed those of glass or porcelain.
- Alite retains its dielectric properties at elevated operating temperatures.
- Alite's smooth, white glaze resists build-up of contaminants on surfaces — easy to see, easy to clean.

From ceramic formulation to finished part, every manufacturing step is handled within our own plant. Strict quality control assures absolute adherence to specifications, utmost uniformity and reliability.

* * * *

When special bushings are called for, it is often possible to save time and money by modifying one of the standard units. However, when necessary a team of Alite engineers stands ready to help you by designing new bushings.

Write for these free helpful brochures. Bulletin A-40R illustrates, describes and gives complete specifications of standard Alite bushings, both high voltage and high amperage. Bulletin A-8 provides detailed descriptions of Alite formulations.

any transducer-sensed variable shows up clearly on this

Sanborn® Amplifier-Indicator

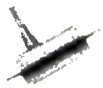
Here is a convenient, economical way to accurately measure variables from Sanborn and other makes of transducers. The Model 311 Amplifier-Indicator consists of an oscillator, high-gain carrier type amplifier, phase-sensitive demodulator, power supply and a large, multi-scale meter for direct-reading accuracy and ease. (A jack permits connection of an external recording or display device.) The instrument is entirely contained in a rugged 9″ x 6″ x 8″ high metal housing with leather handle. Weighing only 8 lbs., the Model 311 is an ideal portable test instrument for laboratory or field use.

Sensitivity . . . . ±250 μv full scale
Attenuator Ratios 2, 5, 10, 20, 50, 100, 200
Carrier Frequency . . . . . . 2400 cps internal, ±2% at 5 V rms
Output Monitor . . . . ±3 volts across load 1000 ohms or higher
Transducer Impedance . . . . 100 ohms min
Calibration . . . . 40 μv/volt of excitation
Zero Suppression . . . . . . Positive or negative (uncalibrated)
4-position switch; each position equal to approx. 5 turns of R BAL control (acts as coarse balance adjustment)
Power Requirements . . . . . 115 volts ±10%, 50-400 cps, 7 watts

Complete, Ready-To-Use Displacement Probe Transducers — Compact Model 580 (flange-mounted) and 581 (threaded) register 0.001″ linear displacement full-scale; 0.5% linearity; ±0.050″ stroke range; optional mounting block and carrier adapter.

Differential Transformers with Strokes up to 20″ — Rugged Linearsyn® series, shielded and unshielded; stroke lengths of ±0.005″ to ±1.0″ in stock, longer on special order; measures displacements as small as 0.000005″.

Pressure Transducers, Differential and Single-Ended — Series 267 and 268 for operation in carrier system have sensitivities of 40 μv/mm Hg/volt excitation and 40 μv/0.1 mm Hg/volt excitation; compact Monel case with standard Luer connectors; working ranges −100 to +400 mm Hg and −40 to +40 mm Hg.



Low Force Transducers — 5 standard ranges 0-1 gram (Model FTA-1) through 0-100 (FTA-100); displacement of 0.010″ full-scale.

OTHER SANBORN TRANSDUCERS (not carrier excited)

Miniature DC Differential Transformer — Built-in carrier system saves space, power and cost, eliminates phase and balancing problems; Model 7 DCDT-050 has ±0.050″ displacement range (other models, to ±3″); hermetically sealed, occupies less than ½ cu. in.

LVsyn® Velocity Transducers — Extremely durable, immersible units; 12 models with strokes 1.3″ to 22″, longer on special order; specials for high pressures, temperatures.

introducing
a new Corporation
for precision production
of measuring and
testing equipment...

Western Electrodynamics

In 1955, Claude M. Hathaway — designer of many leading electronic instruments for science, industry and public utilities — sold his company and retired to his working ranch at Whitewater, Colorado. Five years later, in the seclusion of a complete engineering laboratory which he built at the ranch for the purpose, he worked on new instruments, improved their performance and made startling new discoveries. Repeated testing and checking proved the reliability of a broad new line of products.

Now a new corporation — Western Electrodynamics — has been formed to manufacture and market this wide product line. The temporary manufacturing facility is in production now. A completely modern plant is under construction and will be in operation by summer of 1962.

Western Electrodynamics is your assurance of the matchless Hathaway reputation in a well-founded organization of capable and dedicated men of experience.

New and improved products from Western Electrodynamics include:

Automatic fault-recording systems — To the electric power industry, Western Electrodynamics offers new and advanced equipment for automatically recording faults and abnormal conditions and for monitoring the performance of systems and components under fault conditions. Advances include simplified designs, higher accuracy, faster starting, and immediate record access.

New transient recording oscillograph — For general laboratory use, Model OSD provides increased resolutions of short, fast transients.

Scopograph — A laboratory-quality cathode ray oscilloscope with built-in recording features for standing waves and transient phenomena. Every laboratory needs this most versatile and convenient instrument.

Telemetry and remote-control systems — To industry Western Electrodynamics brings the telemetry developments of the space age. **Digitor 300** monitors an indefinite number of on-off functions over a single radio or metallic channel. **Digitor 500** transmits an indefinite number of measurements and control commands over a single radio or metallic channel. **Digitor** systems find an almost unlimited application in industry for remote measurement and control.

Electronic weighing equipment for industry — Products include electronic weighing components which reduce cost and complexity of weight-batching plants, improved load cells, and built-in motor truck scale which provides an indication of cargo weight at all times.

Strain measuring instruments and systems — Improved and miniaturized equipment for the recording of dynamics strain in machine parts of all kinds.

Measuring and testing equipment — This category includes electrical insulation measuring instruments, vibration and strain measuring devices, and electrical standards equipment.

Write today for 24 page color Facilities Brochure on the plant, its equipment, and key personnel.

for your mass-production wire stripping...

WORLD LEADERS IN

automatic

WIRE PROCESSING

EQUIPMENT

ARTOS MACHINES WILL

★ *MEASURE LENGTHS*

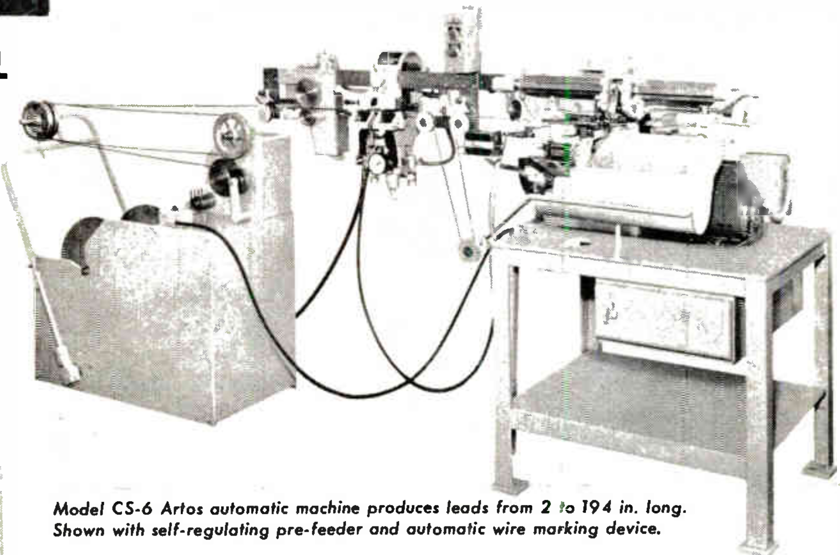
★ *CUT OFF LEADS*

★ *STRIP INSULATION*

...at speeds up to

8,000

pieces per hour!



Model CS-6 Artos automatic machine produces leads from 2 to 194 in. long. Shown with self-regulating pre-feeder and automatic wire marking device.

OPTIONAL AUXILIARY EQUIPMENT

This automatic equipment profitably adapts Artos machines to all of your individual job conditions:

DE-REELING DEVICE—Maintains even tension under all conditions.

MOTOR DRIVEN PRE-FEEDER—For extra heavy reels; self-regulating.

2-PLANE WIRE STRAIGHTENER—For very stiff wires; simplifies collection.

TWIST RETAINER—Saves costly handling.

WIRE MARKER—Identifies leads without color coding or tagging.

TERMINAL ATTACHING EQUIPMENT—Follows stripping in one continuous cycle.

PRE-DETERMINED COUNTER—For automatic machine shut-off.

YOU CAN ECONOMICALLY mass-produce finished wire leads ... to any specifications ... with unskilled labor ... on these Artos automatic processing machines.

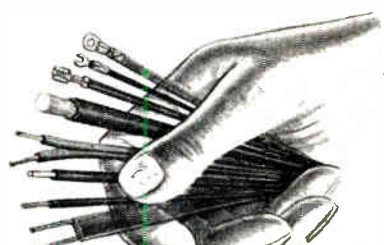
Leads are accurately measured, cut off and stripped without nicking the conductor—*at speeds up to 8,000 pieces per hour!* On some machine models, *terminal-attaching* can also be performed automatically in the same continuous cycle.

Artos machines handle almost any kind of wire without major set-up changes—solid or stranded, single or multiple conductor, with rubber, plastic, asbestos or braided insulation. Wire of 12-gauge and smaller can often be fed two at a time to double the output.

BROAD WORK RANGE

To fit your exact needs, the Artos line includes machines in a broad range of capacities, along with optional auxiliary equipment for every special job requirement. Here is the overall work range that can be handled:

WIRE SIZES: 30 to 000 gauge.
LEAD LENGTHS: 1 in. to 90 ft.
LENGTHS STRIPPED: ⅛ in. to 10½ in.



CUT HARNESS COST

Your wire harness needs can be handled faster and at lower cost by producing the leads on Artos automatic machines. Ask for engineering recommendations—submit details of your problem for expert analysis. No obligation.

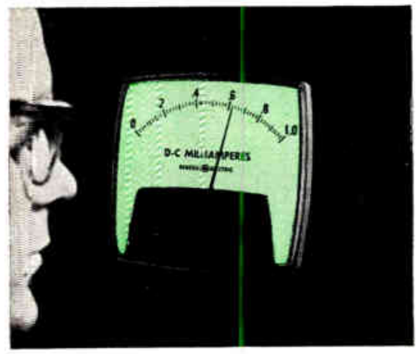
BIG LOOK Panel Meters available in 2½, 3½ and 4½-inch sizes, AC, DC and rectifier-types. Custom scales and a variety of color windows.

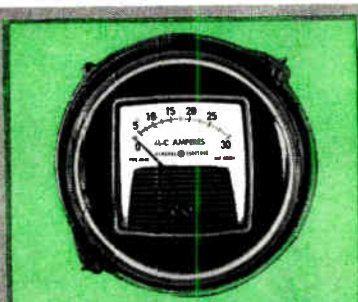
THE BIG LOOK*

PANEL AND TIME METERS FROM GENERAL ELECTRIC



New 4½-Inch AC and DC Panel Meters with mirror-backed or electroluminescent scales. Scale emits soft, even green light.

Full Line of BIG LOOK Elapsed Time Meters for match-and-lineup applications.

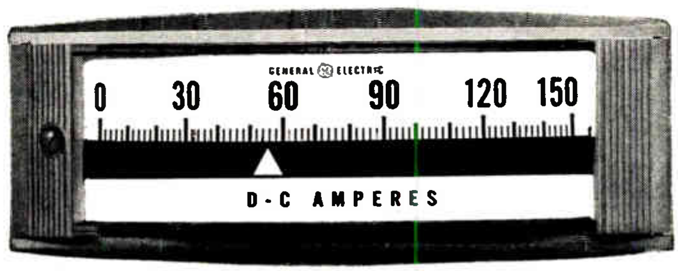


Conduit Case for 2½-inch panel and time meters. Portable test stand, too.

GENERAL ELECTRIC'S BIG LOOK PANEL AND TIME METERS, with compatible styling, bring distinctive appearance and unexcelled readability to your electrical and electronic products and equipment. ■ All BIG LOOK panel meters feature self-shielded d-c mechanism . . . sealed case on 2½- and 3½-inch models . . . snap-on, snap-off cover on 4½-inch model. Full line of a-c, d-c and rectifier-types available. ■ New BIG LOOK time meter family includes 2½- and 3½-inch reset and non-reset models with dust-proof construction . . . plus sealed models for military applications. Six extra-large digits read out from 0 to 99999.9 hours or minutes. ■ Immediate delivery from stock on all standard models and ratings . . . at low prices. Call your local G-E Sales Office or authorized Distributor today, or write for descriptive bulletins GEA-7034 (panel meters) or GEA-6710 (time meters), General Electric Company, Schenectady 5, N. Y. Canadian and foreign inquiries welcomed. *Trademark of General Electric Company.

595-06

NEW! EDGEWISE INSTRUMENTS permit single or cluster mounting . . . save up to 35% of panel space yet have big 4½-inch scale . . . require no panel drilling for stud holes. Vertical and horizontal models available.
Accuracy: ±1½% of full scale on all d-c and on a-c horizontal models, ±2% of full scale on a-c vertical model. Send for descriptive bulletin GEZ-3428.



Progress Is Our Most Important Product

Manufacturers' Cross-Reference Index

This index will serve two purposes:

1) It indicates corporate affiliations between firms, between a parent company and its divisions, etc.

2) It will help you in using the IRE DIRECTORY by suggesting where to look for a firm or division whose name you remember but whose listing in the Alphabetical Directory of Manufacturers may be under another name.

FREQUENCY CONTROL COMPONENTS & SYSTEMS

Bulova Electronics is primarily concerned with research, design, development and manufacture of frequency control devices, components and systems to meet the highest military and industrial specifications. Bulova experience in mastering many of the most difficult problems in miniature design and missile reliability can prove of immense value in your particular program. For more information on the products listed below, design or engineering assistance, write Department 2370.

BULOVA ELECTRONICS

	6WL and 6WU		

BULOVA OSCILLATORS

Bulova crystal controlled oscillators provide the "formula" for precise frequency and time regulation. High precision, sophisticated units, Bulova oscillators satisfy the stringent requirements arising out of higher speeds, decreased instrument time, tight frequency and time control references, shrunken communication and guidance spectrums.

Bulova specializes in tailoring frequency and time control packages and systems to specific requirements: supply output frequencies as high as 100 mc with frequency multipliers; frequencies as low as .001 cps with binary dividers. Stabilities as high as 2 pps 10^9 with very low aging rates are feasible. Miniaturization, too.

"GHIRIBIZZI...?"

we call it progress

The Florentines had a word for Da Vinci's amazing scientific discoveries . . ."Ghiribizzi" (trivial whims and fancies, to be spoken of slightingly and with apology). Today this pioneer of practical developments in anatomic and gravitational theory, guided missiles, airplanes and undersea boats would be courted by industrial recruiters. He would probe for progress in laboratories equipped to delight his scientific soul and administered to inspire productivity in the most creative sense.

Most probably, the environment of his choice would be very much like that at LEL, where teams of distinguished engineers are making significant contributions in the fields of missile telemetry, electronic countermeasures, radar systems and aero-space communications. Their creative efforts have resulted in outstanding examples of Microwave / RF / IF Receiving Equipment . . . equipment that has spelled progress for many of the nation's most important missile and space projects.

Whatever your technological problem . . . LEL engineers can provide a scientific solution, proved in products which achieve practical progress.

For complete details, send for the new LEL catalog.

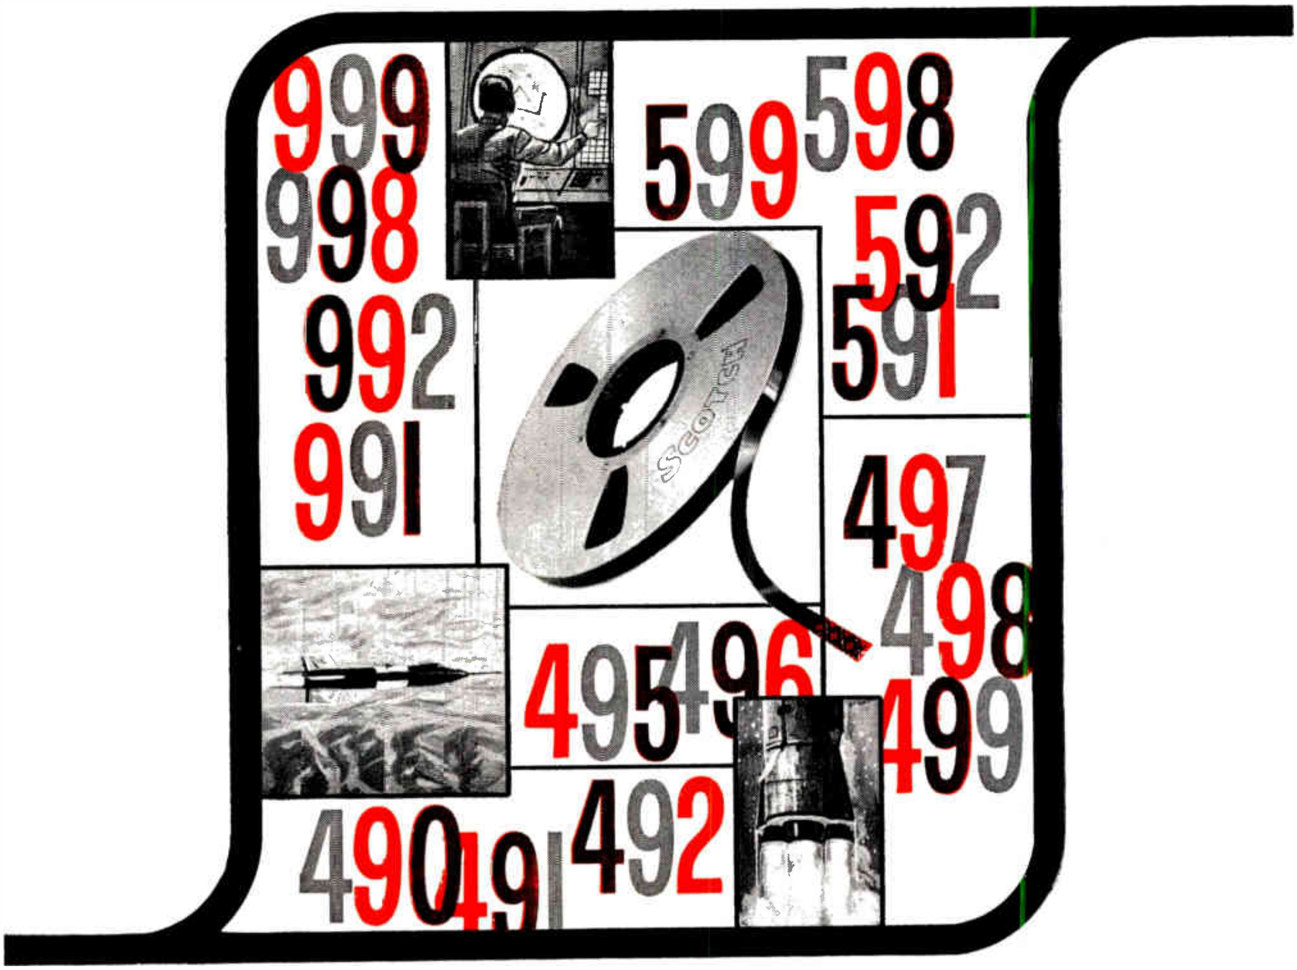
First as a matter of record . . . SCOTCH® BRAND Instrumentation Tapes



World's widest tape selection offers heavy-duty constructions for every instrumentation need!

Today's stepped up pace for data recording calls for magnetic instrumentation tapes that stay cool despite ever-increasing transport speeds, greater tensions, high heat build-up at recording heads. And the "SCOTCH" BRAND Instrumentation Tape line, with a tape for every instrumentation requirement, now includes 16 heavy-duty constructions that conquer difficult operating environments.

