SECOND EDITION
EIGHTH PRINTING—1979

International Standard Book Number: 0-672-20675-7
Library of Congress Catalog Card Number: 77-82885

Printed in the United States of America.

Preface

In compiling the second edition of the *Audio Cyclopedia*, the author is reminded of the statement of one critic, that it was too great an undertaking for one man. However, no group has come forward to compile a revision. The first edition was an attempt to compile an accumulation of more than 30 years of technical data into one book, which the author had entitled "The Audio Engineer's Handbook." The publisher suggested that it had exceeded the handbook category, and recommended the present title, *Audio Cyclopedia.*

Since the first edition, the growth in audio engineering has made the revision a mountainous undertaking, requiring almost two years of unrelenting endeavor. New standards have been established, and the development of solid-state and integrated-circuit devices has opened a wide vista not conceived ten years ago.

The pattern of this edition closely follows the scheme of the first edition. However, the book has been shortened to 25 sections. Section 26 of the first edition (Stereophonic Recording and Reproduction of Disc Records) has been absorbed in other sections, as stereo is a general part of the overall picture and need not be treated as a separate and distinct subject. The first edition received wide acceptance and a large market for it developed outside the United States. Therefore the author has included in this edition many items developed and manufactured in countries other than the United States.

The question was once asked, "Who remembers to bless the hands that milked the cow, when he eats the cheese?" As we enjoy the fruits of today's progress, we would do well to remember men like Leon Scott, who in 1857 first scribed a sound wave, using a stiff bristle attached to a diaphragm actuated by a horn. Between the years of 1858 to 1862, Koenig devoted a great part of his time to improving on Scott's invention and presented the results of his labors in London in 1862, which he termed "Phonograms." However, it remained for men like Edison, Berliner, and Johnson to invent and develop the methods culminating in the cylindrical and disc records so well known today. Valdemar Poulson, the Danish Edison, might be called the father of present-day magnetic recording, and certainly Lord Rayleigh is the father of acoustics and its many phases, with Professor Wallace C. Sabine of Harvard University responsible for modern acoustics. It is of interest to note that in 1711 John Shore discovered the tuning fork, and in 1908 G. W. Pierce described in a paper, "A Simple Method of Measuring the Intensity of Sound," based on his work in measuring sound intensities in auditoriums and of train whistles; thus was born the first sound-level meter. All these men and many more, leave us forever in their debt.

Those of us who have been closely associated with the industry some 40 years more or less, view with pride the progress that has been made. It is gratifying to observe some of our original thinking and experiments becoming a reality with modern materials, components, and facilities. With this in mind, the author has included some obsolete devices, which may still be in daily use, but mainly to offer information to the experimenter. Examples of this are the electret, which has been around for years but is now being utilized as a microphone, and the fuel cell, discovered by Sir William Grove in 1839, which is finding its greatest application in the space age.

The author is deeply indebted to the many engineers who have supplied information for compiling this book, and to the many manufacturers who have freely furnished photographs and technical data required to make this work a reality. Selection of illustrations resolved into the problem of choosing items that would be typical examples of a device, or in some instances where a manufacturer had included features in an instrument that made it unique or of particular interest. The final selection was often difficult; today's market offers a wide variety of good equipment.

The author wishes to pause and personally thank the following: Mr. Robert O. Cook, of Walt Disney Productions; Mr. Arthur C. Davis, of Altec-Lansing; Mr. Wallace Hamilton, of Trans-Canada Laboratories, Vancouver, B.C.; Mr. Jack V. Leahy, of Radio Corp. of America; Mr. Frank E. Pontius, of Westrex Corp.; Mr. Michael Rettinger, acoustical engineer; Mr. Loren L. Ryder, of Ryder Sound Services; Mr. Ross H. Snyder, of Hewlett-Packard Co.; and Mr. Waldon O. Watson, of University City Studios; to mention but a few who made generous contributions. Also, the author is indebted to the following societies for their journals and standards: Acoustical Society of America; Audio Engineering Society; Electronic Industries Association; Institute of Electrical and Electronic Engineers; Institute of High Fidelity; National Association of Broadcasting; Society of Motion Picture and Television Engineers; and the United States of America Standards Institute for their much-used reference sources. In addition, thanks to the publishers of the following: *Audio; Broadcast Engineering; db, the Sound Engineering Magazine; Electronic Instrument Digest; Electronics; Electronics and Communications* (Canada); *Electronics World; Radio Electronics;* and *Wireless World* (England) for their cooperation. Special thanks are offered to my friend and personal physician, Dr. Ronald McAdams, who indirectly contributed to this work.

The first edition of the *Audio Cyclopedia* has often been referred to as "The Sound Man's Bible." If this name fits, the author offers this edition with the conviction that it will serve even better.

HOWARD M. TREMAINE

Preface to First Edition

This book was prompted by the response to a series of lectures presented to naval personnel by the author, in 1945, on "High Fidelity Sound Systems." It is intended as a practical engineering guide for the individual who has an understanding of electronics and desires to apply that knowledge to the recording and reproducing of sound.

In the pursuit of fidelity in sound recording and reproduction, numerous problems have been encountered. While many of the problems have been overcome to a marked degree and much credit is due the research workers whose efforts have thus far advanced the art, a large number of problems still remain to be solved.

The term "high fidelity" is often abused and loosely used, and equipment bearing such a title assumes a great responsibility. Webster defines fidelity as "exactness, as in a copy." High quality sound systems require careful design and adequate test equipment for their proper installation, adjustment, and maintenance.

The ultimate reproduction of sound waves is affected by many factors, each contributing its own particular type of distortion, which may be acoustical, electrical, or mechanical. This distortion may manifest itself as frequency or pitch variations, harmonic distortion, hum, or noise, and any or all of these factors may be interposed between the original recording and the listener.

An attempt has been made to compile sufficient data into one book, in the form of questions and answers, to synthesize sound systems generally, together with their components and allied equipment, and the accepted methods of installation, testing, and operation. Section 22, pertaining to test equipment, describes many pieces of apparatus of different manufacturers. However, no evaluation of their individual merits has been made, but their characteristics and operation are so described that the audio engineer may readily determine which equipment will best meet his needs.

The various sections of this book cover the fundamental concepts of sound waves and treat of their complexity, their behavior, and the equipment associated with their recording and reproduction. The illustrations offer workable circuits with practical valnes. Section 3 discusses the devices used in the motion picture and recording industries for maintaining a constant speed and the control apparatus necessary to achieve this end. Sections 5, 6, and 7, "Attenuators," "Equalizers," and "Wave Filters," include numerous devices and circuits used for motion picture sound recording and reproduction, which are equally adaptable to other types of recording and reproduction.

The improvement of sound mixers, from a simple two-position to an elaborate hybrid-coil design for motion picture rerecording, is described in Section 9. Audio amplifiers are dealt with extensively in Section 12.

Motion picture projection equipment is discussed in Section 19 from the standpoint of the audio engineer.

Magnetic and optical film recording techniques are covered extensively in Sections 17 and 18 and will be of particular interest to those employed in both the motion picture and television industries.

Section 23 discusses the techniques of audio frequency measurements, and Section 24, tbe techniques of installation. These two sections should appeal to the installation and maintenance engineer because of their unusual type of information.

Finally, Section 25, "General Information, Charts, and Tables," contains much useful data for ready reference, including many charts for simplifying mathematical design procedures. Also, references will be found at the end of each section.

The data within this book is the result of over 30 years of experience in audio engineering, particularly in the motion picture industry. Tbe author sincerely hopes the material presented in this work will appeal to both the technician and the engineer.

I wish to extend my appreciation to Dr. George K. Teffeau for his valued suggestions and assistance in editing this book, to Messrs. Jack Laing and Glenn Osborn, as well as to Miss Janice Snyder, for their assistance in making tests for the sections on "Magnetic Recording," and "Optical Film Recording." I also wish to thank the following individuals, manufacturers, and publishers for making much of the data and photographs available for publication.

Lt. Col. James L. Gaylord, former Commander of the USAF Lookout Mt. Laboratory; Lt. Col. James P. Warndorf, present Commander; Mr. Watson Jones, RCA Victor Division, Hollywood, Calif.; Mr. Ralph Wight, Westrex Corp., Hollywood, Calif.; Mr. J. N. A. Hawkins, Motion Picture Research Council; Dr. Oliver Read, publisher of *Radio and Television News;* Mr. C. G. McProud, Editor and Publisher of *Audio* magazine; Mr. Hugo Gernsback, Editor and Publisher of *Radio Electronics* magazine; *Journal of the Society of Motion Picture and Television Engineers; Journal of the Institute of Radio Engineers; Journal of the Audio Engineering Society;* and *Journal of the Acoustical Society of America.* My appreciation also to the many other contributors of data and information.

HOWARD M. TREMAINE

Contents

Note

In an effort to reach worldwide understanding in published scientific and technical work, standardization of terms is essential. The Institute of Electrical and Electronic Engineers (IEEE) standards committee has adopted a number of new standards of electrical nnits and symbols. These were established in close cooperation with many international organizations.

Where standards are quoted, the information has been extrapolated for the essential details given. The term recommended is used to signify accepted industry practice and is not necessarily a standard.

Section 1

Basic Principles of Sound

To the audio engineer, an understanding of the basic principles and behavior of sound generation as well as the response of the human ear, frequency ranges and the levels that are encountered in daily life, especially when recording, are equally as important as the understanding of electronic circuitry. New aspects of sound may be observed with the application of white- and black-sound techniques. Shown are the variations of the Fletcher-Munson curves developed by Churcher and King and Robinson and Dadson of England, and by Pollock of the United States. General phenomena associated with the generation and propagation of sound waves such as the Doppler effect, units of measurement, terminology, equations, ranges of musical instruments, and peak powers are included in this section.

1.1 What is the definition of sound? —It is a wave motion propagated in an elastic medium, traveling in both transverse and longitudinal directions, producing an auditory sensation in the ear by the change of pressure at the ear.

1.2 How are sound waves produced? —By a vibrating body in contact with the air.

1.3 What is the peak-to-peak amplitude of a waveform?—It is the value measured from the positive peak to the negative peak. (See Question 25.149.)

1.4 What is a compressional wave? —A wave in an elastic medium such as air, which causes an element of the medium to change its volume without undergoing rotation.

1.5 What is a longitudinal wave?—A wave in which the direction of displacement at each point of the medium is normal to the wave front.

1.6 What is a shear wave?—A wave in an elastic medium which causes an element of the medium to change its shape without changing its volume.

1.7 What is a transverse wave?—A wave in which the direction of displacement at each point of the medium is parallel to the wave front.

1.8 What is a plane wave?—A wave in which the wave fronts are parallel planes normal to the direction of propagation.

1.9 What is a spherical wave?—A wave in which the wave fronts are concentric spheres.

1.10 What is a cylindrical wave?—A wave in which the wave fronts are coaxial cylinders.

1.11 What is a beat?—A periodic variation resulting from the superpositioning of waves having different frequencies.

1.12 What is a simple sound source? —It is a source which radiates sound uniformly in all directions under free-field conditions.

1.13 What is direct-sound radiation?—Sound emitted directly from the sound source without reflections or echoes.

1.14 What is the effective acoustic center of an acoustic generator?—It is the point at which the spherically divergent sound waves, observed at a remote point, appear to diverge.

1.15 What is considered to be the audible frequency range? — 15 Hz to 20,000 Hz.

1.16 What is noise? — A random sound composed of many different frequencies not harmonically related. If noise is of too great an intensity, it will impair the intelligibility of speech and music, reducing the listening pleasure. The average dwelling has a noise level of about 40 dB above the threshold of hearing. (See Question 1.117.) The noise level of a business office will rise to around 55 dB, while an average factory will indicate about 80 dB. Noise meters (see Question 22.94) do not measure the true noise present, because of the complexity of the waveforms. As a rule, noise meters are equipped with filters and weighting networks, to simulate the human ear hearing characteristics at different levels above the threshold of hearing. Weighting networks are discussed in Question 2.93.

1.17 What are infrasonic frequencies?—Frequencies below 15 Hz.

1.18 What are ultrasonic frequencies?—Frequencies above the audible range of 20,000 Hz.

1.19 What are supersonics?—A term used in aerodynamics to denote a velocity greater than the velocity of sound.

The term supersonics was formerly used in acoustical engineering to designate frequencies above audibility. The term ultrasonics has now replaced the former term supersonics.

The installations are generally of high power and operate above 20,000 Hz, although at times they may be operated at a lower frequency.

1.20 What are macrosonics?—Macrosonics are the utilization of high-amplitude sound waves for cleaning small metal parts, drilling, emulsification, soldering, plating, and the aging of alcoholic beverages.

1.21 What is the energy distribution of human speech?—The greatest energy lies between 200 and 4000 Hz, falling off quite rapidly beyond 6000 Hz. This characteristic is shown in Fig. 1-21.

1.22 What does the term timbre mean?—It is the characteristic quality of a musical instrument which permits it to be distinguished from another. Timbre depends on the harmonic or overtone structure of the instrument. If the harmonics are removed by the use of filters, all instruments will sound similar, except for the pitch.

1.23 What is a transducer?—A device actuated by power from one system and supplying power to a second system. The actuating power may be electrical, mechanical, or acoustical. A loudspeaker is a typical example of an electroacoustic transducer.

1.24 What is a passive transducer?—A transducer whose output waves are independent of any source of power and are controlled by the actuating waves.

1.25 What is an active transducer?—A transducer whose output waves are dependent upon sources of power apart from that supplied by any of the actuating waves. The output is controlled by the actuating waves.

1.26 Define the term octave.—An octave is eight notes of a musical scale, and is the interval between two sounds having a basic frequency ratio of two. It is also the pitch interval between two tones such that one tone may be re-

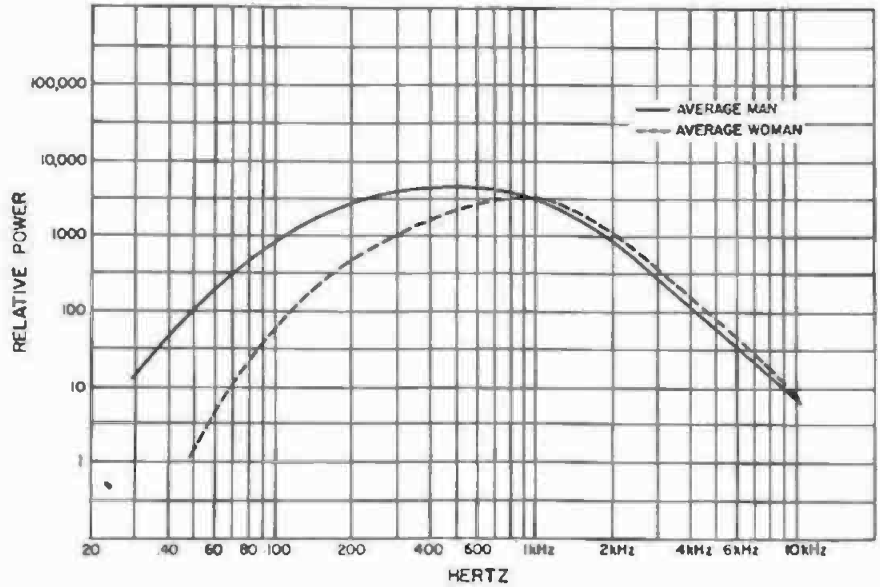

Fig. 1-21. Energy distribution of the human voice.

garded as duplicating the basic musical import of the other tone at the nearest possible higher pitch. An interval in octaves, between any two frequencies, is the logarithm to the base two (or 3.322 times the logarithm to the base 10) of the frequency ratio. The frequency ratio corresponding to an octave pitch interval is approximately, but not always exactly, 2:1.

1.27 What is a semitone, or half-step?—The same as a half-tone or any interval between two tones equal to the 12th root of 2.

1.28 What is a tone?—A sound wave capable of exciting an auditory sensation and having pitch. A sound sensation having pitch.

1.29 What is a chromatic scale?—A musical scale in which the intervals are all half-tones or semitones.

1.30 What is a scale of equal temperament?—A musical scale divided into twelve intervals. It is obtained by alternating the tones from the exact frequency of just intonation as a result of reducing the number of tones per octave.

These frequency ratios are 1, F, F_1, F_2, F_3 . . . to F_{12}, where F is the 12th root of 2 and F_{12} equals 2. The scale consists of 12 equal intervals, including half-tones. In Fig. 1-30 is shown the keyboard of a conventional 88 note piano with the tones indicated in hertz. A (440 Hz) is designated A_4 and the octaves above A_4 are designated A_5, A_6, and A_7. The octaves below A_4 are designated A_3, A_2, A_1, and A_0. The lowest frequency is A_0 or 27.5 Hz. The highest frequency is C_8, or 4186 Hz. The interval between the black and white keys is 100-cents, or an equally tempered semitone. (See Question 1.31.)

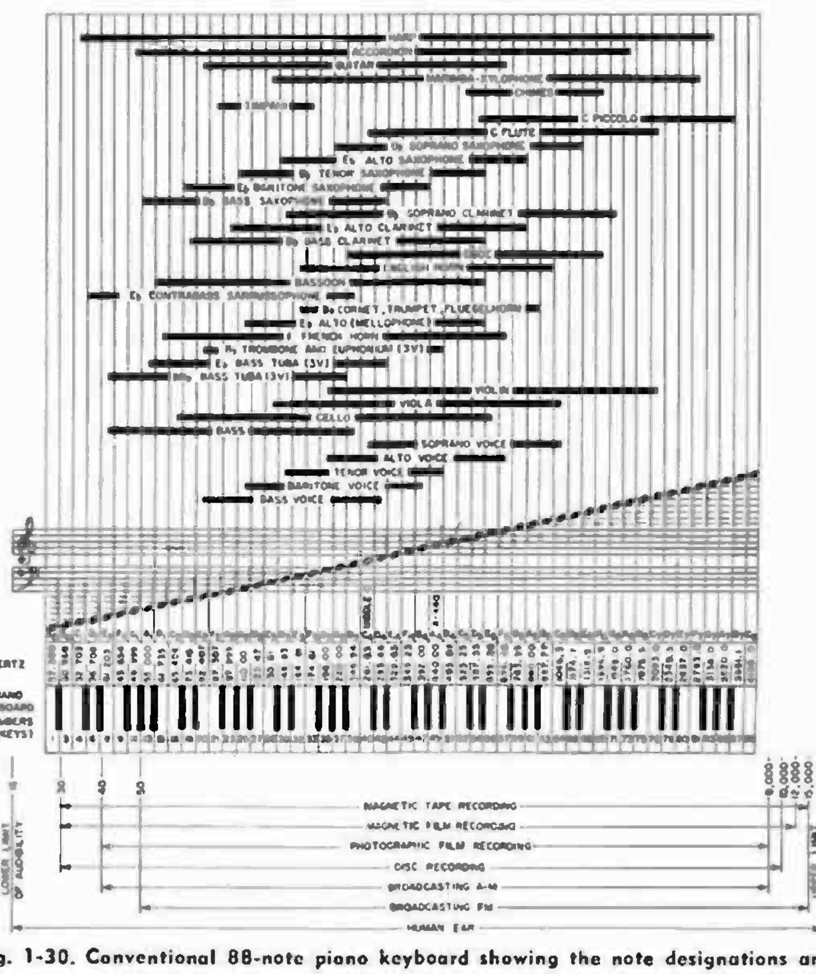

Fig. 1-30. Conventional 88-note piano keyboard showing the note designations and frequency. The audio frequency range of recording and broadcasting stations has been entered for comparison.

The complete spectrum is designated by starting at C_0, 16.351 Hz (not shown), the lowest frequency heard by the average human ear, and counting the octaves above from this frequency up to C^{9}, 16,744 Hz (not shown).

1.31 What is a cent?—An interval between two frequencies whose frequency is the 1200th root of 2. 1200 cents equals 12 equally tempered semitones.

1.32 What is pitch?—The property of a musical tone determined by its frequency and intensity. The higher the frequency the higher the pitch. (See Question 1.77.)

1.33 What is the American standard of pitch?—By agreement, all musical instruments manfactured in the United States are standardized to a frequency of 440 Hz for the tone of A_4. This corresponds to the 49th key on a standard 88-note piano. (See Question 1.30.)

1.34 What is a mel?—A unit of pitch. A 1000-Hz tone at a level of 40 dB above the threshold of hearing is equal to 1000 mels.

The mel scale of pitch is logarithmic above 1000 Hz and approximately linear below 1000 Hz. Any sound heard by an auditor and judged to be "n" times that of 1 mel is "n" mels.

1.35 Define the term microbar.—The microbar is a unit of measurement of sound pressure. One microbar is equal to the sound pressure of 1 dyne per square centimeter, or to a sound level of 74 dB above the threshold of hearing (0.0002 microbar). It is also equal to approximately one-millionth of normal atmospheric pressure. Normal atmospheric pressure equals 1,013,250 microbars. One bar equals 10^6 dynes per centimeter. At one time, the term bar was used to mean 1 dyne per square centimeter. This is no longer used. (See Question 1.82.)

1.36 Define threshold of pain.—The threshold of pain is the minimum value of sound pressure of a given frequency that will cause discomfort or pain to a listener 50 percent of the time, as shown in Fig. 1-36. Discomfort starts around a sound level of 118 dB, if the frequency falls within the range of 200 to 10,000 Hz. Actual pain starts around 140 dB in the same frequency range. It is interesting to note a sound level of 1 pound per-square-foot is equal to plus 147.6 dB; 1 pound per-square-inch to 170.8 dB; and 1 atmosphere to 194.1 dB—all being referred to 0.0002 microbar.

1.37 What does the term damping mean?—It is the introduction of friction or some other type loss, to reduce the vibration of a moving body. Undamped and damped waveforms are shown in Fig. 1-37.

1.38 What is critical damping?—A value of damping which will result in the most rapid response possible without overshooting or no indication of os-

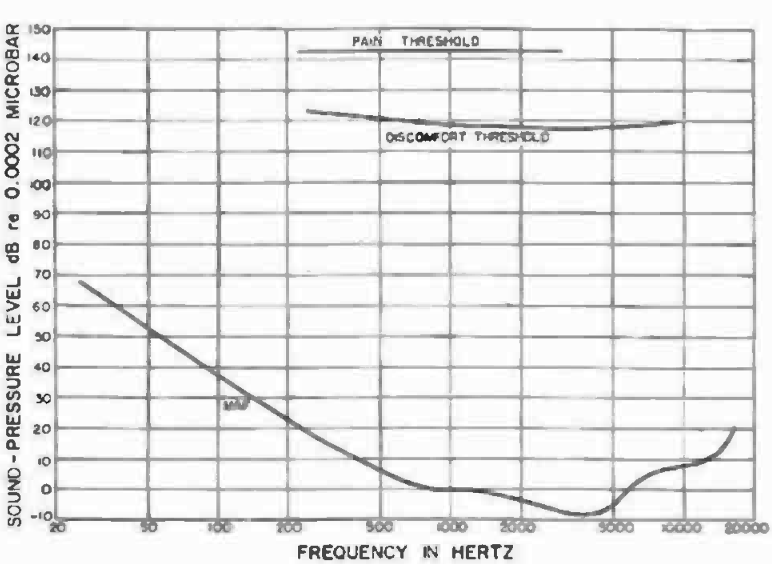

Fig. 1-36. Curves showing the threshold of hearing, discomfort, and pain. (Courtesy, General Radio Co.)

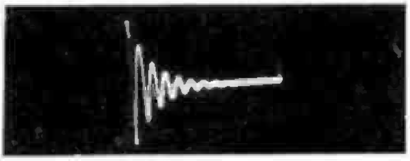
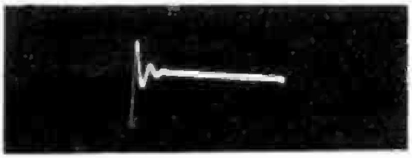


(a) *Undamped.*



(b) *Damped.*

Fig. 1-37. Undamped and damped waveforms.

cillation, is referred to as critical damping. It is the point of change between aperiodic and periodic damping.

1.39 What is periodic damping?—A system in which the damping is so great that, if the system is subjected to a single disturbance, it will come to rest.

1.40 What is aperiodic damping?—Aperiodic damping occurs when the amount of damping is so large that if the system is subjected to a single disturbance, either constant or instantaneous, the system comes to rest without passing through that position. While an aperiodically damped system is not strictly an oscillatory one, it has such properties that it could become an oscillating system if the damping was removed.

1.41 Define the term dyne per square centimeter—One dyne per square centimeter is the unit of force used in acoustical measurements and is the force that will give an acceleration of one centimeter per second, during each second it is operating, to a mass of one gram. One million dynes per square centimeter is equal to one bar. (See Question 1.125.)

1.42 What is a bar?—A unit of sound pressure equal to 10^6 microbars or 10^6 dynes per square centimeter.

1.43 What is superpositioning?—The combination of two or more frequencies, or the superimposing of one or more frequencies upon another frequency. (See Question 1.11.)

1.44 What is a sine wave?—A wave which rises from zero to maximum in one direction, returns to zero in a corresponding, gradual, nonuniform manner, reverses direction and falls below zero to an equal maximum, and returns to zero again during one complete cycle. A typical sine wave development is shown in Fig. 1-44.

1.45 What is a sinusoidal waveform?—An alternating current wave which varies in proportion to the sine of an angle. It is another name for the sine wave described in Question 1.44.

1.46 Define the terms cycles per second and hertz.—A complete turn of events. For a sine wave, it is the complete sequence of the rise from zero to maximum and return to zero, the rise to maximum in the opposite direction, and the return to zero again, as shown in Fig. 1-44.

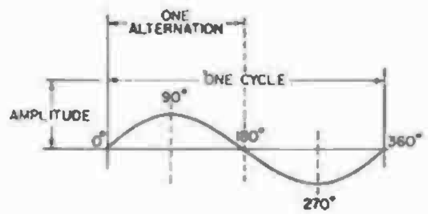


Fig. 1-44. Development of a sine wave.

The common term for measurements, when dealing with frequency, was in cycles per second, abbreviated cps. In 1965, the term cycles per second was changed to hertz in honor of Heinrich Rudolph Hertz, an early German physicist. One cycle per second is stated as 1 Hz; 1 kilocycle as 1 kHz; 1 megacycle as 1 MHz, etc. Either term is used, but *hertz* is preferred.

1.47 What is an alternation?—One-half of a cycle. As an example; a 60-Hz current has 120 alternations per second, similar to that shown in Fig. 1-44.

1.48 What does the term frequency mean?—The number of cycles or vibrations in a given unit of time.

1.49 What is a wavelength?—It is the distance from a given point on one wave to a corresponding point on the next wave, regardless of the frequency. Example: One wavelength in Fig. 1-44 is the distance from zero degrees to 360 degrees.

1.50 State the formula for calculating the wavelength of sound in air.—Experiments indicate the velocity of sound in air, at any frequency, is approximately 1127 feet per second, 343.4 meters per second, or 767.54 miles per hour. The velocity will vary slightly with changes in temperature, increas-

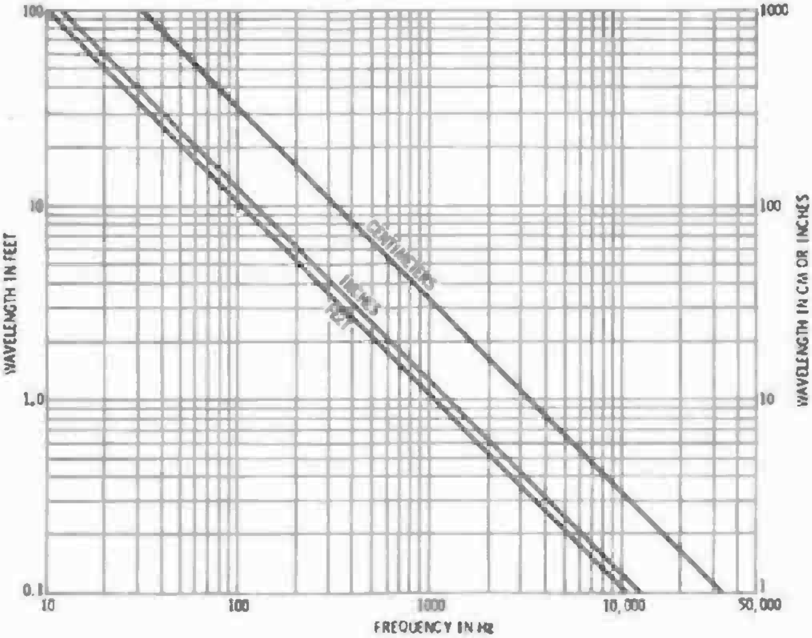

Fig. 1-50. Wavelength of sound in air as a function of frequency. Temperature 20° C @ 760mm pressure.

ing about 1.1 feet per second for 1 degree Fahrenheit, going from 1099 ft per second at 32° F to 1130 feet per second at 70° F. The wavelength of sound in air is equal to the velocity divided by the frequency in hertz. Example:

What is the wavelength of 40 hertz?

$$\lambda = \frac{V}{f} = \frac{343.4}{40} = 8.58 \text{ meters.}$$

where,

V is the velocity of sound in air,
f is the frequency in hertz, at 20° F.

The wavelength for various frequencies in air may be determined from the graph in Fig. 1-50. The graph is entered at the lower edge for a given frequency and followed upward to where it intersects the diagonal line. Wavelength is then read in feet from the left margin, or in centimeters or inches from the right margin.

1.51 Define an eigentone.—It is a resonance in an enclosure, caused by the presence of parallel walls, which causes the generation of standing waveforms. A room of cubical dimensions (dimensions equal in all directions) would have the same resonant frequencies in all directions. This is why good acoustical design does not employ parallel walls, and uses given ratios for length, width, and height.

1.52 What is a fundamental frequehcy?—The principal component of a complex waveform or the component having the lowest frequency. Using the physical definition, the fundamental frequency is called the first harmonic, F_1. In musical terms, the first multiple above the fundamental is called the first harmonic, F^1. (See Question 1.57.)

1.53 What is an overtone?—A harmonic of the fundamental frequency of a complex waveform.

1.54 What is an odd harmonic?—Any frequency that is an odd multiple of the fundamental frequency, such as 1, 3, or 5 times the fundamental.

1.55 What is an even harmonic?—Any harmonic that is an even multiple of the fundamental frequency, such as 2, 4, or 6 times the fundamental.

1.56 What is a subharmonic?—Subharmonics are obtained mathematically by dividing the fundamental frequency by the desired number harmonic. The second subharmonic of 500 Hz is 250 Hz.

1.57 How are the harmonics of a given frequency determined?—Any specified harmonic may be determined by multiplying the fundamental by the number of the desired harmonic. Example: The third harmonic of 100 Hz is 300 Hz. This is in physical terminology. (See Question 1.52.)

1.58 What are the characteristics of the various octaves between 16 and 16,000 Hz?—The frequencies between 16 and 32 Hz are called the first octave and are the frequencies in which the lowest swell tones of an organ are heard, and where the threshold of feeling exists.

Frequencies between 32 and 512 Hz are referred to as the second, third, fourth, and fifth octaves. This is the rhythm section where the lower and upper bass frequencies are found. If the response in the second and third octaves is accentuated, the reproduction will be reverberant and become objectionable to the true music lover. With the proper frequency response, the low frequencies of the drums and piano will be reproduced in their proper perspective.

From 512 to 2048 Hz are the sixth and seventh octaves. If speech is limited to this frequency range, it will have a telephonelike quality, because the human ear starts to approach its maximum sensitivity around 2000 Hz and continues up to 4000 Hz. If the response of the sixth octave is accentuated with respect to other parts of the frequency response, the quality of reproduction will have a hornlike quality. Also, if the response is increased between 1000 and 2000 Hz, the reproduction becomes tinny. Over accentuation of both the sixth and seventh octaves is one of the causes of listener fatigue.

Accentuating the eighth and ninth octaves, 2048 to 8192 Hz, adds presence to the program material and creates the illusion that a person speaking is present in the room. Within these frequencies lie the labial and fricative sounds. Labial sounds are those made with the lips and fricative those cause by the rustling of the breath as sound is emitted by the mouth. As a rule, recording systems are equipped with equalizers for controlling the amount of presence. (See Questions 6.106 and 6.107.)

The tenth octave occupies the region between 8192 and 16,000 Hz. These frequencies add brillance to the reproduction, reproducing the tinkling of bells and the higher frequencies of the triangle, cymbal, and other instruments. It has been proved by exhaustive listening tests that for high quality reproduction of music, the correct balance between the lowest and highest frequencies is obtained when the highest frequency multiplied by the lowest frequency equals 600,000.

Thus, a reproducing system with a low frequency response of 40 Hz and an upper frequency of 15,000 Hz will meet these requirements.

1.59 What is vibrato?—Frequency modulation of a tone or the musical embellishment of a tone. It is employed by vocalists and musical artists to enhance the presentation. The average rate of vibrato is 5 to 7 Hz.

1.60 What is tremolo?—Amplitude modulation of a tone. In an organ, the tone is modulated by a mechanical device.

1.61 What do the terms consonance and dissonance mean?—If two or more tones are sounded simultaneously and they are pleasing to the ear, they are consonant; if displeasing, they are said to be dissonant.

At times, the term mistuned consonance may be used in contrast to beats of nearly identical frequencies, which are termed imperfect unisons. The term mistuned consonants refers to beats between a given frequency and another frequency which is not quite in harmonic relationship with the former, such as 500 Hz and 1002 Hz.