"SCOTCH" Heavy Duty Instrumentation Tapes are made with a special high-potency oxide and binder formulation that minimizes rub-off, withstands temperatures from —40°F to as high as 250° F! Field tests prove these tapes last a minimum of 15 times longer than ordinary tapes—capture signal with certainty despite high pressures and speeds.

The oxide coating affords nearly 1000 times greater conductivity than conventional tapes—drains off dust-attracting static charges to assure a clean tape pass every time! And exclusive Silicone lubrication protects against head wear, extends tape life! These three series of heavy duty tapes are available in a variety of widths and lengths . . .

"400" series heavy duty tapes feature exceptionally long wear, excellent high and low frequency resolution. 8 constructions—.18 and .43 mil oxide coatings on .65, 1, 1.5 mil polyester backings; .56 mil coatings on 1 and 1.5 mil backings.

"500" series heavy duty tapes combine long wear, outstanding smoothness to assure sharp resolution of extremely high frequencies. 4 constructions—1 or 1.5 mil polyester backings; .18 or .43 mil oxide coatings.

"900" series heavy duty tapes, designed especially for Mincom CM-100 series Recorder/Reproducers, provide ultra-smooth recording surfaces for critical short wave length requirements. 4 constructions—1 or 1.5 mil polyester backings; .18 or .43 mil oxide coatings.

Whatever your tape requirements—standard, high output, high resolution, sandwich or heavy duty—there's a right "SCOTCH" Instrumentation Tape. Consult your nearby 3M representative for helpful technical details. Or write Magnetic Products Division, Dept. MDA-52, 3M Company, St. Paul 1, Minn.

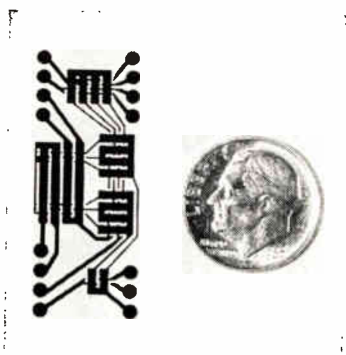
NEWS



CRYOGENIC PROGRESS in inertial guidance is typified by this 32-gate logic element for smaller, faster, more reliable computers. Other current cryogenic work includes high-precision gyros and accelerometers.

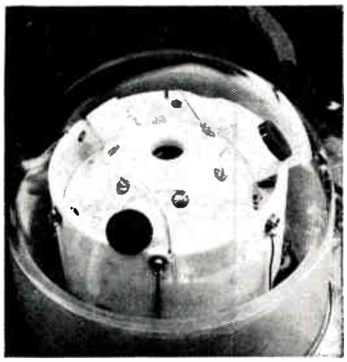
...OF DEFENSE TECHNOLOGIES

GUIDANCE

There are vast differences between the techniques required to guide missile flights and those needed for space ventures. Entirely different problems are presented in the tasks of guiding an air-to-air missile having a few thousand yards range, sending an ICBM to a target thousands of miles away, and boosting men and instruments to the frontiers of space. Experience in each is invaluable in satisfying new mission requirements.

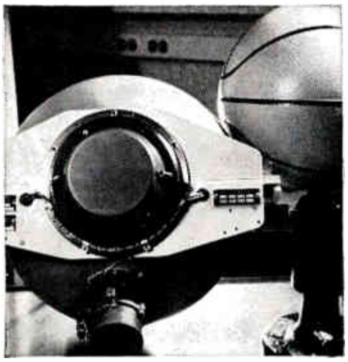
General Electric is producing infrared guidance for the Sidewinder, inertial guidance for the Polaris, and the radio-command system for Atlas ICBM's. It was this phenomenally accurate radio-command guidance that helped put the Mercury-Atlas into earth-orbit.

This wide range of guidance experience is enabling General Electric to apply new devices and techniques (such as electrostatic gyros and cryogenics) directly to existing problems, thus providing continuous and significant upgrading of guidance technologies and capabilities. Current activities include development of reference navigational systems for space and exploration of the best combinations of basic guidance forms for the sophisticated missiles and space vehicles of the future.

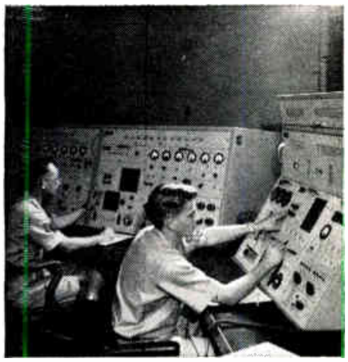


ELECTROSTATIC GYROS are being developed to meet future requirements for accuracies up to 1000 times greater than those attainable with present gyros. Other advantages will be simplicity and long life.

STAR-FIELD TRACKER correlates a viewed star pattern against a stored reference map for spacecraft attitude control. This device may replace the inertial table as an attitude sensor because of its zero drift.



INERTIAL GUIDANCE for Polaris has been extremely successful. Designed by M.I.T. and produced by General Electric, the small MK 2 system will help to extend the range of the advanced Polaris missile to 2500 miles.



RADIO-COMMAND GUIDANCE, already operational and proved accurate and reliable in ICBM and manned orbital flights, is currently being applied to booster programs and missile range instrumentation.

Progress Is Our Most Important Product

The totally new Brush Recorder Mark 200 made these incredibly crisp tracings. No other recorder in existence can match them. Note the line width. It never varies . . . regardless of writing velocity, regardless of chart speed. The writing mechanism is electrically signaled by the position-seeking "Metrisite" transducer . . . no parts to wear, infinite resolution, verifiable dynamic ½% accuracy. Traces are permanent, high-contrast, reproducible . . . on low cost chart paper. The Mark 200 has but three standard controls . . . attenuator, pen position, chart speed. Such fidelity, simplicity and economy are possible with no other direct writing recorder. Write for details . . . they'll speak for themselves.

Genalex Traveling Wave Tubes

now available for quick delivery

The Traveling Wave Tubes listed above are manufactured by General Electric Company Limited of England. They are available for quick delivery from the sole U.S. source, The Avnet System.

The TWC5, with 11 watts output, small signal gain of 39 db (5.8 to 8.2 kmcs) offers the ultimate in present-day performance: plug-in replaceability in the periodic magnet stack while meeting stringent matching and focusing requirements, *plus full life guarantees.* In quantity production and backed by extensive field experience, these tubes insure trouble-free systems.

These TWTs are established types, as are BWOs for all common bands. Avnet/Genalex can provide systems-proven tubes to fill all sockets in any microwave system.

Any tube bearing the Genalex label has long been recognized as embodying the highest technical advances in the Industry. Genalex has been designed into military systems because of compatibility with certain requirements and high performance standards.

For further information about how Avnet/Genalex can reduce your tube costs, or deliver such hard-to-get Traveling Wave Tubes as the TWC5, phone your Avnet Applications Engineer or mail the coupon.

Positions Open

The following positions of interest to IRE members have been reported as open. Apply in writing, addressing reply to company mentioned or to Box No.

The Institute reserves the right to refuse any announcement without giving a reason for the refusal.

Proceedings of the IRE
1 East 79th St., New York 21, N.Y.

THERMIONIC PHYSICIST or ENGINEER

Work will involve the design and development of prototype solar energy thermionic conversion systems for use as the source of electrical power for lunar and planetary spacecraft. Applied research and development directed toward improving reliability, life and efficiency of thermionic energy converters and generators. BS or MS with 1 to 2 years experience desired. Please send inquiries to Jet Propulsion Laboratory, California Institute of Technology, 4800 Oak Grove Drive, Pasadena, Calif. Att. J. I. Adams. An equal opportunity employer.

ASSISTANT or ASSOCIATE PROFESSOR

Applications are invited for an Assistant or Associate Professor of Electrical Engineering. Candidates should be well qualified academically, preferably to the doctorate level, and should have some research, industrial design, or teaching experience. Specialization may be in Control Systems, Circuit Theory, or other fields of Electronics. Write to: Chairman, Department of Electrical Engineering, Sacramento State College, 6000 J Street, Sacramento 19, California.

ELECTRONIC ENGINEER

Graduate Engineer with 8 yrs. of experience in design and development of electrical and electronic instruments, controls and transistor amplifiers. Exceptional opportunity for technical growth and administrative development. Write to: A R & D A—Div. of All American Engineering Co., 135 Main Street, Belleville 9, N.J.

INSTRUMENTAL SCIENCES ASSISTANTSHIPS

Leading to M.S. Degree. Engineering or Physics majors with strong background in instrumentation. Course work in fundamental principles and theory of basic instrumentation and process control. Research work in many fields of laboratory and process instrumentation. Stipend $2200 to $2500 per year. Send transcript and vitae to: Head, Electronics and Instrumentation, University of Arkansas, Graduate Institute of Technology, P.O. Box 3017, Little Rock, Arkansas.

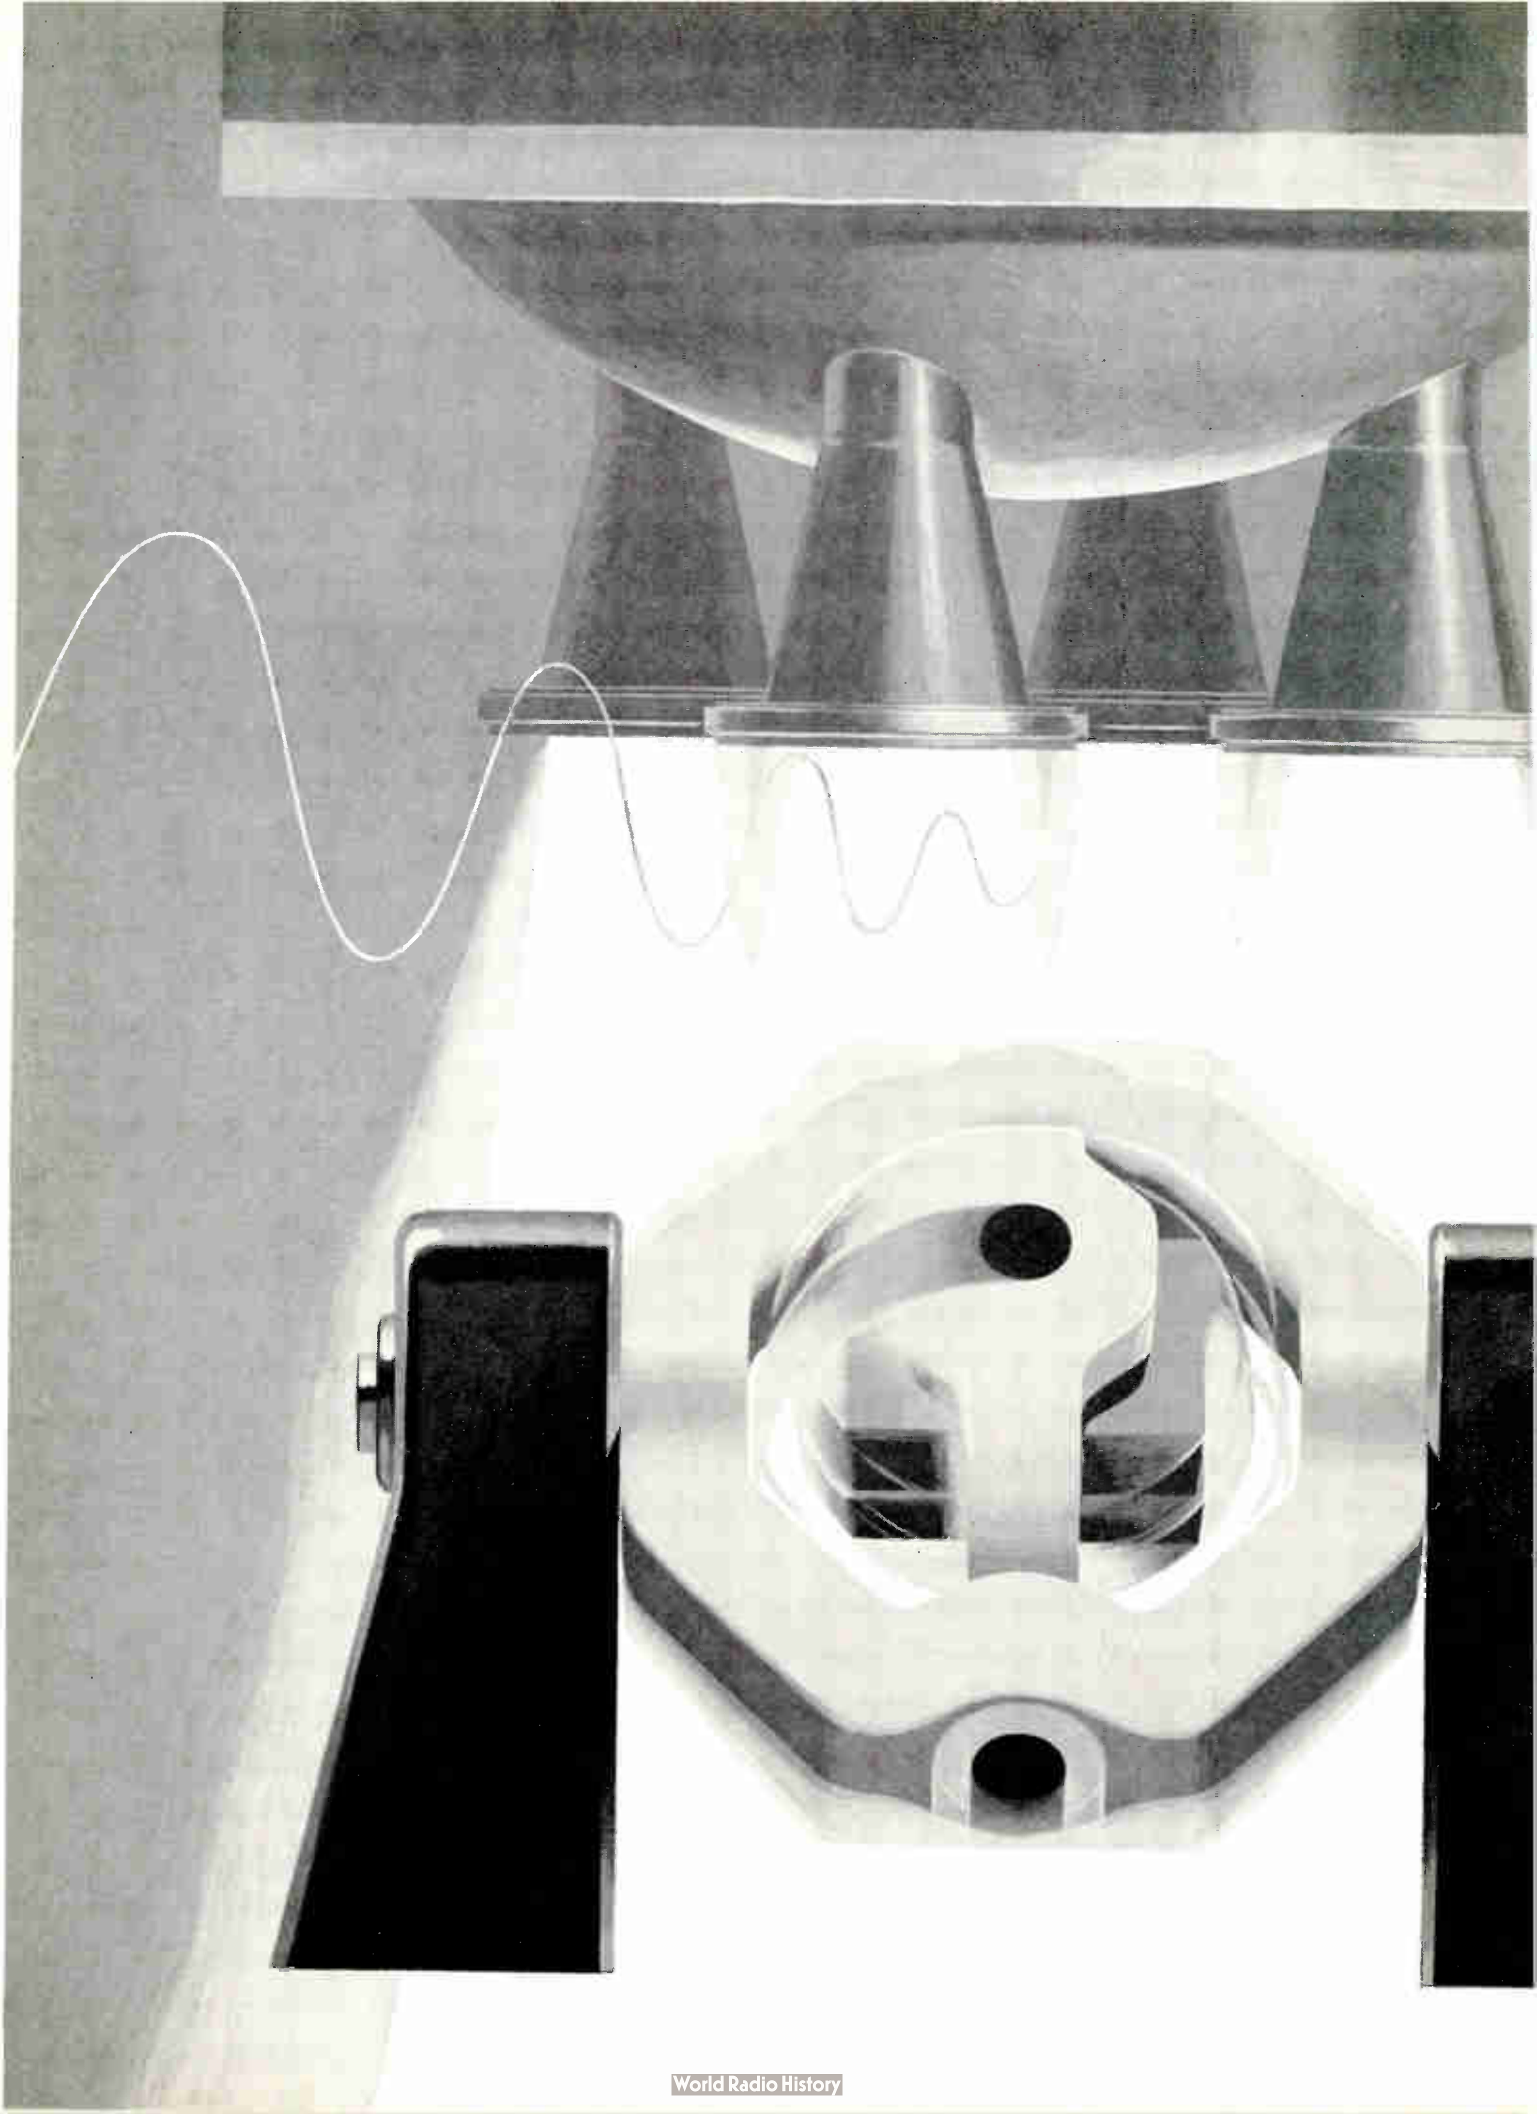
ASSISTANT PROFESSOR OF E. E.

Ph.D. required and competence in Circuit Theory and/or Solid State phenomena desirable. Should have a definite interest in research and some teaching experience. Position available Sept. 1962. Write Head of E. E. Dept., State Univ. of Iowa, Iowa City, Iowa.

ENGINEER-MATHEMATICIAN

Senior position open for analytical engineer or applied mathematician. Salary, pension, and other benefits fully competitive with industry. Ph.D. essential. Course work will be at the graduate and advanced under-graduate level. Ample time and encouragement for personal research work, including participation in activities of University Computation Center with 1620 computer. Pleasant living and working conditions in

(Continued on page 172A)



WHERE ENGINEERING AND PRODUCTION JOIN FORCES

HRB-SINGER MANUFACTURING SERVICES DIVISION*

Exciting careers in technical production are attracting engineers with the highest qualifications to HRB's Manufacturing Services Division. This unusual production facility is fabricating state-of-the-art components, sub-assemblies of major defense systems and complete infrared reconnaissance systems.