1.62 What is a chord?—A combination of three to seven tones harmonically related and sounded simultaneously.

1.63 Define loudness.—It is the intensity of the sound stimulus and, chiefly, a function of sound pressure. However, it is also dependent on the frequency and the complexity of the waveform.

At times it may be advantageous to express the change in loudness in percentage. To do so, the level of the original sound must be known. The graph in Fig. 1-63A gives an approximate answer for different values of the original sound level. The tabulations in Fig. 1-63B were taken from Fig. 1-63A, for reductions of 6 and 10 dB.

1.64 How are the waveforms of program material classified?—They are of a complex nature and seldom of sine-wave characteristic. Typical complex waveforms are illustrated in Figs. 1-64A and B.

1.65 Describe the construction of a complex waveform.—A waveform con-

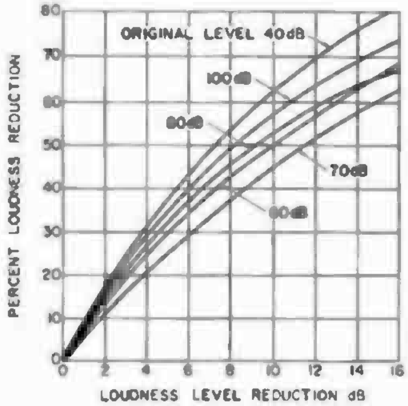

Fig. 1-63A. Percent loudness reduction versus loudness level in decibels.

ORIGINAL LOUDNESS LEVEL (dB)	REDUCTION IN DECIBELS	PERCENT LOUDNESS REDUCTION
40	10 6	62 43
60	10 6	50 33
70	10 6	44 29
80	10 6	53 38
100	10 6	56 40

Fig. 1-63B. Original loudness level versus reduction in decibels/percentage.

sisting of a fundamental frequency and its harmonics, or other frequencies, superimposed. When a complex waveform is viewed on an oscilloscope, it appears as shown in Figs. 1-64A and B. The waveform in Fig. 1-64A is typical of a symphony orchestra, while that in Fig. 1-64B is typical of speech waveforms. It will be noted that neither of the waveforms is of sine-wave character. The speech waveform indicates considerably more amplitude above the line than below; therefore, when transmitting or recording such waveforms, the system must be capable of transmitting or recording the maximum amplitudes without overloading.

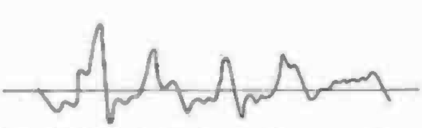

Fig. 1-64A. Waveform of a symphony orchestra as viewed on an oscilloscope.

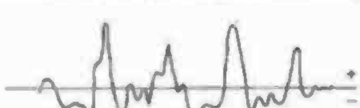

Fig. 1-64B. A typical speech oscillogram showing the energy or amplitude of the positive and negative peaks which are not symmetrical.

Because the maximum peaks are 8 to 14 dB above the average level indicated by a VU meter, it is necessary that this be taken into consideration when setting up a recording channel. If this is not done, serious overload will occur. This latter subject is discussed in Questions 10.27 and 10.28.

1.66 What is a partial?—A physical component of a complex waveform. It may be a frequency higher or lower than the fundamental frequency, and may or may not be harmonically related to the fundamental.

1.67 Define volume range.—It is the difference in amplitude between the softest and loudest passages in a recording or a live pickup. In a recording system, the signal-to-noise ratio of the system determines the maximum volume or dynamic range of that system. For a live pickup, the volume range is limited by the ambient noise level of the recording studio and the system noise combined (Fig. 1-67). Signal-to-noise measurements are discussed in Section 23.

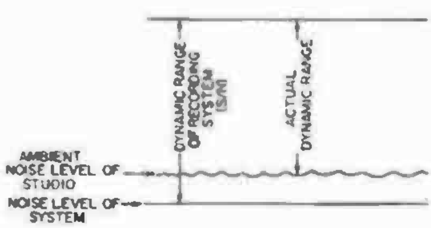

Fig. 1-67. The dynamic, or volume, range of a recording system is limited by its own signal-to-noise ratio, and the ambient noise level of the studio.

1.68 What is the range of the human voice in octaves?—When singing, about two octaves; however, female voices have been known to cover a four-octave range.

1.69 What is the effect of removing the lower frequencies from the human voice?—Because the greater portion of human speech intelligibility lies above

800 Hz, the lower frequencies may be removed without affecting intelligibility. Removing the higher frequencies reduces the intelligibility to the point where speech becomes unintelligible. Articulation tests indicate that, when freqnencies above 1550 Hz are removed, the intelligibility falls off 65 percent.

The reproduction of speech may be limited to a bandwidth of 250 to 3500 Hz with a high degree of intelligibility. For motion-picture dialogue recording, frequencies below 800 Hz are slowly rolled off to where 100 Hz is down 8 to 12 dB, with reference to 1000 Hz. The midrange high frequencies are accentuated 4 to 6 dB to add presence to the speaking voice. This characteristic is shown graphically in Fig. 18-81.

1.70 Does the human ear hear all frequencies with the same intensity?—No, the human ear is less sensitive at both the lower and upper ends of the frequency spectrum, and this characteristic varies with both age and sex as shown in Fig. 1-99A and Fig. 1-99B. The human ear shows its greatest sensitivity between 500 and 6000 Hz. As an example, at the lower intensities, the judged loudness of a 1000-Hz tone varies approximately in proportion to the square of the sound pressure. At the higher intensities, the loudness varies approximately as two-thirds power of the sound pressure.

This relationship should set to rest the contention that the decibel is used in acoustic measurements because the human ear responds to the intensity of sound logarithmically. At no level is a logarithmic characteristic indicated; actually, the loudness is approximately proportional to the sound pressure raised to the 0.6 power.

1.71 What is the frequency range of a telephone system for the transmission of speech?—For quality reproduction of the human voice, a telephone receiver must exhibit good frequency response across a bandwidth of about 3000 Hz, or from 200 to 3400 Hz. The intensity of normal conversation, heard at a distance of 3 feet, is on the order of 60 to 70 dB above the threshold of hearing. The frequency response for a modern telephone receiver and for one manufactured in 1905 is shown in Fig. 1-71.

1.72 What is meant by an inharmonic frequency?—A frequency which is not a rational multiple of another frequency.

1.73 What is instantaneous speech power?—The rate at which sound energy is being radiated by a speech source at any given instant.

1.74 What is peak speech power?—The maximum value of the instantaneous speech power within a given time interval.

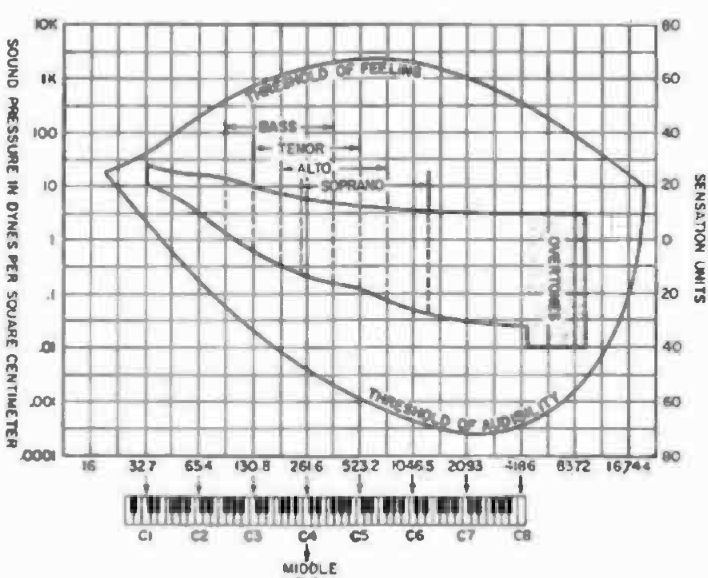

Fig. 1-70. Human ear frequency characteristics compared to the frequency range of a piano.

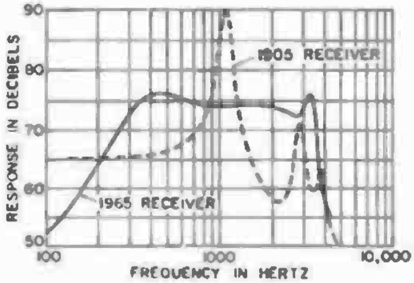

Fig. 1-71. Frequency response of a modern telephone receiver compared to one manufactured in 1905. (Courtesy, Bell Telephone Record)

1.75 ***What is average speech power?*** —The average value of the instantaneous speech power for a given interval.

1.76 ***What are equal loudness contours?***—A group of sensitivity curves plotted for the human ear showing its characteristic for different intensity levels between the threshold of hearing and the threshold of feeling. These data are often referred to as equal loudness contours. The reference frequency is 1000 Hz.

The curves of Fig. 1-76A made by Fletcher and Munson of the Bell Telephone Laboratories, are generally accepted throughout the sound industry as a basis for the design of devices concerned with human hearing. The curves given in Fig. 1-76B were made by Churcher and King of England; those in Fig. 1-76C hy Robinson and Dadson also of England; and those of Fig. 1-76D by Pollack of the United States. Although these curves differ somewhat, they all give the same general information, and are in fairly close agreement with the Fletcher-Munson curves, except for the differences at the higher and lower frequencies. The dotted line in Fig. 1-76C is the minimum audio frequency (MAF) that can be heard by the human ear. The curves of Fig. 1-76D by Pollack were made in 1952 using relatively narrow bands of random noise.

Referring to Fig. 1-76A, it will be observed that the contours are not equally spaced, but generally converge at the lower frequencies. This characteristic causes a change in the quality of reproduced sound when the volume level is changed. As an example: Consider a system carrying two pure tones of equal loudness, 1000 Hz and 50 Hz. Let the 1000-Hz tone have an intensity level of plus 80 dB (re 0.0002 microbar). Following this curve out to 50 Hz it indicates that an intensity level of plus 85 dB is required to make the 50-Hz tone sound as loud as the 1000-Hz tone, or a difference of 5 dB. Assume now that the gain of the system is lowered to where the 1000-Hz tone has an intensity level of plus 40 dB. By following this curve out to 50 Hz, it can be seen that the intensity must be increased to 72 dB to equal the loudness of the 1000-Hz tone, or an increase of 32 dB. It will be noted that in lowering the level, the balance between the low- and middle-range frequencies has been destroyed, and to the ear it appears that the low frequency response is lacking. This is the principal reason for including a loudness control in home reproducing equipment. It also emphasizes the need for establishing a monitor level in a recording studio and maintaining it from day to day to assure uniformity of product. (See Question 5.65.)

Weighting networks used in sound-level meters (see Question 2.93) are based on the Fletcher-Munson measurements, but modified to take into account the random nature of a sound field in an enclosure.

1.77 ***Why do sounds heard by the human ear increase and decrease in pitch as the intensity of the sound is varied?***—It is caused by the nonlinearity of the human ear. It has been determined experimentally that the pitch is related to the basilar membrane, a delicate part of the cochlea, a spiral, cylindrical tube forming the innermost of the three portions of the labyrinth of the human ear. Because of the structure of this membrane, the relationship between pitch and frequency is not exactly linear.

If the intensity of 100 Hz is increased from a loudness of 40 to 100, the pitch will be decreased about 10 percent. At a frequency of 500 Hz, the pitch will be changed about 2 percent for the same increase of intensity.

1.78 ***What is a consonant?***—A speech sound characterized in enunciation by constriction of the breath channel. Letters such as P, G, N, L, R, and W are called consonants.

1.79 ***What are sibilants?***—High-frequency sounds uttered with a hissing effect. The letters S and Z and the combinations SH, ZH, and CH are typical examples of sibilant sounds. These sounds are a constant source of annoyance to the recording engineer.

For motion-picture recording, sibilant sounds are attenuated by the use of a "de-esser" installed in a compressor amplifier, as described in Questions 18.89 and 18.91.

1.80 What is the sound pressure one foot from the mouth of a person speaking in a normal tone of voice?—Approximately one dyne per square centimeter. For a shout, the pressure may rise to 10 dynes per square centimeter, while a whisper may fall to 0.10 dyne per square centimeter.

1.81 How does a typical speech waveform appear on an oscilloscope?—A typical waveform was shown in Fig. 1-64B. It will be noted that the amplitudes of the positive peaks are greater than for the negative peaks, because the human voice is not of a true sine-wave character.

1.82 Define the threshold of hearing.—It is the sound level for a given frequency that the average human ear can just hear 50 percent of the time. The threshold of hearing is relative to a sound pressure of 0.000204 dyue per square centimeter, which equals 0.0002 microbar or 10^{-16} watt per square centimeter. (See Questions 1.35 and 1.41. The point in space must be specified.)

1.83 What is the dynamic range of the human ear?—120 dB, or a ratio of one trillion-to-one. A high quality magnetic-tape recording system has only a dynamic range of 60 dB, or one million-to-one.

1.84 What is an articulation test?—A quantitative measurement of the intelligibility of human speech. The test is conducted by reading selected sentences to a group of listeners. A score is kept by each listener as to the intelligibility of each sentence, word, and syllable. Such tests are used in the testing of telephone and other communication equipment.

1.85 What is the average deflection of the human ear drum for sounds of different intensities?—The variation in deflection is from 10 to 40 millionths of an inch.

1.86 How are acoustic powers added?—If the level is given in decibels, it is converted to power, added or subtracted as the case may be, and then converted back to decibels.

1.87 How much must the loudness of a sound be increased to make it sound twice as loud to the human ear?—Physiologists have devised a scale of loudness, which rank-orders sound from soft to loud in units of sones. The physical quantity measured is the sound pressure level. One thousand Hz is used as a reference frequency, at a sound pressure of 40 dB above the threshold of hearing (0.0002 microbar); this is taken to be 1 sone. Doubling the loudness is equal to 2 sones. The relationship of sones versus sound pressure is shown in the graph of Fig. 1-128. At the low intensities, the loudness of the 1000-Hz tone varies approximately in proportion to the square of the sound pressure, while at the higher intensities it varies approximately two-thirds power of the sound pressure. (See Question 1.70).

1.88 If two tones of the same frequency and intensity are sounded simultaneously, is the sound intensity twice as loud as for a single tone?—No. The overall level of intensity will only be iucreased 3 dB. Fig. 1-88 is a chart for adding acoustic powers. Assume two tones, one plus 30 dBm and one plus 22 dBm, are to be added. What is the acoustical power for the two, in decibels? Since 30 dBm minus 22 dBm is a difference of 8 dB, enter the chart at the bottom for 8 dB and follow the line upward to the intersection of the curve. The value read at the left of the chart, in this case 0.65 dB, is added to the higher power. Thus, the overall level for the two powers is 30.65 dBm.

This chart may be used for adding measured noise levels or for any problem of a similar nature.

1.89 What is a whole tone?—The interval between two sounds whose basic frequencies are a ratio approximately equal to the sixth root of two.

1.90 Define velocity.—It is the time rate of change of position. Unless angular velocity is stated, the term is understood to mean linear velocity.

1.91 What is the velocity of sound through solid materials?—

See Fig. 1-91.

1.92 What is the frequency range through water?—From 2 Hz to 50 megahertz (50,000,000 Hz).

1.93 Does the velocity of sound depend on frequency?—No. The velocity

Material	*Feet per second*
Aluminum	16,740
Brick	12,500
Copper	11,670
Carbon dioxide	846
Glass	16,830
Iron	5130
Lead	4026
Pine (direction of grain)	10,900
Silver	8553
Water	4728
Steel	16,500

Fig. 1-91. Velocity of sound.

of sound is governed by the medium of transmission, the temperature, and the intensity of the sound.

1.94 Show the attenuation of high frequency sound waves in air.—Sound waves are affected by distance, humidity, and frequency. The attenuation in air for several frequencies, at different humidities, is shown in Fig. 1-94.

1.95 What is the decay rate of sound?—The time required by a sound to diminish from its original intensity to the threshold of hearing, or one-millionth of its original intensity.

1.96 How is decay rate measured?—Generally by an oscillator and an automatic graphic recorder. (See Question 22.112. The recorder measures the decay rate in milliseconds. The intensity level at the end of a given decay period, in decibels, is:

$$dB = 10 \, Log_{10} \frac{P_1}{P_2}$$

where,

P_1 is the original intensity in watts,
P_2 the diminished intensity in watts.

1.97 What is the acceleration of a sound wave?—The time-rate of change of the velocity of the point.

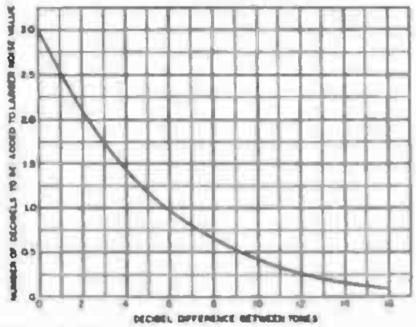

Fig. 1-88. Chart for adding acoustic powers or noise values.

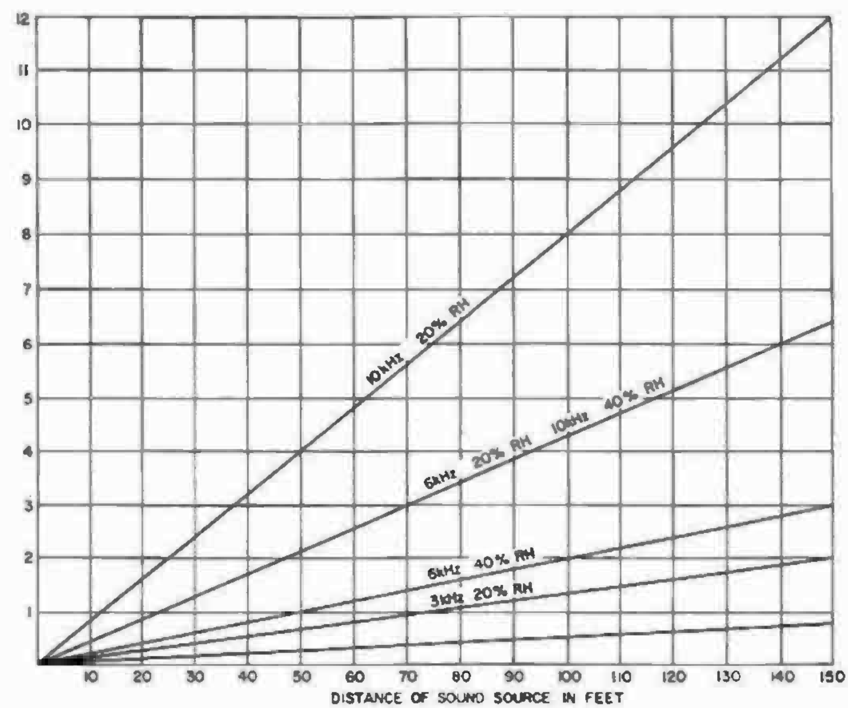

Fig. 1-94. Absorption of high-frequency sound waves in air for a given distance and relative humidity.

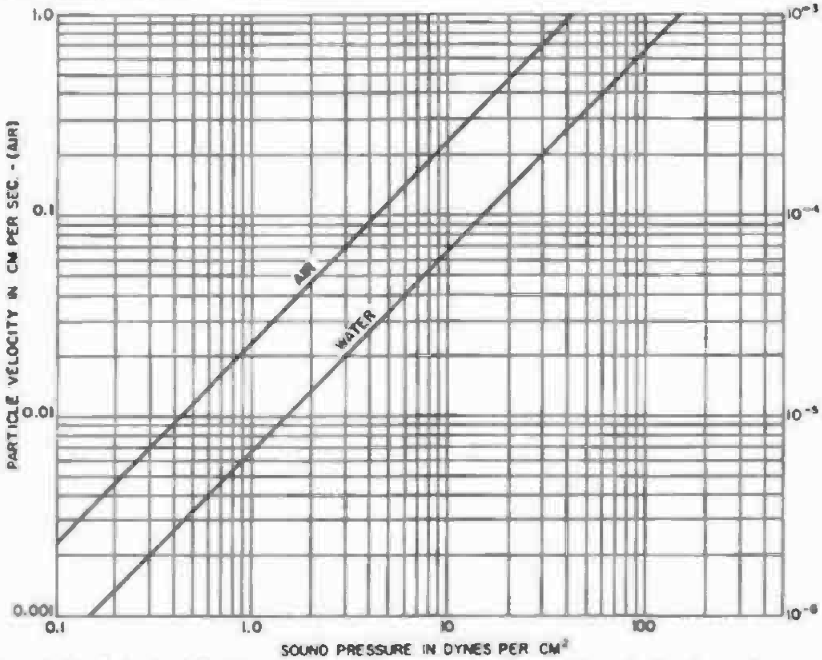

Fig. 1-98. Relationship between sound pressure and particle velocity in a plane wave in air and water at 20° Centigrade.

1.98 What is particle velocity?—It is the velocity of a given infinitesimal part of the medinm, with reference to the medium as a whole, due to the sound wave. The unit of measurement is the centimeter.

This relationship is shown graphically in Fig. 1-98. For example, to find the velocity for a sound pressure of 3 dynes/cm² in water, enter the chart at the lower left edge at 3 dynes, and follow the vertical line upward until it intersects the diagonal line for water; read the velocity at the right margin 0.02 cm/second.

1.99 Show the hearing losses with age for the human ear.—In 1939 The Bell Telephone Laboratories conducted tests at both the New York World's Fair and San Francisco Exposition to determiue the effect of age on the hearing of the human ear. Over one-half million records were made in five age groups, 10-19, 20-29, 30-39, 40-49, and 50-59. The results of these tests are shown in Fig. 1-99A and Fig. 1-99B. It will be noted that the high-frequency loss is less with age for women as compared to men; however, this is reversed at the lower frequencies.

1.100 What law does the growth and decay of a musical instrument follow?—Generally, the exponential law affecting the time required for a tone to reach its fullest intensity and then decrease to a given level of intensity.

1.101 What is meant by the term in phase?—The state or condition existing when two devices or sound waves are in perfect synchronization.

1.102 Explain the relationship of acoustic power to the intensity of sound.—The intensity of sound, independent of its frequency, is proportional to the average of the square of the pressure

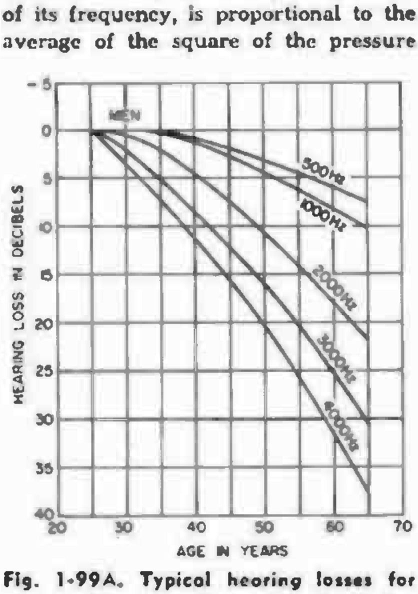

Fig. 1-99A. Typical hearing losses for men. (Courtesy, General Radio Co.)

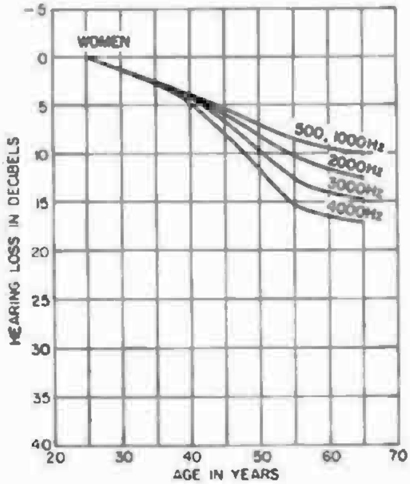

Fig. 1-99B. Typical hearing losses for women. (Courtesy, General Radio Co.)

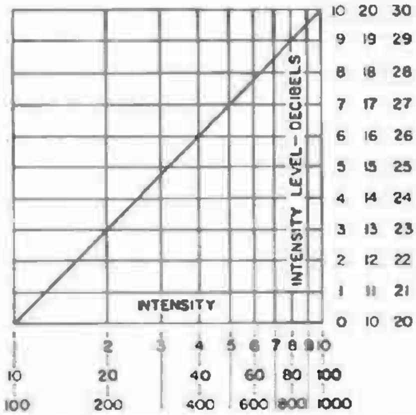

Fig. 1-103. Graphical plot showing the relationship of intensity to intensity level.

taken over a complete pressure cycle. Intensity is defined as the power in watts that is transmitted across one square centimeter of wavefront, perpendicular to the direction in which the sound is traveling. The power of even the most intense sound expressed in watts is extremely small. The unit of acoustical intensity is 10^{-16} watts per square centimeter. This intensity is slightly less than the least intensity of a 1000-Hz tone which is audible to the human ear. Even a painfully intense sound has the intensity of only 1/1000 watt per square centimeter. The square root of the average square (root-mean-square) of the sound pressure that corresponds to 10^{-16} watt per square centimeter, is 0.0002 dyne per square centimeter. A dyne is the force equal to 1/980 of the weight of a gram. Therefore, an rms sound pressure of 0.0002 dyne per square centimeter is equal to about two-millionths of a gram weight per square centimeter. The intensity of sound is generally expressed in 10^{-16} watt units, and sound pressure in 0.0002 dyne per square centimeter.

1.103 Define intensity and intensity level.—As an acoustical device, the human ear is unsurpassed in the range of intensities to which it will respond, without being damaged, as well as in its extreme sensitivity to faint sounds. However, the ear is relatively insensitive to changes in intensity. Roughly speaking, the intensity of a sound must be increased by approximately 26 percent, in order for the ear to register a change in the loudness sensation produced.

The graph in Fig. 1-103, illustrates the relationship between intensity and intensity level. The ordinates of the points on the straight line are ten times the logarithms of the numbers of the horizontal scale. Thus, intensity level is plotted versus intensity. The first vertical scale corresponds to levels of intensities from 1 to 10, the second from 10 to 100, the third from 100 to 1000, etc. The graph may be extended to give the intensity level of any intensity by multiplying the intensity by 10, which raises the intensity level by 10 dB. Thus, the intensity level for 2.5 is 4 decibels; for 25 it is 14 dB; for 250 it is 24 dB; for 2,500,000 it is 64 dB.

1.104 What is the relationship of distance to the intensity of a sound wave?—Sound in free space follows an inverse-square law; that is, the intensity of the sound varies as the square of the distance. If an observer moves to twice the distance from the sound source, the intensity will decrease to one-quarter the original intensity. If the distance is increased to ten times, the intensity will be reduced to one one-hundredth that of the original intensity.

This relationship exists because the area covered by the sound wave increases as the square of the distance. The sound energy is spread out over a greater area; therefore, the energy is decreased inversely by the same amount.

1.105 What is the relationship of a sound wave in air to a sine wave?—The energy of the sound wave in air is proportional to the rms value of the sine wave.

1.106 What is static pressure?—The pressure existing in a medium when no sound waves are present. The pressure is expressed in microbars.

1.107 What is instantaneous sound pressure?—It is the total instantaneous pressure at a point minus the static pressure at that point. Instantaneous sound pressure is stated in microbars.

1.108 What is the maximum sound pressure?—The maximum absolute value of the instantaneous sound pressure occurring during a given cycle, stated in microbars.

1.109 What is peak sound pressure?—The maximum absolute value of the instantaneous sound pressure in a given interval, stated in microbars.

1.110 What is effective sound pressure?—It is the rms value of the instantaneous sound pressures, over a given time interval, at a given point. In the case of periodic sound pressures, the interval must be an integral number of periods or an interval longer than one period.

1.111 How are sound pressure levels stated?—The level, in decibels, of a sound is 20 times the logarithm to the base 10 of the ratio of the pressure of the sound to the reference pressure. Reference pressures in common use are:

(a) 2×10^{-4} microbar.
(b) 1 microbar.

Reference pressure (a) is the one most commonly used for the calibration of microphones and sound level measuring instruments.

1.112 What is the sound power of a source?—The total sound energy radiated by the source per unit of time. The commonly used unit is the erg per second, but it may also be expressed in watts.

1.113 What is the dynamic range of a full symphony orchestra?—From 20 dB to 100 dB above the threshold of hearing. The lowest level will be affected by the ambient noise level of the auditorium.

1.114 How are sound pressures measured?—In microbars. One microbar equals a pressure of one dyne per square centimeter, or approximately one-millionth of the normal atmospheric pressure.

1.115 What is a sympathetic vibration?—An undamped body set in vibration on a certain frequency by airborne sound waves or building vibrations.

1.116 What are Fletcher-Munson contours?—A group of ear characteristics plotted with reference to frequency and pressure, starting at the threshold of hearing. These curves are illustrated in Fig. 1-76A.

1.117 Show typical sound levels encountered in daily life.—The sound levels encountered in daily life are many and vary over a large range of sound pressures. In Fig. 1-117A are shown typical overall sound levels referenced to the threshold of hearing. Typical acoustic power levels for various sources are shown in Fig. 1-117B. These latter levels bear no simple relation to those shown in Fig. 1-117A.

It is generally more convenient to express the ratio between two sound pressures in decibels. Since sound pressure is generally proportional to the square root of the sound power, the sound pressure ratio for a given number of decibels is the square root of the corresponding power ratio. For example, if one sound pressure is twice another, the number of decibels is 6; if it is 100 times as great, it is 40 dB. Sound pressure can also be expressed as sound pressure level with respect to a reference sound pressure. For airborne sound, this reference is generally 0.0002 microbar. The definition of sound pressure level (SPL) is:

$$\text{SPL} = 20\text{Log}_{10}\frac{P}{0.0002} = \text{dB}$$

where,

P is the root-mean-square sound pressure in microbars.

For example, if the sound pressure is 0.00025 microbar, the corresponding sound pressure level is:

$$\frac{1}{0.00025} = 4000$$

$$20\text{Log}_{10} 4000 = 20 \times 3.60 = 72.0 \text{ dB}$$

A chart for converting decibels to pounds per square inch rms pressure, or vice versa is given in Fig. 1-117C.

1.118 What effect does the nonlinearity of the human ear have on hearing?—If a pure sine wave is impressed on the human ear and the intensity is increased, harmonics of the fundamental frequency appear.

Fig. 1-117A. Typical overall sound levels encountered in daily life. The levels are in reference to 0.0002 microbar. (Courtesy, General Radio Co.)

Since the human ear is nonlinear, multiple tones cause the generation of sum and difference frequencies thus creating distortion (see Question 1.77). Using a harmonic wave analyzer, Newman, Stevens, and Davis were able to detect the presence of 66 different frequencies in the electrical response from the cochlea of a cat's ear, when stimulated with 700 and 1200 Hz at a SPL of 90 dB above the threshold of hearing.

This indicates the complexity of the ear and the great number of frequencies generated for only the application of two frequencies. As the number of tones are increased, so are the sum and difference frequencies. Thus, the number of frequencies generated by the ear is tremendeous when listening to a full orchestra. A table of frequencies generated by a cat's ear is given in Fig. 1-118. This phenomenon is termed *aural harmonics.*

1.119 What effect does nonlinear reproduction have on the human ear?— Nonlinear reproduction induces harmonics not present in the original program material. If the high frequency response is reduced, an increase of distortion can be tolerated.

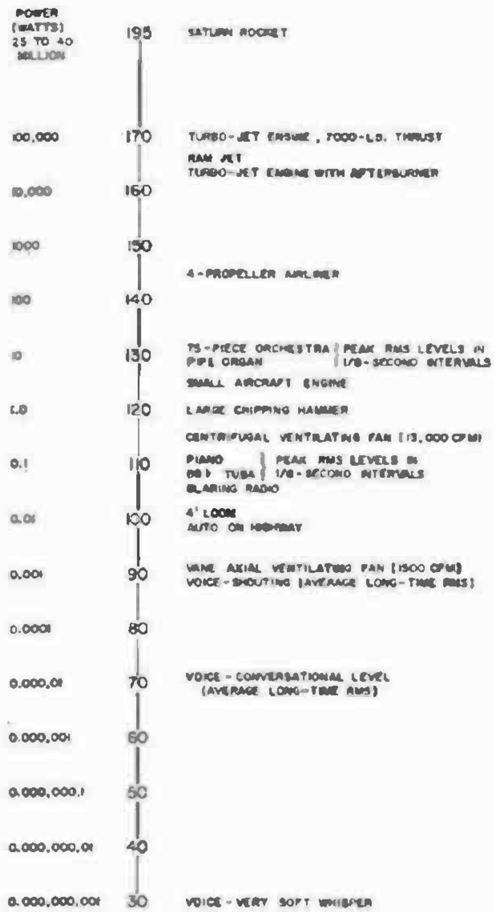

Fig. 1-117B. Typical power levels for various acoustic sources. These levels bear no simple relation to the sound levels of Fig. 1-117A. (Courtesy, General Radio Co.)

Starting from a very low value of distortion and slowly increasing the harmonic distortion will cause the third harmonic to become audible, at low levels, with a value of about 1.25 percent. The second harmonic may be increased to approximately 5 percent before it becomes annoying. Reproducing systems with a high-frequency cutoff of 6000 Hz may tolerate distortion up to 10 percent, while a system extending to 15,000 Hz can not tolerate over 2 percent total harmonic distortion. A good rule to follow is: Before increasing the

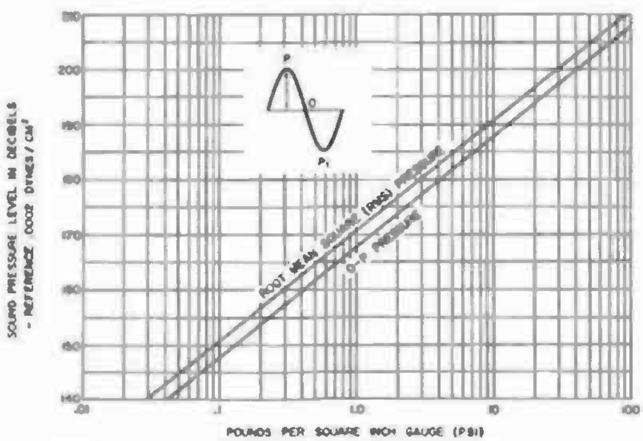

Fig. 1-117C. Conversion chart, decibels to pounds per square inch.

Frequency	Response in % of Fundamentals	Source	Frequency	Response in % of Fundamentals	Source

frequency range of any reproducing system, reduce the harmonic distortion to a negligible amount.

1.120 What is the relationship of a fundamental frequency to its harmonics? —A fundamental tone with its harmonics up to an including the sixth harmonic, is shown in Fig. 1-120.

1.121 What is a free-field?—A sound field free from reflecting surfaces, or sound in free space.

1.122 What is a node or nodal point?—A point on a vibrating body that is free from vibration, or a point of zero potential in an electrical circuit, with respect to ground.

1.123 What is a nodal diagram?— A diagram of a stretched diaphragm showing the points of maximum and minimum vibration for a given set of conditions. Such patterns are made by vibrating a diaphragm having a light covering of sand on its surface. The sand will assume a pattern indicating the various points of vibration.

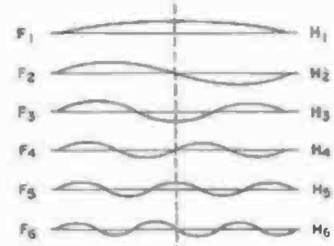

Fig. 1-120. A fundamental frequency and its harmonics.

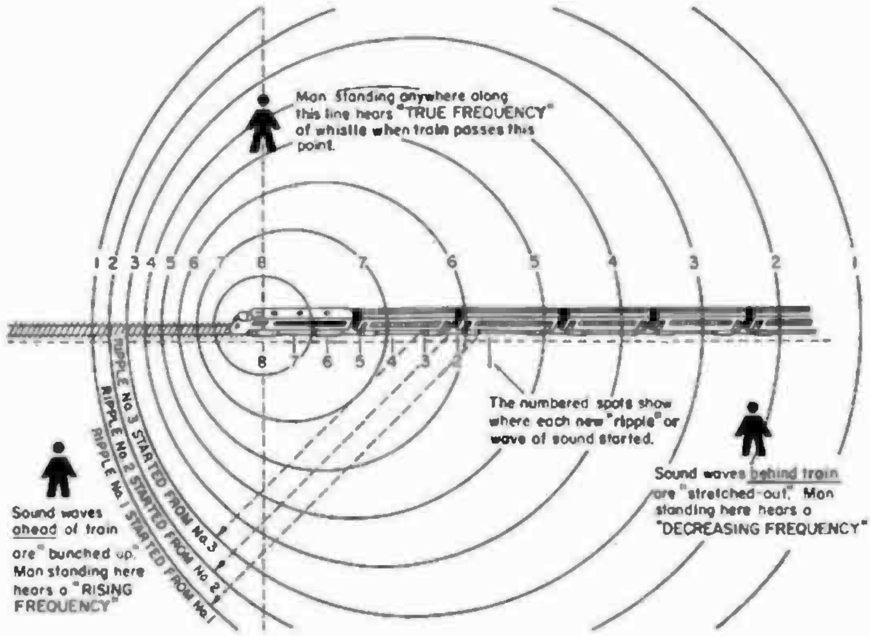

Fig. 1-124. The Doppler effect, showing how the frequency of a train whistle is affected as the train approaches and recedes from the observer.

1.124 What is the Doppler effect?—The change in pitch of a sound heard by an observer when the sound source is in motion. An example of the Doppler effect will be noted when a train blowing its whistle approaches an observer. The sound appears to increase in loudness and pitch. After passing the observer, the pitch and intensity drop quite rapidly until the sound fades out completely.

The increase in pitch is caused by compression of the sound wave as a result of the forward motion of the train being added to the velocity of the sound wave. Conversely, as the train moves away from the observer, the pitch decreases because the speed of recession is subtracted from the normal velocity of the sound wave, resulting in a lower pitch. This effect is illustrated in Fig. 1-124.

1.125 Define the term dyne.—The dyne is a unit of force used in acoustic measurements. Approximately 450,000 dynes equal one pound of force, and 68,944 dynes per square centimeter equal one pound of force per square

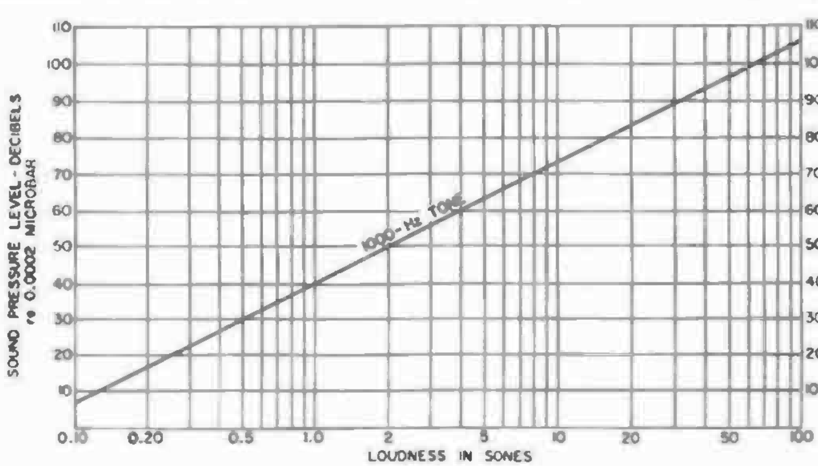

Fig. 1-128. Sound pressure in dB versus sones.

inch. One dyne will exert a pressure of 0.000036 ounce on a surface one centimeter square.

1.126 What are the acoustic pressures generated in average music reproduction?—About 0.005 to 240 dynes per square centimeter.

1.127 What is meant by the term bone conduction?—Sound conduction to the inner ear by the cranial bone rather than by air to the ear drum.

1.128 Define the sone.—It is a unit of loudness graduated in equal steps and is used in the measurement of the human ear characteristics. One sone is equal to 10^{-6} microwatt per centimeter squared. The loudness of a 1000-Hz tone 40 dB above the threshold of hearing is equal to one sone. A tone twice as loud equals two sones, and so on. A millisone is one thousandth of a sone and is often referred to as a loudness unit. A graph for converting decibels to sones and vice versa is shown in Fig. 1-128.

1.129 Define the phon.—The phon is a unit for measuring the loudness level of a pure tone (sometimes called a loudness unit). Because the human ear does not hear on a linear scale, doubling the intensity of a sound does not result in doubling the intensity of the sound at the ear. A true loudness scale would be one that doubles the sensation at the ear when the intensity of the sound is doubled. Such a scale is the loudness scale. Its unit of measurement is the *phon*, with a reference frequency of 1000 Hz.

A graphical plot of phons versus sones appears in Fig. 1-129. A simplified relation between loudness in sones and the loudness level in phons has been standardized internationally (ISO/R131-1959), and is useful to the audio engineer. The relation of sones to phons may be expressed as:

$$S = 2^{\frac{P-40}{10}}$$

where,
S is the loudness in sones,
P is the loudness level in phons.

This relationship is a good approximation to the psychoacoustical data but not accurate enough for research on the subjective aspects of hearing. For example, given a loudness level of 81 phons, in the +1 column in the 80 row, read 17.1 sones.

The loudness scale is employed by comparing the intensity of a tone to the reference frequency. Tones between 800 and 2000 Hz show little difference in loudness. Frequencies that are between 2000 Hz and 8000 Hz show a slight loss. Above a frequency of 8000 Hz, the intensity decreases as the frequency is increased.

Frequencies below 50 Hz require the intensity to be increased 250,000 times to make them equal in loudness to the reference frequency of 1000 Hz. The loudness level in phons of a sound is numerically equal to the sound pressure in decibels relative to 0.0002 microbar at 1000 Hz. A level of 40 phons equals one sone, when referred to 0.0002 microbar.

1.130 What is a summation frequency?—A frequency which is the direct result of two other frequencies being sounded simultaneously, and is the sum of the two frequencies.

1.131 What is the frequency range of musical instruments as compared to the frequency ranges of the human voice, broadcast, and recording systems?

Phons	*0*	*+1*	*+2*	*+3*	*+4*	*+5*	*+6*	*+7*	*+8*	*+9*
20	0.25	0.27	0.29	0.31	0.33	0.35	0.38	0.41	0.44	0.47
30	0.50	0.54	0.57	0.62	0.66	0.71	0.76	0.81	0.87	0.93
40	1.0	1.07	1.15	1.23	1.32	1.41	1.52	1.62	1.74	1.87
50	2.0	2.14	2.30	2.46	2.64	2.83	3.03	3.25	3.48	3.73
60	4.0	4.29	4.59	4.92	5.28	5.66	6.06	6.50	6.96	7.46
70	8.0	8.60	9.20	9.80	10.6	11.3	12.1	13.0	13.9	14.9
80	16.0	17.1	18.4	19.7	21.1	22.6	24.3	26.0	27.9	29.9
90	32.0	34.3	36.8	39.4	42.2	45.3	48.5	52.0	55.7	59.7

Fig. 1-129. Table for converting phons to sones or vice versa. (Courtesy, General Radio Co.)

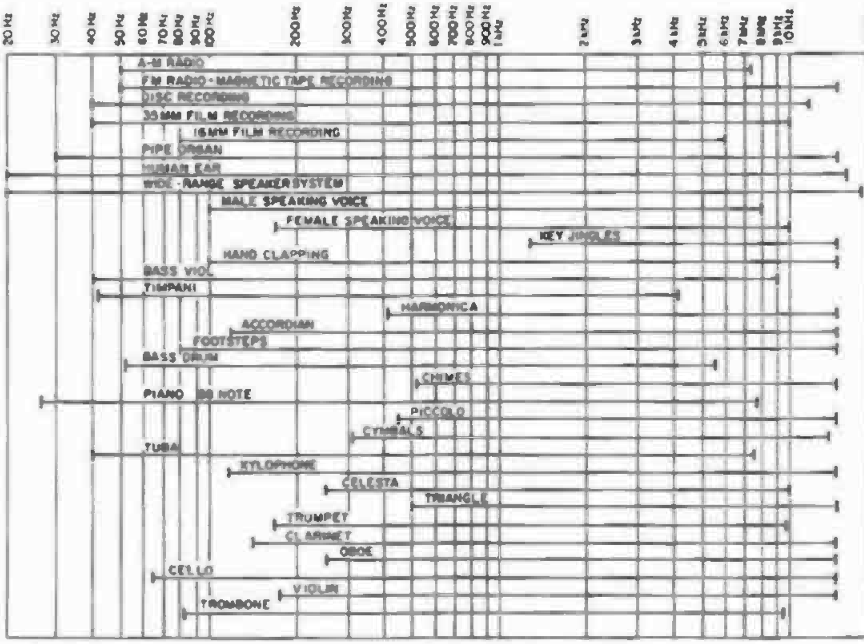

Fig. 1-131. Frequency range required for realistic reproduction of various sound sources.

—A comparison of the frequency ranges of the human voice, recording and broadcast systems, and the human ear is shown in Fig. 1-131. The ranges shown include the fundamental frequencies and their harmonics, with the frequency range indicated for faithful reproduction. Some types of musical instruments generate noise and subharmonics having frequencies below the fundamental frequency. In some instances the fundamental frequency is so low in intensity that it may be filtered out without discerning any change in the characteristics of the instrument. The frequency ranges shown include the more commonly used instruments.

1.132 What are the intensity levels of musical instruments used in an orchestra when referred to the threshold of hearing?

Piano	60 to 100 dB
Organ	35 to 110 dB
Bass drum	35 to 115 dB
Trumpet	55 to 95 dB
Violin	42 to 95 dB
Tympani	30 to 110 dB
Cymbal	40 to 110 dB

The above are intensities measured at a distance of 10 feet from the instrument.

1.133 What value of sound velocity is used in scientific measurements?—For scientific measnrements, the velocity is taken as 1087.42 feet per second, or 331.4 meters per second, at a temperature of 0°C, with zero moisture content at a pressure of one atmosphere. For sound measurements the velocity is taken as 1127 feet per second, or 343.4 meters per second, at a temperature of 20° C. (See Question 1.50.) The speed of sound for any given temperature is:

$$V = \frac{1087 \sqrt{(273 + t)}}{16.52}$$

where,

V is the speed of sound in feet per second,

t is the temperature in degrees Celsius..

1.134 Define the term liveness factor.—This term is associated with the liveness or brilliance of an auditorium or recording stage. Liveness is the sound coming from the source and the reflected sound that an observer hears. The greater the reflected sound, the greater the liveness of the enclosure.

Liveness in recorded or radio sound reproduction creates the illusion that the program is coming from a large auditorium. Liveness may be calculated:

$$L = \frac{1000\,T^2\,D^2}{V}$$

where,

T is the reverberation time of the enclosure in seconds,
D is distance of the sound source from the observer,
V is the volume of the enclosure in cubic feet.

1.135 What is an acoustic shadow? —It is a region of reduced sound pressure, caused by an obstacle in the path of travel of a sound wave. The size and reduction in the intensity of the sound will be governed by the size and shape of the obstacle and the wavelength of the sound wave.

1.136 What is the frequency irregularity of an enclosure?—The irregularity per one-cycle bandwidth expressed in decibels per cycle.

1.137 What is the transmission irregularity of an enclosure?—For an arbitrary band of frequencies, it is the sum of the crest values in decibels, minus the sum of the valley values, also in decibels.

1.138 How much harmonic distortion can the human ear tolerate before the reproduction becomes objectionable? —Experimental data indicate for the modern reproduction, the latitudes shown in Fig. 1-138.

If the high frequencies are cut off at 2750 Hz, up to 15 percent may be tolerated, or about 48 percent intermodulation distortion for the same cutoff frequency.

Adequate phsychological tests have not been made to determine the amount of intermodulation distortion the human ear will tolerate. However, it will suffice to say, amplifiers having low percentage of intermodulation distortion generally sound cleaner than those having a comparable amount of harmonic distortion. For high-quality reproduction, a reproducing system must have less than 1 percent intermodulation distortion. (See Question 1.144.)

1.139 What are the peak powers in watts reached by instruments used in a symphony orchestra?

36-inch bass drum	24.6 watts
15-inch cymbal	9.5 watts
Snare drum	11.5 watts
Piano	0.267 watt
Piccolo	0.084 watt
French horn	0.053 watt
Violin	0.025 watt

As shown above, a bass drum will generate a peak power of 25 watts while a violin will generate only 0.025 watt. This shows the need for an amplifier of considerable power for driving the loudspeaker system, if the recorded material is to be reproduced with realism and low distortion.

To illustrate this point, if a bass drum is struck simultaneously with a violin, 25 watts of power must be handled at the low frequencies while reproducing only 0.025 watt of power for the violin in the higher frequencies. Both these frequencies must be reproduced in their proper perspective covering a frequency range of 30 to 18,000 Hz.

Although a single diaphragm speaker will have difficulty reproducing this type of program material in its true form, it can be reproduced in a fairly satisfactory manner.

The reason this extreme combination of frequencies and powers can be reproduced at all is that the loudspeaker diaphragm responds to different frequencies over various areas of its diaphragm, vibrating around the apex of the diaphragm for the higher frequencies while radiating the lower frequencies from around the areas near the rim of the diaphragm.

In this manner a single-diaphragm type radiator is able to reproduce two or more tones of widely differing powers and frequencies, in more or less the original relationship.

The foregoing discussion illustrates why a multiple speaker system is desirable, because each speaker in the system is confined to a given frequency band. Thus, the greatest efficiency is obtained from each speaker.

	Music	*Speech*
Acceptable	0.7 percent	0.9 percent
Tolerable	1.3 to 1.8 percent	1.9 to 2.8 percent
Objectionable	2.0 to 2.5 percent	3.0 to 4.2 percent

Fig. 1-138. Latitudes in tolerable harmonic distortion.

To smooth out the frequency response where the loudspeakers cross over, a crossover network is used with a tapering cutoff frequency response. This subject is discussed in detail in Section 20.

1.140 What is white sound?—A complex waveform in which the higher frequencies get successively less in amplitude, with steep wavefronts similar to a sawtooth waveform. White sound includes all sounds perceptible to the human ear. A sawtooth waveform consists of a fundamental frequency and even harmonics, while a square waveform includes only the fundamental and odd harmonics. The sawtooth form of sound is called white noise because it is analogous to white light.

1.141 What is pink sound?—White sound was explained in Question 1.140; it contained all frequencies perceptible to the human ear. When the output of a white-noise generator is viewed on an oscilloscope or a graphic level recorder, it displays a rising characteristic of 3 dB per octave, Fig. 1-141A. To bring the response to an equal energy level (uniform output), a pink-noise filter, having an inverse frequency characteristic, is connected in the output of the signal generator. If the output is now mea-

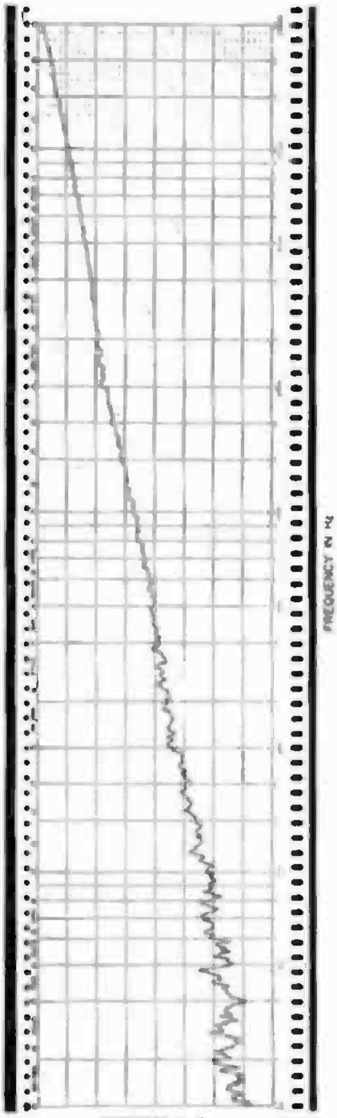

Fig. 1-141A. Output of white-noise generator without pink-noise filter.

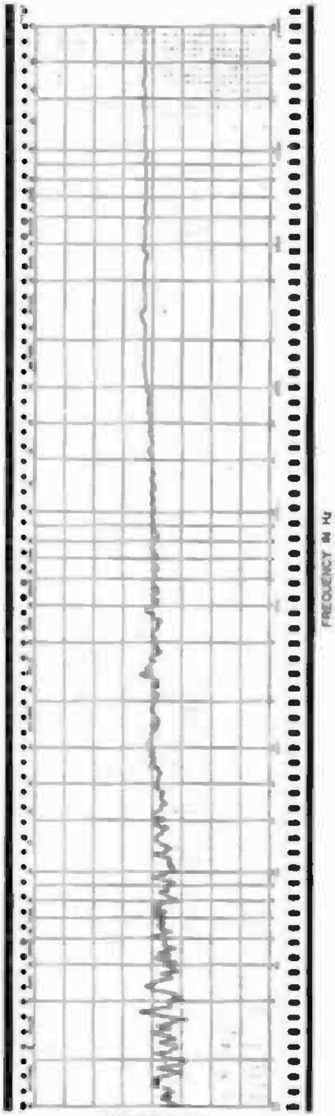

Fig. 1-141B. Output of white-noise generator with pink-noise filter.

sured, it will display a uniform output signal, as in Fig. 1-141B. The signal is now termed pink noise. The sole purpose of the pink filter is for the convenience of measurement. The use of random or white-noise generators is discussed in Sections 22 and 23.

1.142 What is black sound?—It is a term used to denote inaudible sounds. Audible sounds are often referred to as white sound. This latter term is not to be confused with the term white sound as described in Question 1.140.

1.143 What is scale distortion?—When speech or music or both are reproduced in an enclosure such as a room, and at the same acoustic level as the original program material, the reproduced quality will be the same as the original program material.

If the level of reproduction is lowered, a lack of both high and low frequencies will be noted. In some instances a loudness control may be used to correct for this effect. Loudness controls are discussed thoroughly in Question 5.65.

1.144 Explain phase shift, its causes, and the amount that the human ear can tolerate.—Phase shift is caused by the delaying of certain frequencies of a complex waveform in its passage through a sound system or device. The greatest delay is generally at the higher frequencies, particularly harmonics of the fundamental frequency, and is induced by the reactive components of the device or system. If two tones are applied simultaneously to the input and one tone arrives at the output behind the other, phase distortion exists. However, phase distortion is relatively unimportant in a sound system, unless it is great enough to produce a time delay greater than 8 milliseconds at the high frequencies and more than 15 milliseconds below 100 Hz. Phase shift in sound systems is generally measured relative to 1000 Hz. *There is considerable disagreement by engineers, as to how important phase distortion really is.* (See Question 1.138).

1.145 What is listening fatigue and its cause?—The exact cause of listening fatigue is rather vague; however, it is known that such fatigue is not caused entirely by harmonic distortion, because amplifiers having a high degree of listening fatigue will show a low percentage of distortion.

Experience indicates that amplifiers with 1 percent or less harmonic distortion have little effect on the listener. A well-known authority has stated that first order beat-tone intermodulation is of the greatest importance.

This type of distortion may be measured by applying two frequencies not harmonically related to each other to the input of an amplifier and then measuring the sum and difference frequencies at the output. Distortion due to sum and difference frequencies is very annoying because of its nonharmonic relation to the fundamental frequencies of the program material.

1.146 Can sound be transmitted without a medium?—No. This may be demonstrated by the classical experiment of placing an electric bell in an evacuated chamber. If a good vacuum is maintained, no sound will be heard from the bell. If the air is slowly let into the chamber, the bell will be heard, faintly at first and, as more air is let in, the sound of the bell will increase in intensity. With normal atmospheric pressure, the bell will be heard at its normal intensity. The above experiment proves that sound requires a medium for its transmission.

1.147 What is the minimum change in sound level the human ear can detect?—Psychologists have devised various experiments to determine what changes in level can be observed by the average person with good hearing faculties. Under laboratory conditions, when two different levels are presented to the observer, with little time delay between, the observer can detect a difference of 0.25 dB for a 1000-Hz tone at high levels. This sensitivity to change will vary with levels and frequency, but over the range of most interest this differential sensitivity is about 0.25 to 1.0 dB. When the observer is exposed to wide-range random noise (white noise) the detected change is on the order of 0.05 dB, for sound pressures of 30 to 100 dB above 0.0002 microbar (threshold of hearing). Under average conditions, the minimum change likely to be detected is 1.0 dB.

1.148 Define an intertone.—When the human ear hears two tones of nearly the same frequency sounded together, the ear does not recognize them as separate frequencies, but as a single tone. The pitch will lie between the two frequencies, and it is referred to as iutertone.

1.149 Define the term Gaussian noise.—Thermal noise is present in every component of an electronic circuit, and establishes a minimum noise level, under ideal conditions. Thermal noise is said to be white noise and Gaussian. White noise means it has equal power distribution throughout the spectrum, and Gaussian means that the instantaneous magnitude is distributed in accordance with the law of probability, propounded by Karl F. Gauss. (See Question 1.140.)

1.150 What is speed hearing?—It is an electronic device, developed by R. H. Miller of the Bell Telephone Laboratories, which allows hearing of recorded speech at word rates comparable to speed reading. This device uses a harmonic compressor, and has been given to the American Foundation for the Blind. This compressor divides into half the frequency components (harmonics) in a voice recording, while preserving the original time duration. By the doubling of the half-frequency recording, the frequency components are restored to their original values, resulting in normal pitch for a double-speed recording.

The operating principle of the harmonic compressor is as follows: Speech is fed into a bank of 36 bandpass filters, which separate the speech into different frequency components. Output from the filters is fed into 36 frequency dividers, which have the frequencies of the narrow-band signals. The halved-frequency is fed to networks which remove distortion and combine the 36 halved signals into one, where the frequency components are one-half the original input values. This harmonically compressed signal is then recorded on magnetic tape where, by doubling the speed, its halved-frequencies are restored to their original values. Thus the syllabic rate is doubled, without doubling the pitch of the speech.

Speakers who record for the blind speak at an average rate of 160 to 170 words per minute. Doubling the speed without increasing the pitch results in word rates of 320 to 340 words per minute. This compares to average speed-reading rates of 300 to 400 words per minute.

1.151 What is a voice print?—It is a system developed by Lawrence G. Kersta of Bell Telephone Laboratories, for the positive identification of voices, and is similar to the taking of fingerprints. Because each individual develops his own approach to the pronounciation of a given word or sound, and is influenced by the physical characteristics of the vocal cavities and vocal cords, voices can be identified. It is claimed that over 97 percent accuracy was achieved in 50,000 voice prints by this system of identification.

1.152 Can decibels be added or subtracted directly?—No, being a logarithmic value, they cannot be added or subtracted directly. To simplify such operations, the graph in Fig. 1-152 may be used. To add decibels, the graph is entered at Numerical Difference Betweeu the Two Levels Being Added. Follow the line to its intersection with the curved line, then read the Numerical Difference Between Total and Larger Level. Add this value to the larger level to determine the total level. As an example, assume 75 dB and 80 dB are to be combined; the difference is 5 dB. The 5 dB line intersects the curved line at 1.2 dB on the vertical scale. Thus, the total value is 80 + 1.2 or 81.2 dB.

To subtract decibels, enter the graph at Numerical Difference Between Total and Larger Levels, if the value is less than 3 dB. If the value is between 3 and 14 dB, enter the graph at Numerical Difference Between Total and Smaller Levels. Follow the line corresponding to this value to its intersection with the curved line, then either left or downward read Numerical Difference Between Total and Larger (or Smaller) Levels. Subtract this value from the

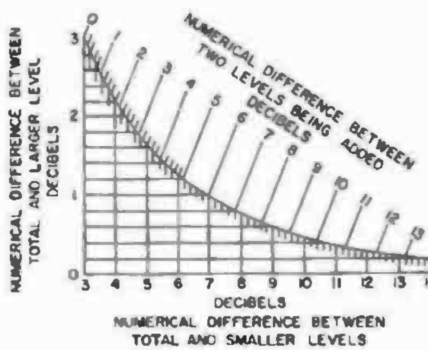

Fig. 1-152. Graph for adding or subtracting decibels (after Musa). (Courtesy, General Radio Co.)

total level to determine the unknown level. As an example, subtract 81 dB from 90 dB; the difference is 9 dB. The 9 dB line intersects the curved line at 0.6 dB on the vertical scale. Thus, the unknown level is 90 minus 0.6 or 89.4 dB.

1.153 What effect does background noise have on acoustic measurements?—Assume a recording stage is being measured, with a ventilating system in operation. How much noise does the ventilating system contribute to the overall noise level? Two measurements are made, one with the system on and one with it off. To ascertain how much the ventilating system contributes, the graph in Fig. 1-152 may be used.

The stage without the ventilating system measures 33 dB (using a sound level meter) and with the ventilating system operating, 37 dB. The difference is 4 dB. Referring to the chart and entering the bottom at a value of 4 dB, following the vertical line to where it intersects the curved line, at the left margin is read 2.2 dB. This value is subtracted from the total measurement (37 dB) leaving a total noise level of 34.8 dB. Therefore the SPL is only increased 2.2 dB when the ventilating system is in use.

1.154 Define the term "G."—The quantity "G" is the acceleration produced by the force of gravity, which varies with latitude and elevation of the point of observation. By international agreement, the value 9.80665 cm/sec^2 equals 386.087 in./sec^2 equals 32.1739 ft/sec^2, has been chosen as the standard acceleration of gravity.

1.155 What is the relationship between sound pressure level (SPL) and acceleration in G's?—A table of sound pressure levels (SPL) in decibels (re 0.0002 microbar) relative to the acceleration in G's is given in Fig. 1-155.

Level in dB	*Accel in G's*	*Level in dB*	*Accel in G's*

Section 2

Acoustics, Studio Techniques, and Equipment

While acoustical engineering is a science within itself, it plays an important role in the daily routine of the audio engineer. This section sets forth the basic principles of acoustics, as applied to sound waves in open air or enclosures. It also deals with treatments of rooms and stages used for recording and reproduction, reverberation characteristics, noise reduction coefficients of acoustic materials, and the shape of enclosures for optimum characteristics. Design factors are given for dubbing and looping stages, soundlocks, monitor rooms, projection facilities, reverberation chambers, and auxiliary equipment, diffusers, flats, microphone booms, tempo regulators, and synthetic reverberation units. Techniques for setting-up stages, and microphone placement for small intimate groups or large symphonic orchestras are discussed. Explanations of anechoic and reverberant chambers, Rayleigh disc, Helmholtz resonator, weighted curves, ambiophonic reproduction, wave trains, sound power, and sound levels are given.

2.1 ***Define the term acoustics.***—It is a science dealing with the production, effects, and transmission of sound waves; the transmission of sound waves through various mediums, including reflection, refraction, diffraction, absorption, and interference; the characteristics of auditorium, theaters, and studios, as well as their design.

2.2 ***Define acoustic impedance.***—It is the force per unit area on a given surface of a sound medium divided by the flux through that surface. Expressed in ohms, it is equal to the mechanical impedance divided by the square of the surface. The unit of measurement is the acoustic ohm.

2.3 ***Define acoustic ohm.***—A unit of acoustic resistance. It is equivalent to a sound pressure of one dyne per square centimeter producing a volume velocity of one cubic centimeter per second. It is also used when referring to acoustic impedance or reactance.

2.4 ***What are the preferred frequencies for acoustical measurements?***—In January 1960, The Acoustical Society of America sponsored the USASI(ASA) Standard S1.6-1960, covering the frequencies recommended for acoustical measurements. These frequencies are given in Fig. 2-4 and the order of preferences is indicated by the size and style of type. It will be noted that the order frequencies used for measurements, such as 256, 512, 1024, etc., have now been changed to 250, 500, 1000 Hz, etc.

Frequencies for use with bandpass filters are also given and are geometric center frequencies of the bands. For example, the lower and upper cutoff frequencies for an octave band filter centered on 8000 Hz are, respectively, 5600 Hz and 11,200 Hz, these being the preferred frequencies in the series of half-octave intervals. For certain measurement purposes, it may be convenient to depart slightly from the regular geometric series in order to obtain the nearest round-number approximation.

For audiometry, (see Question 22.42) in addition to octavely spaced frequencies, such as 1000, 2000, and 4000 Hz, the frequencies 3000 and 6000 Hz have been used rather than 2800 and 5600 Hz or 3150 and 6300 Hz.

2.5 ***What is an acoustic labyrinth?***—A specially designed baffle arrangement for use with a loudspeaker to re-

inforce the low-frequency response and prevent cavity resonance. Such a device is shown in Fig. 20-66.

A labyrinth is not always in the form of a baffle, but could be a tube filled with hair-felt, as is sometimes used in microphones.

2.6 ***What is an acoustic line?***—An acoustic equivalent of a sound chamber at the rear of a loudspeaker.

2.7 ***What is acoustic response?***—It is a measurement of the *reverberation* characteristics of an enclosure, which might be an auditorium or stage.

2.8 ***What is an acoustic pickup or sound box?***—A nonelectric pickup for reproducing disc records. A needle or stylus is connected by mechanical linkage to a mica or dural diaphragm. Flexing of the diaphragm, caused by the movement of the needle in the sound track of the record, disturbs the air in a horn to which the sound box is coupled. Movement of the air in the horn produces sound waves which are heard by the ear.

2.9 ***What is an acoustical equalizer?***—A small metal tube at the rear of a microphone to release the pressure behind the diaphragm, thus preventing mechanical distortion of the diaphragm which would, in turn, produce electrical distortion.

2.10 ***What is acoustic treatment?***—The application of acoustic or sound-absorbing material to a room or enclosure to obtain the desired acoustic characteristics.

2.11 ***What is an acoustic feedback?***—An audible howl or singing noise caused by sound waves feeding back from a loudspeaker to a microphone. It is generally caused by placing a loudspeaker too close to a microphone. Acoustic feedback can also be caused by sound leaking through air ducts.

2.12 ***What is meant by the term "a brilliant stage"?***—A stage in which the high frequencies predominate. Such stages are also referred to as being live or hot. This characteristic is caused by hard or reflective surfaces of the stage, such as ceilings, walls, floors, etc.

2.13 ***Define the term noise-reduction coefficient.***—It is the attenuation afforded by the acoustic treatment in an enclosure by the materials involved. In computing the reverberation time of an auditorium, stage, or theater, the absorption coefficients at a single frequency of 500 Hz is used (originally 512 Hz was used). In rating the effectiveness of absorbents in the reduction of room noise, the average coefficients of frequencies of 250, 500, 1000, and 2000 Hz are used. The average is then termed the noise-reduction coefficient or NRC. (See Question 2.4.)

2.14 *What is the effect of a high ambient noise level on human beings?*—Workers become irritable and fatigued; also, permanent injury to the hearing may result.

2.15 *What frequencies are most annoying to the human being?*—Frequencies above 2000 Hz.

2.16 *What is a flutter echo?*—A multiple echo in which the reflections occur in rapid succession. If the echo is periodic and in the audible range, it is referred to as a musical echo.