The Division maintains the following modern facilities: Production Department, Mechanical Design and Drafting, Etched Circuitry, Machine Shop, and Quality Control and Testing. These facilities offer the engineer the opportunity to choose his work from all lines of technical production, from conception and design to fabrication, check out and field test. Close liaison with HRB's R and D departments helps the Division engineer keep abreast of new concepts and developments in the industry.

In addition to this excellent technical environment, HRB offers unusual employee benefits. These include company-paid graduate study at The Pennsylvania State University, generous hospitalization, life insurance and vacation programs as well as a company-paid retirement program.

If you are interested in learning more about career opportunities at HRB-Singer, write George H. Rimbach, Supervisor of Personnel, Dept. R-3.

**for technical data write Dept. MSD.*

attractive uncrowded city. Address inquiries to Robert A. Chipman, Chairman E. E. Dept., University of Toledo, Toledo 6, Ohio.

TEACHING POSITION

Expanding work in the Department of Electrical Engineering, Air Force Institute of Technology, requires an added staff member. Ph.D. desired, but M.S. with appropriate experience may be satisfactory. Beginning salary approximately $9000-$12,000 depending on qualifications. Employment effected according to Civil Service Regulations. Address inquiries to Head, Department of Electrical Engineering, Air Force Institute of Technology, Wright-Patterson AF Base, Ohio.

TEACHING AT ALASKA

The University of Alaska will have an opening for an instructor or assistant or associate professor. We are teaching electronics and communications and are ready to expand into power system engineering. Research might be on the ionosphere or in northern problems in communications or power. Write to J. G. Tryon, Head, Department of Electrical Engineering, University of Alaska, College, Alaska. Airmail please.

ENGINEER

E.E.—Audio Circuitry. Design of commercial high-fidelity, phonograph, and AM-FM tuner circuitry. Responsible for overall equipment performance, components, evaluation and follow-through. Transistor circuitry experience desirable. Generous salary and benefits. Write Mr. R. D. Sommer, Westinghouse Television-Radio Division, Metuchen, N.J. An equal opportunity employer.

TEACHER

Teaching position in electrical engineering. M.S. or Ph.D. with interest in teaching and developing courses in an electrical engineering undergraduate program. Openings are immediately available in Electronics, Energy Conversion, Electromagnetic Fields and Power Systems. Salary commensurate with background and experience. Write to Harley Anderson, Chairman, Electricity & Electronics Department, General Motors Institute, Flint 2, Michigan.

SYSTEM ENGINEERING—EARTH SCIENCES

Creative electrical/electronic engineers to conduct research and development program on automation in data accumulation, reduction and processing in geology—geophysics, water resources investigations, geodesy, photogrammetry and allied fields including development of new techniques and equipment for sensing, transmitting, logging, processing and storing of mass data. Contact Placement Officer, U.S. Geological Survey, Washington 25, D.C.

ELECTRONICS ENGINEER—SALES

We are manufacturer's representatives selling high-quality instruments and OEM components to the electronic industry. The complexity of the product we handle requires a man having a BSEE degree and several years of experience. Fine, challenging opportunity with a fast growing organization. Compensation is by drawing against commission for field sales work. Contact Mr. George L. Boyden, Saunders & Company, 53 Prospect Street, Waltham 54, Mass.

ELECTRONIC SALES—INTERNAL

Inside technical sales. The expanded scope of our activity as an electronic manufacturer's representative has created an opportunity for a man to assist field salesmen by conducting mailing and phoning programs for our Waltham office. Ideal opportunity for a capable, disabled veteran. Secretarial skills such as shorthand and typing would be preferred but not necessary. Contact Mr. George L. Boyden, Saunders & Company, 53 Prospect Street, Waltham 54, Mass.

ELECTRONICS ENGINEER—EXPERIMENTAL SURGERY

For research program involving electronic organ and muscle control. M.S. or equiv. exp. servomechanisms; digital computers; transistor circuitry. Industrial background desirable. N.Y. area. Write Box 2069.

ELECTRONIC ENGINEER

Inductive Devices. Well established and growing company located in Culver City, Calif. has an excellent opportunity for a capable engineer to organize and manage the design and manufacture of low pass, high pass and band pass filters and electro-magnetic delay lines. Salary will be commensurate with training, experience and ability to manage. Liberal company benefits. Box 2070.

PHYSICISTS AND MICROWAVE ENGINEERS

SRI's expanding research efforts in our Electromagnetics Laboratory have created unique opportunities for M.S. and Ph.D. physicists and engineers with backgrounds and interests in the following areas: Lasers; Microwave Components; Low- and High-Power Microwave Filters; Solid-State Filters; Parametric Amplifiers. Our work involves theoretical and experimental research. Located on the San Francisco Peninsula, SRI offers rich professional association, industrial-level salaries and advanced study opportunities. Please send resume or contact R. K. Ditmore, Stanford Research Institute, Menlo Park, California. An equal opportunity employer.

TEACHING POSITION

Excellent teaching opportunity will be available beginning September. 1962. Ph.D. preferred but will consider outstanding candidates with lesser qualifications. Attractive full-year contract available. Salary range is $7500-$9500. Location in the Midwest at a medium-size private university. Send complete resume to Box 2071.

ELECTRONIC ENGINEERS

Speidel Corporation's Industrial Division offers exceptional opportunities for electronics engineers with B.S., M.S. and Ph.D. degrees to assume intermediate, senior and project engineer responsibilities in new programs for aerospace and commercial fields. Speidel desires men with experience in one or more of the following areas: Field Theory, Transistor Circuits, Magnetic Tape Recording, Electro-Mechanical Instruments, and Circuit Analysis for work on development of Recorder-Reproducers and Magneto-hydrodynamic Gyros. Contact (call collect 8 a.m.–8 p.m.) Mr. Joseph Motherway, Chief Engineer, R & D, Speidel Corp., Industrial Div., Speidel Industrial Park, Warwick, Rhode Island. REgent 9-7000. An equal opportunity employer.

(Continued on page 176A)

A RARE OPPORTUNITY

Stanford University, in Palo Alto, California, is now forming the nucleus of the engineering team building the world's largest electron accelerator. This two-mile linear microwave device will enable physicists to explore deeper into the atom than ever before. Those engineers and scientists selected to participate in this challenging project will share in the pleasures of . . . the cultural environment of the beautiful San Francisco Peninsula . . . the opportunity to work in an exciting intellectual atmosphere . . . four weeks paid vacation . . . an excellent retirement plan.

Electronic engineers with several years' experience are needed for senior positions in the research and development of such disciplines as:

- *microwave systems and components*
- *pulse circuits and pulse modulators*
- *ultra high power klystron tubes*
- *data handling equipment for accelerator central control systems*

PLEASE SEND YOUR RESUME TO:

Mr. G. F. Renner, Placement Manager
Stanford Linear Accelerator Center
Stanford University, Stanford, California

STANFORD LINEAR ACCELERATOR CENTER

CAMBRIDGE ELECTRON ACCELERATOR

Inquiries are invited from electronics engineers to join the staff of the M.I.T.-Harvard 6 Bev Electron Accelerator. Experience in one or more of the following specialties is desirable: design and development of dc to nanosecond circuits, data handling and computer techniques. Excellent qualifications and 3 to 5 years practical experience required. Resumes, including salary requirements, should be addressed to the Director, Cambridge Electron Accelerator, Harvard University, 42 Oxford Street, Cambridge 38, Mass.

DEPUTY TECHNICAL DIRECTOR—ISRAEL

A practical engineer with a minimum of 7 years working experience and at least 3 years in development or design and series production scheduling of work on electronic components, such as coilpacks, I.F. transformers, potentiometers, tuning condensers, etc. This position is available on a 3 year contractual basis. For information inquire COMOI, 515 Park Ave., New York 22, N.Y. Plaza 2-0600.

ELECTRONICS TECHNICIANS

Excellent opportunities for experienced electronic technicians at large university radio observatory in development and operation of low noise radiometers with digitized output operating at UHF and microwave frequencies. Give resume of experience, references, and salary desired. Address correspondence to: Director, Ohio State Univ. Radio Observatory, 2024 Neil Avenue, Columbus 10, Ohio.

ASSOCIATE PROFESSOR OF E. E.

Position open September 1962 to teach undergraduate and graduate courses. Must have Ph.D. degree, or M.S. with equivalent experience. Specialty in networks or electromagnetic theory. Submit resume to Chairman, Electrical Engineering Dept., University of North Dakota, Grand Forks, North Dakota.

PH.D. OPENING

Excellent opportunity for Ph.D. with background in microwaves and/or solid state. Some teaching and some research required. Private consulting encouraged. Department has Ph.D. program. Good salary and rank arrangements will be made for exceptional man from either the industrial or academic fields. Address replies to: Dr. Fred Schumann, Chairman, Electrical Engineering Department, Vanderbilt University, Nashville, Tennessee.

MANAGER ADVANCED SYSTEMS ENGINEERING

Responsible for performing systems design for proposals, improved systems, integrating inputs (technical design & program planning). Provide preproposal and proposal & technical integration with customer up to award of contract, provide advanced research studies. Should have experience in technical direction of Airborne Weapon Systems. Send resumes to: Jordan-White, Inc., 420 Lexington Avenue, New York, N.Y.

(Continued on page 178A)

Positions Open

(*Continued from page 176A*)

MANAGER, ADVANCED SURVEILLANCE & RECONNAISSANCE SYSTEMS ENGINEERING

Responsible for performing preliminary systems design for proposals of new, improved systems, integrating technical design and program planning. Provide preproposal and proposal integration with customer to award of contract, manage system study programs, perform advanced research studies, provide master planning and guidance for advanced engineering programs in surveillance & reconnaissance systems. Should have knowledge of guidance, control, processing, communications subsystems. Send resume to: Jordan-White, Inc., 420 Lexington Avenue, New York, N.Y.

PROFESSOR OF ELECTRICAL ENGINEERING

The Department of Electrical Engineering seeks a Ph.D. for research and teaching in an expanding graduate program with emphasis on circuit analysis and synthesis, and the application of solid state devices. Should have experience in securing and directing sponsored research. Applications and inquiries may be sent to John E. Dean, Head, Department of Electrical Engineering, Colorado State University, Fort Collins, Colorado.

ENGINEER-PHYSICIST

Senior level engineer-physicist—Mathematician needed to direct active and existing program directed toward a better understanding of the fundamental mechanisms involved in sputtering phenomena. Should have experience in the ion bombardment field, and should be familiar with x-ray and electron microscopy as well as ultra high vacuum techniques. Support facilities excellent, subordinate personnel well qualified, and a high degree of freedom to conduct basic research. Send complete resume to Box 2072.

BROADCAST ENGINEER

Long term European assignment with private organization engaged in construction and operation of large high-powered shortwave radio stations. Top qualifications, experience and executive ability desired. Good salary plus overseas benefits. Reply to Box 2073.

TEACHING AND RESEARCH PROFESSORSHIP

Unusual opportunity for electronic engineer or physicist to initiate research program in electronics in rapidly growing urban institution. Income, with research, competitive with industry. Ph.D. or equivalent required. Reply to Dr. T. S. Peterson, Chairman, Division of Science, Portland State College, Portland 1, Oregon.

TRANSFORMER ENGINEER

Minimum 2 yrs. experience design and audio, power, MIL and industrial transformers. Expanding to multi-plant operations, both coasts. Top salary, full benefits, profit and pension plans. West Coast telephone 213-HO 3-5694; East Coast telephone 516-LOcust 1-6050. Person to contact for interview arrangements, Mr. Richard K. Chaber, Vice President, Engineering, at 516-LOcust 1-6050, Microtran Company, Inc., Valley Stream, N.Y.

ELECTRONICS ENGINEER, B.S. or M.S.

Unique opportunity in small expanding company for a versatile and resourceful man trained

(*Continued on page 180A*)

ENGINEERS, EE:

Our "Universal" Approach to QC Means Much Broader Technical and Managerial Responsibilities for

EVALUATION ENGINEERS

Because of the cost and complexity of the systems we develop and produce, our engineers simply can't afford the luxury of making a prototype for evaluation purposes. In almost every case, the first piece made . . . is shipped!

The situation becomes even more formidable when you analyze the number and types of subsystem interfaces, rigorous performance and reliability standards involved, and the number of subcontracting vendors whose individual quality standards must be equated with our own.

Small wonder that our Evaluation Engineers operate over such a broad spectrum of technical and managerial responsibilities. In briefest terms, these include:

1. Functional evaluation of military systems.
2. Environmental testing of the systems.
3. Determination of the uses for test equipment and preparation of test equipment specs.
4. Customer liaison on system performances and quality characteristics.
5. Technical leadership of quality operations to control the system requirements.
6. Design review for quality characteristics.

Product scope encompasses inertial navigation systems, analog and digital computers, optical alignment systems, antennas, electronic torpedoes, servo systems. BSEE is required.

Our location is convenient, western Massachusetts offers a host of cultural and 4-seasons recreational advantages for the entire family.

For more information, or to apply, please forward your resume in strict confidence to Mr. D. F. Kline, Div. 53-ME, Ordnance Department, General Electric Co., 100 Plastics Avenue, Pittsfield, Mass.

GENERAL ELECTRIC

An Equal Opportunity Employer

Positions Open

in RF techniques, field theory, general electronics, feedback amplifier design and servomechanisms. Development, prototype and initial production runs. Minimum 3 years experience desirable. Reply to Boonton Polytechnic Company, P.O. Box 125, Boonton, New Jersey.

ELECTRICAL ENGINEERING

Staff positions beginning September, 1962. Undergraduate-graduate teaching and research in networks, systems, microwaves, and materials. Write to Joseph C. Michalowicz, Head, Department of Electrical Engineering, The Catholic University of America, Washington 17, D.C.

PROFESSOR OF PHYSICS

Ph.D. with teaching experience to be Department Head. To handle advanced undergraduate courses and to initiate research. College of Liberal arts and sciences. Resume to: R. B. Winslow, Department of Physics, Wheeling College, Wheeling, W.Va.

CRITICAL VACANCIES AT GRIFFIS AIR FORCE BASE, ROME, N.Y.

Research Psychologist (Physiological, Experimental & Engineering)	GS-180-7	$5355 pa
Civil Engineer (Gen)	GS-810-9	$6435 pa
Electronic Engineer (2) (Electro Magnetics)	GS-855-11	$7560 pa
Electronic Engineer (Gen)	GS-855-11	$7560 pa
Industrial Engineer	GS-896-11	$7560 pa

Positions Wanted

By Armed Forces Veterans

In order to give a reasonably equal opportunity to all applicants and to avoid overcrowding of the corresponding column, the following rules have been adopted:

The IRE publishes free of charge notices of positions wanted by IRE members who are now in the Service or have received an honorable discharge. Such notices should not have more than five lines. They may be inserted only after a lapse of one month or more following a previous insertion and the maximum number of insertions is three per year. The IRE necessarily reserves the right to decline any announcement without assignment of reason.

Address replies to box number indicated, c/o IRE, 1 East 79th St., New York 21, N.Y.

ENGINEER

Military retired. Over 20 years training and experience in electronics maintenance and operations management for USAF. Some R&D associated with 8 years assignments on special projects. Interested in electronics or geophysical operations with possible assignments in Australia or New Zealand. Box 3978 W.

TEACHER

B.S. and M.S. in E.E.; present position Research and Development Engineer with six years

(*Continued on page 182A*)

CAN YOU TAKE IT?

Do you have what it takes to manage a research or development program in advanced technologies? We have several important opportunities for highly qualified scientists and engineers. The demands are exacting—but the rewards are high (up to $25,000). Your resume must show achievements in any of these areas:

- COMMUNICATIONS TECHNIQUES
- WEAPONS SYSTEMS ANALYSIS
- SOLID STATE PHYSICS—CIRCUITRY
- ANTENNA DESIGN
- DIGITAL EQUIPMENT ENGINEERING
- MICROWAVE COMPONENTS AND SYSTEMS
- RADAR SYSTEMS AND TECHNIQUES

All fees and relocation expenses paid by our client companies. Negotiations will be held in strict confidence.

ACT NOW!

SEND YOUR RESUME TO:

Mr. J. Edward Beauregard
Dept. C-1

ABBOTT'S

EMPLOYMENT SPECIALISTS
150 Tremont St., Boston 11, Massachusetts

GOODYEAR AIRCRAFT CORPORATION

Arizona Division

is expanding its Electronic facilities and has long range positions that will challenge your talent in the technical areas listed below:

SR. DEV. ENG'R.

Develop wideband i-f amplifiers, i-f oscillators, i-f isolation amplifiers & related circuits.

SR. DEV. ENG'R.

Develop X-band radar circuits & equipment including wave guide assemblies & related circuits.

SR. DEV. ENG'R.

Servomechanisms, design close loop control system.

SR. DEV. ENG'R.

Develop radar transmitters & modulators including pulse forming networks, transformers, protection circuits, X-band amplifiers & related circuits.

SR. PACKAGING ENG'RS.

Layout packaging & detailing layout of electronic sub-assemblies including i-f and r-f units.

All qualified applicants will receive consideration for employment without regard to race, creed, color, or national origin.

Request Application or Send Resume To:

Engineering Personnel
Goodyear Aircraft Corporation
Litchfield Park, Arizona

Similar Positions at Goodyear Aircraft Corporation, Akron, Ohio.

Open once every 19 months

We just can't send a Mariner spacecraft to Venus any time we feel like it. Because of the different orbits of Earth and her most brilliant neighbor, we have only about one month, every 19 months, to get a shot at it.

Even at that, the launch window opens only one to two hours each day of that month.

The men with their noses pressed hardest against the pane are the scientists and engineers at Caltech's Jet Propulsion Laboratory. These are the men who designed the Mariner and its payload of scientific instruments. These are the men who'll find out what the moon is made of and if there's life on other planets. They keep their fingers crossed long after the last stage is fired.

But they know luck's a luxury we can't afford in other-world exploration. JPL needs minds. The kind of minds that won't leave anything to chance...that know what to do when the window goes up. If you have that kind of mind, maybe JPL is your kind of place. Write us about yourself. If you have a mind to.

JET PROPULSION LABORATORY
4804 OAK GROVE DRIVE, PASADENA, CALIFORNIA
Operated by California Institute of Technology for the National Aeronautics & Space Administration

jpl

All qualified applicants will receive consideration for employment without regard to race, creed or national origin / U.S. citizenship or current security clearance required.

Positions Wanted

By Armed Forces Veterans

(Continued from page 180A)

experience. Desires teaching position in Fall of 1962. Box 3979 W.

SYSTEMS ENGINEERING

M.S.E.E., 5 years experience digital and analog systems. Interested in process analysis, simulation, feasibility study, and proposal preparation related to development and application of process control computers. Box 3980 W.

ELECTRONICS ENGINEER

Age 32, married. Desires challenging position offering security and advancement possibilities. Twelve years experience in ground radar and communications. Five years of experience has been in systems engineering, primarily microwave. Training and supervisory experience; Commercial pilot. Box 3981 W.

REPRESENTATIVE/SUPERVISOR

Age 35. B.S. Mathematics, *summa cum laude.* Engaged continuously since 1951 in electronics teaching and field engineering. Sound, comprehensive background in electronics, radar, and computers. Fluent German and French. Thorough training in business administration. Successful supervisory experience. Would welcome overseas assignment. Box 3984 W.