2.17 *What does the term "tubby" mean?*—Reproduction lacking in definition, or an accentuation of the low frequencies resulting in a barrellike reproduction.

2.18 *What is a dead room?*—One in which an overamount of sound-absorbing material has been used so that most of the high frequencies are absorbed. The reproduction from a room of this type will be dull and lacking in presence.

2.19 *What does the term "hangover" mean?*—Acoustically, it is undesirable reflections causing excessive echoes. In an amplifier, hangover is caused by a low internal damping factor. (See Question 12.177.)

2.20 *What is masking?*—The inability of an auditor to hear certain sounds because of the presence of other sounds. Masking is most noticeable at the higher frequencies.

2.21 *What takes place when a sound wave is reflected?*—When a sound wave is traveling through a medium such as air and encounters another medium such as water, cold air, or a solid object, and the second medium is larger in comparison to the wavelength of the emitted sound, part of the sound is reflected back from the object in a manner similar to a beam of light. The balance of the sound is absorbed into and transmitted by the second medium.

If the sound wave strikes the second medium at an angle, a large part will bounce off and will be reflected at an angle which is exactly equal to the angle of incidence. See Fig. 2-21A. If the emitted sound wave is in an enclosure similar to that shown in Fig. 2-21B, an observer situated as shown will hear reflected sound as well as the direct sound from the sound source.

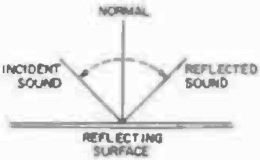

Fig. 2-21A. Reflected sound.

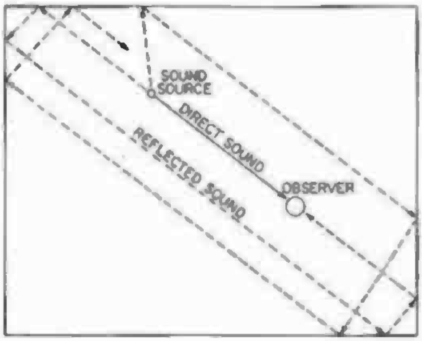

Fig. 2-21B. Reflected and direct sound in an enclosure.

Reflected sound has the effect of increasing the intensity, causing out of phase conditions, and adding reverberation. All of the above effects vary with the acoustical treatment of the enclosure. If the reverberation is excessive, the intelligibility is reduced.

2.22 *What is confusion or scattering?*—The jumbling of sound waves resulting from interference caused by objects in the path of transmission producing unintelligibility.

2.23 *Define interference.*—Interference is caused by sounds coming from different directions, or by reflection and mixing with the original sound. Under such conditions, the intensity of the sound may be increased or decreased, depending on the phase relationship of the waveforms at any given instant.

2.24 *What is rarefaction?*—The state of being less dense. The opposite of compression.

2.25 *Define diffraction.*—When sound encounters an object in its normal path of travel, it bends around the object, causing eddy currents behind the object. This is diffracted sound. Low frequencies bend around an obstacle more easily than high frequencies. This phenomenon is also called scattering.

2.26 *What is refraction?*—It is a change in the direction of a sound wave, caused by the nature of the medium of transmission. This can be caused by air temperature, since the

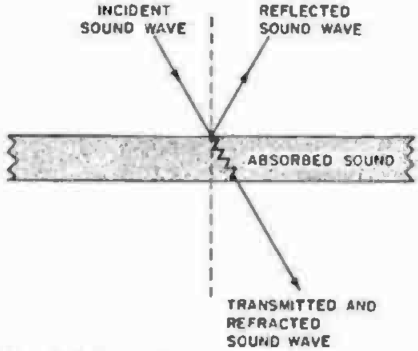

Fig. 2-26. Incidence, reflection, absorption, and transmission of a sound wave striking a flat surface. The term refracted is also applied to the transmitted sound wave because of its change of direction.

velocity of sound increases as the temperature increases. Refraction also takes place when a sound wave strikes a surface such as water or a wall, as shown in Fig. 2-26.

2.27 ***What is the angle of refraction?***—The angle measured between a perpendicular erected at the point of contact with a surface and a wave, ray, or beam refracted from that surface.

2.28 ***What is dispersion?***—The separation of a complex sound wave into its frequency components, caused by a change in velocity. This action is analogous to sunlight being passed through a prism. (See Fig. 2-28.)

2.29 ***What is acoustic absorptivity?***—The ratio of sound energy absorbed by the surface of a given material to that which arrives at the surface from the source. A porous material will break up a wave train, slow the waves down, and, finally, absorb them. The action is similar to water on blotting paper.

2.30 ***What standard is used for comparison when rating the coefficient of absorption of acoustic materials?***—One square foot of air, free from reflections.

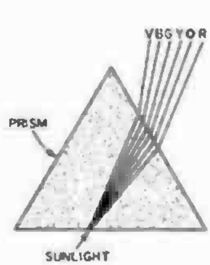

Fig. 2-28. Dispersion of sunlight through a prism.

2.31 ***Is the absorption coefficient of acoustic materials the same for all frequencies?***—No. It is not constant and varies with frequency and the angle of incidence. Generally, the data given for acoustic materials are for a frequency of 500 Hz. However, data for other frequencies are available from the manufacturer of the material. A table of absorption coefficients is given in Question 2.32.

2.32 ***What are the absorption coefficients for general building materials and furnishings?***—See Fig. 2-32.

2.33 ***What is a sabin unit?***—A unit of absorption equivalent to the absorption of 1 sq. ft. of surface which will absorb all incident energy. The unit is named for its originator, Wallace C. Sabine.

2.34 ***Define the term reverberation period.***—It is the time required for a sound in an enclosure to die away to one-millionth of its original intensity, or decrease 60 dB. The reverberation time of any enclosure may be calculated by the formula:

$$T = \frac{V \times 0.049}{AS}$$

where,

- T is the reverberation time in seconds,
- V is the volume of the enclosure in cubic feet,
- A is the average absorption coefficient of the enclosure,
- S is the total surface area in square feet.

Reverberation is the persistence of sound within an enclosure after the original sound has ceased. Reverberation may also be considered as a series of multiple echoes, decreasing in intensity, so closely spaced in time as to merge into a single continuous sound and eventually be completely absorbed by the treatment of the enclosure and to a degree, by dissipation of the energy into the air. However, this latter factor is generally ignored and only the wall treatment is considered.

If a loudspeaker is placed in a room and a continuous frequency applied, a wave train will be built up, spreading in all directions. Upon striking the boundaries of the room, the wave train is partially absorbed and partially re-

Coefficients above were obtained by measurements in the laboratories of the Acoustical Materials Association. Coefficients for other materials may be obtained from Bulletin XXII of the Association.

Fig. 2-32. Absorption coefficients for different materials.

flected not once but hundreds of times. Thus, the average intensity of the sound is built up to a steady state, in which the rate of emission just equals the rate of absorption at the boundaries. This indicates that time is required to set the body of air in an enclosure in motion.

If the source of sound is now cut off, the sound does not cease immediately, but generally dies away. The average intensity at any one instant decreases at a rate which is proportional to the average intensity at that instant. This indicates the logarithm of the average intensity is decreasing at a uniform rate, or the drop in intensity level expressed in decibels is proportional to the time measured at the instant of cutoff of the sound source.

Fig. 2-34C shows an oscilloscope display of a decay recorded in an enclosure. It can be observed that the decrease in amplitude with time follows approximately the average curve of the right half of Fig. 2-34A, but with a larger fluctuation thereafter.

Reverberation has considerable ef-

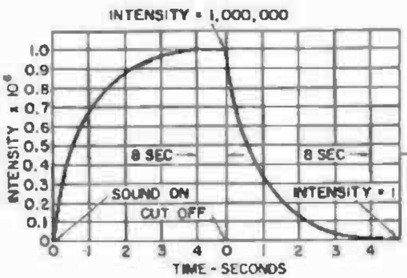

Fig. 2-34A. Typical decay curve. Plotted time versus intensity.

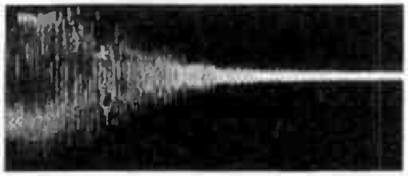

Fig. 2-34C. Oscilloscope display corresponding to Fig. 2-34A.

fects on speech. If the auditor is close to the speaker, no great difficulty will be experienced in clearly understanding the speaker. If, however, the speaker raises his voice, each syllable is prolonged, running into succeeding syllables, with resulting confusion and loss of intelligibility. For music, individual notes are prolonged by the reverberation and have the effect of a piano played with the loud pedal held down continuously. To arrive at the reverberation time for a given enclosure, the area of each surface in the enclosure is multiplied by its absorption coefficient, and the sum of these, plus the absorption due to objects such as chairs, drapes, people, etc, gives the average absorption coefficient in the formula.

2.35 ***What is the recommended reverberation time for theaters, auditoriums, recording and broadcast studios?***— A graphical presentation of the recom-

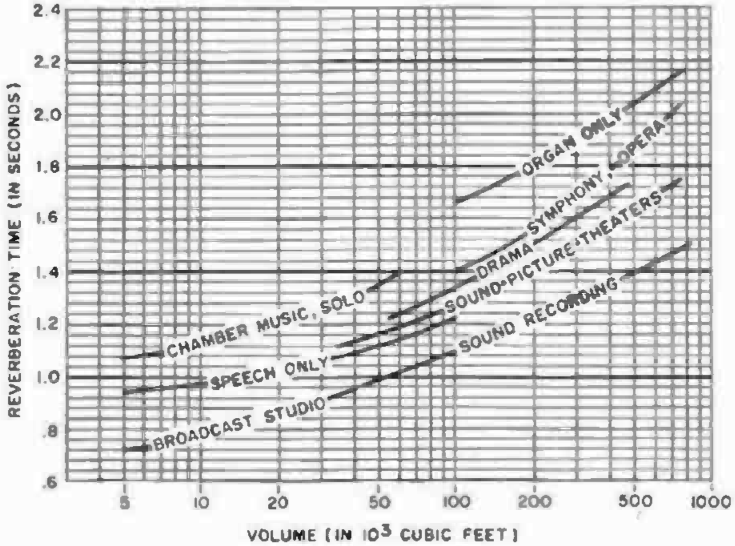

Fig. 2-35A. Recommended reverberation time for various types of auditoriums, at a frequency of 512 Hz.

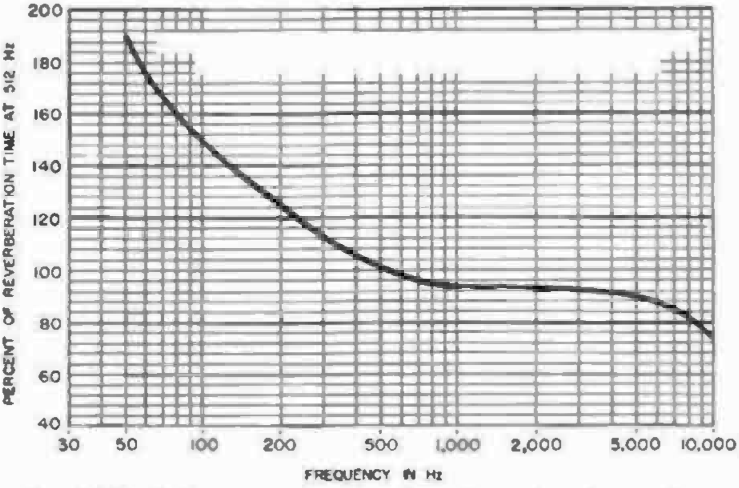

Fig. 2-35B. Optimum reverberation times for various frequencies.

mended reverberation time for various types of enclosures is shown in Fig. 2-35A. Fig. 2-35B shows the optimum reverberation time for different frequencies. In Fig. 2-35C is plotted the optimum reverberation versus room volume in cubic feet, at 512 Hz. (See Question 17.136).

2.36 ***Define optimum reverberation time, and tell how it is governed.***—Optimum reverberation time is the most desirable reverberation time for an enclosure of given dimensions. This is governed by the cubic volume of the enclosure and the absorption factors of the walls, ceiling, floor, and other furnishings.

2.37 ***How is artificial reverberation added to an auditorium, and what is the purpose?***—The basic purpose of adding artificial reverberation to an existing auditorium or stage is to control the acoustics electronically, and improve the overall acoustics of the enclosure.

It is common practice in broadcast and television studios to overtreat the studio to reduce the noise created by the movement of equipment and actors around the stage. If the treatment is carried to the extreme, as it sometimes is, the sound reproduction is flat to both the listener in the studio and over the air. It also has a pronounced effect on the musicians as the reproduction of their instruments does not sound normal and this leads to difficulties. To overcome this difficulty and still retain the heavy acoustic treatment, controlled electronic reverberation is induced into the enclosure or stage. This electronic system of reverberation is termed ambiophony, and has been used quite successfully by the British Broadcasting Co., and in several auditoriums and music halls in the United States.

Artificial reverberation can be achieved in several ways. One system employs an electromechanical device, using amplifiers and rods or springs for the delay networks. The electroacoustic system is similar, except echo chambers are used for the delay. A third system employs magnetic recording techniques. The signal is recorded on an endless magnetic tape, and the signals from several playback heads spaced at various distances from the recording head are combined. The all-electronic system employs logic circuits to provide the delay.

A typical installation might consist of as many as 60 loudspeakers placed around the walls and ceiling of an enclosure. The speakers radiate the orchestral music, through the time delays, and radiate about as much sound as the walls normally would if they were not highly absorbent. Each speaker has a time delay of such a value that it radiates at the approximate time it would take the sound to reach that particular speaker position in the studio. The randomness of true reverberation is achieved by not connecting the speakers according to the delay appropriate

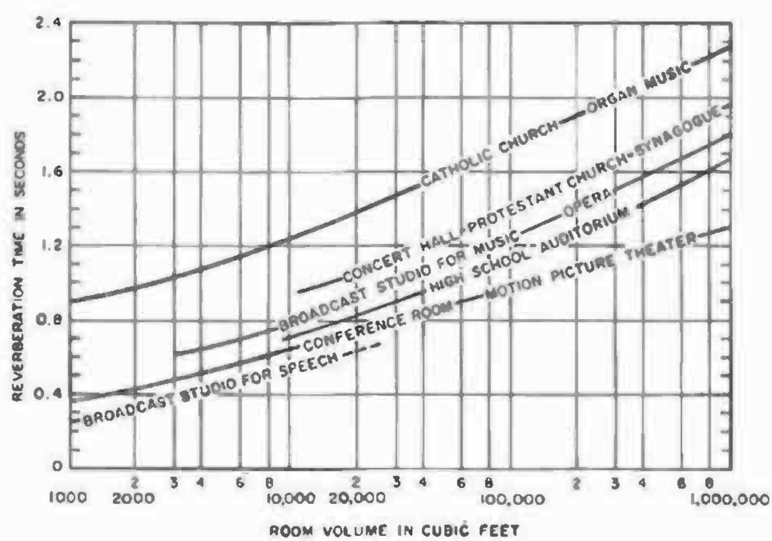

Fig. 2-35C. Reverberation time versus cubic volume, at 512 Hz.

to their exact position, although they generally approach their true position.

Because some regeneration is picked up by the microphones supplying the input to the reverberation system, care must be taken in adjusting the level of the system. Two completely separate microphone systems are used for feeding the broadcast and ambiophony systems, with the necessary equalization. Such installations are still in the experimental stage and each installation becomes a specialized system. Magnetic reverberation units are discussed in Question 17.136.

2.38 What requirements constitute an ideal studio?—According to Wallace C. Sabine, an outstanding authority in the field of acoustics and architectural design, they are: (1) that the sound in the studio be sufficiently loud; (2) that the components of a complex sound wave maintain their relative intensities; (3) that successive, rapidly moving sounds, either music or speech, be clear and distinct from each other; and, (4) that all extraneous noises must be reduced to a negligible amount.

2.39 What shape rooms are to be avoided when constructing enclosures for recording and reproduction of sound?—Flat, untreated surfaces; concave surfaces, as they concentrate and focus the sound; parallel walls, because they produce standing waves; and cubical shaped enclosures, because they produce standing waveforms. (See Questions 2.41 and 2.49.)

2.40 What are the preferred ratios of dimensions for studios and auditoriums?—The height, width, and length should be in the following ratios:

1. Small rooms ....1 to 1.25 to 1.6
2. Long rooms ....1 to 1.25 to 3.2
3. Average shaped rooms 1 to 1.6 to 2.5
4. Low ceiling rooms ...1 to 1.25 to 3.2

Number 3 indicates the preferred dimensions.

To minimize the effects of standing waveforms set up by parallel surfaces in an enclosure, it is desirable to choose the major dimensions that are not integral to each other. Resonance effects in an enclosure introduce frequency discrimination and create peaks and valleys in the characteristics of the room. Secondly, it introduces a persistence or hangover effect in the sound at or near resonance. Frequency discrimination results in a hollow sounding characteristic, especially if the resonant frequencies are widely separated (walls close together) which is generally the case in small rooms. The effects of resonance may be reduced by absorption, by changing the dimensions of the room, and by changing the shape of the reflecting surfaces.

By proportioning the three major dimensions in a ratio of the cube root of two (or multiple), good distribution of the natural resonances may be obtained. As an example using a ratio of 1:1.6:2.5 (average shaped room) for a ceiling height of 16 feet, the width is 25.6 feet (16×1.6) and it is 40 feet in length (16×2.5). For a small room using ratios of 1:1.25:1.6 with a ceiling of 12 feet, the dimensions are 12 ft $\times$ 15 ft $\times$ 19.2 ft, whereas in an average room the ratios change and the dimensions are then 12 ft $\times$ 19.2 ft $\times$ 30 ft. Diffusion and control of the high and low frequencies may be obtained by the use of polycylindrical diffusers explained in Question 2.76.

2.41 What are standing wave trains?—When a sustained tone is emitted in an enclosure consisting of parallel walls, a standing wave train is set up. Standing waves are created when two wave trains, moving in opposite directions, interfere. Walking along the room produces the sensation of an increase and decrease in the intensity of the sound. This sensation is noted because of passing through the zero and maximum peaks of the wave.

When a reflected waveform exactly matches compression with a rarefaction of the original sound wave, the sound waves reinforce themselves as they are reflected back and forth, thus increasing the amplitude. Reinforcement at critical frequencies can result in an increase of 20 dB or more. Serious reinforcement can occur when the wavelength is twice the ceiling height. Standing waveforms can also be generated at harmonic frequencies of the fundamental frequency.

Standing waves may be prevented by nonparallel walls, multilevel ceiling sections, and polycylindrical diffusers on the walls and ceilings, as in Fig. 2-66B.

2.42 What is the effect of a long reverberation time?—Both speech and music will be blurred and may become unintelligible, because of the overlapping of successive sounds.

2.43 Explain the purpose of diffusion in a studio. Diffusion in a studio improves the acoustical response because the energy in the room is not reduced and the reflections which occur per unit of time are increased. Thus, the intensity level of the individual reflections is reduced, and the reverberation characteristic smoothed out, resulting in a higher intelligibility and an added definition to both music and speech.

2.44 What is the frequency range required for high quality reproduction of speech and music?—For speech only, 100 to 6000 Hz with a volume range of 40 dB. For music, 40 to 15,000 Hz, with a volume range of 70 dB. Most audio systems designed for high-quality reproduction will reproduce up to 20,000 Hz and higher, some extending up to 100,000 Hz. The question then arises: why such a wide frequency range? A wide frequency range is required for music to reproduce inaudible frequencies which beat with frequencies in the audible range, producing sum and difference frequencies. Such frequencies lend realism to the reproduction. However, to make use of such wide frequency bauds, the harmonic distortion and intermodulation distortion must be reduced to negligible amounts. Also, the distortion due to phase shift must be at a minimum and the frequency characteristics uniform.

2.45 What is the recommended cubic footage per person for 35-mm and 70-mm motion picture theater projection?—In the past years the cubic footage per person recommended for theaters projectiug 35-mm films was approximately 125 cubic feet per person. However, with the advent of wide-screen projection systems and stereophonic sound reproduction, the space per person has been increased 250 percent or more. This is particularly true for theaters built for 70-mm projection.

Seating arrangements used in North America generally employ a layout whereby the aisles are placed down the center of the seating area or about one-third from the side walls. In this arrangement, erroneous localization of stereophonic sounds often results in the picture action and sound not coinciding. This has been overcome to a great extent by the use of *Continental* seating arrangements (as used in Europe) whereby the aisles are placed along the *side walls* rather than in the seating area.

Using the above arrangement optical distortion of the picture is reduced, and better sound reproduction is obtained for those seated at the sides of the theater. This has also led to the redesigning of the floor rise, and spacing of the seats. Nonparallel walls and special treatment of the side and rear walls reduce the effect of flutter echoes. Details of this type seating arrangement are given in the reference.

Review rooms and small theaters used on motion picture lots where the seating capacity is between 20 and 40 people generally employ about 250 to 500 cubic feet per person.

2.46 What effect does an audience have on the acoustics of a theater?—Unless the house has been specially designed, the effect may be considerable. The projectionist generally increases or decreases the reproduced sound level when the audience decreases to about half-house. Modern theaters have overcome this problem by using seats which have an absorption coefficient equivalent to the average person, thus reducing the need for frequent changes in the sound level.

2.47 What amplifier power is recommended for motion picture theaters?—The power requirements are given on the graphs of Fig. 2-47A and Fig. 2-47B. The shaded portion of the curve indicates the minimum and maximum recommendations. Since the average theater amplifier system must have a fairly wide dynamic range and be capable of handling heavy sound effects, an amplifier on the heavy side should be selected rather than one that will just meet the requirements. Present-day theaters require at least 40 watts of power with low distortion and noise. It is not uncommon in the larger theaters to find amplifier installations with 100 to 250 watts of power output. Power output versus seating capacity of a theater is shown in Fig. 2-47A, and power versus volume in cubic feet is shown in Fig. 2-47B. These data are based on recommendations of the Motion Picture Research Council.

2.48 Define acoustic reflectivity (reflective coefficient).—The acoustic re-

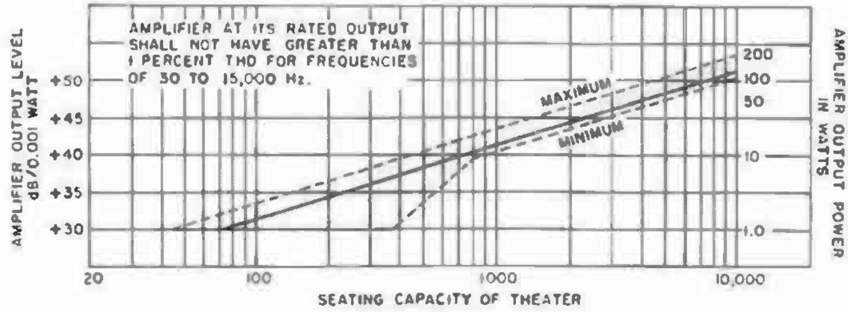

Fig. 2-47A. Relationship of optimum amplifier power output versus theater seating capacity.

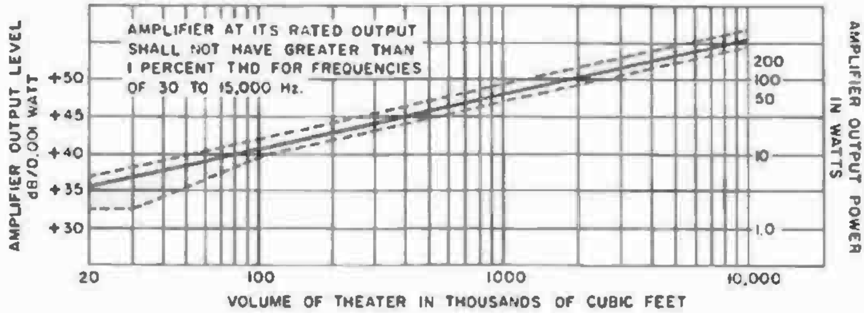

Fig. 2-47B. Relationship of optimum amplifier power-output level to theater volume in cubic feet.

flectivity of a surface is not a generator; it is the ratio of the rate of flow of sound energy reflected from a surface to that of the incident rate of flow, and may be calculated:

$$\frac{\text{incident rate of flow of sound energy}}{\text{reflected rate of flow of sound energy}}$$

Unless otherwise specified, all possible directions of incident flow are assumed equal, and values given apply to a portion of an infinite surface thus eliminating edge effects.

2.49 ***What shape walls are recommended for theater construction?***—The walls should be nonparallel or convex shaped, as shown in Fig. 2-49. The cubical volume should be in accordance with the seating capacity recommendations given in Question 2.45.

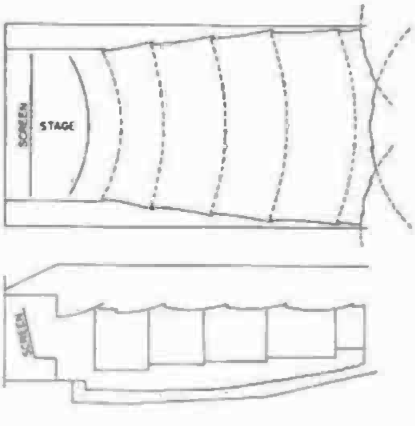

Fig. 2-49. Recommended wall shapes for motion-picture theater construction.

The auditorium width should be from 50 to 70 percent of the length and the ceiling height not more than 40 percent of the length. Nonparallel surfaces should be employed. The walls and ceilings must be broken up thoroughly to diffuse the sound.

The average absorption per square foot of floor space should be the same as for the ceilings and walls. The seats should be well upholstered and the aisle carpets Ozite-lined. The backstage area should be so shaped and acoustically treated that resonant reinforcements of sound will not be reflected to add distortion to the reproduction in the auditorium.

2.50 ***How are low-frequency vehicle and earth rumbles prevented from being***

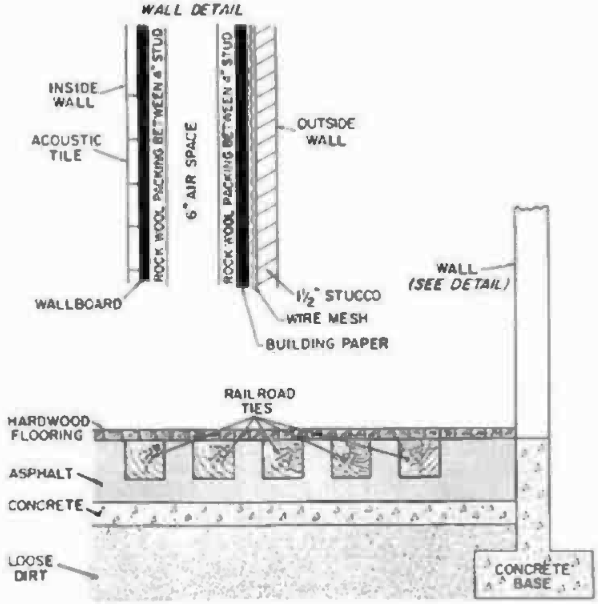

Fig. 2-50A. Cross-sectional construction of a motion-picture sound-stage wall, floor, and foundation.

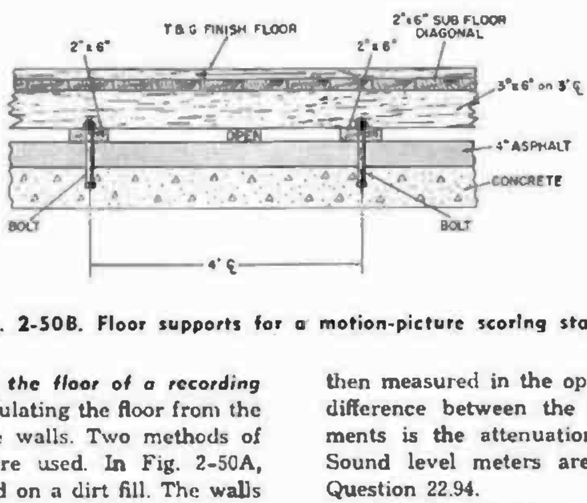

Fig. 2-50B. Floor supports for a motion-picture scoring stage.

transmitted to the floor of a recording stage?—By insulating the floor from the earth and side walls. Two methods of construction are used. In Fig. 2-50A, the floor is laid on a dirt fill. The walls are supported on rockers set on a cement foundation. In Fig. 2-50B, the floor is supported on 3×6-inch beams supported by 2×6-inch members laid on an asphalt fill on a cement foundation.

The interior construction of a typical scoring stage is described in Question 2.66.

2.51 How is the attenuation of the wall illustrated in Fig. 2-50A measured?—A Klaxon horn is placed against the outside wall and the sound transmission through the wall is measured with a sound level meter at a point near the wall. The sound level of the Klaxon is then measured in the open air and the difference between the two measurements is the attenuation of the wall. Sound level meters are discussed in Question 22.94.

2.52 Describe the use of lead sheeting for acoustic treatment.—For many years, it has been known that lead can be used in the acoustical treatment of an enclosure, and that the greater the weight per square foot of isolation, the greater the transmission losses. The acoustical efficiency of any material as a sound barrier depends not only on its weight, but on its stiffness. Lead is classed as a heavy limp material, having a density of two to three times that of most building materials, and 10 to 15 times that of wood. Lead is a limp material, in an acoustical sense. It has been demonstrated that if two equally effective barriers are constructed, one of lead and the other of conventional building materials, the lead barrier will be the lighter of the two.

If the transmission loss of a lead partition is plotted against frequency (Fig. 2-52A) it will show the loss increases with frequency up to the point where the transmission loss reaches approximately 55 dB. Above this frequency, a dip in the transmission loss occurs. At the lower frequencies, the loss is set by the

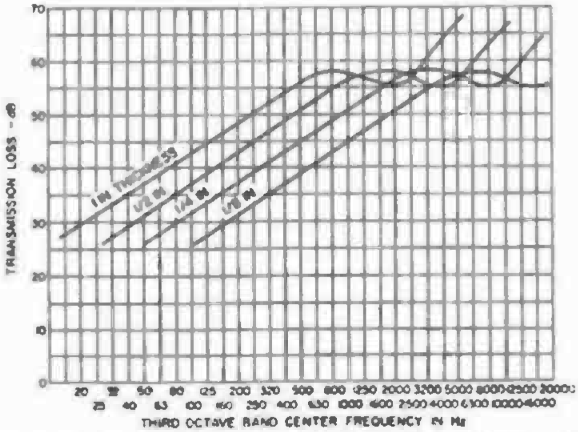

Fig. 2-52A. Transmission loss through solid chemical lead walls. (Courtesy, Lead Industries Association)

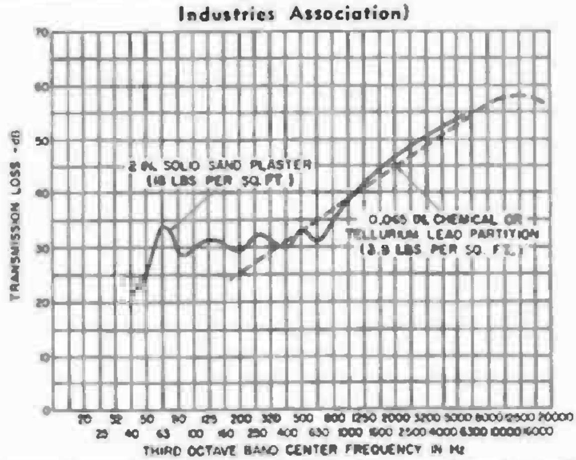

Fig. 2-52B. Comparison of a 2-inch solid sand-plaster wall and a wall of 0.065-inch lead. (Courtesy, Lead Industries Association)

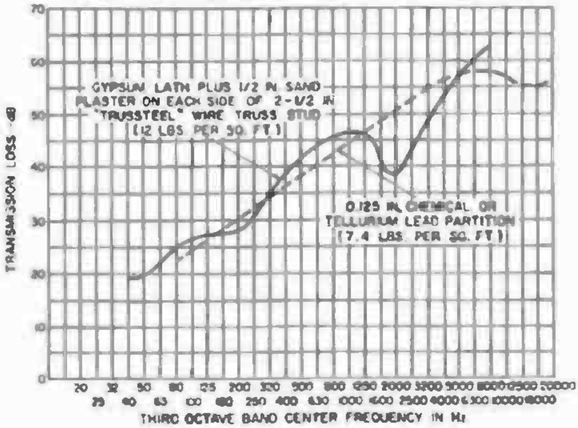

Fig. 2-52C. Comparison of plaster wall and 0.125-inch lead wall. (Courtesy, Lead Industries Association) weight of the lead. The dip in the characteristic at the higher frequencies is caused by the stiffness of the lead.

For existing enclosures, lead cloth, similar to leaded vinyl plastic may be used in wall paper fashion. Lead sheets 1/16-inch thick can be obtained with wood veneer laminated to one side of the sheet, with a pressure sensitive adhesive on the opposite face.

Fig. 2-52B is a plot of a 2-inch solid sand-plaster wall, compared to an 0.065-inch lead wall. In Fig. 2-52C a lead wall 0.125-inch thick is compared to a plaster and stud wall, and in Fig. 2-52D a staggered stud wall is compared to a 0.23-inch lead wall. Lead is also useful in isolating floors and stages from building structures, and increasing the transmission loss through monitor rooms and vocal room walls. It is also excellent for reducing the noise of rotating machinery. A suggested barrier for high-intensity low-frequency sounds is shown in Fig. 2-52E. The lamination consists of vinyl film, 1/8-inch lead sheet, 3 inches of low-density Fiberglas, 1/8-inch lead, and a final cover of vinyl plastic.