EDUCATIONAL TELEVISION

Experienced broadcaster desires position as operations manager or assistant manager. Some teaching experience. Presently employed in designing of closed circuit TV. Will forward detailed resume on request. Box 3985 W.

ENGINEER

B.E. in Electrical Engineering 1953; P.E.; experience in all phases of manufacturing of electronic gear. Single, age 30. Will complete B.F.T. at American Institute for Foreign Trade in June; speak Portuguese. Desire position in management or technical sales in Brazil. Box 3986 W.

BIO-MEDICAL ENGINEER

10 years experience, publications, MSE (EE), desires teaching and/or research in medical engineering. Would like opportunity to initiate and guide research projects. I am principally an idea man. Box 3987 W.

ELECTRICAL ENGINEER

Electrical Engineer, BSEE 1950, desiring position as field engineer for system installation and for customer liaison with manufacturers, or as test engineer to design production tooling or test and quality control. Prefer Texas area. Box 3988 W.

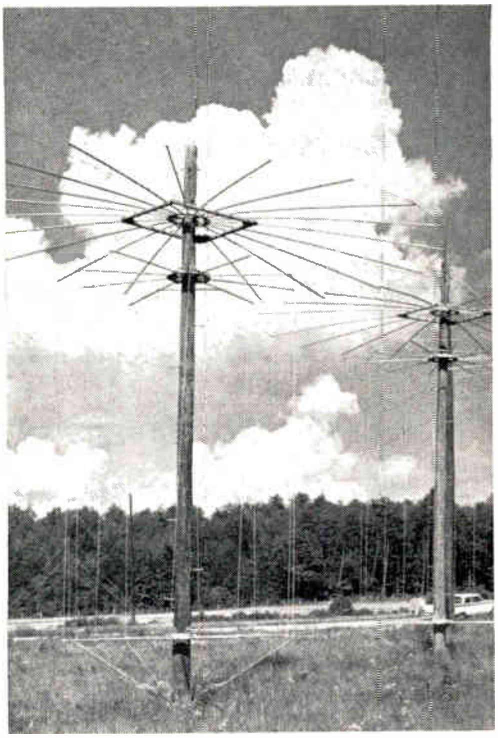
ENGINEER

B.E.E. with highest honor, Georgia Tech. 1950, 24 hours of graduate school. 2½ years design of two way mobile radio transmitters; 3 years manager of test laboratory; 5⅔ years manager of advance development group (automatic test and adjustment equipment). Desires challenging position with growing company. Box 3989 W.

SALES MANAGER

B.S. EE, Age 35, Married, 8 years experience in Electronic Component sales plus two years experience as project engineer for component manufacturer. Successful record in increasing sales. Tripled sales in present territory in three years. Box 3990 W.

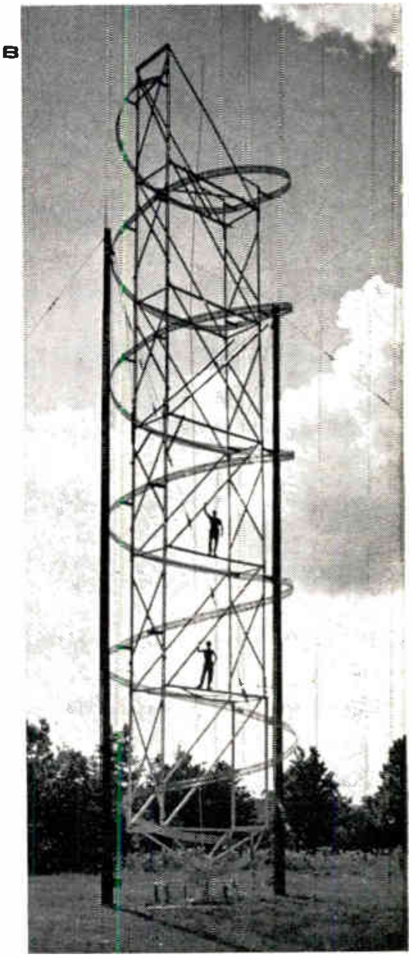
(Continued on page 184A)



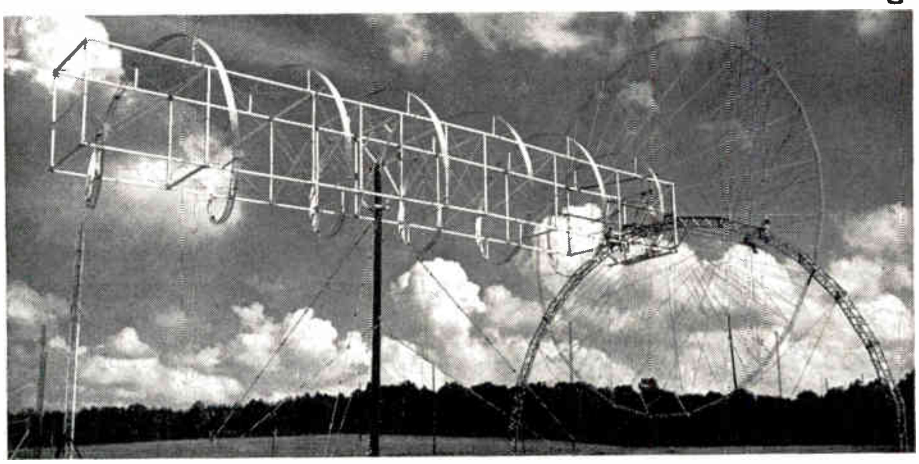
A

CLIMATE FOR CREATIVITY

B



C



A *Portion of a high gain broadband monopole, phased array, designed for electrical steering in azimuth and controlled elevation beamwidth.*

B *100 ft.-high, circularly polarized, axial mode broadband HF helix.*

C *Circularly polarized helical antenna for HF, trainable in azimuth.*

The creative scientist needs a climate where his ideas can flow freely . . . where he can find independence within a group dedicated to pursuits similar to his own. Because his creative work is the basic product of the Electro-Physics Laboratories, we have dedicated ourselves to the preservation of such a climate.

- Project responsibility is based on technical achievement.
- Programs are planned so that research personnel guide their projects from the concept stage, to applied research, to prototype development.
- Sympathetic and efficient administrative support is provided, which permits research personnel to focus their full talents on technical problems.
- The importance of the research effort instills in all participants a very real sense of contributing to our national purpose.

Staff appointments are available for research projects now under way and others still in the conceptual stages. Current problems include the investigation of ionospheric propagation in general and as applied to communications, the development of new and unique communications techniques, and the investigation of upper atmosphere phenomena by means of unusual rocket probe techniques. The available supporting laboratory program is being expanded to develop equipment and techniques for applications in these fields.

Security clearance helpful. For additional details, please write to: Mr. William T. Whelan, Director of Research and Development.

ELECTRO-PHYSICS LABORATORIES

FLORIDA SALES REPRESENTATIVE

An aggressive engineer with M B A and established O.E.M. contacts is available to sell your electronic instruments or components. Age 30, married. Ultimate goal is to establish a representative organization. Box 3994 W.

PUBLICATIONS ENGINEER, SENIOR

Experience: Supervisor, computer manuals group; 18 years experience in electronics and writing. Graduate of Capitol Radio Eng. Inst., B.A. in English at Univ. of Md. 30 sem. units graduate study in English plus misc. training courses in electronics. Box 3995 W.

MICROMINIATURE COMPONENT ENGINEER

Graduate engineer, age 35, with ten years' experience in design, development and production of semiconductors, resistors, capacitors and microminiature circuits, seeks responsible position with manufacturer or user. Experience includes semiconductor device fabrication, thin films, photolithography, ceramic and glass-to-metal seals, ultramicrominiaturization techniques. Box 3996 W.

ELECTRONICS TECHNICIAN

Retiring from military service April 1963 with twenty years of communications-electronics experience. Graduate civilian and military schools. Resume upon request. Box 3997 W.

COMMUNICATIONS ENGINEER

Currently recalled as Captain in U.S. Army Security Agency. Industrial R & D experience in radio DF, communications satellites, and military communications systems. B.S. and M.S. in EE; PE; Ph.D. course work; languages; age 31; highest clearances. Desires long term assignment in Europe in communication systems engineering or management. Box 3998 W.

ELECTRICAL ENGINEER

Elect. Engr. Tech; RCA T3 Grad; Married; 28; Evening student at CCNY. 2½ yrs. with switching systems engineering dept. of R & D lab. Desires challenging position with room for advancement in N.Y.C. Box 3999 W.

The Calibre of an Aerospace Organization Is Evidenced by the Calibre of the Problems Put To It by its Customers — and by the Company to its Engineers

Engineers, Scientists

what's your opinion:

1

ON HOW TO STORE AND PRESSURIZE CRYOGENIC PROPELLANTS IN SPACE, MAINTAINING INSTANT READINESS?

At Bell Aerosystems, Design Engineers are carrying on a concentrated attack on this problem, as it relates to space propulsion rocket engines, where weight and reliability are at a premium. This is an expanding activity at Bell. *Your* professional contributions will be welcomed if your experience and background equips you to analyze steady-state and transient heat transfer effects interrelated with thermodynamics and chemical kinetics of pressurization under varying space environments.

2

ON HOW TO DESIGN A DE-CRABBING SYSTEM TO AUTOMATICALLY ALIGN AIRCRAFT LONGITUDINALLY IN CROSS-WIND LANDINGS?

Correct alignment within 3 seconds of touchdown has been obtained by Bell engineers, in developing an all-weather landing system for conventional aircraft, successfully tested in 4000 landings of USN and USAF planes. Opportunities exist to participate in advanced studies of full spectrum of problems of automatic landing of very high-speed, advanced spacecraft.

3

ON HOW TO IMPROVE THRUST-TO-WEIGHT RATIO OF ELECTRO-STATIC PROPULSION DEVICES?

Applied research and advanced development in thermoelectrics for space propulsion is an important field of interest at Bell. As a qualified member of an R & D group in this area you would be concerned with finding practical answers to applications of electro-static propulsion for such missions as: interplanetary trips to Venus; interorbital transfers; deep space probes; satellite orientation control. Investigations are also in progress to develop light-weight ionization and neutralization systems; methods of creating, controlling and accelerating plasmas.

If you would like to pit your talents against the more significant and challenging problems of the Aerospace Age, why not look into the wide variety of professional openings at Bell, some of which are listed below. Bell Aerosystems originated the AGENA rocket engine, HIPERNAS inertial systems, the revolutionary Reaction Control Concept for space vehicle steering and many other advances in missilery, avionics and propulsion ... is now working on such diverse programs as the HYDROSKIMMER air cushion vehicle for the Navy, and a realistic space simulator for astronauts.

INERTIAL GUIDANCE

Various degree levels with 2 to 8 years specific experience in one of the following areas: logic design and magnetic memory development: low frequency design and development involving servos; systems and component testing, resolver chains, gyros, accelerometer integrators; inertial instrument development.

ELECTRONIC SYSTEMS

MS preferred, with minimum 5 years experience for synthesis and analysis of advanced systems such as air traffic control, target locators, visual simulators and feed-back controls. Openings also in Tucson, Arizona.

SYSTEMS ENGINEERING

BS in ME, Applied Math, AE or Physics. Experienced in the dynamics of closed-loop systems, guidance, mechanics of vehicle flight, space mechanics, analog and digital computing systems.

OPTICAL DEVELOPMENT

Advanced Engineering degree with minimum of 10 years experience in the design and construction of optical devices. For original design of optical equipment such as visual simulation apparatus, airborne sighting systems, and precision instrumentation.

DYNAMICS ENGINEERING

Degree in Math or Physics with experience in operation of analog computer equipment. To perform dynamic analysis of aircraft and missile systems, mechanization and operation of analog computer equipment in systems synthesis, design and evaluation.

AUTOMATED ARTILLERY FIRE PLANNING

TRADING HOURS FOR MINUTES WHEN IT COUNTS

Targets to destroy... troop movements to cover... a bridge to save... a gun emplacement to wipe out... a precisely coordinated schedule of firepower and manpower and brainpower.

The Divisional Fire Plan, prepared automatically by electronic computers in 12 minutes, tells the captain where every artillery battery will hit—and when. He checks his Schedule of Fires against the tactical map, applying human judgement, experience and intelligence to the information supplied by the computers. If he wants to, he can alter or refine the schedule—even scrap it completely and have a new one in his hands in a few minutes.

A simulation exercise today; a powerful system in the field tomorrow.

At recent exercises, an Army-Industry team successfully demonstrated that automatic data processing systems can help to reduce the time it takes to prepare a Divisional Fire Plan from a matter of hours to a matter of minutes. When computers process ballistic solutions at electronic speeds, they aid in achieving first-round target hits. This means saving ammunition—conventional or nuclear. It also means surprise—hitting the target while it is unprepared and vulnerable. The long-range program of developing Command Control Information Systems is now being extended to other Tactical Field Army functions, utilizing the FIELDATA family of equipment.

Development and testing of artillery fire planning and control systems are being done by the U.S. Army Electronic Proving Ground, Fort Huachuca, Arizona, with the cooperation and support of the U.S. Army Artillery and Missile School, Fort Sill, Oklahoma. Technical assistance is being provided by Ramo-Wooldridge, a Division of Thompson Ramo Wooldridge Inc.

Challenging openings now exist at Ramo-Wooldridge's Fort Huachuca office for experienced computer programmers, systems analysts and test and applications engineers. All qualified applicants will receive consideration for employment regardless of race, creed, color or national origin.

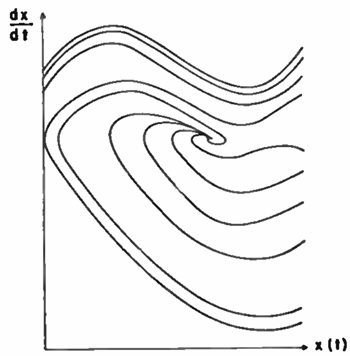
NON-LINEAR DIFFERENTIAL EQUATIONS

The non-linear differential equation shown above the phase-plane plot governs the behavior of one form of the well-known electronic circuit used for the reception of weak communication signals. The circuit, known as the phase-lock loop, has a mechanical analog consisting of a mass subjected simultaneously to non-linear restoring and resistive forces.

$$\frac{d^2x}{dt^2} + (\alpha + \kappa \cos x)\frac{dx}{dt} + \gamma \sin x = \beta$$



INTEGRAL CURVES IN THE PHASE PLANE

Simpler equations of this basic type have been studied for a number of years, and computers have produced many phase-plane plots for special values of the parameters, such as shown above. For fuller understanding of the circuit operation, however, new analytical methods are being investigated at Philco which may give an overall picture of the solutions of this, and even more general, equations.

This study is typical of the Philco Scientific Laboratory's activity in applied mathematics. Philco offers attractive staff positions in this field and in a number of others such as electrodynamic theory, optical communications, pattern recognition, and solid state electronics. Applications and inquiries may be addressed to: Mr. R. A. Ruth, Philco Scientific Laboratory, Blue Bell, Pennsylvania.

PHILCO SCIENTIFIC LABORATORY

PHILCO®

A SUBSIDIARY OF *Ford Motor Company*

an equal opportunity employer

if you have your eye on an exciting future......

■ ■ ■ ■ ■ ■ exciting things are happening at Eimac. Who's the world's foremost developer and manufacturer of electron power tubes? Eimac—with a long line of firsts in the field. The first modern beam magnetic optics. The first practical matrix cathode. The first metal-ceramic tubes. The first modulating anode.

Eimac tubes have powered the first satellite bounce communication. The longest command-response achieved by man. The first radar contact with the moon. Venus. And the sun.

Tomorrow: not even the sky's the limit.

You can make this exciting future **your** future. Each of our development laboratories has openings for microwave tube or power grid tube development engineers. If your forte is developing new higher power, higher frequency tubes, or cavities or test equipment. Or if you have a flair for solving tube production problems and advancing production techniques and equipment, there are exciting challenges to investigate at Eimac. You'll work in an area renowned for its concentration of electronics industry, sunny weather, fine schools and pleasant living conditions. If you can qualify, write: Mr. C. F. Gieseler, Department C, Eitel-McCullough, Inc., San Carlos, California. An equal opportunity employer.

KEEP YOUR EYE ON Eimac

A typical example of advanced design by Lockheed-California Spacecraft

Will command centers based in space be an outstanding development in the ten-year span from 1967 to 1977?

The answer at Lockheed-California Company's Spacecraft Organization is—Yes. Proof: the Spacecraft design pictured here. It reflects the maturity developed in our thinking about manned space systems.

The station—aeroscope traffic control center of the 1970's—will be assembled in orbit in a series of pieces brought together by rendezvous techniques. Included: Command center; living quarters; maintenance station; radar and infrared sensing devices; nuclear power supply; communication links with the earth and other space vehicles. As now planned, 12 people will man the vehicle. Their tour of duty will be measured in weeks.

For four years Lockheed-California Spacecraft has concentrated on the needs of man in space. Activities embrace all fields pertaining to development of complex spacecraft as well as supporting technologies. An operation of such magnitude opens many doors of opportunity.

Scientists and Engineers of outstanding talent and training are needed to develop new Spacecraft, Aircraft, ASW concepts in: Human Factors; Physics (theoretical, plasma, high-energy, solid state, infrared, optics, nuclear); Thermodynamics; Servosystems; Reliability; Guidance and Control; Dynamics; Electronic Systems; Aerospace Ground Equipment; Bioastronautics; Systems Integration and Trade-Off; Space Mechanics; Sub-Systems Synthesis and Analysis; Nuclear, Electric and Liquid Rocket Propulsion; Electronics Research; Hydrodynamics. Send résumé to: Mr. E. W. Des Lauriers, Manager Professional Placement Staff, Dept. 1805, 2402 N. Hollywood Way, Burbank, California. An equal opportunity employer.

COMMUNICATIONS and RADAR & DATA-HANDLING ENGINEERS/SCIENTISTS

SADTC

The *SHAPE AIR DEFENCE TECHNICAL CENTRE* has a few vacancies for qualified engineers/scientists for technical investigations and planning studies concerning NATO Air Defence Systems. Candidates should be university graduates with at least 5 years' professional experience in a responsible position, and should have worked in one or more of the following fields:

COMMUNICATIONS

- —Line transmission techniques
- —Operation of communications networks
- —Digital techniques
- —Microwave systems and techniques
- —Scatter communications
- —HF radio voice or telegraph systems

RADAR & DATA-HANDLING

- —Military ground environment systems
- —Calibration, test and evaluation of military radar systems
- —Radar data extraction, IFF and data-handling systems
- —Radar electronic counter counter measure techniques
- —Air traffic control and guided weapon control systems
- —Digital data extraction, transmission and display techniques

Duties will include the writing of technical reports.

The SADTC is an international establishment located in The Hague, Netherlands, and has staff from many NATO nations. The work offers challenging problems and is of a unique international character.

The basic salary will depend on background and experience and will be supplemented by a foreign allowance of between 60 and 70%. Reimbursement of the cost of moving families and household effects to The Hague and back to the country of origin after termination of contract is made. Staff members benefit from a number of concessions such as freedom from income tax in the Netherlands on the total emoluments.

Applications, including detailed information on professional qualifications and experience, should be sent to: The Director, SHAPE Air Defence Technical Centre, P.O. Box 174, The Hague, Netherlands.

ELECTRONIC ENGINEERS

R & D

Outstanding career opportunities for engineers with at least a B.S. in Electrical Engineering or Physics to work in our Systems Engineering Group. Should have strong analytical capability with at least 3 to 5 years research experience in one or more of the following areas:

INFRARED DETECTION SYSTEMS
MEDICAL ELECTRONIC SYSTEMS
MAGNETIC TAPE RECORDERS

Duties entail project responsibility from the concept stage, through design, to model fabrication. The Mechanics Research Division provides scientific research and development services both for the government and industry.

Salaries commensurate with experience. Excellent opportunity for personal and professional growth contributing to diversified and challenging projects. Liberal company benefits including a full tuition reimbursement plan. Chicago suburb location. Kindly forward your resume in confidence to R. B. Martin, Dept. I-15.

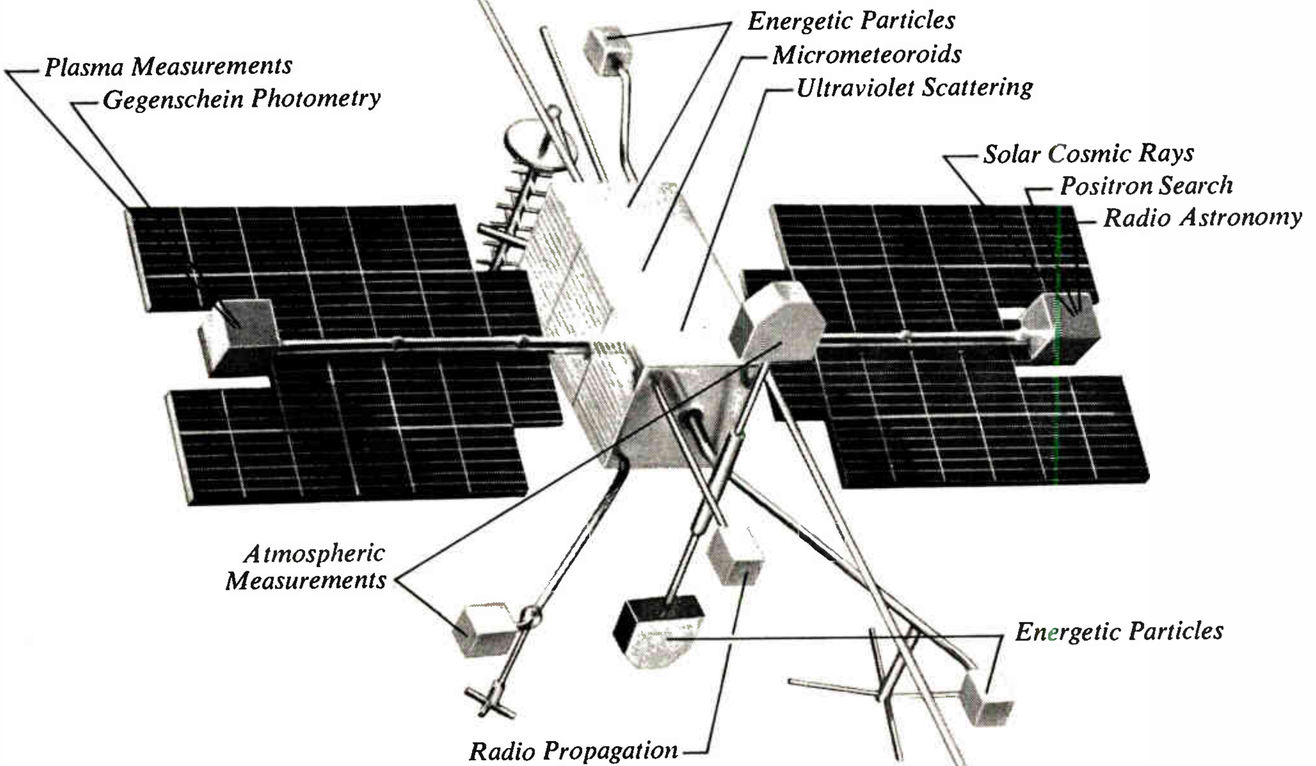
Magnetic Fields

OGO: its first mission. Sometime in 1963, OGO (NASA's Orbiting Geophysical Observatory) will be launched into an elliptical orbit around the earth. It will gather, process and transmit data on the physics of near-earth and cislunar space. Here are some of the studies OGO may undertake in this initial flight: *Energetic particles,* with nine separate experiments on the flux and characteristics of these particles (including cosmic ray and plasma studies). *Radio propagation and astronomy,* through measurements of ambient radio energy not accessible from earth. *Micrometeoroids,* to determine the mass distribution and direction of interplanetary dust in the vicinity of earth. *Magnetic fields,* their intensity, direction and variation near earth and in space. *Atmospheric measurements,* to study the pressure, temperature and composition of earth and cislunar space. *Ultraviolet scattering,* from hydrogen in space. *Gegenschein photometry,* to study sunlight scattered by interplanetary matter. OGO will be launched into a wide range of orbits and may carry as many as 50 different experiments on each of its missions. This Orbiting Geophysical Observatory will be one of the most versatile earth satellites man has ever built.



**Captions indicate possible arrangement of instrumentation clusters which OGO may carry.*

OGO: its challenge. Today OGO demands advanced techniques in spacecraft design and development to meet its need for flexibility. It is a challenging responsibility to STL engineers, scientists and supporting personnel, who design it, fabricate it, integrate it, and test it. This versatile spacecraft will be manufactured at STL's vast Space Technology Center where expanding space projects (OGO, Vela Hotel and other programs) create immediate openings for engineers and scientists in fields such as Aerodynamics; Spacecraft Heat Transfer; Analog and Digital Computers; Applied Mathematics; Electronic Ground Systems; Power Systems; Instrumentation Systems; Propellant Utilization; Propulsion Controls; System Analysis; Thermal Radiation; Trajectory Analysis. For Southern California or Cape Canaveral positions, write Dr. R. C. Potter, One Space Park, Department —I, Redondo Beach, California, or P. O. Box 4277, Patrick AFB, Florida. STL is an equal opportunity employer.

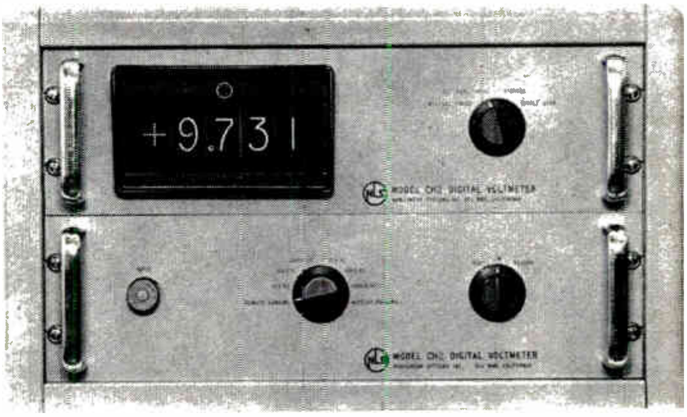
NEW!

4 MAJOR DIGITAL VOLTMETER ADVANCEMENTS FROM NLS

Now Measure Varying Voltages With Great Accuracy . . . Make 15,000 Highly Accurate DC Measurements/Sec . . . Measure VDC-Ratio-Ohms to 5 Digits . . . Buy a Quality DVM for $1,460

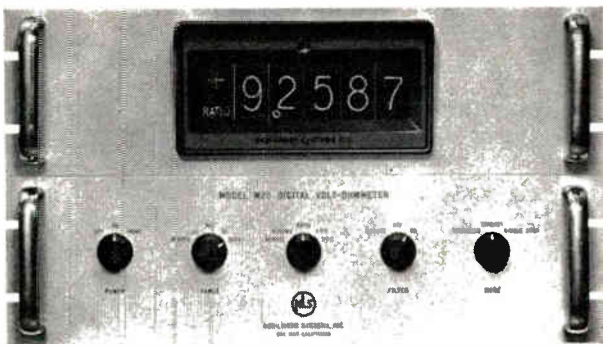


CH2 DIGITAL VOLTMETER

CH2 SAMPLE-AND-HOLD DIGITAL VOLTMETER — permits you to measure varying voltages at a definite point in time — with accuracy never before approached . . . starts to measure within 0.5 μsec., and is totally unaffected by voltage change during measurement . . . features accuracy of ±0.01% ±1 digit, constant input impedance of 10 megs, wide measuring range (up to 1,000 v.), and extremely high slewing rates up to 300,000 v./sec. (rate at which CH2 can "catch up to" and "follow" input changes). Price: $6,985.

MODEL 15 A/D CONVERTER

MODEL 15 A/D CONVERTER — 4-digit instrument bringing high accuracy to high-speed measuring and data logging . . . 15,000 measurements/sec . . . accuracy: ±0.01% ±1 digit from 0 to full scale from 0 to 40°C . . . any range from ±1 to ±100 v. full scale . . . true bipolar digital output, high output current, uses internal or external clock . . . constant input impedance. Price: $4,985.



M25 VOLT-RATIO-OHMMETER

M25 5-DIGIT VOLT-RATIO-OHMMETER — ultra-reliable instrument measuring DC volts, DC ratio and ohms with full 5-digit resolution of 0.001% and accuracy of ±0.01% of reading ± 1 digit over entire range of ±0.0001 to ±999.99 v. and .1 ohm to 1 meg . . . 10 to 1000 meg input z . . . twice speed of fastest stepping switch DVMs . . . advanced transistor circuitry with ultra-reliable mercury relays with 171 years life expectancy . . . input filter . . . remotely programmable . . . fully automatic . . . data logging output . . . AC or low-level DC with accessories. Price: $5,985

484A VOLTMETER-RATIOMETER

484A DIGITAL VOLTMETER-RATIOMETER — most versatile and highest quality instrument at low cost . . . measures ±0.001 to ±999.9 VDC and DC ratio up to ±99.99% . . . ±0.01% accuracy . . . 10 meg input . . . auto range and polarity . . . input filter . . . built-in auto print control . . . only a few dollars more than cheapest DVMs without such quality features as plug-in stepping switches that can be replaced in seconds for troubleshooting, snap-out readout, wire-wound resistors, epoxy fiberglass circuit boards . . . measures AC or low-level DC with accessories. Price: $1,460. **784 DIGITAL OHMMETER** — low-cost companion to 484A with same high quality features: $1,460.

LOOK TO NLS FOR DIGITAL VOLTMETERS — These instruments represent additional measuring achievements from the company that offers you the world's most complete line of digital voltmeters and associated instruments — most complete by purpose and by price. Prices are F.O.B. destination in U.S.A.

Exploring the possibilities in Coherent Light

At Bell Laboratories, Donald F. Nelson studies a beam of coherent red light produced by a continuously operating ruby optical maser. The heart of the device is a uniquely shaped ruby crystal immersed in liquid nitrogen in the tubular glass dewar extending from upper left to center. Light from the mercury arc lamp (lower center) is reflected by round mirror at left to mirror at right and then is focused on the ruby crystal to produce maser action. Coherent light emerging from end of dewar is picked up by a detector.

Is it feasible to take advantage of the enormous bandwidth available at optical frequencies? Could coherent light, for example, be sent through protecting pipes to provide high-capacity communication channels between cities?

To study such possibilities it is, first of all, necessary to have a source of continuous coherent radiation at optical frequencies. Such a source was first produced when Bell Laboratories scientists developed the gaseous optical maser.

Recently, our scientists demonstrated the generation of continuous coherent light by solid materials. Using a crystal of neodymium-doped calcium tungstate, a material developed at Bell Laboratories, continuous optical maser action was obtained in the near infrared. It has also been attained with visible light, using a new optical "pumping" arrangement to excite a ruby crystal. (See illustration above.)

Multichannel light highways for communications are still far from realization. But with continuous sources of coherent light available, it becomes possible to explore the problems of modulating, transmitting, detecting, amplifying and, in general, controlling light for possible communications applications.

BELL TELEPHONE LABORATORIES

World center of communications research and development

From G-V® the world's most experienced time delay engineers!

INSTANT RESET THERMAL TIMING ELEMENT, TYPE DM

- Used in industrial and communications equipment
- Instant reset during or after delay
- Delay intervals from 2½ seconds to 6 minutes
- Heater voltages from 6.3 to 230 volts
- Full temperature compensation

RED LINE THERMAL TIMING RELAY

- The low cost timing relay
- Rugged, steel sheathed heater
- Shatter-proof — no glass
- Dust tight metal enclosure
- Tamper proof
- Factory preset
- Octal size
- Available from stock

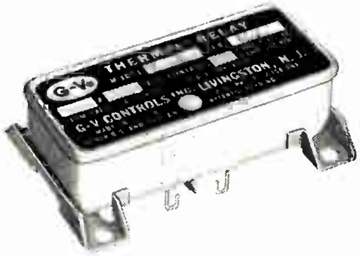
Stock Time Delays: 2, 5, 10, 20, 30, 45, 60, 90, 120 and 180 seconds

Stock Heater Voltages: 6.3, 26.5, 115 and 230 volts

VOLTAGE & CURRENT SENSING RELAYS

- For overload protection, voltage regulation, overvoltage cut off, under voltage alarm, low frequency cut off, battery charge control
- Available in R, T, and H Series, Miniature Size — Flanged or Plug-in
- Heater voltages from 2 to 230 volts
- Heater currents from .015 to 5 amps
- Heater resistances from 1 to 12,000 ohms

PT THERMAL RELAY



- The most precise, sturdiest thermal relay ever built
- Operates up to 2,000 cps, 20 g vibration and 50 g, 11 ms shock
- Time delay: 3 to 120 seconds. Tolerance ±5%.
- Heater voltages: 6.3 to 115 v. for delays up to 12 sec; 6.3 to 230 v. for longer delays.

ADJUSTABLE TRANSISTORIZED TIME DELAYS

- Time Delays—1 millisecond to 10 minutes
- Superior recycling characteristics both during and after timing cycles
- Protected against premature operation due to transient voltage surges
- Protected against lengthening or shortening delay due to change in voltage during timing
- Protected against damage through applying reverse polarity

H SERIES TIME DELAY RELAYS

- Hot wire heaters
- Short delays — rapid recovery
- Hermetically sealed, still adjustable
- Meet military requirements
- Miniature Size, Flanged or Plug-in

For time delays of 1/10 to 5 seconds.

Heater voltages up to 32 volts AC or DC.

ELECTRICAL THERMOSTATS

- Hermetically sealed, still adjustable
- Fast response to temperature change
- Bracket, flange or pipe plug mounting
- Vibration up to 2,000 cycles per second
- Accurate repeatability

Operating temperatures from —65° to +300°F.

Contact ratings to 1,000 watts.

R SERIES TIME DELAY RELAYS

- Metal sheathed heaters
- Hermetically sealed, still adjustable
- Meet military requirements
- Miniature Flanged, Miniature Plug-in or Octal Size

For time delays of 12 to 240 seconds.

Heater voltages up to 230 volts AC or DC.

T SERIES TIME DELAY RELAYS

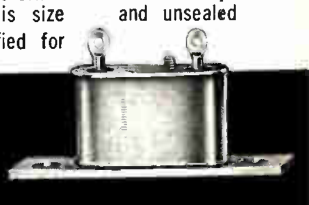
- Ribbon heaters
- Medium delays–faster recovery
- Hermetically sealed, still adjustable
- Meet military requirements
- Miniature Flanged, Miniature Plug-in or Octal Size

For time delays of 3 to 12 seconds.

Heater voltages up to 160 volts AC or DC.

VE SERIES MINIATURE ELECTRICAL THERMOSTATS

- Temperature operated switches in crystal can size
- Twice the contact motion and twice the contact moving force ordinarily found in thermostats of this size
- Fully qualified for military applications under vibration up to 2,000 cps, yet economical enough for commercial use
- Available factory-set and hermetically sealed or adjustable and unsealed



For complete information, write today or call (Area Code 201) 992-6200, Mr. George Compton.

WE SHARE YOUR PRIDE

on this, the 50th anniversary of the Institute of Radio Engineers, because one of the original founders of the I.R.E. also founded our company, the HOGAN FAXIMILE CORPORATION.

The man who helped found us both: the late Dr. John V. L. Hogan, pioneer in radio, television, and facsimile development.

We here at Hogan Faximile try to continue Dr. Hogan's lifelong tradition of attacking new frontiers in the communication and allied fields. And we've been fortunate enough to have made some valuable gains. For instance, through engineering and chemical R & D teamwork, Hogan Faximile has developed and produced...

...*High-speed plotters and printer plotters* for Polaris, B-70, Nike Zeus, and other programs. These plotters are used in data logging, countdown recording, flight test data reduction, and other applications.

...*Event-analyzing recorders,* which can also provide instantaneous spectrum analysis.

...*A high-speed data retrieval system* to print out copy from microfilm or hard copy by remote.

...*A microdensitometer* to measure both the line and background density of microfilm, so as to determine proper settings for reproducing microfilm of a predetermined quality.

...*Fully transistorized commercial facsimile equipment* to operate at speeds of a page in six minutes, three minutes, or one minute. This equipment contains such advanced features as automatic background control, automatic stack feed, and automatic copy cut-off.

...*Electrolytic recording paper* capable of high marking speeds and with desired characteristics for special applications.

Hogan Faximile know-how in the graphic communications and allied fields can assist you in obtaining your project goals.