2.53 ***What differences may be expected between the theoretical and practical designs for an enclosure of given dimensions?***—The absorptivity of acoustic materials varies with the angle of incidence. Using the absorption coefficients supplied by the manufacturer of the particular material at hand, results in a mean value. Actual measurements made in an enclosure may not coincide with the theoretical reverberation time. This may be due to the lack of sound diffusion causing constant reflection angles.

2.54 ***What effect does a highly polished surface have on sound waves?***—It reflects the sound waves in a manner

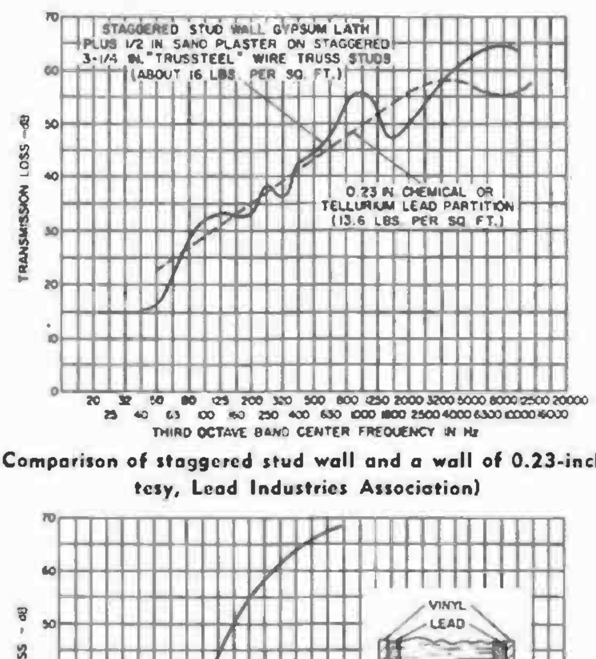

Fig. 2-52D. Comparison of staggered stud wall and a wall of 0.23-inch lead. (Courtesy, Lead Industries Association)

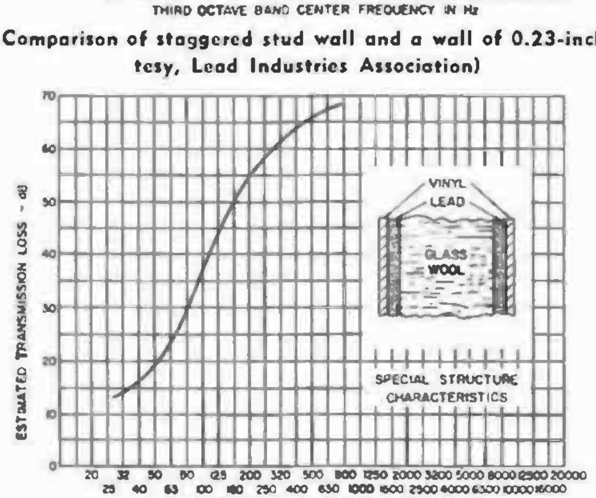

Fig. 2-52E. Suggested construction of a barrier for high-intensity, low-frequency isolation. (Courtesy, Lead Industries Association)

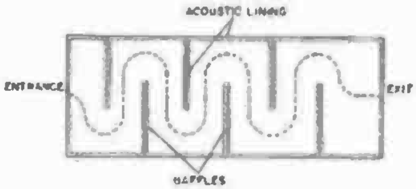

Fig. 2-55. An air duct with sound baffles.

similar to a mirror. (See Fig. 2-21A.)

2.55 *How can sound be prevented from entering an enclosure through an air duct?* —The duct is lined with an acoustic sound-absorbing material such as rockwool or *Ultracoustic*. Baffles covered with the same material are placed at intervals in the duct, as shown in Fig. 2-55.

2.56 *Define acoustic transmittivity.* —The acoustic transmittivity of an interface or spectrum is the ratio of the rate of flow of transmitted sound energy to the rate of incident flow. All directions of incident flow are assumed to be equally probable.

2.57 *Show the construction of a monitor room glass window.* —A typical installation is shown in Fig. 2-57. The glass panels are set in either cork or rubber seals at both the top and bottom, to prevent vibration of the glass from building noises. The glass must be of plate, at least ⅜-inch thick, and preferably ½-inch thick. The panel on the studio side is tilted at the top about 5 degrees to reduce light reflections, and

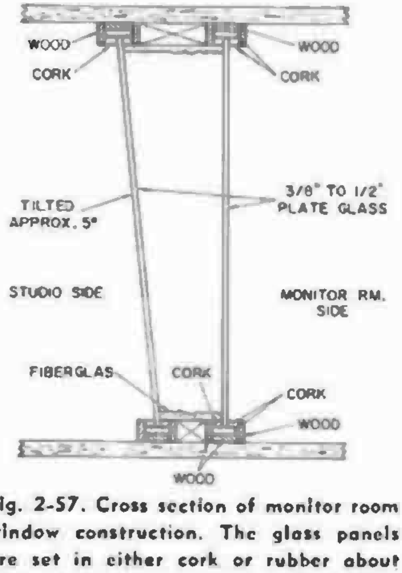

Fig. 2-57. Cross section of monitor room window construction. The glass panels are set in either cork or rubber about 6 to 8 inches apart at the bottom.

to prevent it from acting as a direct reflector in the studio. By using the construction shown, it is possible to achieve 50-dB reduction in sound transmission at 500 Hz.

2.58 *Show the reverberation characteristics for a music-scoring stage and a production-shooting stage.* —For music-recording stages, the desired reverberation will be somewhere between 0.8 and 1.8 seconds, depending on the cubic volume of the stage. After the acoustic treatment has been completed, reverberation measurements are made and additional treatment in the form of live and dead panels are added to bring the measured characteristic nearer the desired characteristic. If polycylindrical diffusers were not included in the original design, they may have to be added to secure the proper diffusion, and to control the low-frequency end of the frequency spectrum. Generally the final reverberation characteristic will be somewhat of a compromise between the desired and a practical characteristic. In Fig. 2-58A, the reverberation characteristic is shown for a music-scoring stage of 210,000 cubic feet, at Republic Corporation, North Hollywood, California. The actual measured reverberation time is plotted versus the ideal and desired characteristic, for comparison. Interior views of this stage are shown in Figs. 2-66A and 2-66B.

Motion picture production-shooting stages are treated in a different manner. These stages are designed to have a high rate of attenuation to outside noises and to prevent reflection from the walls, also to deaden sounds generated within the stage itself. As a rule, a production stage has a reverberation period of 0.6 second at 500 Hz. In the final analysis, the motion picture set will control the acoustics of the sound pickup by its construction materials. The reverberation characteristics for Stage 19 at Republic Corporation are shown in Fig. 2-58B. The volume of this stage is 600,000 cubic feet.

In both stages, the reverberation characteristics will be altered when they are in use. For the music stage, the reverberation characteristic at the higher frequencies will be decreased by the presence of the musicians and their equipment, while the production stage varies from time to time as sets are moved or changed and the number of

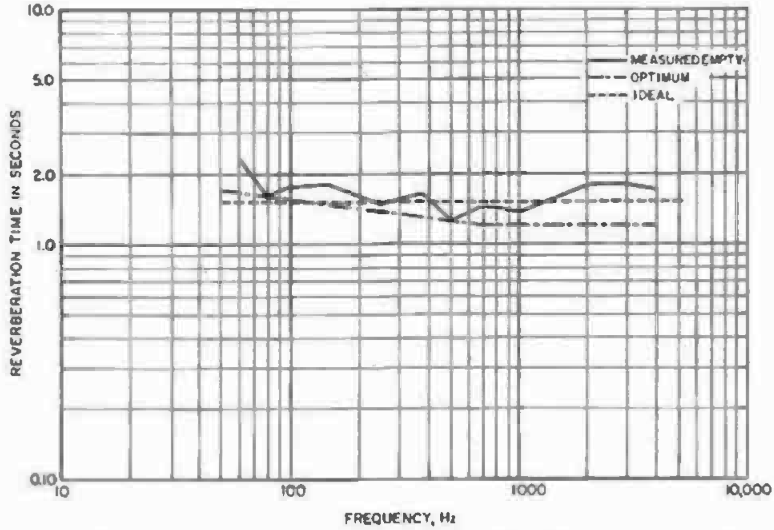

Fig. 2-58A. Reverberation characteristics of Republic Corporation music-scoring stage shown in Fig. 2-66A and 2-66B.

personnel and amount of equipment are varied.

2.59 ***How are the acoustic characteristics of a sound stage measured?***— The acoustic characteristics of a sound stage may be measured in several different manners. The simplest method is shown in Fig. 2-59A. Here a warble tone oscillator is applied to a power amplifier and a loudspeaker system, and frequencies of interest projected into the enclosure. The output from the loudspeaker is picked up, using a sound level meter, and the measurements plotted frequency by frequency. This method is not too accurate, and will give only a general idea of the enclosure characteristics, indicating the peaks and valleys caused by the generation of standing waveforms in the enclosure. If the frequency response of the loudspeaker system is known, this may be taken into consideration when plotting the final results. A measurement made in this manner does not give any indication of the reverberation characteristic, only the frequency characteristic.

A second method (Fig. 2-59B) employs a random-noise generator and a power amplifier to drive a loudspeaker. The projected white noise (if a pink-noise filter is used, see Questions 1.41 and 1.42) is picked up with an octave band analyzer, and applied to a high speed graphic level recorder. In this latter system, the white noise is broken down into frequency bands of ⅓ octave or less, and the sound levels measured. The final characteristic is then plotted in third-octave bands to show the characteristic of the enclosure.

To measure the reverberation period, tones are radiated from a loudspeaker, either by the use of a tone-burst generator, or by hand keying the frequencies of interest. When the tone-burst method is used, an audio oscillator is connected to the tone-burst generator input, as shown in Fig. 2-59C. The generator is set for the desired time interval of tone. The signal is picked up by

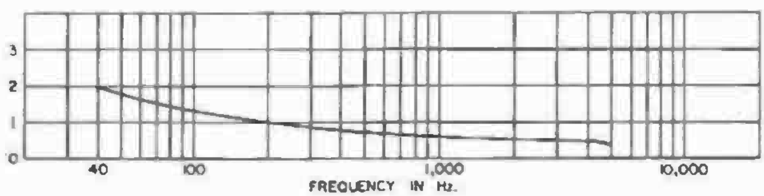

Fig. 2-58B. Reverberation characteristics of Republic Corporation sound Stage-19. Volume 600,000 cubic feet.

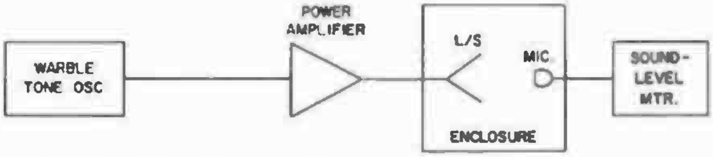

Fig. 2-59A. Setup for measuring acoustic characteristics using a warble oscillator and sound-level meter.

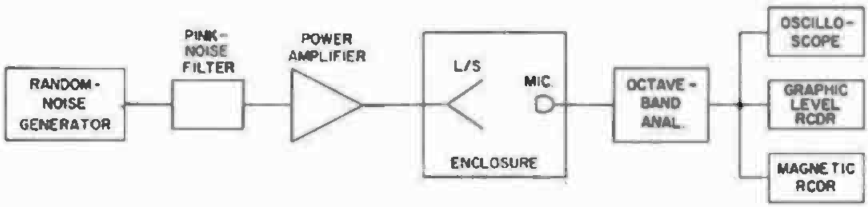

Fig. 2-59B. Setup for measuring the characteristics using a random-noise generator, pink-noise filter, and an octave-band analyzer.

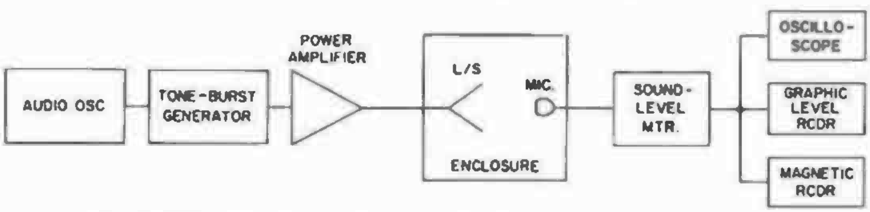

Fig. 2-59C. Setup for making reverberation measurements using a tone-burst generator.

the sound level meter, and recorded on the graphic level recorder, or observed on an oscilloscope.

Another method often used is to fire a pistol in the enclosure, and record the shot on a magnetic recorder. The tape is then played backward through a bandpass filter and an integrating network and the reverberation time computed. Magnetic-tape recorders may be used for recording acoustic tests, provided they have the required dynamic range and are not driven into overload. The reverberation characteristic shown in Fig. 2-58B was made by means of filtered gun shots and the use of a sinusoidal tone. The difference between the two methods was on the order of 10 percent.

It is desirable, although not absolutely necessary, that the frequency characteristics of the loudspeaker system be measured before making acoustical tests, and also that the amplifier used for driving the loudspeaker has a flat response below and beyond the frequencies used in the measurements. It is also desirable that the output from the signal generator supplies a constant signal level to the amplifier input.

The loudspeaker characteristic can be measured by using a constant input to the amplifier, while observing the frequency response on the sound level meter. Knowing the characteristic of the loudspeaker will many times account for peaks and valleys in the final measurement. The sound level meter microphone should be placed close enough to the loudspeaker to eliminate the effect of reflections from surrounding objects, when measuring the characteristics of the loudspeaker. A better method would be to measure its response in the open air.

2.60 ***What is a scoring stage?***—A music-recording stage. This term originated in the motion picture industry.

2.61 ***What are the essential differences between a stage designed for recording music and one designed for recording dialogue?***—A stage designed for recording music is much brighter and larger, and has a longer reverberation time than one designed principally for dialogue recordings. Dialogue stages are rather dull and have a short reverberation period.

2.62 ***How is separation obtained between a vocalist and an orchestra?***—By the use of a separate microphone placed behind an acoustical flat. A glass window in the flat permits the vocalist to observe the orchestra conductor for cueing. A rug is placed under the microphone to prevent reflections from the floor.

2.63 ***How can an artist be cued when singing with an orchestra?***—A single headphone is sometimes used; however, this is not always satisfactory because some artists can not sing and hold the headphone. Also, it bothers them to have one ear covered. A method which has proved to be quite successful is shown in Fig. 2-63. Two small loudspeakers without baffles are mounted on a stand supported at ear level, about six inches from the artist. The sound level from the speakers is held quite low and the microphone is placed at a position for minimum pickup. The loudspeakers must be electrically in phase.

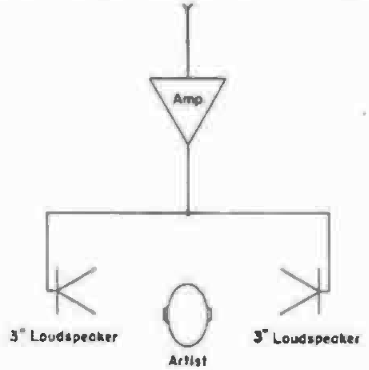

Fig. 2-63. Loudspeakers for cuing an artist singing with an orchestra.

2.64 ***What is a choir room?***—A room adjacent to a scoring stage, with a glass panel in the wall separating the two. The choir to be recorded is placed in the choir room for better separation and control. A loudspeaker operating in the choir room is used for cuing purposes. Headphones, fed from the monitor system, are provided for the conductor so that he may hear the overall mix.

2.65 ***How may a choir and orchestra be recorded if a choir room is not available?***—The choir is separated from the orchestra by acoustical flats. Two microphones, separated by about 10 feet, and placed forward of the group, are used for the choir pickup. The microphones must be electrically in phase.

2.66 ***Show the interior construction of a motion picture scoring stage.***—In Figs. 2-66A and B are shown two views

Fig. 2-66A. View of Republic Corporation scoring stage looking toward the screen. Polycylindrical diffusers may be seen along the sidewalls and on the ceiling.

Fig. 2-66B. Rear view of Republic Corporation scoring stage showing polycylindrical diffusers on rear wall and ceiling.

of the music scoring stage at Republic Corporation, North Hollywood, California. It will be noted the stage has been diffused by the use of polycylindrical diffusers on the walls and ceiling, and that the stage is tapered toward the screen. The walls are constructed in a manner similar to that shown in Fig. 2-50A. The outside walls are coated with a layer of stucco plaster supported on wire mesh. Under the wire is a layer of building paper. All this is supported on four-inch wooden studs. The space between the studs is filled with rock wool. Next, is an air-filled space of six inches and then four-inch studding filled with rock wool. Again, building paper and, finally, the interior finish, which consists of acoustic tile and other materials.

2.67 ***What are the recommended reverberation characteristics for recording stages?***—Scoring stages: fairly live and well diffused. Scoring-stage monitor rooms: slightly deader than a theater. Recording stages: similar to a medium-size theater.

2.68 ***If motion picture projection is used in conjunction with a scoring or dubbing stage, how are the walls of the projection room treated?***—To provide fire protection and, at the same time, a high degree of acoustic isolation, the walls of the projection room are constructed using eight inches of concrete. The interior of the booth is treated as prescribed by fire regulations. Two pieces of optical glass are used in each porthole to isolate the sound of the projectors from the stage. The wall facing the interior of the stage is treated, as are the other walls. As a rule, polycylindrical diffusers are placed horizontally across the face of the projection room wall in the stage just above the portholes to break up the flatness of the surface, as shown in Fig. 2-66B.

2.69 ***Describe how the entrance doors to a production stage are constructed.***—The exterior doors are constructed similar to a walk-in refrigerator door, with interlocking edges similar

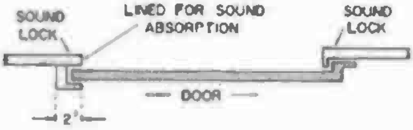

Fig. 2-69. Plan view of a typical sound-stage door installation. The sound lock on the left side starts at the floor and continues to the top and across to the right side. Rollers at the bottom support the weight of the door when it is opened.

Fig. 2-72A. Teleprompter unit with script. The "hot line" appears to the right of the plastic pointer.

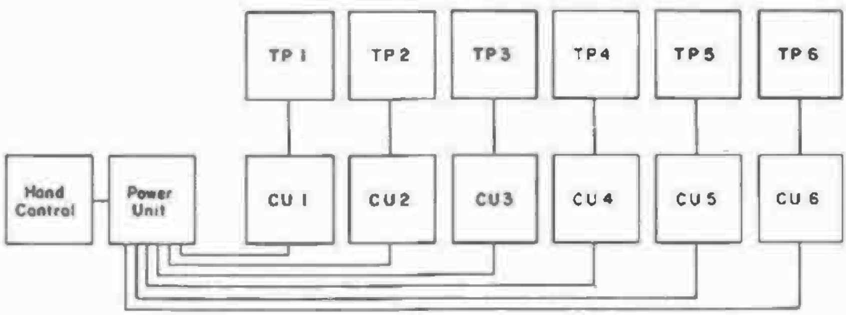

Fig. 2-72B. The block diagram for a six-unit Teleprompter system. The power unit at the left will supply sufficient power for one to six repeater units.

Fig. 2-72C. Two Teleprompter control units and one power unit.

to a bank-vault door. The outer door leads into a small vestibule, with an inner door placed far enough away from the exterior door to prevent opening both doors at the same time. As a rule, signal lights are placed both outside and inside the stage to indicate when a door is being opened. The interior door may be a regular door that has been treated acoustically on its inner surface. The interior of the vestibule is heavily treated acoustically.

Large doors used for bringing in sets and equipment generally weigh several thousand pounds. The most economical design is a concrete slab, reinforced with steel rod, which may be cast in one piece. Hydraulic seals are provided at the sides and bottoms, and interlocking sound barriers for the top and sides (Fig. 2-69).

2.70 ***How is the sound of footfalls eliminated when making dolly shots during production?***—By means of heavy woolen socks worn over the shoes of the operating crew.

2.71 ***When using a loudspeaker for acoustic measurements on a stage, how is the formation of standing wave trains prevented?***—By use of a warble-tone oscillator or film reproduced by the projection system. As a rule, frequencies above 1000 Hz do not require warbling, unless the enclosure is quite small. Standing wave trains are discussed in Question 2.41; stage measurements in Question 2.59; and warble oscillators in Question 22.52.

2.72 ***What is a teleprompter?***—It is a device beyond the sight of the audience, for presenting written material such as a script to an actor or speaker for the purposes of prompting. It is used in production of both television shows and motion pictures.

A teleprompter system consists of one to six variable-speed prompter units such as that shown in Figure 2-72A, which carry the script on a paper roll; a power supply unit; and a hand control for varying the speed of the

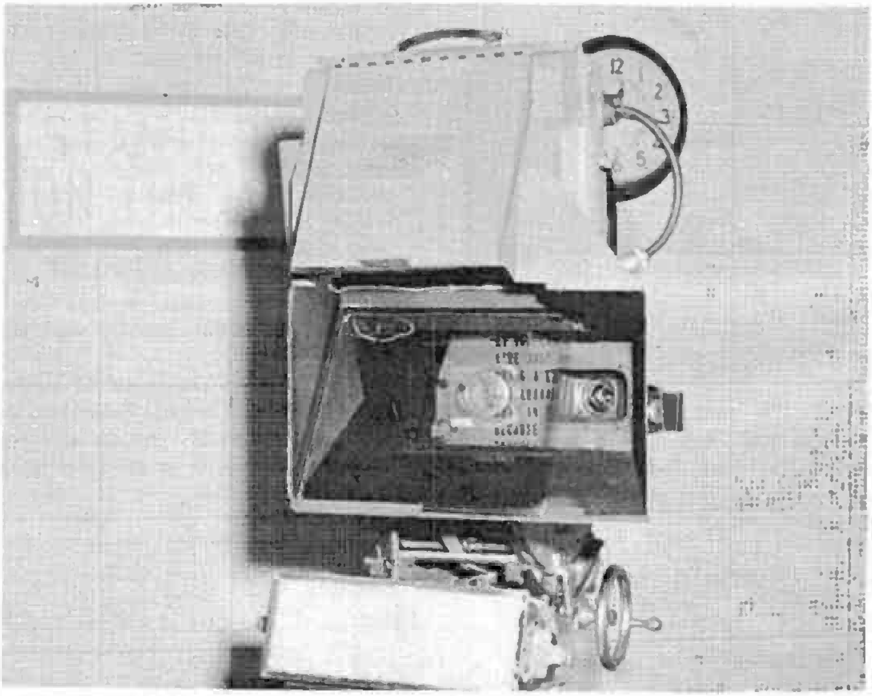

Fig. 2-72D. A Teleprompter unit mounted on a standard motion-picture camera. The image of the script may be seen on a glass plate in front of the Tellens unit in front of the camera lens.

prompter transport systems and reversing their direction for rewinding. The speed of the teleprompter units may be controlled from a few inches per minute to several feet per second, permitting the operator of the system to follow the action on a set, or to adjust the speed of the prompter transport system to accommodate the talking speed of the speaker. The speed of the prompter units is controlled in such a manner that the "hot line" is always in line with a large plastic pointer at the left of the script.

A block diagram for a typical system employing six prompter units is shown in Fig. 2-72B, while Fig. 2-72C is a view of two control units, a power supply, and the variable-speed hand control.

The script is typed on a special typewriter called a Videoprinter which has type 52 times larger than that normally used on a standard typewriter. This size type permits the script to be read up to distances of 25 feet, and more, which is adequate for most purposes.

For scenes which require the narrator to peer directly into the camera lens, a special type mounting for the prompter unit, called a Tellens, has been developed which can be mounted on a standard motion picture camera as shown in Fig. 2-72D. The image of the script is projected downward from the prompter unit onto a piece of clear glass set at an angle of 45 degrees in front of the camera lens. As the person being photographed looks into the camera, the image of the script is seen on the glass plate in front of the camera lens.

The reversing switch on the hand control permits the operator to quickly rewind the script to any particular line in a matter of seconds. Script changes are retyped and fastened to the script by plastic tape. Each prompter unit is well lighted and designed to be mounted using a stand or special support on the camera dolly.

2.73 ***What is a diffuser?***—A wooden panel with an uneven surface as shown in Fig. 2-75. These devices are constructed of ¼-inch plywood and placed in different positions near the source of sound pickup to add reverberation and a degree of liveness to a pickup in a large stage.

2.74 ***Describe the construction of acoustic flats.***—Acoustic flats are used on music scoring and looping stages for the purpose of separating a vocalist, a group of singers, or an actor in the case of looping. The flats are constructed of 2-inch × 4-ft × 84-inch wooden frames, diagonally braced and filled with rock wool or Fiberglas. The exterior surface treatment is varied; that is, one flat has a plywood and acoustic tile surface, another a soft surface of cheesecloth with Fiberglas backing and acoustic tile. Pull-pin hinges are provided for locking the flats together, similar to a Japanese screen, to form a semicircle. Thus, the interior acoustics of the enclosure may be varied to acquire the necessary acoustical environment. A window is provided in one flat for the vocalist to watch the conductor, or for an actor to view the screen when looping. A carpet is placed on the floor to prevent reflections and foot noises. Constructional views are given in Fig. 2-74A, for a typical group of such flats.

For a large group of voices to be separated from the orchestra, several panels are used, similar to those discussed, but constructed somewhat differently. Each panel is 4 ft wide × 12 ft in height, and contains a glass panel, with plywood the first 4 ft up from the floor, as shown in Fig. 2-74B. The frames are constructed of 2 × 4's with pull-pin hinges. The interior surfaces of the panels are crossed-braced and filled with rock wool or similar material to prevent resonance effects and to increase the isolation. In setting up the panels for use, care must be taken that no two surfaces are parallel, as shown in Fig. 2-74C. Carpet is placed on the floor to prevent reflections and eliminate foot noise. Only about 10 to 15 dB of isolation may be expected from an enclosure of this nature.

2.75 ***What is a splay?***—A curved surfaced diffuser as shown in Fig. 2-75.

2.76 ***Describe the construction of a polycylindrical diffuser.***—Polycylindrical diffusers consist of a plywood panel bent in the form of a convex surface. Such devices are used in rerecording stages, music-scoring stages, broadcast studios, and in some instances theaters. Their purpose is to provide a maximum

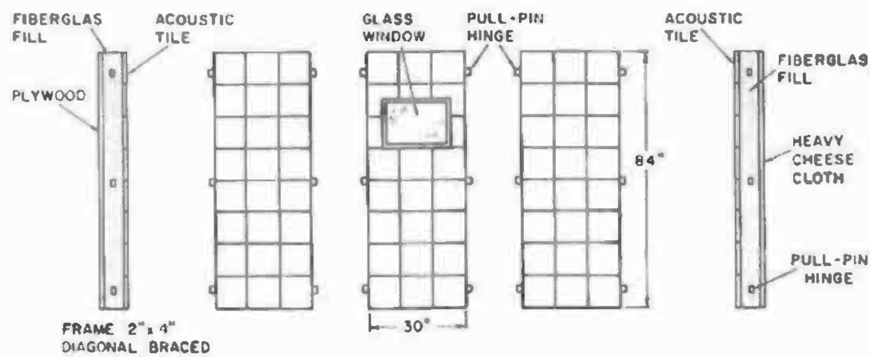

Fig. 2-74A. Acoustic flats used for separation of a vocalist, or for looping.

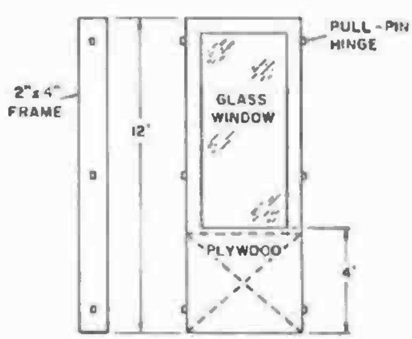

Fig. 2-74B. Glass-paneled flats for enclosing a choral group.

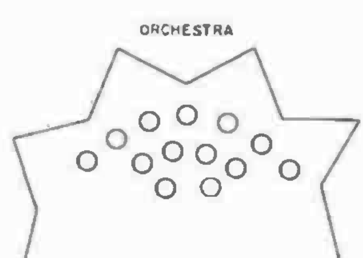

Fig. 2-74C. Ten to twelve such panels are placed around the group, as shown in the floor plan.

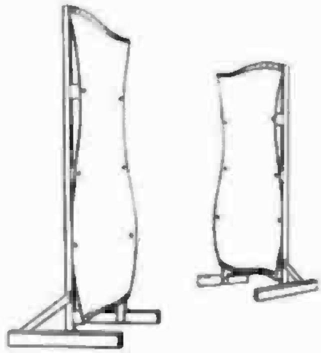

Fig. 2-75. Curved surface diffusers or splays.

of diffusion and aid in the control of the low-frequency reverberation characteristics of the enclosure. The diffuser, because of its curved surface, reflects the high frequencies at many different angles. At the low frequencies, the panel acts as a diaphragm and breathes, dissipating the low-frequency energy in the form of heat. The construction of such diffusers is given in Fig. 2-76A, with the details of their measurements in Figs. 2-76B and C.

When finished, the surfaces of the panel may be painted with a bright glossy paint and then laquered. A dull surface paint must not be used, as a highly reflective surface is necessary. The internal space is filled with loose rock wool, or a backing of 2-inch Fiberglas, placed on the supporting wall. The curved panel must be securely braced; the braces are randomly spaced to prevent selective resonance. The curvatures of the panels between the various diffusers are varied also, and their axes disposed to be mutually perpendicular in the three orthogonal planes. Diffusers may be used in both the vertical and horizontal planes as well as across ceilings and back walls. For a studio 40 feet in length, two such diffusers will be required for each wall, running vertically from the floor to the ceiling, placed directly across from each other, as shown in Figs. 2-76D and E. In small rooms, the ceiling diffusers may be omitted if the ceiling surface is at different angles or broken up. For large stages, the general plan of that shown in Figs. 2-66A and B may be followed.

Concave surfaces must be avoided, as they are points of concentration, and focus the sound rather than diffuse it. It should be mentioned that sheet *Masonite* cannot be used successfully in the construction of polycylindrical diffusers since the material is not stiff enough. To have the proper stiffness, the plywood must be at least $\frac{1}{4}$ inch in thickness.

2.77 ***Show the polar frequency response of a polycylindrical diffuser compared to a flat-surfaced splay.***—A polar plot for a flat and curved baffle is shown in Fig. 2-77. It will be noted that the angular reflection of the curved surface, with respect to frequency, covers over 100 degrees, while the flat panel covers only 40 degrees. This illustrates very clearly the advantages of a curved surface over that of a flat surface.

2.78 ***What is a baffle plate?***—A partial plate placed in an air duct to prevent exterior noise from entering an enclosure. Baffle plates also reduce the rushing sound of the air as it is forced through the duct. The construction of such a duct is shown in Fig. 2-55.

2.79 ***What is an echo?***—The repetition of a sound caused by reflection from a surface. To be an echo, the reflected sound must be $\frac{1}{20}$ of a second or longer behind the original sound.

2.80 ***What is an echo chamber?***—A highly reverberant room which is loug and narrow and has hard walls. A loudspeaker is placed at one end of the room and a microphone at the other. The sound to be reverberated is sent into the loudspeaker, picked up by the microphone, amplified, equalized, and mixed with the original program material. Because of the hard walls, multiple reflection echoes are produced. Typical echo chamber designs are shown in Fig. 2-80. At (a), the microphone is separated from the loudspeaker by a partition running almost the full length of the room, to secure a greater delay. In (b) is shown a plain room with the loudspeaker at the farthest end. For this type of operation, the microphone and speaker are moved to secure the desired results. At (c), a movable partition has been installed at the center of the room and is remotely controlled to alter the length of the reverberation period. Sketch (d) is a similarly constructed room, except the end and side walls are set at an angle.

Echo effects may also be generated by the use of 1-inch pipes, or larger, ranging from 25 to 100 feet in length. In the early days of radio, such systems were constructed by coiling the pipes several feet in diameter, and placing microphones at intervals of 25 feet to achieve the delay times. The sound was introduced into the pipe at one end, using a horn-type driver unit. For a distance of 50 feet the delay is 1/20 second, and 1/10 second for 100 feet. The disadvantage of this method of creating reverberation is the tremendous loss of high frequencies and the amount of equalization and amplification required

The wall directly behind the console is broken up in a vertical direction. The console sets on a platform 12-inches high.

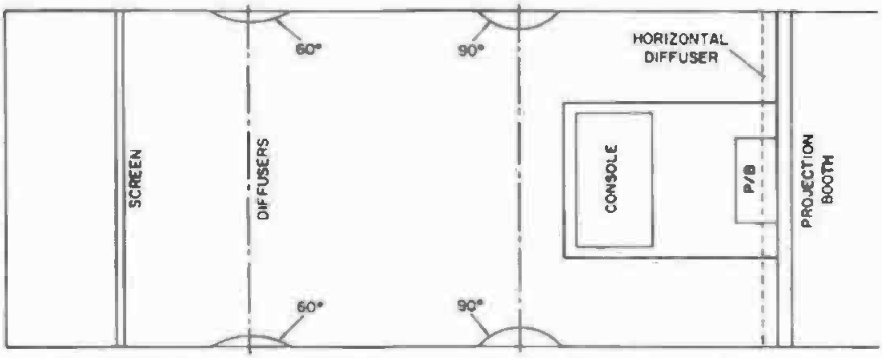

Fig. 2-76E. Floor plan of dubbing stage showing the positions of the polycylindrical diffusers.

to return the signal to a point where good intelligibility is attained. Because of the short duration of the reverberation, the signal picked up by the microphones must be fed back to the driving source, and consequently multiple delays are created. For a pipe 50 feet in length, the loss at 5000 Hz is approximately 23 dB, and for 100 feet it is approximately 45 dB. Because of these problems, this system is no longer used. Artificial reverberation also may be generated electronically or by electromechanical means, as discussed in Questions 2.128 to 2.130. A typical reverberation system using a pipe is shown in Fig. 2-80B.

2.81 ***How is an echo chamber constructed?***—Typical interior dimensions are: Length 18 feet, width 15 feet, ceiling height 12 feet, consisting of about 3200 cubic feet and a reverberation

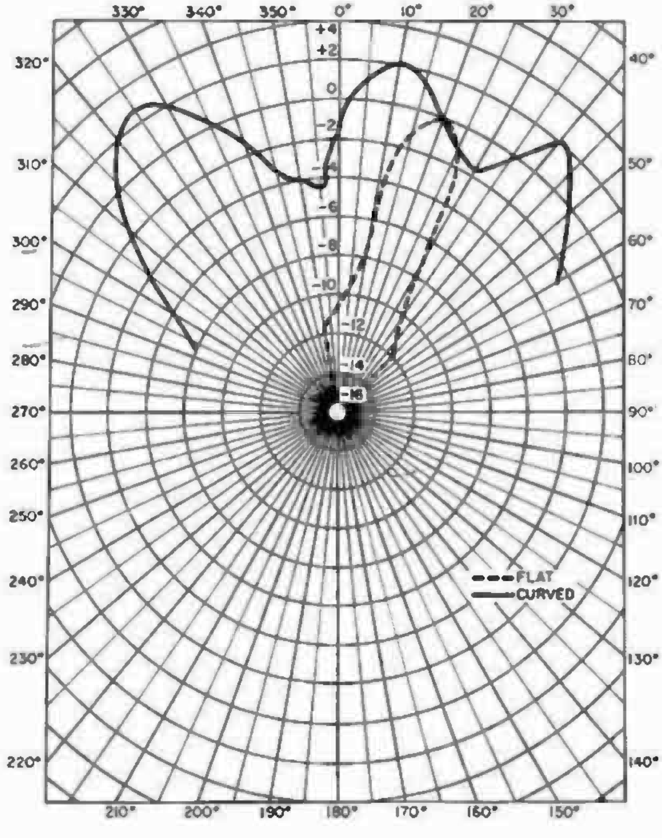

Fig. 2-77. Polar frequency response of a flat baffle as compared to a curved baffle.

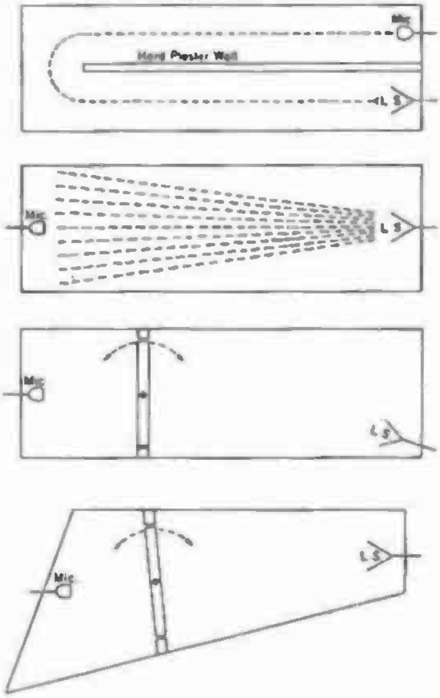

Fig. 2-80A. Echo chamber designs.

time of approximately 3.8 seconds. The floor should be smooth cement and the walls covered with hard, smooth plaster. The ceiling must be nonparallel to the floor. The speaker may be moved and microphones with different pickup characteristics used to secure the desired effect. However, a room with the microphone and speaker in fixed positions and a movable partition are the most convenient to operate. Echo chambers may also be constructed as shown at (d) in Fig. 2-80A. The ideal echo chamber is one constructed using six-inch concrete walls. To be effective, an echo chamber must have a minimum of 2500 cubic feet.

2.82 ***How is an echo chamber connected into a recording channel?***—The output of the source of sound to be reverberated is bridged with an amplifier and applied to the power amplifier driving the loudspeaker in the reverberation chamber, as shown in Fig. 2-82. The reverberated sound is picked up by a microphone, amplified, equalized, and applied to the input of the recording channel through a mixer pot.

A different method of combining the signal in the recording channel is shown in Fig. 9-49. When combining the reverberated sound with the original material, the reverberated sound is mixed at a level approximately 20 dB below the original. This gives the best results, with the highest intelligibility for speech.

A separate echo chamber is required for each microphone to be reverberated.

2.83 ***What is an anechoic chamber?*** —An enclosure in which the reflected sound is negligible. Such rooms are used for measuring the characteristics of microphones, loudspeakers, and other acoustic transducers, and to provide environmental conditions similar to the outdoors. Fig. 2-83A shows an anechoic test chamber at the Bell Telephone Laboratories, Murray Hill, New Jersey. To eliminate surfaces that would reflect

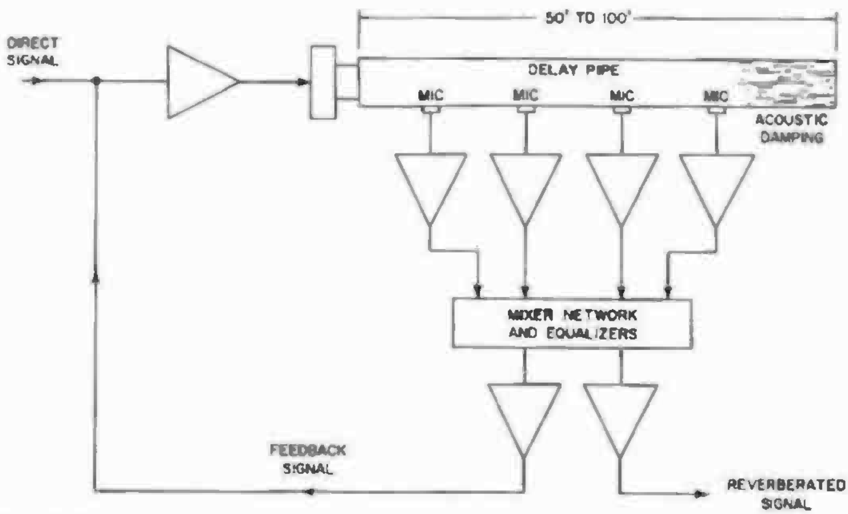

Fig. 2-80B. System for generating artificial reverberation using pipe delay lines.

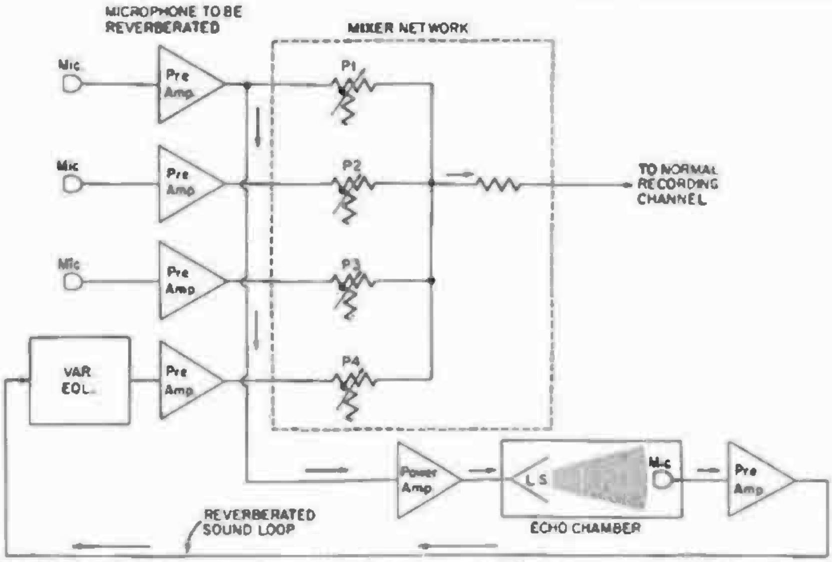

Fig. 2-82. Block diagram for connecting an echo chamber to a recording channel.

sound, the walls, ceiling and subfloor are lined with sawtooth wedges of Fiberglas to a depth of five feet. The flooring consists of high strength steel cables $^{9}/_{100}$-inch thick, strung under tension in two-inch mesh. The chamber dimensions are 35 × 28 × 28 feet. The volume is 27,440 cubic feet. With the interior treatment as shown, the absorption at the walls is 99.98 percent of all incident sound energy in the audible range.

In Fig. 2-83B, is shown a corner of the anechoic chamber of the Electro-Voice plant in Buchanan Mich., used for engineering development and quality control. The main chamber is 35 × 26 × 26 feet and has a volume of 23,660 cubic feet. The walls are treated in the same manner as described for the chamber in Fig. 2-83A. In addition to the main chamber, there are two smaller adjoining chambers; one houses a standard loudspeaker calibrated from 20 to 20,000 Hz, traceable to the National Bureau of Standards; the second is a smaller chamber that will accommodate loudspeakers up to and including a diameter of 30 inches. A standard exponential horn is also available for testing high-frequency driver units.

The ventilation of the main chamber is through three wedges located in widely spaced positions to prevent reflections. Twenty-two circuits are available from the chamber for connections to signal sources and test equipment. Exterior to the chambers are automatic curve tracing and polar pattern graphic recorders. The entire facility is set on its own foundation, which completely isolates it from the main building.

Two chambers, similar in construction are in use at the Altec-Lansing plant in Anaheim, California. One is used for engineering and a second for routine production testing. Fig. 2-83C is a view of the test equipment outside the chamber used for research and development. The equipment includes preamplifiers, power supplies, graphic level recorder, oscillator frequency counter, and other devices. The equipment shown in Fig. 2-83D is used for routine testing of microphones and other devices. The device to be tested is supported by a pulley arrangement and cords for orienting and ease of operating. The test equipment consists of a graphic level recorder, oscillator, preamplifier, vacuum-tube voltmeter, and associated equipment.

2.84 ***Describe the construction of an anechoic chamber.***—Anechechoic chambers are enclosures that are echo-free, within a specified frequency range. To achieve this condition, the sound energy absorption must be between 99 and 100 percent. Or to state it in another way, the sound-pressure reflections must be between 10 percent and zero. The point at which the energy absorption drops below 99 percent or the pressure reflection exceeds 10 percent is known as the low-frequency cutoff frequency. The curves in Fig. 2-84A show the low-fre-

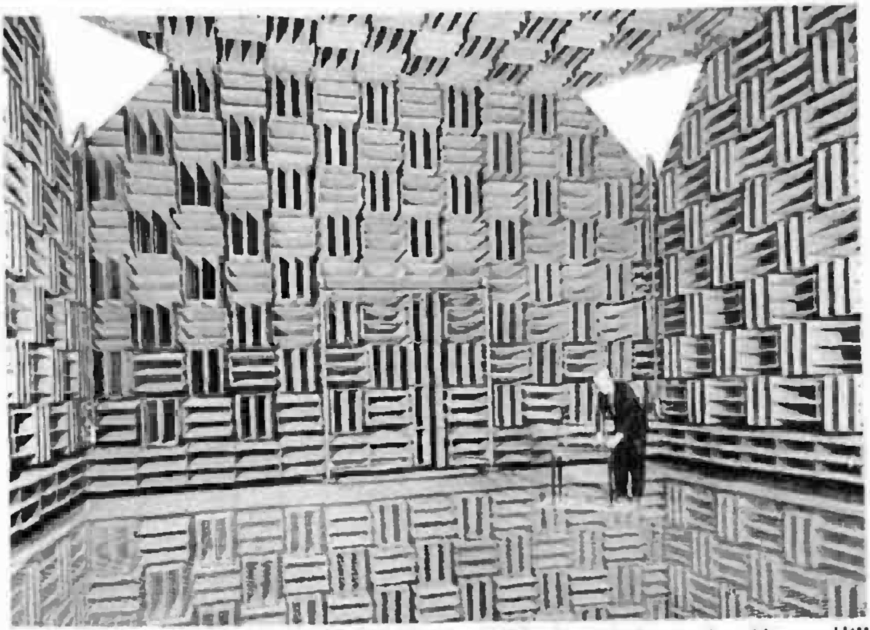

Fig. 2-83A. The anechoic chamber at the Bell Telephone Laboratories, Murray Hill, New Jersey.

Fig. 2-83B. Testing a microphone in the Electro-Voice anechoic chamber.

quency cutoff points for 60, 130, and 250-Hz. The table of cutoff frequeucies recommended for different types of testing is given in Fig. 2-84B.

The actual dimensions for any type anechoic chamber will be determined by the type equipment to be tested. For general acoustical research, the minimum free-field dimensions (the distance from the edge of one wedge to another on the opposite wall) cannot be less than one wavelength of the cutoff frequency, and the largest dimension not less than half a wavelength of the cutoff frequency. The principal factor affecting the free-field dimension is the size of the equipment under test. Measurements at a specified frequency should be taken no closer than a quarter wavelength from the sound radiating surface and no less than one quarter wavelength from the points of the surrounding wedges.

To obtain a satisfactory environment, the anechoic wedges are generally installed in an attenuating structure similar to that of Fig. 2-84C. The outside enclosure may be built on the ground or on an existing floor, or floated on springs, lead, or some type of acoustic

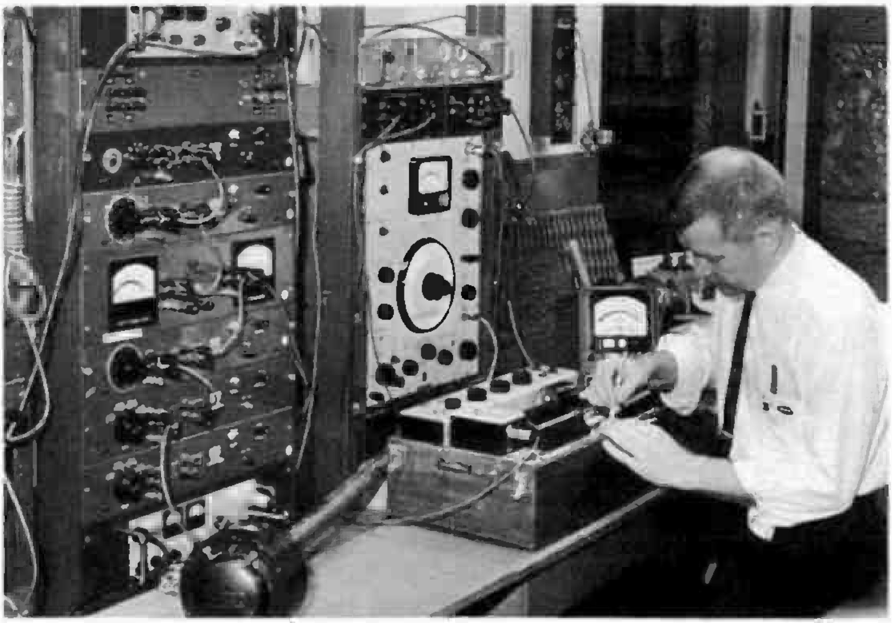

Fig. 2-83C. Test equipment for research and development of loudspeakers and microphones, outside the anechoic chamber in the Altec-Lansing plant.

Fig. 2-83D. Routine production test equipment outside the Altec-Lansing anechoic chamber. The device to be tested is hung from a pulley-and-cord arrangement for ease of operation and orientation.

isolation material. The door in the outer structure must have an attenuation characteristic equal to the outer walls. The inner surface of the chamber door is be treated in the same manner as the inner walls, in order that the anechoic characteristics are not compromised.

To achieve adequate ventilation, twelve complete changes of air per hour will be required, with controlled humidity and temperature. The air from the ventilating system is introduced through a plenum silencer into the chamber through special ventilating wedges (Fig. 2-84D). Velocities up to 250 fpm may be fed to the interior, without introducing noise. A graphical plot of the lower cutoff frequency versus the depth of treatment of the chamber is given in Fig. 2-84E. Typical wedges are shown in Fig. 2-84F.

The question is sometimes raised, what effect if any, does the grating used for the floor have on measurements made in an anechoic chamber? The study of the effects of the floor becomes quite complex. In practice, the floor is a metal grating or nylon cables suspended from the walls. If a grating is used, the openings are generally 1 or 2 inches in depth and 2 inches in length. Thus the slit width is less than half the wave length for frequencies below 3000 Hz. The open area is often in excess of 90 percent of the total area, and consequently when a sound strikes the grating, under normal incidence the reflection is negligible. However, there is a certain amount of reflection. This subject has been treated extensively by Ingard. The reader is referred to the reference at the end of this section.

A portable anechoic chamber, manufactured by the Eckel Corporation, is shown in Fig. 2-84G. The surfaces of the *Fiberglas* wedges are covered with No. 2, 19-gauge hardware cloth. The interior of the chamber shown has a free-field space of approximately 21 cubic feet.

2.85 ***What is the purpose of adding reverberation to program material?***—To enhance the original material by adding brilliance and to create the illusion that the material was originally recorded in a large auditorium. If properly controlled and equalized, the results can be very pleasing. Reverberation is also used for producing sound effects, such as to simulate a large room or cavern. Equalization may be necessary as the reverberation chamber distorts the original frequency characteristic.

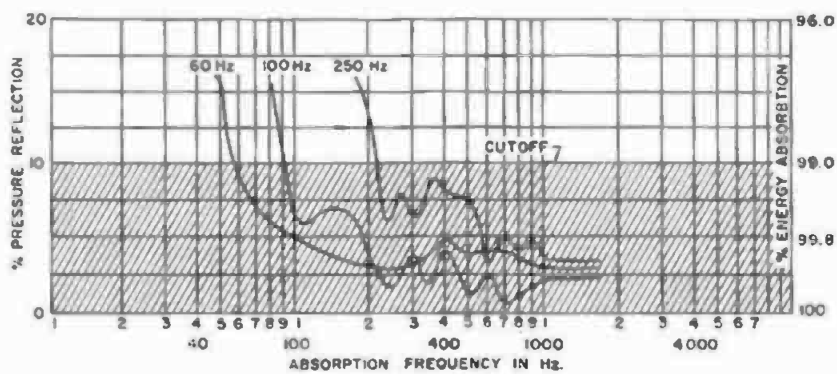

Fig. 2-84A. Absorption characteristics for typical wedges of the Eckel Co.

Type of Testing	Low-Frequency Cutoff Point
Aircraft	75 Hz
Audio	125–400 Hz
Automotive	60 Hz
Electrical Communications	60-200 Hz
Jet Engine	150 Hz
Machinery	75-150 Hz
Musical Instruments	60 Hz
Psycho-Acoustic	150 Hz
Transformer	100 Hz

Fig. 2-84B. Recommended cutoff frequencies for different types of testing.

2.86 ***What is the optimum number of musicians for a given size studio, based on the program material?***—The number of musicians will vary, depending on the program material and the size of the room or studio. Based on experience, the recommended number is given in Fig. 2-86.

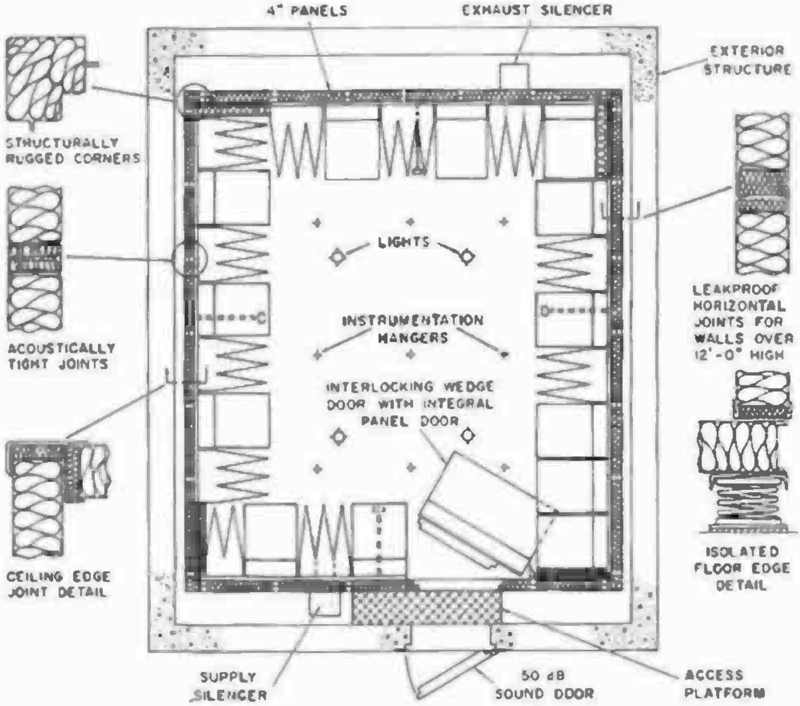

Fig. 2-84C. Typical plan for an anechoic chamber. The interior door is designed so that the wedges mounted on its inner surface interlock with the wedges on the wall to permit the door to open parallel to the wall. (Courtesy, Eckel Co.)

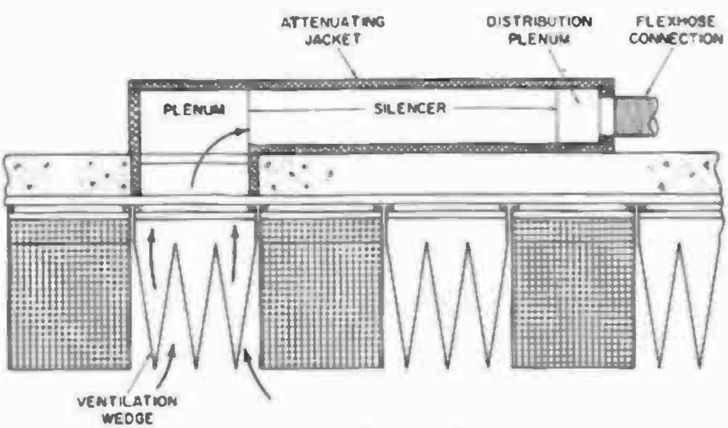

Fig. 2-84D. View showing the installation of the air silencer and plenum.

Volume in Cubic Feet	*Broadcast Studio*	*Auditoriums*	*Scoring Stages*
10,000	12	—	—
20,000	25	6	10
50,000	50	9	22
100,000	130	19	36
200,000	250	31	70
500,000	—	62	140
1,000,000	—	105	240

Fig. 2-86. Recommended number of musicians will vary.

2.87 ***What are acoustic pendants?***— Octahedral-shaped devices suspended from the ceiling of a recording stage or auditorium to break up reflections from a flat or curved ceiling. The pendants are constructed from ⅜-inch plywood and vary in height from 1 to 3 feet. The diameter at the center varies from 6 to 12 inches. These devices should be hung in a scattered manner from the ceiling at varying heights, if the ceiling is flat. If the ceiling is curved, as shown in

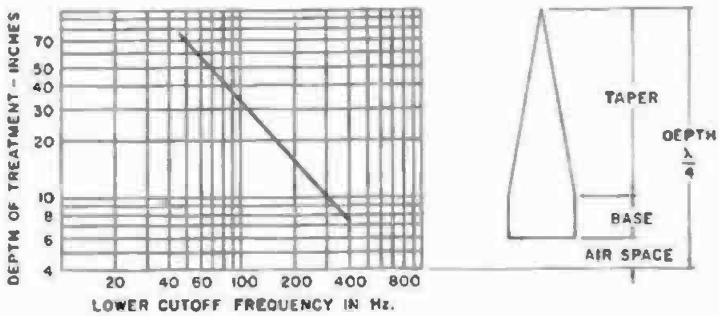

Fig. 2-84E. Lower cutoff frequency versus depth of treatment on the interior walls of an anechoic chamber.

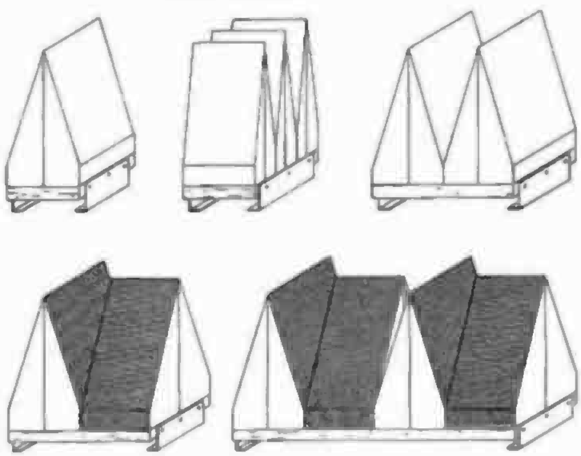

Fig. 2-84F. Typical *Fiberglas* wedges used for the interior treatment of anechoic chambers, with and without hardware screen.

Fig. 2-87, they may be hung at a uniform height. It may be desirable, in some instances, to cover every other one with *Celotex* to provide soft and hard surfaces. The whole purpose is to break up concentrated reflections from the overhead to the side walls and floor. Rooms having strong concen-

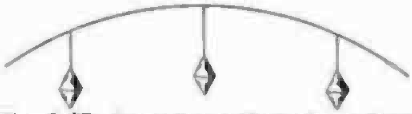

Fig. 2-87. Acoustic pendants hung from a curved ceiling to break up reflections.

trated reflections from the ceiling may be altered to have quite even reflective qualities by the use of these acoustic pendants.

2.88 ***What are the middle-range frequencies?***—Frequencies between 400 and 3500 Hz.

2.89 ***Define the terms sound-pressure level and sound-power level.*** — Sound-pressure level (SPL) is used to express the level of a sound that has been measured using a sound level meter. The reference for these measurements is 0.0002 microbar. Sound level meters do not measure acoustic power. Sound-power level (PWL) is the acoustical power generated by a sound source. Sound-pressure level may be expressed as:

$$SPL = 20 \, Log_{10} \frac{P}{0.0002} \, dB$$

where,

P is the root-mean-square sound pressure in microbars.

Because the range of acoustic powers met with in daily life are on the order of one billion-billion (10^{18}) to one, it is quite convenient to relate these powers using the decibel, which is logarithmic. The reference for these measurements is 10^{-12} watt. The power level may be calculated:

$$PWL = 10 \, Log_{10} \frac{W}{10^{-12}} \, dB$$

where,

W is the acoustic power in watts.

Since 10^{-12} watt corresponds to a level of minus 120 dB, the above equation may be more easily expressed:

$$PWL = 10 \, Log_{10} \, W + 120$$

where,

W is the acoustic power in watts.

Since 10^{-12} is a power ratio corresponding to minus 120 dB, the quantity 10 Log_{10} W which is the value of decibels corresponding to the numerical value in watts, can be readily obtained from the decibel tables that are given in Section 25. As an example: 0.2 watt corresponds to a power level of $-17 + 120 = 103$ dB. Power levels for sounds that are frequently encountered are given in Fig. 1-117.

2.90 ***What is a Rayleigh disc?***—A device invented by Lord Rayleigh in 1882 for measuring sound pressures. The instrument consists of a small light-weight disc, suspended vertically by means of a quartz fiber or annealed bronze wire. A small mirror is cemented to one side of the disc and is supported in a draftless square or tubular chamber constructed of open-mesh silk. When an air stream, whose pressure is to be measured, strikes the surface of the disc, the disc tends to align itself with the direction of fluid and pressure flow. A beam of light focused on the mirror surface permits the angle of deflection to be accurately measured by means of a calibrated lens system also focused on the mirror.

Such a device may be used for calibrating the frequency response of microphones, with a high degree of accuracy, by interposing the disc assembly in an airstream path between a microphone and loudspeaker unit. The loudspeaker unit is excited by an oscillator. Since the speaker characteristics must be isolated from the measurement, the pressure generated by each frequency of interest is adjusted for the same deflection of the disc, so that the microphone under calibration sees the same pressure at all frequencies. The microphone output is then amplified, and the electrical characteristics are measured in the usual manner. The loudspeaker must be of good quality and of low distortion. The microphone preamplifier must have a uniform frequency characteristic and low distortion.

Initially the disc is set to an angle of 45 degrees, which is the angle of the greatest sensitivity, by adjusting the suspension head at the top of the disc enclosure. When the disc is subjected to an air stream, it assumes an angle different than 45 degrees. The angle of deflection is held constant to a reference frequency for each frequency of interest used in the calibration. Barnes and West have shown that if the resonance of the disc falls within the audio spectrum, it can produce errors up to 10 percent in the vicinity of resonance. As an example, a disc with a diameter of 1.6 cm and a thickness of 0.0045 cm has a resonance of 1800 Hz. However, the addition of the mirror to the one side of the disc reduces the resonance somewhat. Since barometric pressure and temperature affect the measurement, they are noted and corrections are made to the final plot.

2.91 ***What is a Helmholtz resonator?***—A cavity resonator which is open to the outside air through a single small hole. Air blowing across the hole will cause a sound to be generated at a frequency dependent on the volume of the cavity. A cross-sectional view of such a resonator is shown in Fig. 2-91.

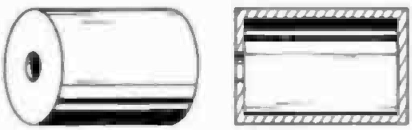

Fig. 2-91. Helmholtz resonator consisting of a cavity with a single hole open to the outside media.

2.92 ***What causes an organ pipe to vibrate?***—Organ pipes are constructed with a reed at the lower end which vibrates when air is forced into the pipe. Sound waves are set up which travel up and down the pipe which is of such length that the wave of air will just have time to travel the full length of the pipe during the interval required by the reed to make one complete cycle. When this occurs, the frequencies of the reed and sound wave synchronize. This is called resonance. At the top end of the pipe is a movable plug for tuning the pipe to the exact frequency. A 16-Hz organ pipe is 32 feet long.

2.93 ***Define the term weighted curve and its usage.***—A weighted curve is a frequency-response curve with a special characteristic. Weighted curves are more commonly associated with sound-level meters used for acoustical measurements. (See Question 22.94.)

Sound-level meters manufactured *prior to 1961* employed frequency characteristics as given in Fig. 2-93A *and are now considered to be obsolete.* In 1961 the industry adopted the American Standard ASA (now USASI) S1.4-1961 shown in Fig. 2-93B. There are also two international standards, ISO R123 and ISO R179. Both the American and International Standards agree within 0.20 dB.

Given in Fig. 2-93C is the USASI Standard S1.4-1961 with the frequency response extended at the lower end to 10 Hz, and at the upper portion to 20,000 Hz. Also included is an additional characteristic curve, N (*it is not a standard*). This latter characteristic is a *proposed* characteristic to be used for the measurement of broadband noise such as encountered in the noise measurement of jet aircraft engines.

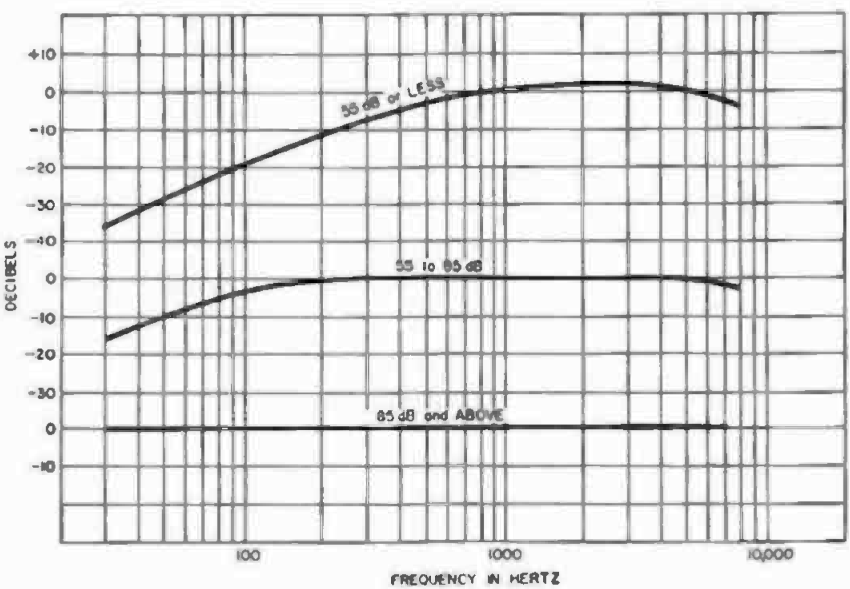

Fig. 2-93A. Weighted curves for sound-level meters manufactured prior to 1961 (ASA 224.3-1944).

The selection of a weighted curve for a particular measurement, is generally predicated on the type noise to be measured. As an example, curve "A" of Fig. 2-93B is often employed when making *speech-interference* measurements, while curve "B" is used for traffic surveys. Whenever a single measurement is made, the reading should be described—curve "A" 45-dB weighted curve, and for "B" 20-dB weighted curve. In the past, for single readings the following rule was used. For levels below 55 dB, characteristic "A" was selected; curve "B" was used for levels of 55 to 85 dB; and above 85 dB, characteristic "C" was used (flat). However, curve "A" is the one most generally employed. Readings taken with curves "A" and "B" are referred to as *sound-level readings*, and those made using curve "C" (flat) are referred to as *sound-pressure levels.*

It is recommended in general that readings be made using all three characteristics to indicate the frequency distribution of the noise. With the same level on all three characteristics, the sound generally predominates *above* 600 Hz. For levels using the "C" characteristics which are higher in level compared to curves "A" and "B," the greater part of the noise is probably *below* 600 Hz (see Question 5.98).