HOGAN FAXIMILE CORPORATION

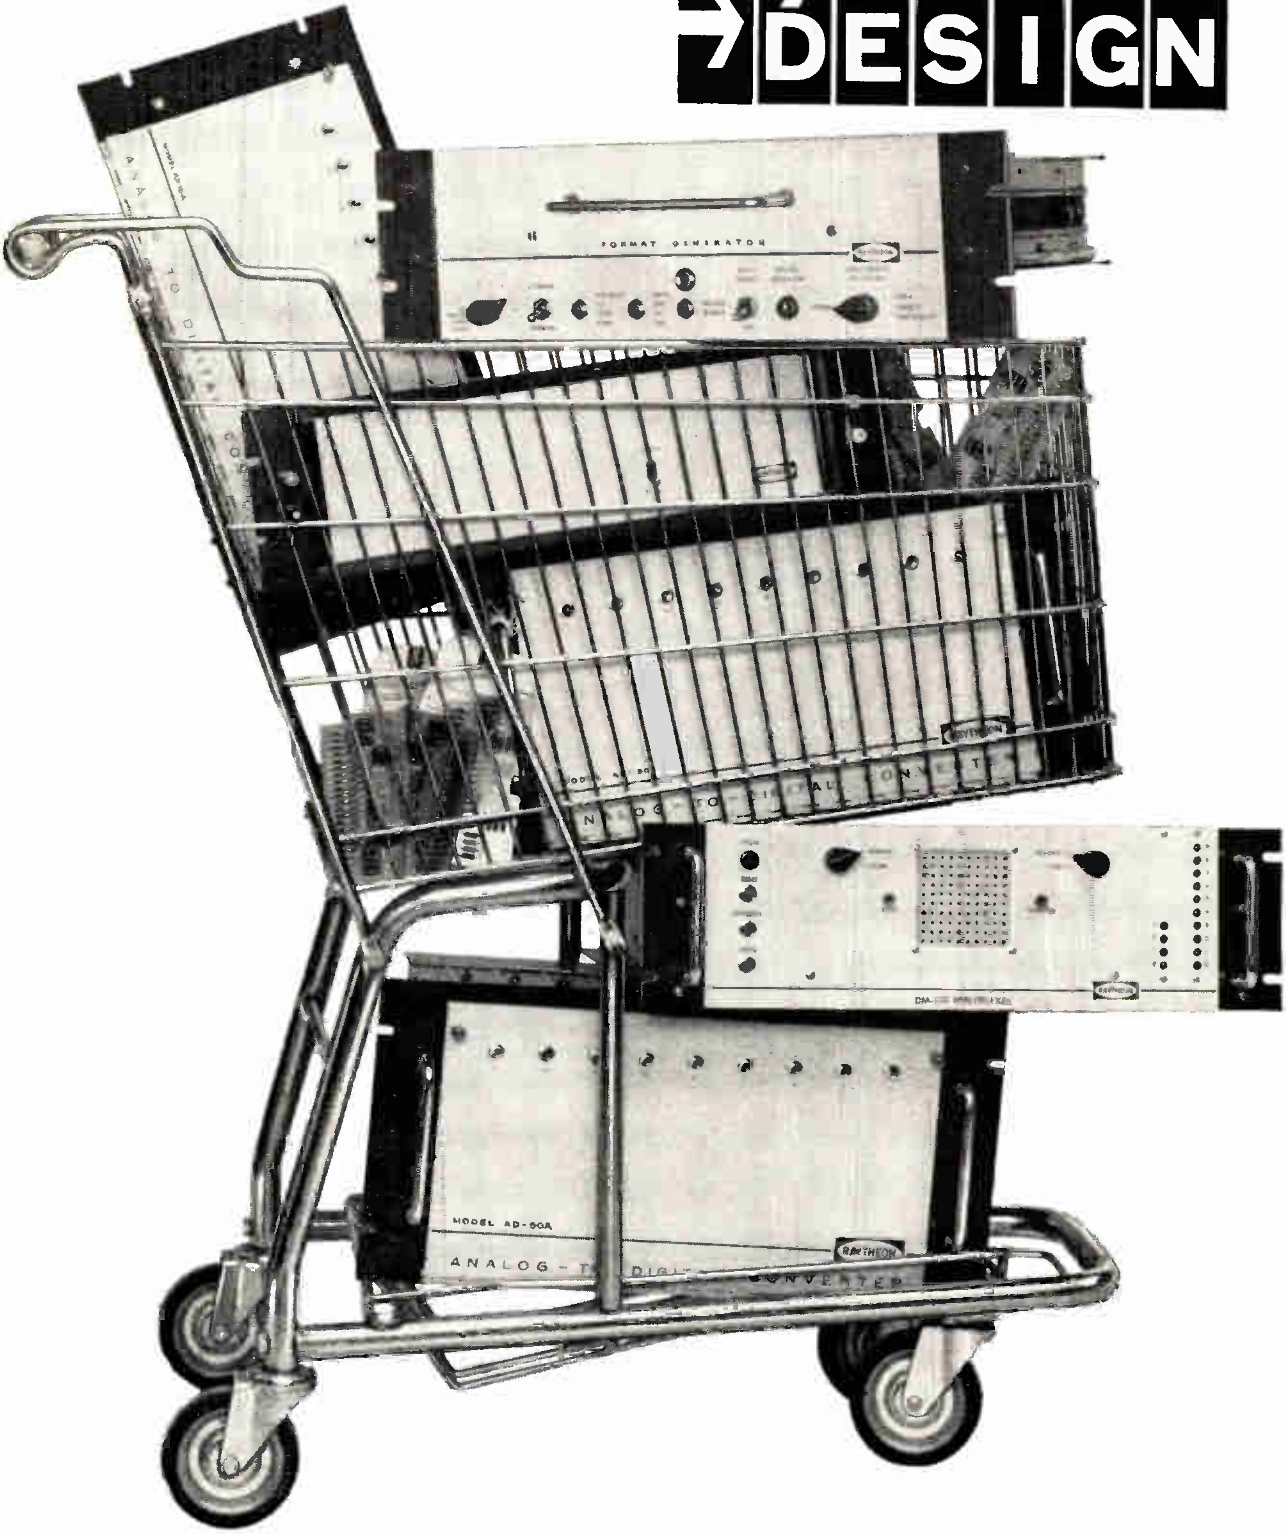
Off the Shelf!

Raytheon Data-Design's High Speed Digital Handling Units

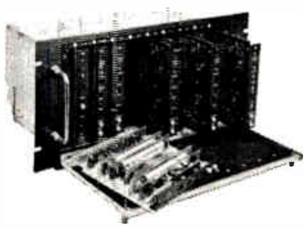
DATA-DESIGN



Complete Line . . .

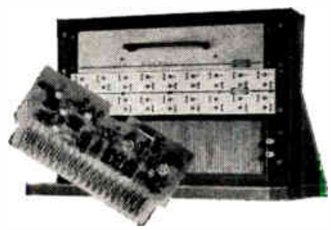
The Raytheon DATA-DESIGN units described below are unmatched in the digital field today for speed, accuracy and expandability. Together they form the fastest, most expandable data acquisition and conversion systems ever built. Each of these units is now available off-the-shelf from Raytheon, for system integration by the user.

Also available from Raytheon's unique DATA-DESIGN Service is the design and manufacture of complete digital systems or units based on your individual requirements and specifications.



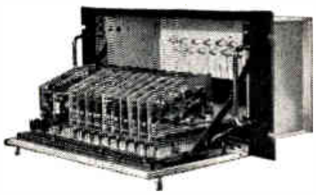
AD-50A Ultra-High Speed
ANALOG-DIGITAL CONVERTER

Up to 5 million samples/second. Up to 8-bit accuracy output, with lower bit outputs available at reduced cost. Digitizes pulses less than 0.3 microseconds wide. Direct, useable readout every 0.2 microseconds. 25 nanosecond aperture time. Every output valid and useable immediately. No need for sample and hold circuitry in most applications.



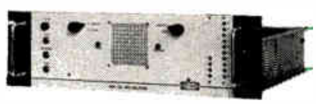
High Speed
MEGACYCLE BUILDING BLOCKS

Adaptive circuitry adjusts power requirements to load for minimum power drain. In quiescent state, draw 1/7th the power of conventional blocks. Temp. Specs. –30° to –65°C. "Worst Case Analysis" criteria used in all block designs. Interchangeable wiring panels mean only one step from logical design to finished equipment.



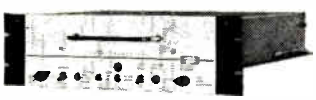
AD-10A High Speed
ANALOG-DIGITAL CONVERTER

Up to 500,000 complete 10-bit conversions/second. Serial readout at 5-mc bit rate; parallel readout at 500-kc word rate. Plug-in module construction. Synchronous or asynchronous operation.



DM-120 High Speed
MULTIPLEXER

Up to 1 million analog switchings/second. Expandable from 2 to 24 channels. As many as 576 channels obtained by stacking up to 24 Raytheon DM-120's. Compatible with both Raytheon Converters and with Raytheon Power Supply Units. For Multiplexer-Converter System, one Raytheon DPS-1A will power both units.



FORMAT GENERATOR

Arranges and prepares binary data from the conversion equipment in proper format for suitable entry into a computer or a tape storage unit. Also provides record identification information and parity check pulses on each character to be entered. Available in formats compatible with most major computers.

(Continued on page 228A)

For the vital telemetry link of the Agena Launch system, Lockheed chose HELIAX. The requirements of this launch complex link, typical of careful missile range instrumentation, illustrate the advantages of HELIAX.

No RF Noise: The unique Andrew connector design captivates inner conductor to outer conductor, eliminating RF noise from sliding connector contacts.

No RF Leakage: The continuous copper outer conductor protects the circuit from other RF signals.

Low Loss, Low VSWR: Insures maximum circuit reliability, minimum signal distortion.

Flexible, Rugged: The corrugated outer conductor of HELIAX makes it the only flexible air dielectric cable. This corrugated outer conductor withstands high crushing forces and heavy vibration.

Easy to Install: Andrew connectors are easily attached in the field, even by inexperienced personnel. HELIAX flexibility makes it much easier to pull into place on the tower and through ducts.

No Corrosion Problem: HELIAX, made of copper, is less affected by corrosive fumes and fluids present in launch areas.

These advantages make HELIAX the preferred coaxial cable for all RF transmission.

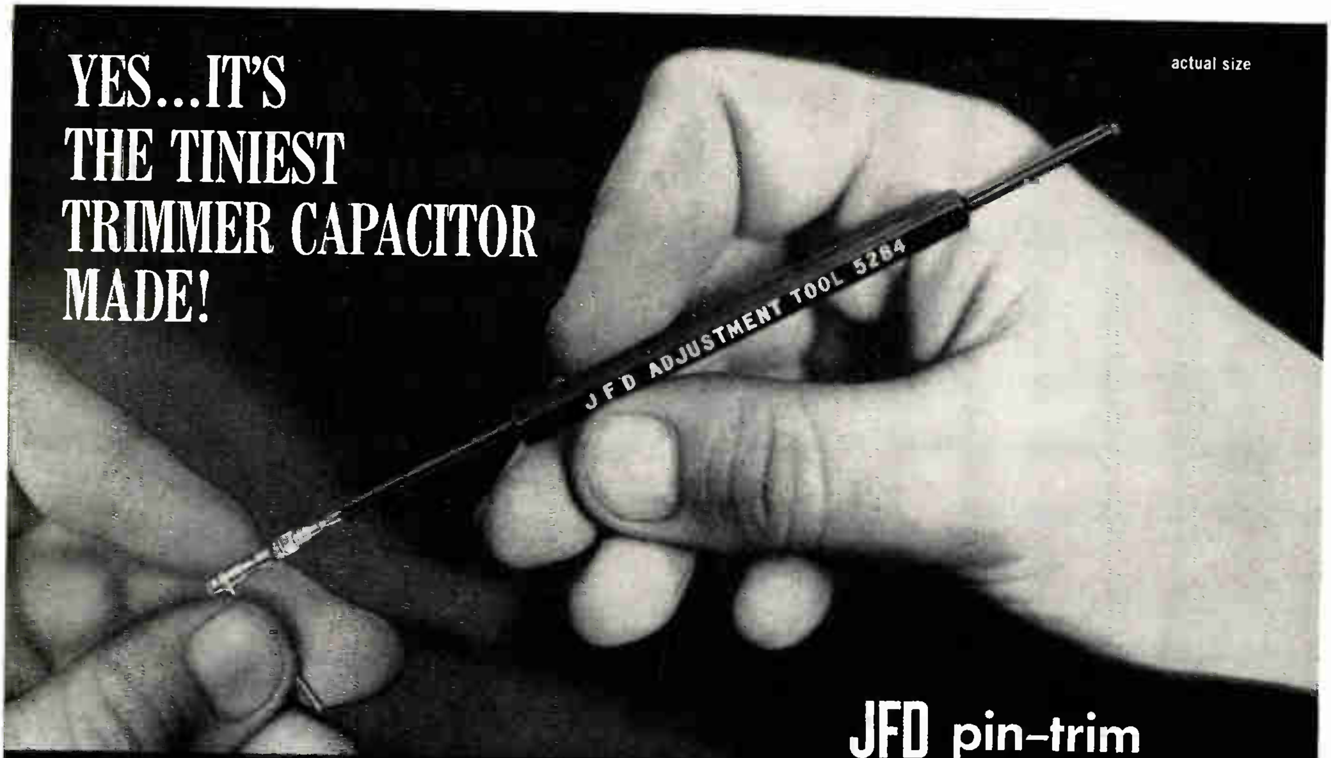
YES...IT'S THE TINIEST TRIMMER CAPACITOR MADE!



JFD pin-trim

If you are designing for missile environments or applications requiring more capacity in less space, look in to the Pin-Trim. It provides a practicable solution to the challenge of end-product miniaturization with high operational stability.

The new Pin-Trim delivers: (1) more capacitance per cubic centimeter than any other conventional piston trimmer; (2) 75 per cent less weight and 50 per cent less volume than JFD's own miniature trimmers; (3) greater sensitivity; (4) finer adjustment.

If you are looking for maximum compactness between stacked circuit boards, or less stray capacitance in a given area, check the JFD Pin-Trim specifications for your subminiature trimmer applications.

For further data, call your local JFD Field office or your JFD franchised Industrial Distributor.

- Overall diameter: 1/8 inch. Overall length above panel: 3/8 inch to 1 inch.
- Double the sensitivity of JFD standard trimmers. Special adjust mechanism provides 102 turns per inch for extra fine adjustment.
- Increased maximum to minimum capacitance ratio per unit (minimum: 0.5 pf.).
- Operating temperature −55° to +125°C.
- Low temperature coefficient of capacitance.
- Anti-backlash design for precise tuning resolution.
- Low inductance for high frequency use.
- Ultra linear tuning assures accurate alignment—absolute repeatability. Standard slotted end for screwdriver adjustment.
- Rugged shock and vibration resistance.
- 500 V. DC working voltage.
- 10^6 megohms insulation resistance.
- Q factor of 500 (measured as per JFD #5178).
- 0.5 inch ounce tuning torque.
- Meet or exceed applicable performance requirements of MIL-C-14409A.

JFD Adjustment Tool No. 5284 (illustrated) available at 85¢.

25 years ago we ran this ad.

Technology has changed since then. But not Eimac's position as industry leader.

Today, as 25 years ago, Eimac leads the way in electron power tube technology. With its research, engineering and manufacturing capabilities, Eimac can always be counted on to meet tomorrow's tube needs today. Another reason to keep your eye on Eimac for advanced power grid tubes, high power klystrons, microwave devices, accessory products. Eitel-McCullough, Inc., San Carlos, California. Subsidiaries: Eitel-McCullough, S.A., Geneva, Switzerland; National Electronics, Geneva, Illinois.

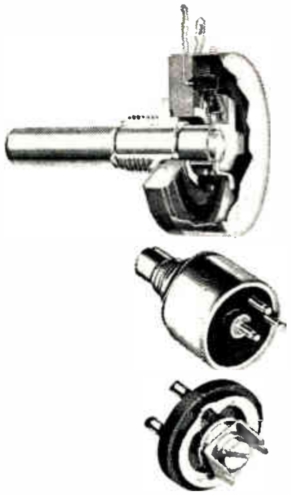
Centralab: a RELIABLE source for RELIABLE PRODUCTS

FOR MILITARY & COMMERCIAL APPLICATIONS

Most CENTRALAB products are available for immediate delivery in industrial quantities at factory prices, from CENTRALAB stocking distributors.



HOT MOLDED COMPOSITION VARIABLE RESISTORS

Meet MIL-R-94 environmental and test requirements. Provide smooth noise-free operation and high stability for which hot molded units are well known.

2 WATT @ 500V—Raised resistance track reduces surface contamination. Wide clearance between bushing and collector track for increased high voltage stability. Carbon collector and pick-off brushes.

1-3/32" diam., 5/8" deep. 500 ohms—5 meg, linear taper; 10K-2.5 meg log taper.

3/4 WATT @ 350V—Metal enclosed units, available with triple "O" ring shaft seal. 23/32" diam., 1/2" deep. Same resistances as 2 watt unit.

1/2 WATT @ 350V—Similar construction as 3/4 watt. 1/2" diam., 15/32" deep. 100 ohms—5 meg, lin. taper.

1/3 WATT at 350V TRIMMER—locking type variable fixed resistor. Extremely resistant to shock vibration, acceleration, can be encapsulated. 19/32" diam., 11/32" deep. 50 ohms—5 meg, linear taper.

Write for Group G bulletins.

VARIABLE RESISTORS

1/4W. Linear Motion, wirewound 100 to 20K ohms and composition 10K to 2.5 meg. .250" x .325" x 1.250".

1/10W. Microminiature, 0.286" diam: **Ultraminiature**, 0.502" diam; **Subminiature**, 5/8" diam; 500 ohms to 10 megs. **1/4W. and 1/2W. Subminiature**—For instruments and military. 43/64" diam. 500 ohms to 2.5 megs.

1/4W. Multiple Miniature—Up to 4 variable and 9 fixed resistors on a 3/4" x 2-1/4" steatite plate. 1000 ohms to 5 megs.

1/2W. Standard—For radio, TV. Single, Twin or dual-concentric. 15/16" diam. 250 ohms to 10 megs.

1-1/2W. Wirewound—for military and instruments. 11/16" diam., 5/16" deep. 4 ohms to 30K ohms.

2-5W. Wirewound—For instruments and TV. Single or dual-concentric. 1-5/32" diam. 1 ohm thru 100K ohms. Also available as 20 watt audio L and Bridged T Pad attenuators.

Write for Group B bulletins.

ELECTRONIC SWITCHES

Subminiature rotary—15/16" diam. for military and high reliability applications. Rating 0.5 amp. at 6VDC, 100 ma. at 110VAC. Laminated phenolic, steatite, single or multiple sections.

Miniature rotary—1-1/4" diam. for military and high reliability applications. Rated 2.0 amps. at 15VDC and 250 ma. at 110VAC. Available single or multiple ceramic, Mycalex and phenolic sections.

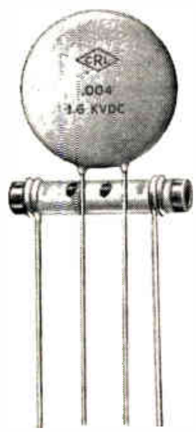
Standard rotary—1-5/16" diam. laminated phenolic or steatite insulation, single or multiple sections. Rating 2 amps. at 15-VDC. 150 ma. at 110VAC. (Resistive load.)

Heavy-duty power—For transmitter, industrial control, laboratory testing, military, commercial. 2-13/16" diam. 7-1/2 amp. rating at 110VAC. 25,000 cycles minimum.

Spring return—1-5/16" diam., coil or C-type springs, phenolic, steatite, single or multiple sections.

Specialized—Lever, slide, tone, tuner sections, others.

Write for Group P bulletins.



CERAMIC CAPACITORS

Ultraminiature—3 to 10VDC, 0.22—2.2 mfd.—for low power factor transistor applications.

Temperature compensating—Discs, tubulars, 150 v to 6,000 VDCW. 1 mmf.—0.1 mf. Capacitance +100 to —5250 ppm.

Bypass—Coupling—Discs, tubulars, 150 v to 6,000 VDCW, 1 mmf.—0.1 mf.

High Voltage—High Accuracy—High Voltage types, up to 30,000 VDCW, High Accuracy types, ± 1% tolerance, 500 VDCW, up to 2,500 mmf.

Trimmer—Tubular or flat. Meet MIL-C-81A specifications. 1 mmf. to 400 mmf. 500 VDCW.

Feed-thru—10—5000 mmf., 500—1,500 VDCW, bushing, shoulder, ring, eyelet, resistor-capacitor combinations.

Specialties—Stand-off, button-shape, potted, other capacitors.

Write for Group D bulletins.

PACKAGED CIRCUITS

Complete computer and Radio-TV circuits, amplifiers, oscillators, detector networks, resistor networks—including transistors, capacitors, resistors, wiring and inductance, manufactured to your specific performance limits.

PEC* circuits result in substantial savings in assembly costs. These high reliability packaged circuits can be supplied in a wide variety of terminals for printed circuit board applications.

1/2W. resistors meet applicable MIL-R-11 specifications, 50 ohms to 50 megs. Capacitors up to .01 mmf.

Write for Group Y bulletins.

*Trade Mark

ENGINEERED CERAMICS

High alumina—85%, 95%, 99%—for high frequency, high temperature applications close tolerance (±.00025") designs. L6A Jan-I-10 grade.

Grade Jan-I-10-L5A steatite, Grade L2A Corderite, and Grade L2A Electrical Porcelain. For applications where high dielectric and compressive strength, high dimensional stability, low loss and low power factor are required, there is a CENTRALAB ceramic material for the job.

CENTRALAB also specializes in metalizing of ceramics, for hermetic seals or mechanical attachment of other ceramic or metal parts.

Write for Group X bulletins.