2.94 ***Define the term ambiophony.***—It relates to a method of inducing artificial reverberation into an auditorium, by use of loudspeakers in the ceiling and around the walls. Each group of loudspeakers is delayed in their reproduction the appropriate amount of time, corresponding to the normal delay for its position. Thus, an auditorium may be treated in such a manner that reverberation is induced only by the electronic reverberation system. (See Question 2.37.)

2.95 ***What is prescoring?***—Music recorded prior to the shooting of a motion picture or television scene. The

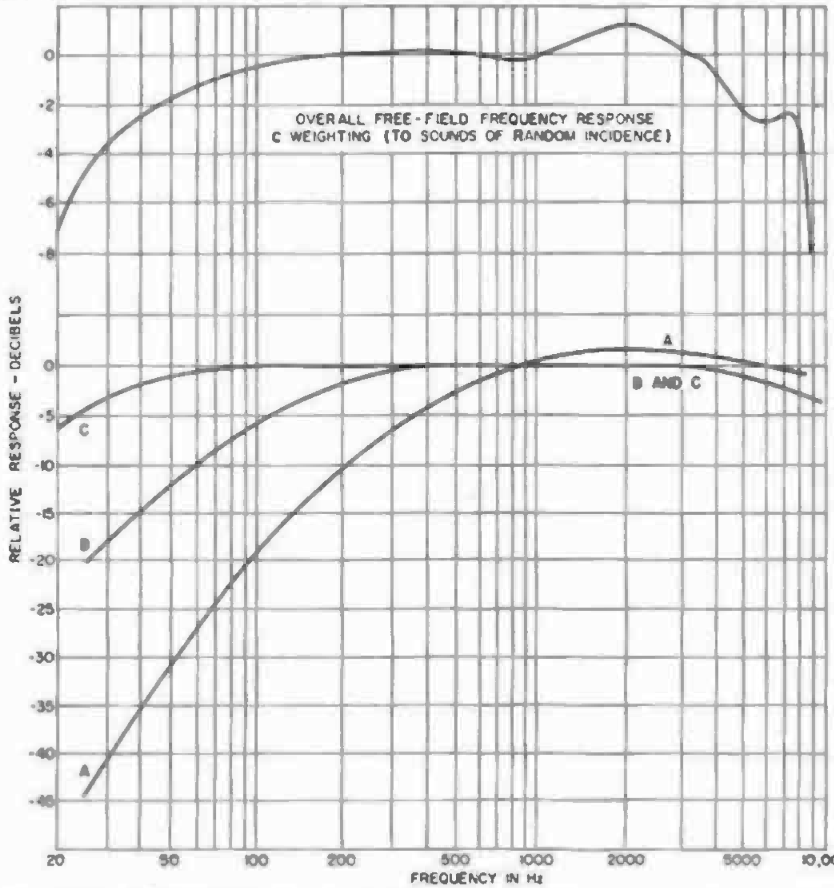

Fig. 2-93. USASI (ASA) Standard S1.4-1961. Weighted curves for sound-level meters. Used in all instruments manufactured since 1961.

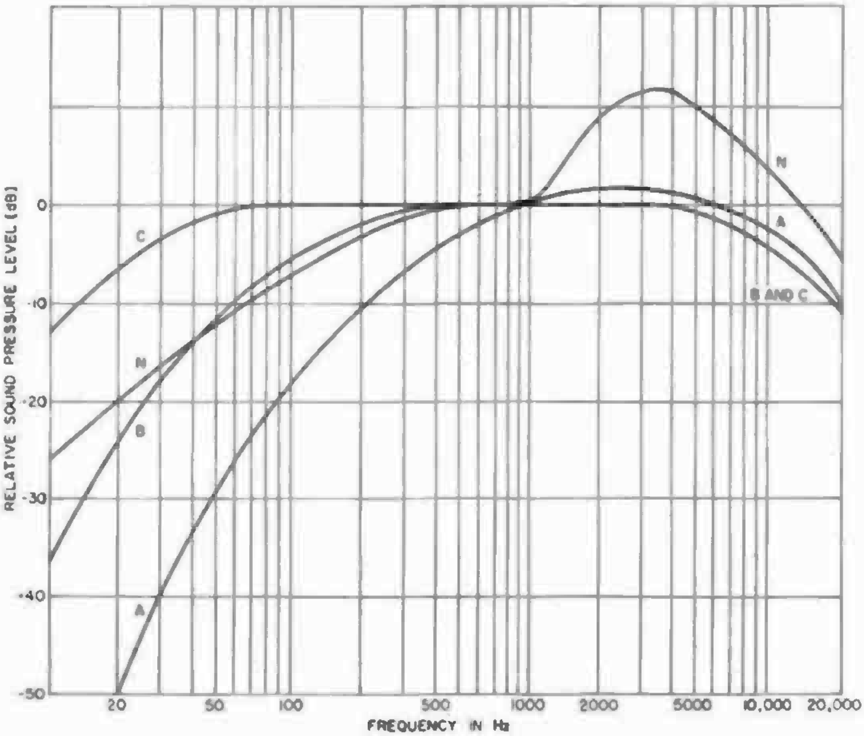

Fig. 2-93C. USASI (ASA) Standard for sound-level meters plotted to indicate the frequency response from 10 to 20,000 hertz.

sound track is played back from loudspeakers on the stage and the action is synchronized with the sound, and photographed. This method is generally used in the production of large scenes in musical motion pictures or scenes where it is impractical to record the action and sound simultaneously.

2.96 ***What are the sentences used for testing sibilance?***—Sister Susie is sewing shirts for soldiers. Or, she sells seashells by the seashore.

2.97 ***How should reverberation be added to program material to produce the illusion of a large auditorium?***—The reverberated signal is fed to the recording channel in such a manner that it is not too apparent, but is the result of natural reverberation in the studio. At appropriate times, such as during rests or other silent spots in the program, the reverberation is increased slightly to give the effect of a large hall. Equalization must be included to correct for the frequency distortion of the echo chamber. (See Questions 2.80, 2.81, and 2.82.)

2.98 ***What does the term truck-in mean?***—It is an expression used in the motion picture industry to indicate that the camera moves in on the subject to be photographed or being photographed.

2.99 ***What is a reverberant chamber, and what is its purpose?***—The reverberant chamber is the direct opposite of an anechoic chamber discussed in Question 2.83. It is constructed of highly reflective surfaces. An important factor of any noise-producing device is the total radiated sound-power level (SPL) or the acoustical energy generated by the device. Sound-power level is proportional to mechanical energy. If the PWL of a device is known before its installation, it is possible to predict the noise level it will produce in its final environment.

Reverberant chambers are generally constructed using sheet-metal walls, and having solid surfaces without any acoustical backing. Stiffening braces are used to hold the surface flat. Other surfaces such as *Masonite*, *Transite*, and similar materials may be used instead of metal. Figs. 2-99A and B are plans and cross-sectional views of typical reverberant rooms. A table of absorption coefficients for a reverberant room using octave-band filters is given in Fig. 2-99C.

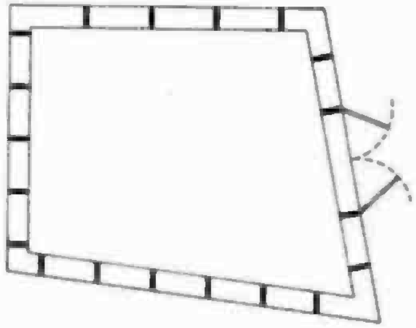

Fig. 2-99A. Plan view of reverberant chamber.

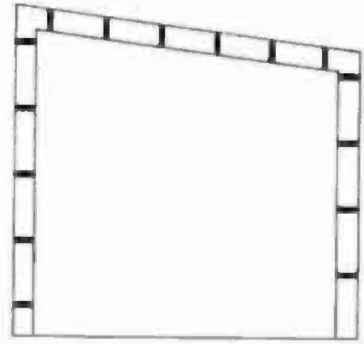

Fig. 2-99B. Cross-sectional view. Cubic volume approximately 2100 cubic feet.

Octave Band Freq.-Hz	*Meas. Abs. Coeff. ( )*
75- 150	0.056
150- 300	0.056
300- 600	0.040
600-1200	0.031
1200-2400	0.029
2400-4800	0.040
4800-9600	0.045

Fig. 2-99C. Typical reverberant room absorption coefficients for structures as shown in Fig. 2-99A and 2-99B.

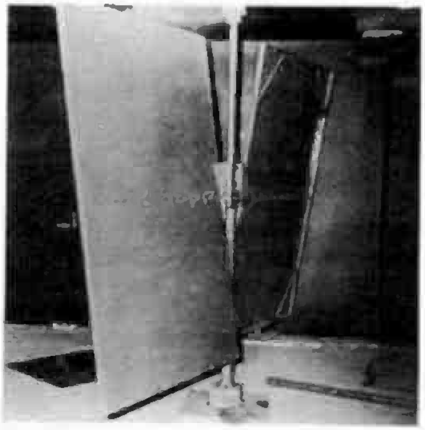

Fig. 2-99D. Interior of reverberant chamber manufactured by Industrial Acoustics Co., Inc. The panels shown in the center of the room can be revolved simultaneously both horizontally and vertically.

If the device being tested has a relatively constant acoustic output, the sound-pressure level will be essentially uniform and constant in a reverberant room. The sound-power level of such items as a fan, motor, pump, or similar device which distributes acoustical energy over a wide band of frequencies can be determined by a few simple measurements in a reverberant chamber. The sound power level may be computed:

$$PWL = SPL + 10 \log_{10} V - 10 \log_{10} T - 19 \text{ dB—re: } 10^{-13} \text{ watt}$$

where,

V is the room volume in cubic feet,
T is the reverberation time of the room in seconds,
SPL is the sound pressure level measured in decibels.

Reverberation time is calculated using the formula given in Question 2.34, or measured with a high-speed level recorder. The terms T and V are essentially constant for a given room, therefore the PWL can be obtained from the SPL measurements, once the room has been measured.

A reverberant chamber should be constructed to meet the following conditions: The walls must not be parallel, and its dimensions must not be similar. The device to be tested is placed near a wall on the floor, never in the exact center of the room. The microphone or device under test should be rotated to avoid measurement of standing waveforms. In Fig. 2-99D, the interior of a reverberant room is shown, with revolving panels that revolve simultaneously, both horizontally and vertically.

Other measurements made using a reverberant room are absorption coefficients and random calibration of microphones, loudspeakers, and other devices. Industry is making extensive use of the so-called quiet room for measurement of household appliances. The room is constructed with panels composed of sheet metal, with an interior perforated metal surface and an acoustical fill sandwiched between the metal sheets. Such rooms are used for the checking of production runs and isolating areas where it would be impractical to install extensive acoustical treatment.

Reverberant rooms may be constructed using 8-inch concrete block. A typical room constructed for microphone and loudspeaker research may have the following inside dimensions: 19.5-feet long, 13.67-feet wide, and a ceiling height of 11.4 feet. The ceiling consists of 2-inch hollow-core prestressed concrete beams. The inside is sealed with *Butyl* rubber-asphalt compound. The walls are coated with ¾-inch gypsum plaster finished with ¼-inch hard lime plaster, and the floor is covered with clear alkyd enamel. The door is a five-inch acoustical door, hung in a double frame, and carefully sealed to the concrete block structure. The inside volume is 3070 cubic feet, with a boundary of 1290 square feet. The measured response for such a room is shown in Fig. 2-99C.

2.100 What is a* Sono-Vox *sound-effects machine?—A device for producing the effect of a train whistle, an automobile horn, or a musical instrument talking. It is used quite extensively in radio commercials. The *Sono-Vox* makes the production of articulated sounds possible although the human voice is not actually used. The human speech mechanism is employed, replacing the normal vocal cord output by the sound it is desired to articulate.

Referring to Fig. 2-100, it will be noted that on the left is shown the dialogue sound track to be articulated and the person who is to act as the articulator. The sound-effects track is connected to the *Sono-Vox* amplifier which drives the *Sono-Vox* articulators. These devices are placed against the throat of the articulator who is seated in front of a microphone connected to a recording channel.

The articulator mouths the desired words but is careful to make no sound. The *Sono-Vox* articulators at the throat will transmit the sound from the sound effects track into the larynx. The sounds emerging from the throat of the human articulator are picked up by the microphone and recorded. Thus, a whistle or bell is made to talk.

2.101 How is a microphone boom constructed?—A microphone boom is a mechanical device consisting of a retractable metal tnbe or rod mounted on a dolly, as shown in Fig. 2-101A. The microphone is suspended at the end of the rectractable tube on a turret head, which may be rotated by the boom operator towards the actors for the best sound pickup.

A typical microphone boom, manufactured by the Fisher Boom Company, is shown in Fig. 2-101A and is used extensively in the production of motion pictures and television shows. The retractable tube may be extended to 16 feet and the microphone turret head rotated through 360 degrees. The bearings are *Neoprene*-sealed ball bearings, for quietness and ease of operation. The boom is demountable and, packed for shipment, weighs approximately 210 pounds.

A large studio-type microphone boom manufactured by The Mole-Richardson Co. is illustrated in Fig. 2-101B. This boom weighs about 500 pounds and is constructed similarly to the one previously described, except it is not readily portable.

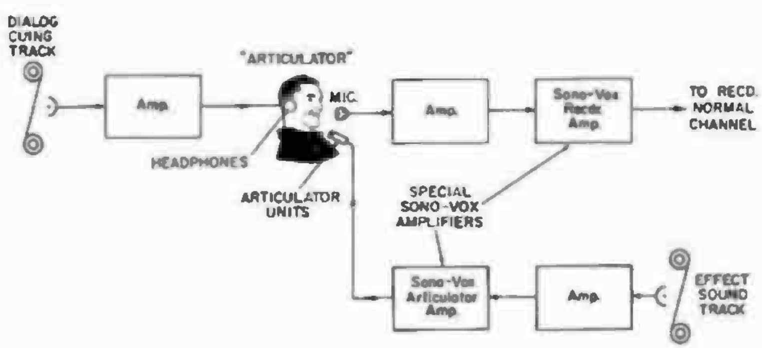

Fig. 2-100. *Sono-Vox* sound effects recording channel.

Fig. 2-101A. A light-weight portable microphone boom manufactured by the Fisher Boom Co.

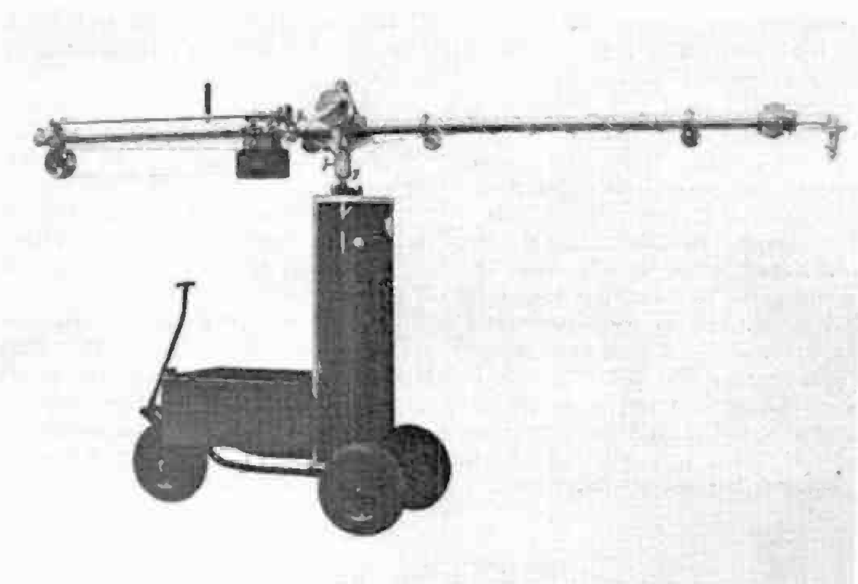

Fig. 2-101B. A heavy studio microphone boom manufactured by the Mole-Richardson Co.

2.102 *What is a turret head?*—A rotatable microphone support on the end of the retractable tube of a microphone boom, as shown in Figs. 2-101A and B. Tilting mechanisms are often mounted on the turret head for the purpose of moving the microphone in a vertical plane.

2.103 *What is the advantage of supplying the microphone boom operator with headphones?*—To aid him in maintaining uniform sound quality. The boom operator's headphones are connected to the same monitor circuit as the mixer's. Thus, the boom-man hears as the mixer hears. As a rule, the boom operator's headphones are also connected to a communication circuit so that the mixer may give him orders when necessary.

2.104 *Describe a radio playback system used for motion picture and television production.*—A system that has been used to good advantage is the radio playback system which utilizes a transmitter and individual receivers. Each principal and others concerned carries a miniature radio receiver connected to a hearing aid earpiece. A low powered radio transmitter is set up on the stage and connected to a loop antenna which surrounds the set. Working within the loop, the actors listen to the music picked up by the miniature receivers and sing and dance as the case may be. Provision is also made for the director to give orders to the actors while they are in action. (See Questions 2.95 and 4.72.)

2.105 *What is a review room?*—A small theater, on a motion picture lot, for reviewing the finished product or daily work. These rooms are maintained to a standard for uniform quality of picture and sound reproduction.

2.106 *What is the peak intensity of sound that may be expected in a review room?*—At least 80 dB above the threshold of hearing; therefore, the walls should be well insulated and diffused.

2.107 *Define the term noise criteria.* —It is the *maximum* permissible noise level for a given enclosure, measured in

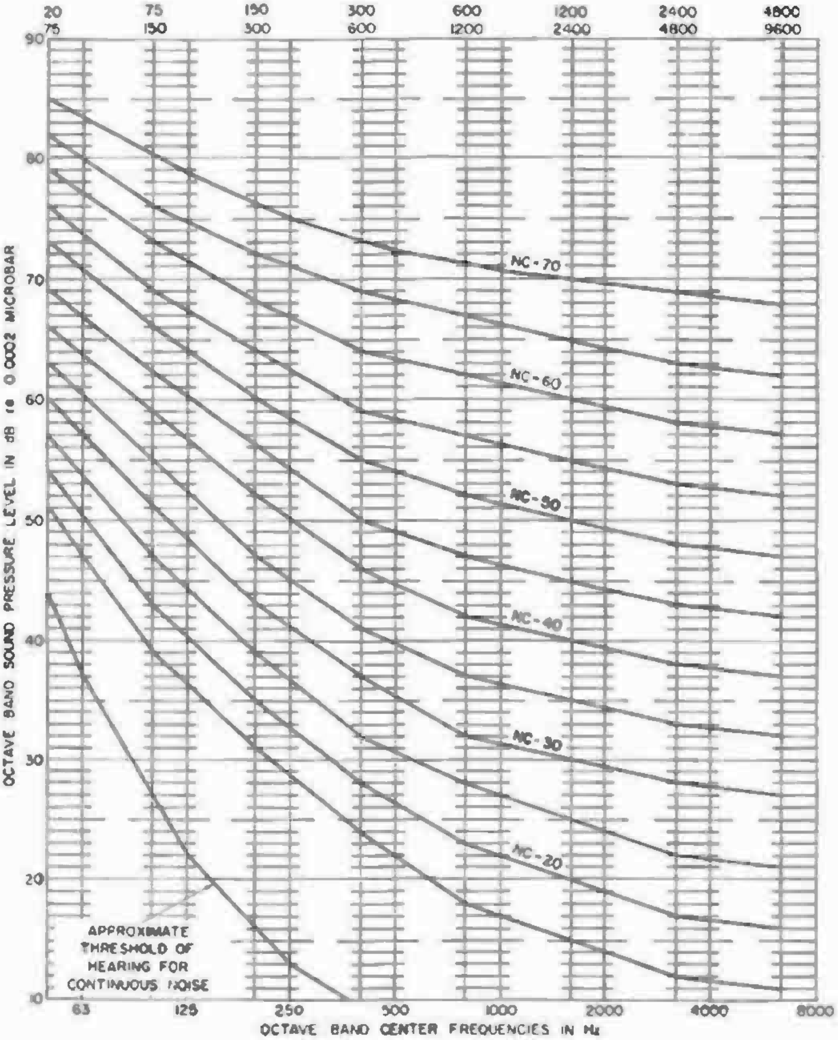

Fig. 2-107. Noise criteria, or NC, curves indicating the maximum permissible noise level for given type enclosures.

octave-bands as a function of the octave-band center frequency. A group of such curves is shown in Fig. 2-107. Curve NC-20 is the one most commonly employed for theaters, concert halls, studios, and similar structures. However, the NC-15 curve should be used whenever possible. The curves include all noises, such as external noises and leak-through from other studios, internal noises, and the ventilating system. The curve at the lower left, is the approximate threshold of hearing for continuous noise.

2.108 ***What is the average ambient noise level of a theater?***—Approximately 40 dB above the threshold of hearing.

2.109 ***Why is it desirable to reduce the low frequencies when recording dialogue?***—To remove tubbyness from the voice caused by playing too close to the microphone; also, to reduce the low-frequency accentuation caused by sets and reflected sounds. (See Question 18.81.)

2.110 ***Describe the construction of a looping stage.***—Looping stages are generally used for post-synchronization of a new sound track for an existing picture. The recording of a new sound track may be necessary for several reasons—the dialogue had noise in the background; it could not be shot on location because of expense or area; certain characters are to be revoiced; a sound track must be replaced due to technical difficulties; or the picture is to be revoiced for another language.

The enclosure of a looping stage is designed so that the walls can be readily altered to change the acoustic conditions to match a particular scene or effect. By moving a group of acoustic panels on the walls, the reverberation of the stage may be changed from a dead stage to a live stage. A group of movable wall panels on a looping stage at Universal Studios, Universal City, California, is shown in Fig. 2-110B, with a floor plan shown in Fig. 2-110A.

Referring to the floor plan, on the north wall is a total of 9 panels, with 5 panels that are movable approximately 180 degrees. Each panel is 4 ft × 16 ft, hinged at the top and bottom, supported by a pipe running parallel to one edge. The inner and outer surface of each panel is treated to be acoustically hard and soft. It will be noted the wall surfaces behind the fixed panels are treated acoustically and are quite dead. The panels are set at an angle of approximately 10 degrees. The fixed panels act somewhat as a flat splay as discussed in Question 2.77. The panels on the west wall are also movable, but are only 2 ft × 13 ft in height, as they must clear the projection room ports above. The treatment of the west and south wall panels is similar to the north wall panels. The stage volume is

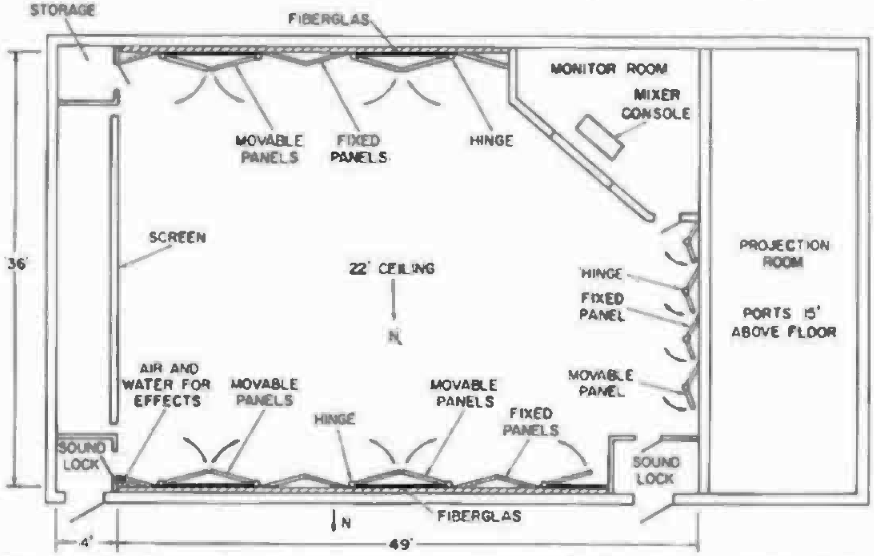

Fig. 2-110A. Floor plan of looping stage at Universal Studios, Universal City, California. In addition to looping operations, this stage is used for making sound effects and can, if necessary, be used as a dubbing stage.

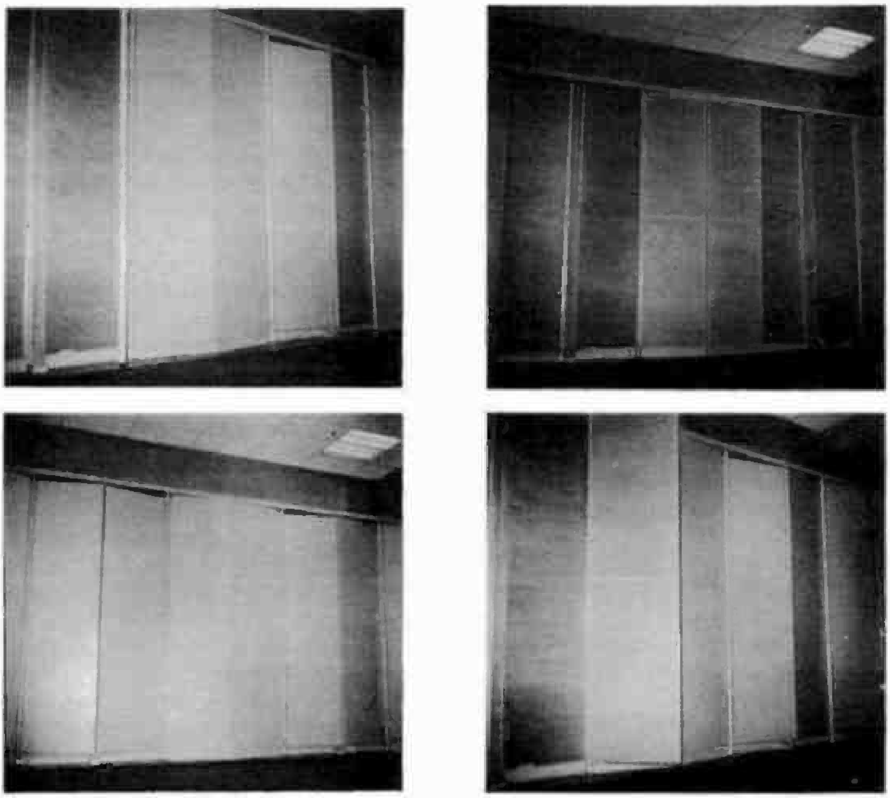

Fig. 2-110B. Interior views of a looping stage at Universal Studios, Universal City, California.

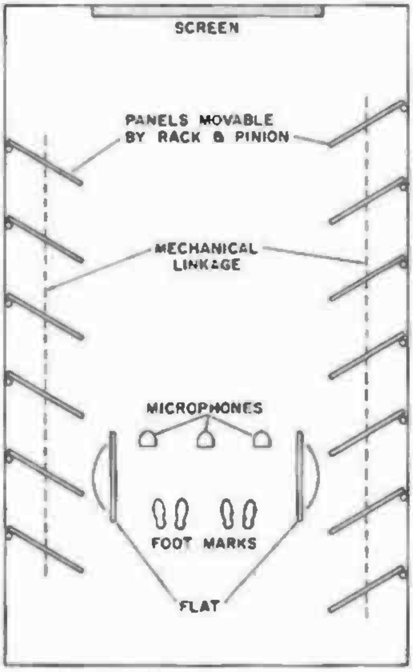

Fig. 2-110C. Looping setup using two flat panels, with movable panels on the walls.

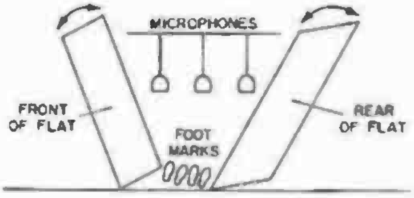

Fig. 2-110D. Looping setup using two panels set at an angle of 10 to 15 degrees.

on the order of 39,000 cu. ft. Wall areas above the panels are set at an angle for diffusion. At the east end of the stage, is a standard motion-picture screen and loudspeaker for projecting the scenes to be looped. The monitor room in the southwest corner of the stage is equipped with a mixing console and other necessary equipment. Outlets are provided on the south wall for microphones, headphones, and intercommunication. Four views of the north wall panels are given in Fig. 2-110B, showing placement for different combinations of the acoustic panel surfaces.

In Figs. 2-110C and D are shown two setups that may be used for looping.

Two flats of the proper acoustical properties are set one on each side of the actors, at an angle of 10 to 15 degrees, with a slight angle with reference to each other. The microphones are hung from the overhead at a fixed distance. Footmarks are placed on the floor for the best position of pickup and future reference. The side wall panels are acoustically hard and soft with the walls behind the panels treated for a high absorption. The panels are linked together, mechanically, and operated by a motor-driven rack and pin arrangement. Thus, for matching the original environment the mixer may adjust the acoustics of the room as he listens to the original sound track.

Looping equipment is discussed in Questions 17.223 to 17.227.

2.111 What Is 3-D sound?—The The term applied to three-dimensional or stereophonic sound.

2.112 What is a monaural sound system?—A sound system consisting of one source of sound, such as a radio, magnetic tape, a record, and the like, using a single loudspeaker for reproduction. It is also termed monophonic.

2.113 What Is a binaural sound system?—A system consisting of two microphones at the point of pickup, placed in the same relationship to each other as the ears of a listener. The microphones are connected to separate amplifier systems and transmit the program material to the listener through headphones. Each headphone is connected to its own amplifier. Such systems are considered to be as nearly perfect as present-day knowledge will permit. The block diagram of such a system is shown in Fig. 2-113. True binaural sound cannot be achieved with loudspeakers, only headphones. When

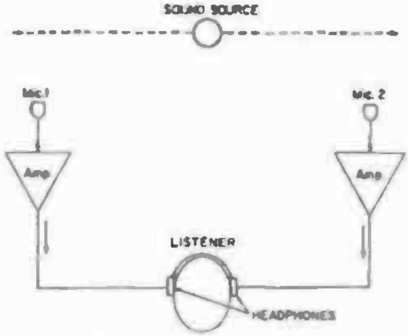

Fig. 2-113. A true binaural sound-reproducing system.

loudspeakers are used it is two channel stereophonic sound.

2.114 What is a stereophonic sound system?—A system using two or more microphones with a separate amplifier and loudspeaker for each microphone channel. This system is also referred to as an auditory perspective system. With such an arrangement of equipment, the sound travels from one speaker to the other as the principals move across the stage. Such a system permits an orchestra to be reproduced closer to its proper perspective.

2.115 Describe how a production stage may be altered acoustically for recording music.—Stages designed for production shooting generally have a reverberation period on the order of 0.5 to 0.6 second, and are not suitable for the recording of music unless the reverberation period is lengthened. Such stages may be used for music recording by the use of a group of polycylindrical diffusers (Fig. 2-76D). These diffusers are placed about 1 foot apart in a semicircle at the rear of the orchestra and slightly forward at the sides, as illustrated in the floor plan drawing of Fig. 2-115.

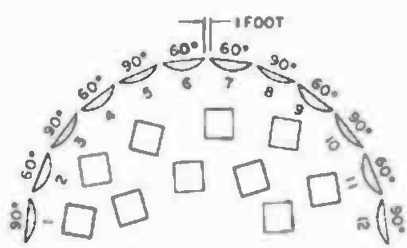

Fig. 2-115. Floor plan for setting up polycylindrical diffusers to record an orchestra. The squares represent the acoustic clouds hung from the overhead.

After construction, the diffusers are backed by hanging a Fiberglas blanket from top to bottom; however, in some instances they may be left open. They are held in vertical position by sand bags at the bottom and stage braces at the sides. Assume a total of 12 panels are to be used, they are made up in pairs having 60- and 90-degree convex surfaces and placed alternately as shown in the illustration.

In addition to the diffusers, acoustic clouds about four feet square made of plywood are hung from the overhead 12 to 15 feet above the orchestra. No two are to have the same exact angle relative to the floor. The surface of these clouds is sprayed with lacquer as are the diffusers. In the construction of such diffusers and clouds, *Masonite* should not be used as it is not stiff enough. Two by four wooden braces set edgewise are used across the upper surface of the flat panels used for clouds which, if not braced, may vibrate, causing rattles and buzzes. (See Question 2.76.)

2.116 What is acoustic gain?—It is the difference in sound pressure level between an unassisted performers acoustic output, and the same performance using a sound reinforced system as measured at a given observation location.

auditorium?—This is an expression used to indicate that the acoustic peaks in an enclosure have been reduced by the use of a series of tuned circuits in the electronics of the sound system feeding the enclosure. Although this method of correcting the acoustic characteristics of an enclosure was used by Volkman of RCA in motion-picture theaters in a simplified form as early as 1930, it has remained for Dr. C. P. Boner and his son, C. R. Boner, with the aid of modern test equipment to realize the full capabilities of such a method.

To tune an auditorium, a small loudspeaker is placed about two feet behind a microphone placed in the position where it will be normally employed. The loudspeaker is directed into the microphone and the auditorium, and is energized using a random-noise generator. The output of the speaker is adjusted for an SPL of about 80 dB, as measured on a sound-level meter close to the microphone. The initial adjustments are accomplished with the sound system off. A reading of the speaker level fed by the random-noise generator is then taken at the extreme rear of the auditorium with a sound-level meter. The sound system is now energized with the random-noise generator and the gain adjusted just below the point of feedback.