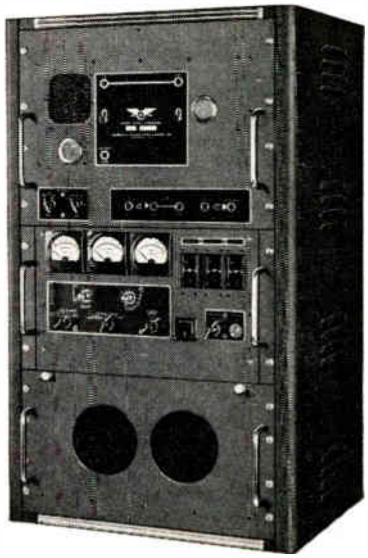
AEROCOM PRESENTS VHF AM TRANSMITTERS and RECEIVERS

AEROCOM communications equipment is designed with both performance and reliability in mind, and is produced by experienced personnel using high-quality materials. The following features are found in all three transmitters: Single crystal controlled frequency (plus an additional frequency ½% away from main frequency): stability ± .003% or ± .001% over temperature range of 0° C to + 55° C, any humidity up to 95%; audio system incorporates high level plate modulation, with compression; forced ventilation with air filter is employed. Welded steel cabinets.

Model 10V1-A—1000 Watts output—Successfully being used in Troposcat service for communications with aircraft beyond the optical horizon. Frequency range 118-153 mc. Can be completely remote controlled by using AEROCOM's remote control equipment. All tuning from front panel by means of dials. Power requirements 210-250 V 50/60 cycles, single phase.



Model VH-200—200 Watts output in range 118-132 mc. Excellent for both point-to-point and ground-to-air communications. Press-to-talk and audio input may be remoted using single pair of telephone lines. Power requirements 105-120V 50/60 cycles. Also available for use above 132 mc; output drops gradually to 150 watts at 165 mc.

Model VH-50—50 Watts output. Frequency range 118-153 mc. Outstanding low power transmitter for ground-to-air service. With remote control provisions; main power control with front panel switch. Convection cooling for press-to-talk service—otherwise forced air cooling. Power requirements 115/230 V 50/60 cycles.

Model 85 VHF Receiver. A high performance, low noise, single channel crystal controlled, single conversion VHF receiver. Stability normally ± .001% (with oven crystal ± .0005%) over temperature range 0° C to + 55° C. Sensitivity ½ microvolt or better for 1 watt output with 6 db signal to noise ratio. Standard selectivity bandwidth 30 kc; other widths available. Spurious response down 90 db. Frequency range 118-154 mc. Power requirements either 115 V or 230 V 50/60 cycles. Made for standard rack panel mounting.

As in all AEROCOM products, the quality and workmanship of this VHF equipment is of the highest. All components are conservatively rated. Replacements parts are always available for all AEROCOM equipment.

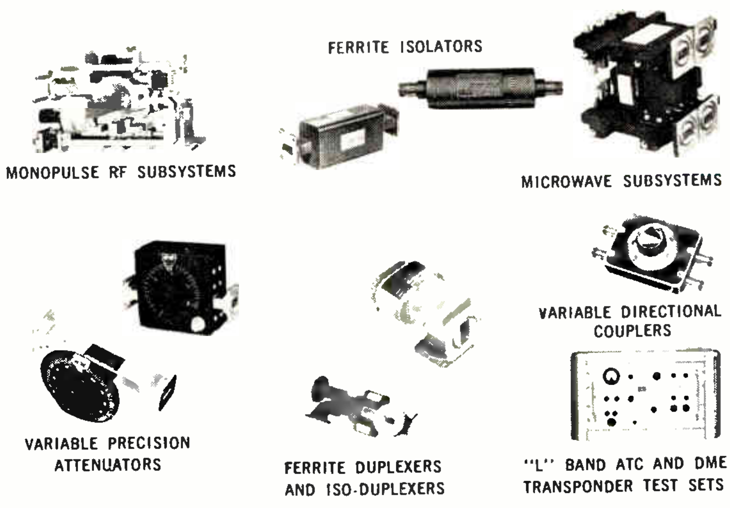
MICROWAVE EQUIPMENT

FORMERLY MICROWAVE Kearfott DIVISION

KEARFOTT MICROWAVE DIVISION BECOMES

MICRO-RADIONICS, INC.



Acquired by the aggressive, young management team who formerly guided Kearfott Microwave Division, M-R-I will extend its line of high quality products, long recognized as the finest in the microwave field. Now integrated into one complete facility, M-R-I can offer a quick reaction capability to fit any development, engineering, or production requirement.

M-R-I engineering experience, acquired over the many years under the Kearfott banner, is being supplemented by new state-of-the-art advancements, a value analysis team, and improved production methods. Representatives located in major cities, coast-to-coast, are ready to assist with your microwave design needs.

Creative engineers are invited to investigate the rewarding opportunities at M-R-I.

General Electric is currently supplying to customers doing advanced circuit work special tunnel diodes with switching speeds expressed in millipicoseconds (thousandths of a trillionth part of a second....) faster than can be measured by present day instruments. The best of these devices switches in the time it takes light to travel 6/1000 of an inch! We are also supplying the TD-100 series "off the shelf," with nominal switching speeds of 15 to 50 picoseconds. TD-101, 102, 103 and 104 have peak currents of 100, 50, 22 and 10 ma, with maximum capacitances of 6, 5, 4, and 2 pf respectively.

Recently introduced tunnel diode matched pairs (TDP-1 through 5) guarantee peak currents to be DC and AC matched within ± 1% over the entire temperature range from 15 to 55°C, making possible high performance logic circuits, memory circuits, and level detectors. Also available: low level switching tunnel diodes in both axial or TO-18 package, with peak forward current ratings from 1 to 22 ma; high speed microminiature switches from 1 to 10 ma; miniature microwave communication tunnel diodes from 1 to 10 ma; and computer back diodes with forward current ratings from 5 to 30 ma. Prices now range as low as $1.35 in 1000-up quantities.

Ask your G-E Semiconductor Products District Sales Manager about these and other production tunnel diodes *now available* to meet your particular requirements in applications such as switching circuits, oscillators, converters, and data and signal processing. For your free copy of "Applications for Tunnel Diodes" by John Phelps, G-E Manager-Application Engineering, write to Semiconductor Products Department, Section 23E126, General Electric Company, Electronics Park, Syracuse, New York. In Canada: Canadian General Electric, 189 Dufferin Street, Toronto, Ont. Export: International General Electric, 159 Madison Ave., N.Y. 16, N.Y.

GENERAL ELECTRIC

This is TELONIC Versatility...

A Sweep/Signal Generator for Audio to 3000 MC

As a major designer and manufacturer of RF instruments and components, Telonic once again leads the field with the introduction of the SM-2000 Sweep and CW Signal Generator. New from every standpoint, the SM-2000 provides unmatched versatility for laboratory or production operations. Now, with one instrument and several, interchangeable plug-in oscillators, an engineer can cover a frequency range from audio to 3000 mc.

Telonic has designed 19 different oscillator heads for specific and general purposes that enable the user to change range of the SM-2000 in a matter of seconds. For general applications, only two plug-in units are necessary to cover frequencies from .5 to 2000 mc. And, in addition, the operator may select four different functional modes with the SM-2000—swept RF, modulated swept RF, CW, and modulated CW. He can set attenuation from 0 to 60 db in 1 db steps with the two built-in attenuators. He also has provisions in the instrument for use of an external marker, or for adding up to eight fixed, plug-in markers if desired.

All these features are combined with the fine basic performance that has made the name Telonic synonymous with the best in RF instrumentation—low VSWR, high display linearity and excellent workmanship. If you would like more complete details on this new sweep generator please write for Technical Bulletin T-233.

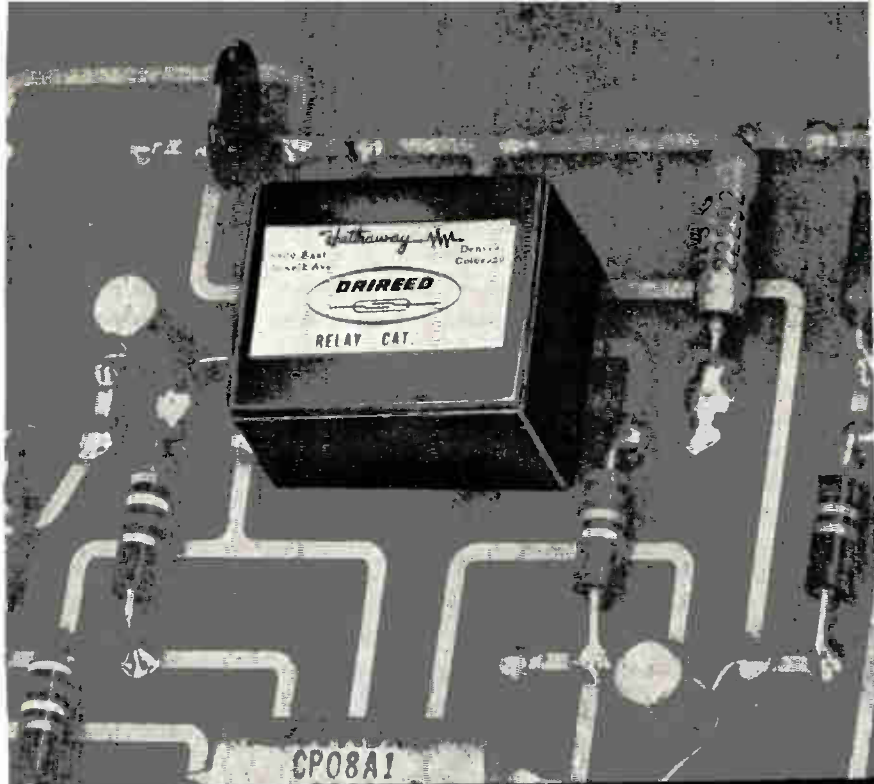
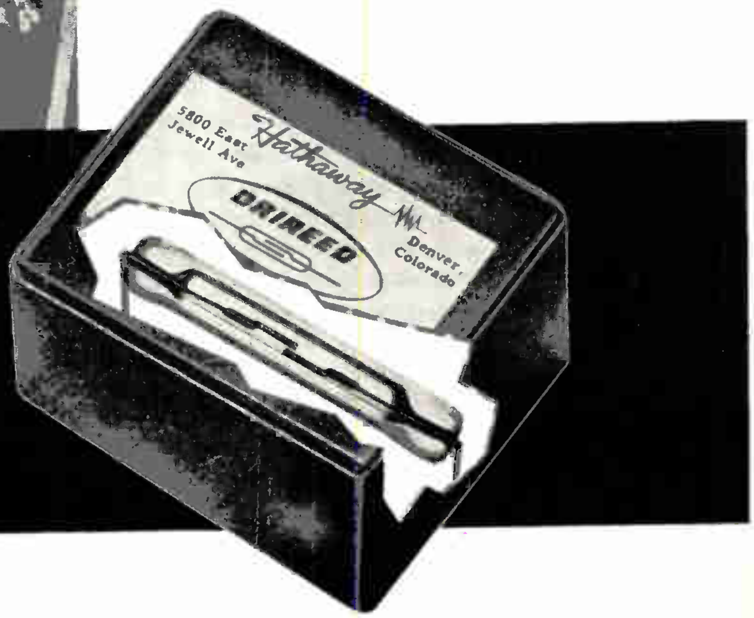
BEECH GROVE, INDIANA—PHONE STATE 7-7241



Hathaway

HATHAWAY DRIREED RELAYS SAVE UP TO 75% DESIGN SPACE

...and give the reliability
of solid state units
at a fraction of their cost



Heart of Hathaway Relays is the Drireed—industry's most nearly perfect switch.

- **Vibration:** 20 G's to 2,000 cps, energized or non-energized
- **Shock:** 50 G's
- **Operate time typical:** 800 microseconds, including bounce, for 28 vdc unit at nominal voltage
- **Closed contact resistance:** .05 ohms nominal
- **Natural contact frequency:** 2,700 to 3,200 cps
- **Contact rating:** 10,000,000 operations at 100 milliamperes, 115 V 60 cps resistive. 50,000,000 operations at 100 milliamperes, 28 vdc resistive. 1,000,000,000 operations at 2 milliamperes, 28 vdc

Miniaturization with solid state reliability and the advantages of low cost and drift free operation is accomplished in the Hathaway Drireed Relay. The Form A type pictured above is designed for either printed circuit or on the chassis mounting. An ideal application is scanning very low level signals at a rapid rate without the use of rotating parts or brushes.

Hathaway relays are ideally applicable to satellite components, ground support equipment and anti-submarine detection equipment. The same operational superiority is available to all applications requiring economy of weight and space, long life, fast, trouble-free action, resistance to shock and vibration, and immunity to the effects of acceleration.

Relays engineered and manufactured to your requirements are a Hathaway specialty... we will furnish a modular assembly of any number of contacts in a completed form.

What can these relays do for your design? For information, contact your Hathaway representative, call or write us at the address below.

RAYTHEON PHASED ARRAY ASSEMBLY includes Amplitron,* ferrite circulator and TWT in single package. Complete assemblies are precisely matched mechanically and electrically to provide identical performance throughout the array.

*Raytheon Trademark

Raytheon tubes bring new modular solution to phased array problems

TYPICAL OPERATING CHARACTERISTICS

	Model CLM Circulator*		QKW 1013 TWT	QKS 1012 Amplitron
Peak pwr.	15 kw	Pk. power out.	5 kw	100 kw
Average pwr.	800W	Av. power out.	400W	2.5 kw
Frequency (Mc)	1215-1400	Frequency (Mc)	1215-1400	1215-1400
Isolation	18 db min.	Gain	50 db	13 db
Insertion loss	0.4 db max.	Efficiency	20-25%	70%
VSWR	1.25	Pulse dur.	750μs	500μs

*3-port Wye-junction circulator with load.

New permanent magnet concept makes possible half wavelength mounting of transmitter tubes

Raytheon now has an advanced Amplitron, TWT and ferrite circulator for modular mounting in a permanent magnet lattice. The new assembly provides excellent efficiency, bandwidth and gain over a wide range of power output levels.

The TWT-circulator-Amplitron assemblies are expressly designed for minimum noise and uniformity of phase and gain characteristics from unit to unit. To provide greater operating flexibility, the TWT employs a modulating anode and isolated collector.

Raytheon can offer the new combination at low cost and in large quantities. Write today for complete technical details. Address Raytheon Company, Microwave and Power Tube Division, Waltham 54, Massachusetts.

MICROWAVE AND POWER TUBE DIVISION

why Ampex uses NIKON OPTICAL COMPARATORS

The new Ampex AR-300, developed principally for military and scientific applications, is the only recorder capable of covering a 4-megacycle bandwidth. It can capture and record phenomena beyond the range of any equipment in use today.

The most vital component in the AR-300 is its rotating recording head, designed to achieve the high, head-to-tape velocity required for wide band response, yet maintaining a relatively low, reel-to-reel speed.

Nothing in the manufacture of the AR-300 proved as critical as the production of this head. Most of its parts did not lend themselves to conventional inspection methods. While .0001″ tolerances had to be maintained, Ampex standards call for inspection equipment capable of at least 10 times the required accuracy.

This inspection problem was finally solved when the task was assigned to a Nikon 6 Optical Comparator. Not only did the Nikon Comparator provide the exact measurements required during 'in-process' inspection, but it also permitted consistent duplication of these measurements, time after time.

Today, the Nikon 6 has a permanent position on the AR-300 production team. Furthermore, there are now five additional Nikon comparators serving Ampex in other production projects, and in development—helping to maintain the high quality standards for which Ampex products are justly famous.

Why not investigate what a Nikon comparator can do for you? Write for complete, illustrated catalog to Dept. IRE-5.

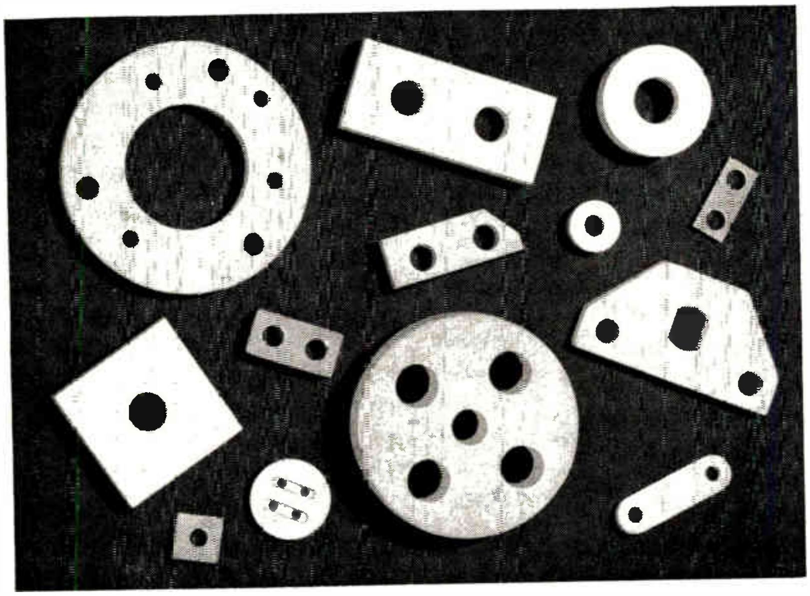
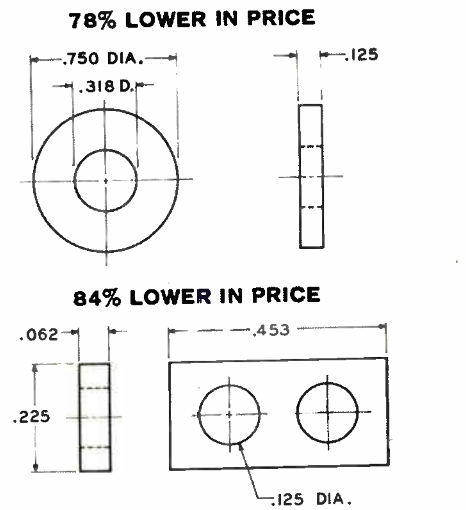
Ferride Coil Under Inspection Showing Size Relationship

New cost savings for users of dielectric materials





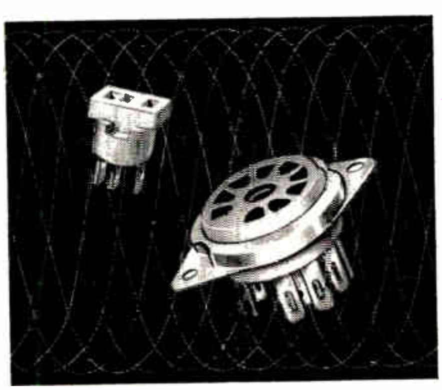
. . . a progress report on the MYCALEX METHOD from Jerome Taishoff, President, Mycalex Corporation of America

"We're proud to announce the MYCALEX METHOD: a unique molding and finishing technique that delivers higher-performance parts at lower cost. In line with our policy, we pass all savings on to our customers.

"The diagram above outlines typical savings –78% and 84%–both in addition to the temperature endurance, total dimensional stability, dielectric strength and low-loss SUPRAMICA® and MYCALEX® have delivered for years."

Your choice of SUPRAMICA 620 "BB", 560 and 555 ceramoplastics, as well as MYCALEX 410 glass-bonded mica.

So to ease your profit squeeze . . . get top-grade electronic-insulation materials for less than ever . . . look into the new MYCALEX METHOD. Send blueprints and drawings for specifics.



IN SUPPLY

Sockets of MYCALEX glass-bonded mica are yours in standard or custom-designed types. Also supplied in SUPRAMICA ceramoplastics on special order . . . sockets illustrate the complex configurations in which these versatile materials can be produced.

IN SERVICE

For 11 years, MYCALEX tube sockets in important AM, FM and low-level audio circuits have helped to make this custom-made Fisher TRI 6G the superb radio-phono-TV instrument it is.

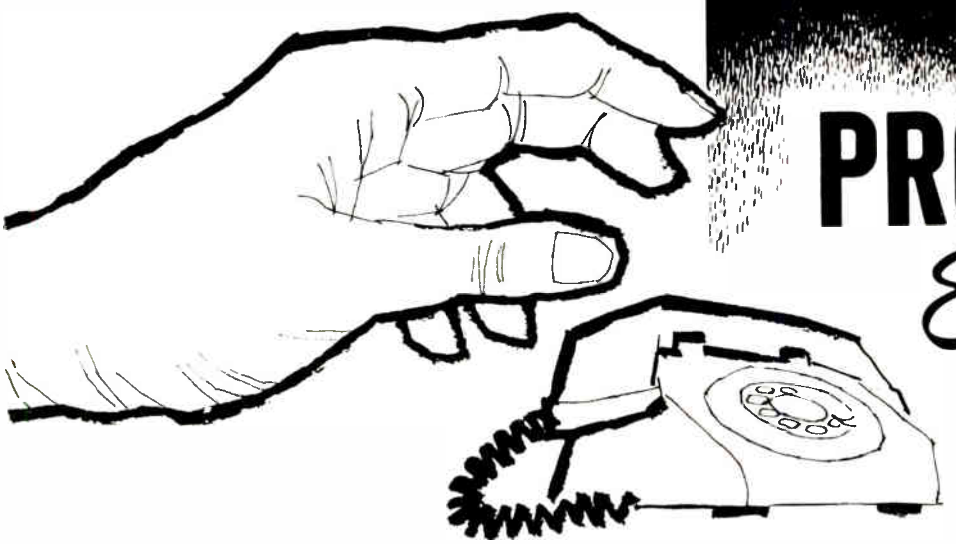
WHAT IS A DAY SAVED WORTH TO YOU?

components & cable ordered now reach you *tomorrow*

when you call



PROGRESS *Electronics*

AUTHORIZED DISTRIBUTOR:

AMPHENOL · BORG · ipc · DAGE · CANNON PLUGS · GREMAR · HUGHES · ITT · S · Fenwal Electronics · ZT

Now OEM projects need not be held up for lack of essential parts. Whatever you might need — connectors, plugs, thermistors, transistors, cables, switches and potentiometers — Progress Electronics can supply them to you *from stock*. No fuss, no worry, no costly waiting — phone in your order today, you'll get them tomorrow!

We carry the *Amphenol-Borg* line. *IPC, Dage* — we have them. *Cannon, Fenwal, Gremar, Hughes, ITT, Silicon, Zippertubing* — just about every famous name in the book. And we continue to add lines for an even more complete service. We've also added warehouse space — 6,000 square feet, this year, in New York alone. This enlarged stock of high-precision components and cable is all ready for sameday shipment to those who pick up the phone and call.

How good is our service? It's tops, and here's the proof: electronics engineers and companies keep coming back to us, and recommend us to others. (You'll recommend us, too!) So we're growing. This year, we've added 10 men to our New York staff. And up in Canada, we've opened a new office in Montreal, for faster service to our Canadian clients.

Our speed should suit you fine! Write us for catalogs, or better still, call us for a specific item you need in a hurry.

Immediate delivery at factory prices guaranteed:

Field Emission Corporation

CONHEX SUB-MINIATURE R. F. CONNECTORS

Designed and manufactured to meet the industry's demand for a better connector. Real gold-plated, not just flashed. Maximum impedance match, minimum VSWR. Available in Crimp-On or Clamp-On designs.

SCREW-ON
Clamp-On

SNAP-ON
Clamp-On, Crimp-On

PRESS-FIT® TEFLON TERMINALS

Sealectro and only Sealectro makes Press-Fit terminals. Ultra-quality provides optimum reliability and assembly ease. Available in all standard EIA colors.

SUBMINIATURE STANDOFFS
Teflon bushings in diameters from .148" to .218". Choice of lugs, including turrets.

SUBMINIATURE FEEDTHRUS
For connections through chassis or casing. Choice of lug designs including hollow-tube.

MINIATURE STAND-OFFS
For components and assemblies stressing higher voltages. Wide choice of lugs and turret designs.

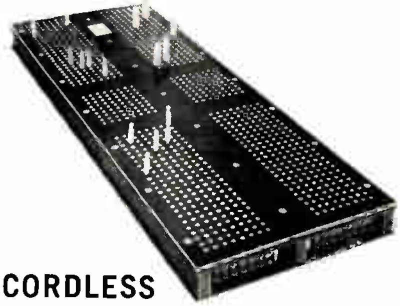
MINIATURE FEEDTHRUS
For handling voltages up to 4000 VDC. Wide choice of bushing diameters and lengths.

SEALECTRO COMPONENTS OFFER PROVEN RELIABILITY IN ALL INDUSTRIAL AND MILITARY APPLICATIONS

PRESS-FIT® TEST JACKS AND PLUGS

Male and female. Ideal for test instrument probes, jumper plugs and multiple pin plugs. Test jacks for printed circuitry.

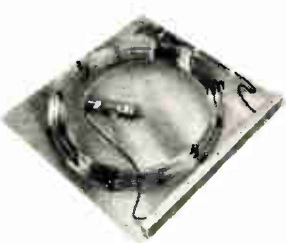
SEALECTOBOARD



CORDLESS PROGRAM BOARDS

The revolutionary program board. Simplifies multi-channel switching. Provides complete connections with insertion of single pin. No cord clutter. Accessories include component holders for inserting diodes, resistors, or other components at any circuit point. Available in any X- and Y- configuration. Standard Proto-Kits including board, shorting pins and component holders available from distributors.

DELTIME MAGNETOSTRICTIVE DELAY LINES



Longer delay times utilizing the magnetostrictive principle for maximum stability and mechanical ruggedness. Delay times up to 10 milliseconds at repetition rate of 655 KC with return-to-zero, or 5 millisecond delay at 1 MC with return-to-zero. Suitable for data storage. Completely humidity and magnetically shielded. Many standard fixed and variable models available.

(Continued from page 130A)

The appointments of **Gerald Smith** (SM'56) as Director of Development Engineering, and **Ronald G. Oschmann** (M'56) as Section Manager for Electronic Systems in the company's Development Engineering Systems Department have been announced by Daystrom, Incorporated, Military Electronics Division, Archbald, Pa.

G. Smith

R. G. Oschmann

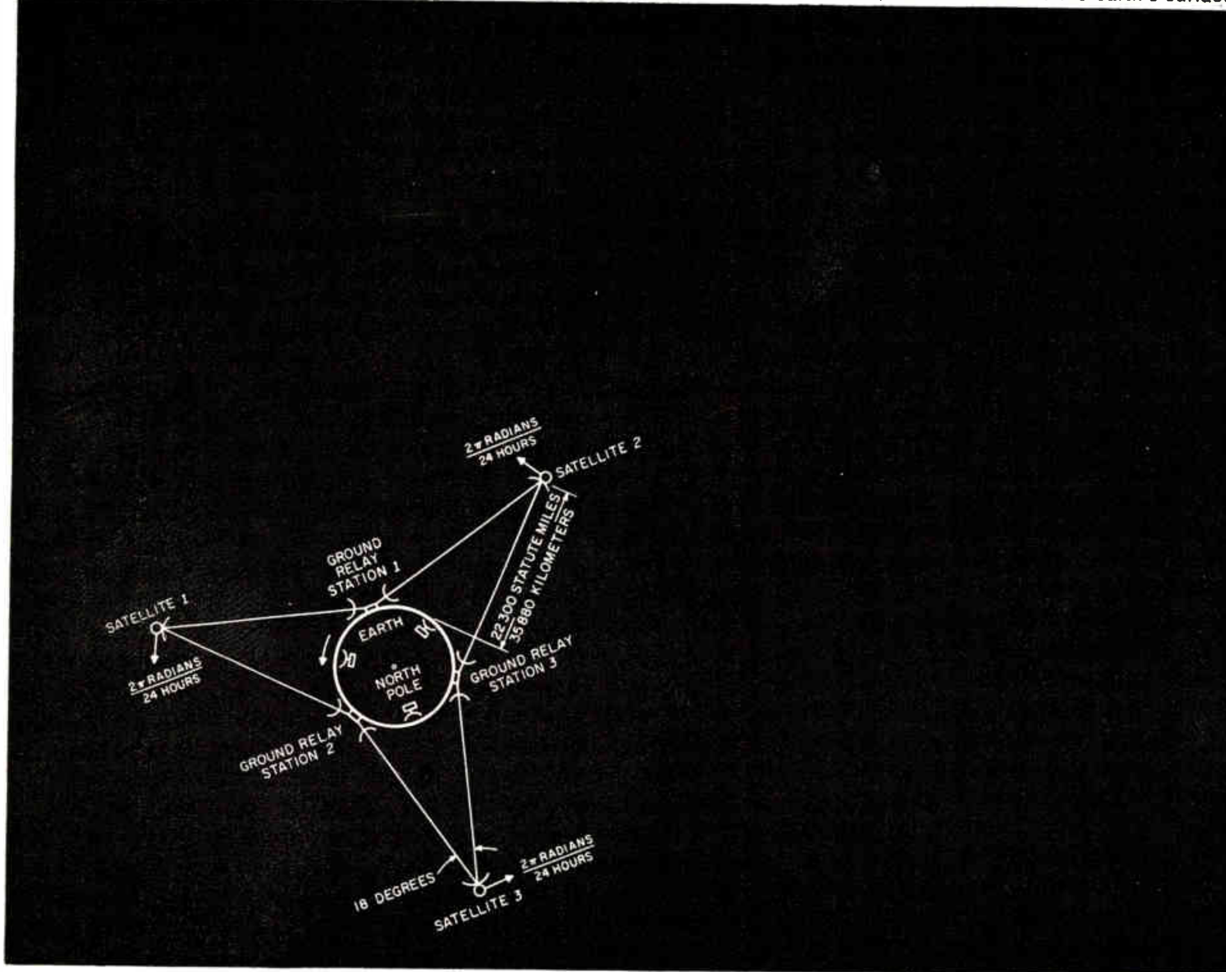
Mr. Smith joined Daystrom, Incorporated in 1952 as an electronic engineer in the Research and Development Department. His service also included the position of Senior Engineer, Development Engineer and Section Manager for Electronic Systems. Prior to joining Daystrom, Incorporated, he was associated with Marine Electric Co. and National Union Tube Co.

Mr. Smith attended City College of New York and graduated magna cum laude with a B.S. degree in electrical engineering. He received his Master's degree in electrical engineering from the Stevens Institute of Technology. He is a member of Tau Beta Pi and Eta Kappa Nu.

Mr. Oschmann joined Daystrom, Incorporated in 1952 as an electronic engineer. He accepted a position in 1954 with the Curtiss-Wright Corp., returning to Daystrom in 1955. Since then he has held a variety of engineering positions with the company.

He is a graduate of the Pennsylvania State University with a B.S. degree in electrical engineering.

The geometry of a satellite communication system in which each satellite maintains a fixed position relative to the earth's surface.*



THE "WHY" OF SATELLITE COMMUNICATION

In the past 60 years the world's population has nearly doubled. Demographers expect it to re-double in the next 20 years. This "population explosion" has triggered a "communication explosion" of such vast proportions that even planned cable and microwave capacity soon will be outstripped. Today, it is obvious that new communication channels must be opened./At ITT we have invested many thousands of man-hours and dollars in our conviction that a radio-relay satellite system is a feasible and economic way to expand world telephone capacity and provide a reliable data transmission and television link as well. In fact, at ITTFL we already have a satellite ground station terminal built and ready to function. We have become deeply involved in other pioneer space communication projects too, such as the RELAY and COURIER programs. Backed by the skills of scientists and engineers in 24 countries, ITT associates and divisions are actively engaged in creating communications systems and hardware to serve future generations./International Telephone and Telegraph Corporation, ITT Building, 320 Park Avenue, New York 22, N. Y.

NEW KEITHLEY MILLIOHMMETER

fast, accurate, direct-reading

—permits low resistance measurements from 10 micro-ohms!

Accurate low resistance measurements can now be read directly with a maximum sample dissipation of only 10 microwatts. Exceptionally stable, the Keithley Model 503 requires no balancing—as encountered in Kelvin Bridges—and is designed for rapid measurements. The line-operated 503 supplies an output voltage usable either for chart recording or control functions.

The measurement technique involves an ammeter-voltmeter method using an ac test current. Four terminals are employed, two furnishing a known test current to the sample and two measuring the resultant voltage drop. The voltage is measured by a synchronous ac voltmeter sensitive only to the test current frequency.

The Model 503 lends itself to a wide variety of applications by combining laboratory precision with production line ruggedness. Typical uses include measurements of internal resistance of dry cells, resistivity profiles of thermoelectric materials and low value resistors; measurement of temperatures with thermistors and resistance changes in conductors due to temperature and humidity effects; as well as dry-circuit testing of relay contacts, semi-conductor resistivity measurements, contact resistance of vibrators, relays and choppers, and safe measurement of fuses and squibs.

RANGE: 0.001 to 1000 ohms full scale. The test current, the input voltage drop, and sample power dissipation for full scale readings are given below.

Range Ohms	Applied Current ma, rms	Voltage Drop µv, rms	Maximum Power in Sample Microwatts
0.001	100	100	10
0 003	33	100	3 3
0.010	10	100	1 0
0 030	3.3	100	0 33
0 10	1.0	100	0 10
0 30	0 33	100	0 033
1 0	3 0	3000	9

1000	0 003	3000	0 009

ACCURACY: 1% of full scale on all ranges for meter indications. 0.5% of full scale on all ranges at output voltage terminals.

SPEED OF RESPONSE: 0.25 second to 90% full scale on all ranges.

STABILITY: No visible drift after 15 minute warmup.

REPEATABILITY: Within 0.25% of full scale range setting.

OUTPUT CHARACTERISTICS: +100 millivolts dc at full scale, output impedance 800 ohms.

CALIBRATION: Provision for verification and adjustment on front panel.

POWER REQUIREMENT: 105-125 volts, 50-1000 cps, 30 watts. May be wired for 210-250 volt line.

TWO-IN-ONE CONSTRUCTION — A new package design permits choice of bench or rack mounting by means of a conversion kit supplied with each unit at no extra cost.

PRICE:
Model 503 . . . . **$675.00**
Model 503C (Contact Meter Model) **825.00**

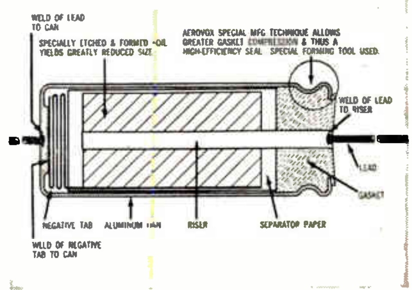
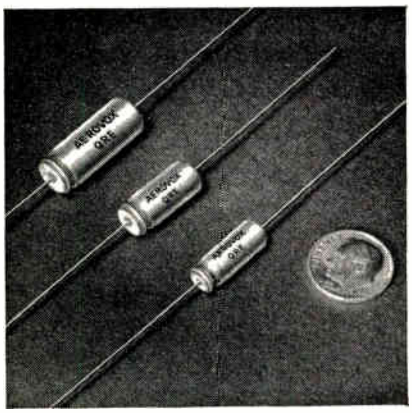
PRODUCT NEWS FROM AEROVOX

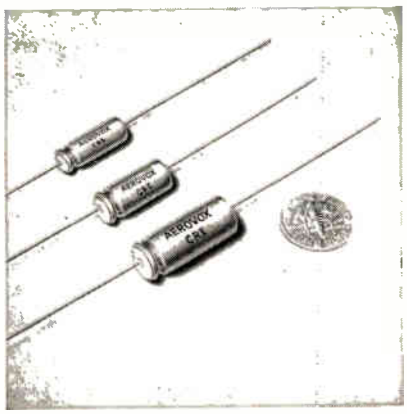
New Long-Life 85°C Electrolytic Capacitors in Ultra-Miniature Sizes a Product of New Design and Manufacturing Techniques

Aluminum-cased units permit circuit applications previously impossible

A new series of ultra-miniature tubular electrolytic capacitors is now available from Aerovox. A product of the continuing Aerovox program of advanced research and development, the greatly reduced sizes of these high-quality units have been made possible by the use of a revolutionary etching and formation process. All critical terminations are welded, thus eliminating the danger of open circuits with the passage of time in service. A unique, high-efficiency seal has been produced by specially designed forming tools which were developed by Aerovox after months of intensive engineering effort to improve on conventional sealing methods.







TYPE QRE SPECIFICATIONS

Operating Temperature: −40°C to +85°C
Capacitance Tolerance: standard capacitance is −10% to +100% of rated capacitance.

DC Leakage Current:

Volts DC	Current – Microamperes
3 to 6	1.0
10 to 15	2.5
25 to 50	5.0
100 to 150	15.0

Surge Voltage:

Rated DC Working Voltage	Surge Voltage (Max.)
3	5
5	8
6	10
10	14
12	15
15	20
25	45
50	70
100	125
150	175

TYPE CRE SPECIFICATIONS

Operating Temperature: −30°C to +85°C
Capacitance Tolerance: standard capacitance is −10% to +100% of rated capacitance.

DC Leakage Current:

Volts DC	Current–Microamperes
3 to 6	1.0
10 to 15	2.5
25 to 50	5.0
100 to 150	15.0

Surge Voltage:

Rated DC Working Voltage	Surge Voltage (Max.)
3	4
6	8
12	15
15	18
25	40
50	65
100	125
150	175

High-Reliability Type QRE
Due to a totally new design concept, Aerovox has achieved a new industry high for capacitors of this type. Type QRE capacitors offer a useful life expectancy of more than 10 years when operated within ratings.
The combination of long life, ultra-miniature size, and outstanding temperature characteristics now makes available an aluminum electrolytic capacitor which can be used in many circuit applications heretofore not considered possible with capacitors of this type. Design engineers in the computer and communications fields in particular can benefit from the extraordinary advantages offered by Type QRE. These units are manufactured in specially constructed super-clean "White Room" production areas where only the most experienced operators are employed. An exhaustive 100% testing program assures you high-reliability performance.

Commercial Type CRE
Type CRE ultra-miniature units are ideally suited for use in bypass, filter, and coupling applications in low voltage, compact, miniaturized equipments. This is especially true where assembly space is at a premium, such as personal radios, hearing aids, microphones, and wire receivers.

Availability
Aerovox Type QRE and CRE Ultra-Miniature 85°C Aluminum Cased Electrolytic Tubular Capacitors are available in prototype quantities for immediate delivery from the factory. See your Aerovox Representative for delivery information on production quantities.

Complete Technical Data
Call your nearest Aerovox Field Representative or write today for a free copy of Bulletin 201B7 (Type QRE) and 201B6 (Type CRE).

exploring moon craters or detecting ocean-bottom seismic whispers!

On the 50th anniversary of the IRE, electronics boundaries extend from outer space to ocean depths. Scientists and engineers exploring these once inaccessible realms require an ever-increasing flow of new materials, products and services. ■ To aid these space-age pioneers, Texas Instruments has developed telemetry and command-control equipment for space and lunar vehicles, nuclear fuel cores for naval reactors, and undersea seismic stations that will function unattended at 1600 fathoms. These are typical accomplishments of TI's unique combination of technologies—ranging from basic materials; through the manufacture of electronic components, assemblies and systems; to the world-wide application of geoscience. ■ Wherever you work in electronics, you can rely on TI products and services. Write today for brochure describing how TI capabilities can help you.