At this point of gain, the SPL of the sound system is noted. Subtracting the first measurement from the second gives the acoustical gain of the auditorium. As a rule the average auditorium will yield about 1 to 2 dB of acoustic gain. With the auditorium properly tuned, up to 30 dB of acoustical gain is possible. This will permit the full frequency range to be realized, thus increasing the intelligibility of speech and also enhancing the reproduction of music.

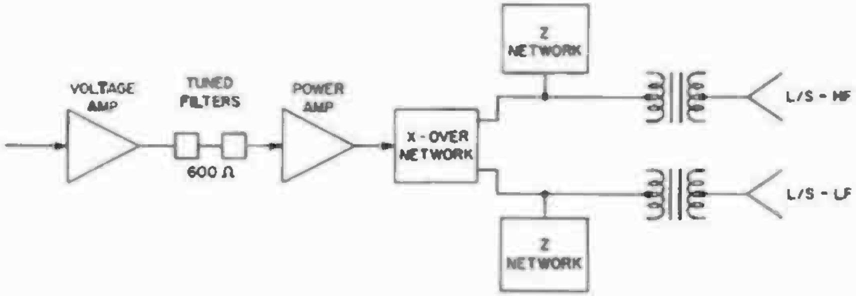

Fig. 2-117G. Impedance-correcting networks used with the DuKane *Varacoustic* sound control system.

Dr. Boner's method of tuning an enclosure is to employ a group of tuned filters between a separate voltage and power amplifier, transformer coupled by a 600-ohm impedance line (Figs. 2-117A and B). It is in this line that the tuned filters are connected.

Through the use of such filter sections, the gain of the amplifier system is reduced at the *peak frequencies* of the auditorium, resulting in an *inverse electrical correction that simulates a uniform (or approximately uniform) acoustic response.* It is not uncommon in some auditoriums to encounter peaks on the order of 20 dB or more. It should be understood the acoustics of the auditorium are not corrected, but the frequency characteristics of the amplifier system are *altered inversely* to the auditorium characteristics to compensate for the acoustical peaks. The amplifier system is of *uniform frequency* characteristics without the filters.

This system of correcting for acoustic peaks is generally used where one or more microphones are employed. *This method of acoustic correction for motion picture theater reproduction is not recommended at this time, since the sound system would not be compatible with the frequency characteristics used for recording motion pictures.*

After inserting the first peak filter, the sound system is again energized and the next largest peak noted. A tuned filter of the correct frequency is inserted in the link circuit and adjusted for the peak amplitude. This same procedure is followed until all the major peaks are removed. Small peaks may now be removed in order of their importance. It is possible in a large auditorium to employ 20 to 100 tuned filters. In a well-tuned auditorium, an acoustic gain of 15 to 20 dB can be expected. Notch filters suitable for this work are discussed in Question 7.12. (See Question 2.116.)

A second method of tuning an auditorium, developed by Arthur C. Davis and Don Davis of Altec Lansing Corp., accomplishes similar results, except the tuned-circuits are constant-impedance bridged-T filters spaced ⅓ octave apart. It is claimed for this method of tuning that *hangover and ringing* effects in the tuned circuits are avoided; also, the impedance remains constant, whereas tuned circuits are not of constant-impedance. In setting up this latter system, a method of determining the peak frequency of the auditorium and adjusting requires only the use of an oscilloscope. This system has been termed *Acousta-Voicing* by Altec Lansing.

Pictured in Figs. 2-117C and 2-117D are front-panel views of the Altec-Lansing system, showing the filters and their controls. The small group is used where a small number of filters is required. The larger group will supply corrections for 24 different frequencies.

A response curve (A) taken from the left hand loudspeaker of a two-channel stereophonic reproducing system in a given enclosure is indicated in the graph of Fig. 2-117E. Frequencies of constant amplitude were applied to the amplifier system, and the acoustic response of the enclosure was measured by means of a sound-level meter. The frequency response of the amplifiers without the filters was uniform over the indicated frequency range given at the lower edge of the graph.

Superimposed curve "B" is the *inverse* electrical response of the bridged-T filter sections alone. Each filter section is capable of being attenuated 14 dB. Greater attenuation for a given frequency can be achieved by adding a second filter of the same frequency. The lower curve "C" represents the *acoustical* response of the enclosure after the introduction of the various filter sections, again read with a sound-level meter. It will be observed that the rising characteristic at the low-frequency end and the midhigh frequency portion of the spectrum has been reduced, resulting in the listener hearing a more uniform acoustical response in the auditorium. The right-hand amplifier system was treated in a similar manner.

If the problem is one involving only two or three peaks, peak frequencies may be reduced by connecting tuned circuits or other type filters in the output of the power-amplifier feed line to the speakers. (See Fig. 20-137.) Or, the amplifier system may be altered as discussed in Question 6.96 under Equalizers, a method still used in some theater equipment. When using filters in the output line of a power amplifier, the insertion loss of the filter must be quite low; if it is not, considerable power will be lost.

In evaluating the two systems, the first system described employs filters tuned to the *exact frequency* of the auditorium peak frequency. In the latter system, the filter frequencies are *fixed*, but separated in ⅓ octave intervals. Therefore, it is possible that a filter frequency may be almost on the peak but not exactly. Also, the adjustment range is in 1-dB steps, whereas the tuned-filter type is adjusted to the *exact amplitude* of the peak.

Using either of the two systems in an auditorum results in greater acoustic gain by the reduction of acoustic feedback and the removal of objectionable peaks in the auditorium. Listening to reproduction through either of the above two systems, a noticeable improvement is observed.

A third system, manufactured by the DuKane Corp., termed *Varacoustic* sound control is pictured in Fig. 2-117F. Although only four filters are shown, any number may be employed, and they are similar to those employed by Dr. Boner. In addition to the filters (connected in a 600-ohm link between the voltage and power amplifier) are impedance-correcting networks in parallel with the lines from the crossover network feeding the loudspeaker sections. These networks tend to hold the speaker impedances fairly close to their design value which normally varies over a considerable range. (See Questions 20.89 to 20.91.)

2.118 Show a typical microphone placement plan for monophonically recording an orchestra and vocalist.—Such a plan is shown in Fig. 2-118, using a split recording channel. The final microphone placement will be governed

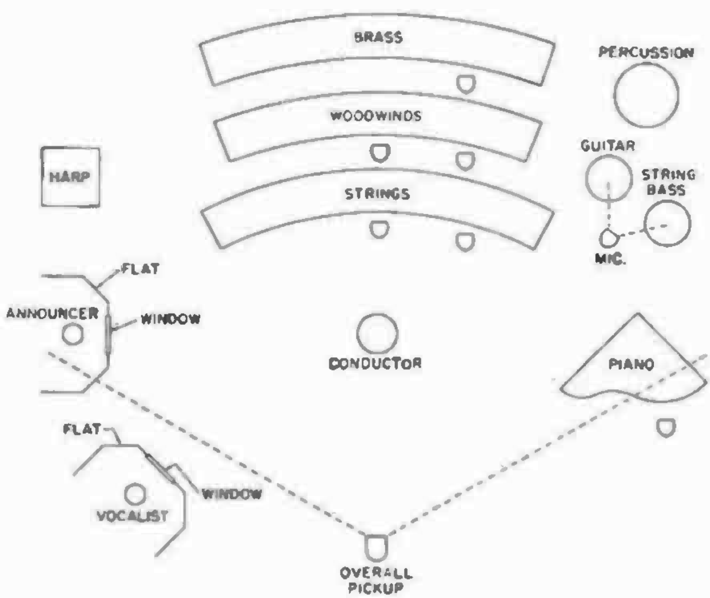

Fig. 2-118. Suggested microphone floor plan for monophonic recording of a large orchestra and a vocalist.

by the solo instruments, number of musicians, and the type of music to be recorded.

2.119 What is meant by presence? —A quality in the reproduction that gives the impression to the listener that the person speaking is present in the room.

2.120 How is presence obtained in recording?—By microphone placement, proper equalization in the midfrequency range, the acoustics of the recording studio, and the signal-to-noise ratio of the studio and recording system.

2.121 In what part of the frequency band is presence equalization introduced?—In the frequency range from 1500 to 5000 Hz. Recording characteristics are discussed in Question 18.81. These same recording characteristics are also used with magnetic tape and disc recording. Presence equalization may also be added during rerecording or when transferring sound tracks.

2.122 How are microphones set up on a music-scoring stage?—There are no fixed rules regarding microphone placement on a music stage; however, the usual method is to employ individual microphones for the solo instruments and vocalist. Separate microphones may be used to build up the woodwinds and strings, depending on the orchestration, and if the pickup is monophonic or stereo. (See Question 2.74.)

2.123 What is the recommended placement for a single microphone orchestra pickup?—Approximately 20 to 30 feet in front of the orchestra and snspended at a height of 12 to 18 feet above the floor. A capacitor or amplitude-modulated microphone is often used for this type pickup. If too much reflected sound is heard, move the microphone closer to the orchestra. This will also improve the definition. For dance bands a higher order of definition is required than for a large orchestra. One or more microphones may be required for solo instruments and a vocalist. Velocity microphones with directional characteristics should be used for the latter positions.

2.124 Show the microphone placement for a small dance band.—Such a setup is shown in Fig. 2-124, and is typical of that used for broadcast and recording. Each microphone covers a group or an individual instrument. The microphones should be placed close to the instruments to obtain a high order of definition.

2.125 Show the microphone placement for a small television show.—A typical setup for a small television studio, presenting action on a set, intermixed with commercials, and using a musical background, is shown in Fig. 2-125. A unidirectional microphone should be used on a boom to reduce reverberation and background noise of the stage.

2.126 How are microphones placed for a radio broadcast show?—The presentation of a radio broadcast show is slightly different from that of other type microphone pickups. The actors

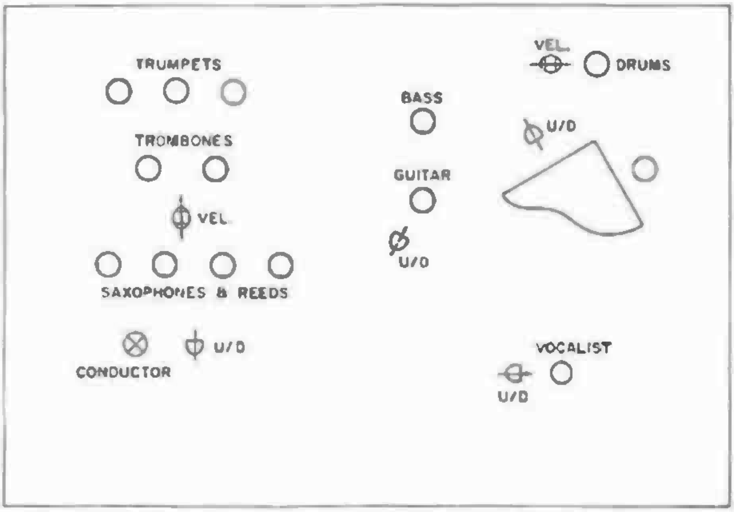

Fig. 2-124. Typical instrument and microphone setup for a small dance band.

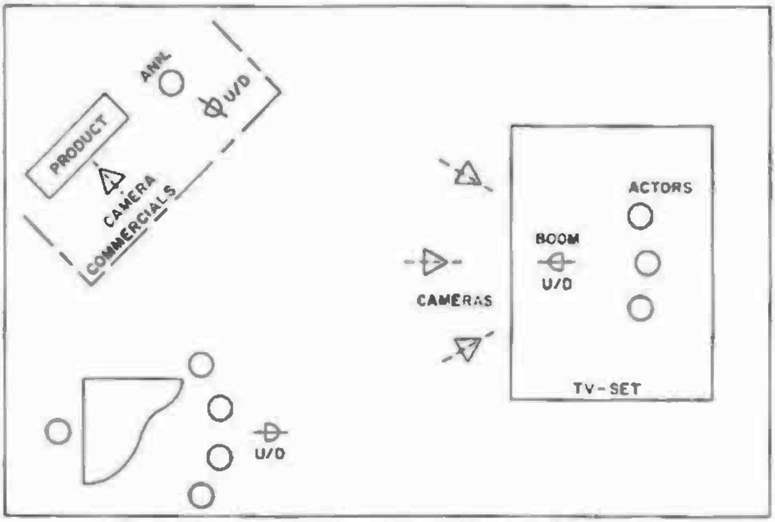

Fig. 2-125. Typical setup for small television studio.

are generally placed on each side of a ribbon-velocity microphone (figure-8 polar pattern) to eliminate the need for stepping up to the microphone. The orchestra and announcer use unidirectional microphones to reduce noise and pickup from other parts of the production. The sound effects man is placed behind flats, for isolation (Fig. 2-126). A unidirectional microphone is also employed here. (See Question 4.47.)

2.127 ***Show the basic placement for recording or broadcasting a large symphony orchestra.***—The basic plan for microphone placement, when recording or broadcasting a large symphony orchestra, is shown in Fig. 2-127. Although only a few microphones are shown, actually in such a large operation microphones would be placed in several other positions to pickup a soloist or a group of instruments. This would be particularly true for television. An overall microphone is suspended about 15 feet above the orchestra, and about 50 to 25 feet in front of the first row of instruments. Considerable care must be taken to balance the orchestra for a uniform pickup. If the recording or broadcast is to be released

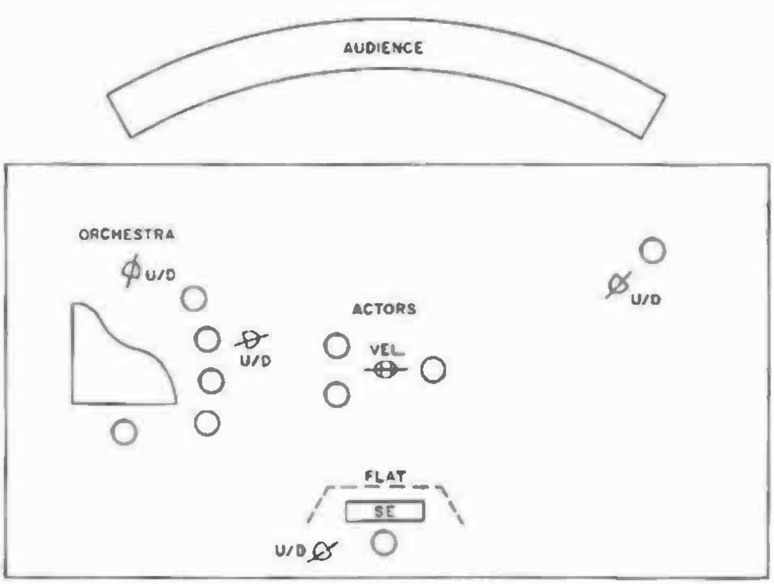

Fig. 2-126. Typical microphone setup for radio broadcast show.

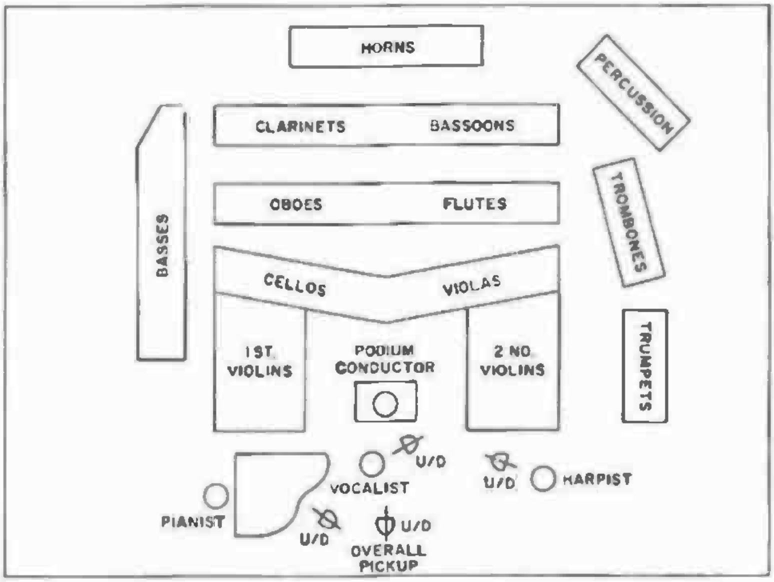

Fig. 2-127. Basic setup for large symphony orchestra.

stereophonically, dual microphones and special placement techniques are employed.

2.128 Describe the different methods used to produce artificial reverberation.—Over the years there have been many different methods of generating artificial reverberation. Among these methods are magnetic recorder-reproducers employing several reproducer heads spaced at intervals along the tape to induce delay. Another method uses long metal pipes laid in a straight line or coiled, with a loudspeaker unit at one end and a microphone at the other. Additional microphones are placed at intervals along the pipe to induce delay. Another design, the echo chamber, propagates the sound by means of a loudspeaker in a room with hard walls. The sound is fed to a loudspeaker and picked up by a microphone at the opposite end of the room. Another method employs the transmission of sound waves through a group of steel springs or liquid. In this design, vibrations are picked up from the sides of the tank, thus inducing delay.

The most commonly employed instrument is one using a large metal plate. This method is discussed at length in Question 2.130. (See Question 2.80.)

2.129 Describe the construction of a reverberation unit employing steel springs.—Reverberation units employing steel springs are often used with electronic organs and in some type units designed to be used with radio receivers. Reverberation is the prolongation of sound waves by repeated reflections, and if the reflection is long enough to be delayed 1/20 second, it is then classed as an echo.

The device shown in Fig. 2-129A is electromechanical, and introduces multiple echoes by means of reflections set up in a network of coiled springs about 3 feet in length. The audio signal, when fed into the reverberation unit, is converted into mechanical energy by a moving-coil driver unit at the top of the spring assembly. The driver unit is similar in design to a dynamic loudspeaker unit, but without a diaphragm. Waveforms are transmitted through the coiled springs, which have the property of conducting the sound waves more slowly than the speed of sound through air. In this manner, a spring of sufficient length can be made to produce a delay comparable to that in a large auditorium.

The driver unit (A) induces vibrations into the stirrup (B) by its vertical motion. Springs 3 and 4 hold the stirrup in position, but permit it to move with freedom in the vertical plane. Spring 1, at the far left, balances the tension of the other springs, through lever (F) above the driver unit. Springs 1, 3, and 4 are almost entirely immersed in oil, as they act largely as dampers, to stabilize the response of the driver unit and to prevent undesired reflections.

Sound waves from the stirrup travel downward through the open spring 5 at the far right, to a ceramic pickup (C), where the mechanical signal is converted to an electrical signal and fed to a preamplifier. The first reflected signal is delayed about 1/5 second from the original signal, which goes directly to the output amplifier. The same waveform also travels downward through spring 2 which enters a small oil damping tube. At the bottom of this spring, the wave is reflected back at a reduced intensity caused by the damping action of the oil. At the stirrup, the horizontal lever (D) transfers the wave to the right hand spring 5, then to the pickup (C), producing a second reflected sound, which is about 1/18 second behind the direct signal. Little energy is absorbed by the pickup unit and the wave again is reflected back through spring 5. The first reflected signal transverses spring 5 and is transferred by lever (D) and travels downward through spring 2, to the short oil tube. Here again the wave is reflected and reduced in intensity. It then retraces the same path to the pickup, and produces a third reflection which is about 1/15 second behind the direct signal. The second reflected signal is similarly repeated, and this process continues over and over, resulting in a series of signals about 2/15 second apart, until they are dissipated by the friction of the oil in the short tube.

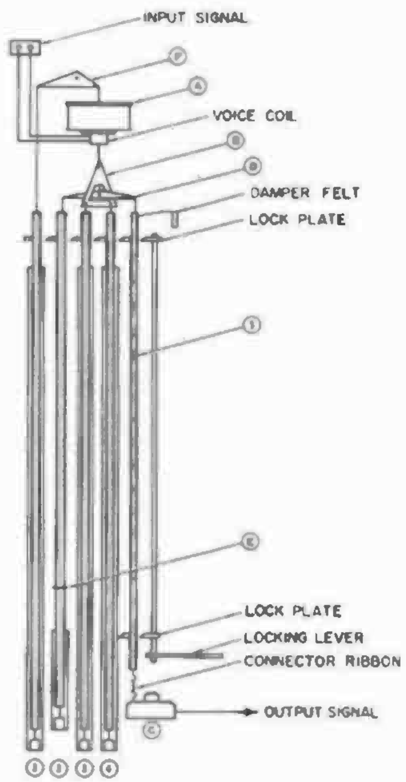

Fig. 2-129A. Interior construction of an electromechanical reverberation unit employing coil springs.

Above the short oil tube is placed a reflecting pin (E) attached to spring 2 which causes a partial reflection, thus smoothing out the overall response. The higher the level of the oil in the short tube, the less the number of reflections. Therefore, adjusting the oil level changes the reverberation time. Generally when the oil level has been established once, it is not changed, and only the electrical controls are used to control the amount of reverberation. A block diagram of the external connections is shown in Fig. 2-129B. The use and connections for reverberation units and controls in conjunction with recording consoles, are discussed in Section 9. (See Question 2.128.)

2.130 ***Describe the construction of a reverberation unit employing a steel plate.***—Because of the limitations of the

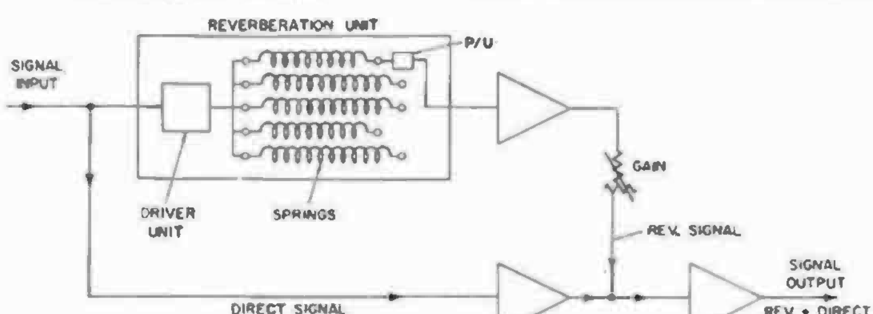

Fig. 2-129B. External connection for an electromechanical reverberation unit.

various methods of producing artificial reverberation, discussed in Question 2.128, and the space required for the construction of an echo chamber (Question 2.81), other means had to be developed for the generation of controlled synthetic reverberation. In Figs. 2-130A and 2-130B is shown a device invented by Dr. W. K. Kuhl, of Hamburg, West Germany and manufactured by EMT of Germany. The reverberation unit is obtainable for either monophonic or stereophonic reproduction. However, the stereophonic type may be used for either monophonic or stereophonic reproduction. As the basic principles are the same for either type, only the stereophonic type will be discussed.

The EMT reverberation unit utilizes the physical properties of metal to achieve its effect, by the use of a specially selected annealed steel plate. The plate is excited by an impulse which sets up within the plate, bending

oscillations that will produce reflections which increase in density with time. Reflections in a three-dimensional room, such as an echo chamber (Question 2.81), become more dense as a function of the square of time. In comparing the two systems, the human ear is unable to recognize the difference between these two operating modes.

Through appropriate steel and critically chosen dimensions, it is possible to produce a plate that will have an adequate number of oscillations. The length and frequency response of the decay time produce an artificial reverberation effect which is comparable to that obtained using a conventional echo chamber. Referring to Fig. 2-130B, the principal component of the unit is a 1/32-inch steel plate (A), suspended at its four corners by steel wires under tension, in a tubnlar steel frame (B). At the front (Fig. 2-130A), parallel to the steel plate is a Fiberglas plate (A) suspended on a pantograph mechanism to permit its movement toward or away from the steel plate. At a position of 1/8 inch from the plate, the reverberation time is reduced to 1 second at 500 Hz. *At no time does the absorbent material come in actual contact with the steel plate.* The movement of the damping plate may be accomplished by the use of a manual control (C), or by the use of a remote control from the mixer console. The reverberation time is indicated in fractions of a second on a remote meter at the console.

In selecting the material for the plate, its internal damping and the resulting reverberation must be taken into consideration. Losses in the plate are additively formed by the nonfrequency-dependent and the frequency-dependent

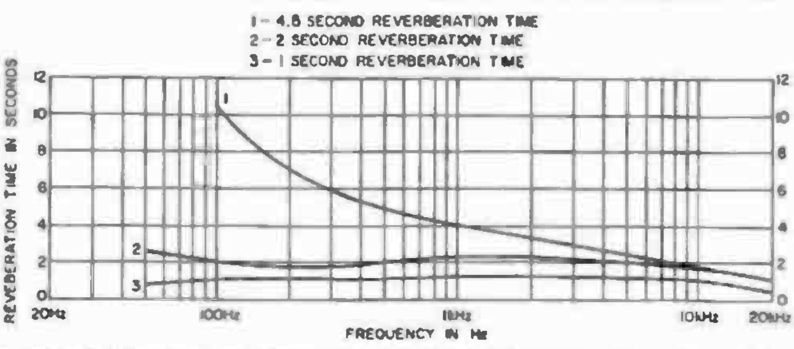

Fig. 2-130F. Reverberation times as a function of frequency for various distances between reverberation and damping plate.

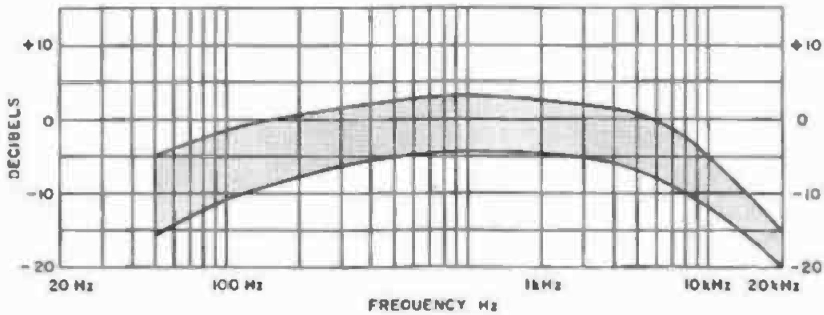

Fig. 2-130G. Tolerance range of the frequency response for an EMT 140st reverberation unit, using white noise with ⅓-octave filter on 25-Hz warble-tone generator. A 2-second reverberation time.

parts which are caused by the heat conductivity loss of the bending modes. For the high frequencies the nonfrequency-dependent parts predominate. For the midrange and low frequencies, the frequency-dependent parts predominate. Since phase velocity of the bending mode of the plate in the entire frequency range is smaller than the velocity of air, damping of the plate through the greatly reduced radiation of airborne sound may be neglected, when compared to other damping causes. Damping is approximately directly proportional to the frequency, and inversely proportional to the thickness of the plate.

The plate is of a high quality cold-drawn steel, approximately 3 feet × 6 feet × ⅟₆₄ inch in thickness, and will cause a time delay of about 5 seconds at a frequency of 500 Hz. The plate must be completely undamped, and extremely flat. Referring again to Fig. 2-130B, the tubular frame supporting the plate has three transverse bridges. One carries the moving-coil driver unit (C), while the other two carry two crystal contact microphones or pickup units, (D and DD). The frame also supports the damping mechanism for controlling the length of the reverberation time. (See Fig. 2-130C).

The steel plate is excited by an audio signal applied to the driver unit, which is similar in construction to a dynamic speaker unit, but without a diaphragm. The reverberated signal is picked up by the contact microphones, (D and DD). Since these microphones are acceleration-sensitive, their output voltage rises at the low frequencies around 250 Hz, stays constant up to 900 Hz, and falls off at a rate inversely proportional to the frequency. The resonant frequency of the microphones is well beyond 20,000 Hz. The internal capacitance of the crystal microphone is approximately 500 pF. The vibrational patterns set up in a plate for a monophonic unit are shown in Fig. 2-130D.

At a frequency of 1000 Hz, the travel time between the driving unit and the microphone is about 6×10^{-3} seconds, which equals the time a sound wave in air travels 6 feet. Because of this short time of travel of the flexing waveforms, the successive repetitions follow in rapid sequence, with the number of reverberations growing with time.

When adding reverberation to stereophonic recordings, two separate conditions must be satisfied. First, it must extract from the stereo signal its direct componeut, and second, it may not as a result adversely affect the significant information contained therein. To achieve this eud, use is made of a so-called "M" channel, which is formed by the addition of two stereo signals, according to the formula, $A + B = M$ (See Question 4.62). This is accomplished by feeding a part of the unreverberated signal output to microphones D and DD through isolation networks, to a common bus. For compatibly recorded signals, this addition of signals D and DD into an "M" channel produces a monophonic signal containing all the information of the two stereophonic signals. The two reverberated signals from the microphones are incoherent and bear no relationship. This is an important factor, for the two resulting stereo signals with echo must have between them a statistically distributed directional and informational content. The frequency response of the reverberation time, without additional damping, corresponds approximately to that of an empty stone-walled church, or about 5 seconds at 500 Hz. At the low-frequency end there is a rise, and toward the high frequencies a decline of about 1.5 seconds, out to 10,000 Hz.

The driving amplifier is so designed that the third order harmonics will not exceed 0.6 percent for a peak level of 1.55 volts at the input, using white noise through a ⅓-octave filter. This takes into consideration the statistical power distribution of sound modulation which normally drops toward the higher frequencies. Signal-to-noise ratio, measured at the output of one contact microphone preamplifier, using a reference frequency of 300 Hz with a reverberation time of 2 seconds, is greater than 60 dB.

Several of these units may be installed in a single room, without fear of interference, as there is practically no sound radiation. The ambient noise level of the room should not exceed 40 dB SPL. To eliminate low-frequency noises transmitted through the structure, the units should be set on resilient mountings, spaced about 1 foot apart.

A block diagram of the internal and external connections for the stereophonic unit and its associated equipment, is given in Fig. 2-130E. The reverberation characteristics as a function of frequency for various distances of the damping plate from the steel plate, is shown in Fig. 2-130F, and the frequency tolerance, using a white-noise generator and ⅓ octave filter, at a reverberation time of 2 seconds, is given in Fig. 2-130G. The same information may be obtained, using a 25 Hz warble oscillator. The internal input impedance is 1000 ohms, and the internal output impedance is 25 ohms, and is designed to operate into a 200-ohm load impedance.

The complete unit is mounted in a wooden case, and weighs approximately 400 pounds. The external and internal appearance of the monophonic unit is the same, except for the additional amplifiers and contact microphone.

The installation of the described reverberation unit is quite critical, if the maximum capabilities are to be realized. The manufacturer's instructions must be followed closely, as the adjustment of the steel-plate tension is all important. The use of reverberation equipment is discussed in Section 9.

2.131 What is a tempo regulator?—A device that may be attached to a standard magnetic-tape recorder, for changing the program length without changing the pitch, or changing the pitch without changing the program length.

In Fig. 2-131A is shown a tempo regulator, manufactured by ELTRO GmbH & Co., Heidleberg, West Germany, threaded for tempo regulation. For pitch control the machine is threaded as shown in Fig. 2-131B. For pitch control the most critical component is the rotating-head assembly, which consists of a single magnetic head-coil, with four separate playback headgaps 0.0002-inch in height, spaced 90 degrees apart at the perimeter. It is essential that the four gaps match perfectly with respect to three important details. First, the angular spacing must be exactly 90 degrees. Second, the four gaps must be absolutely parallel to each other. Third, the output from all four heads must

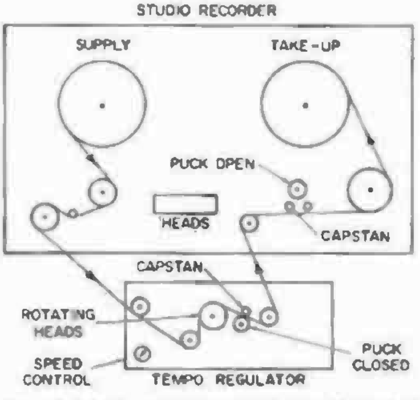

Fig. 2-131A. Tempo regulator threaded for tempo regulation.

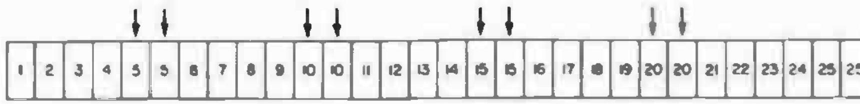

Fig. 2-131D. Playback with an expansion of 20 percent. Every 5th section is repeated as indicated by the arrows.

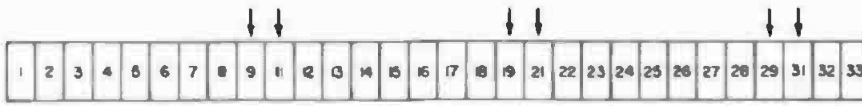

Fig. 2-131E. Playback with a compression ratio of 10 percent. Every 10th section is omitted.

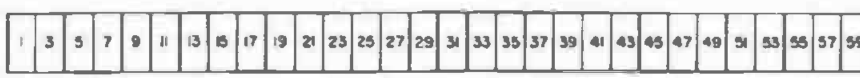

Fig. 2-131F. Playback with a compression ratio of 50 percent. Every 2nd section is omitted.

correspond within 1 dB, over a frequency range of 30 to 15,000 Hz.

The head-coil is comparable to those used on a standard tape recorder. The output of the rotating-head assembly is connected in place of the playback head on the studio recorder. The magnetic tape is threaded around the rotating-head assembly, to make a 90-degree wrap-around covering two head-gaps. During playback, the rotating head scans the tape by one gap, leaving the tape as the next gap starts to scan. This action provides continuous reproduction regardless of the tape speed or the rotational speed of the head.

The capstan of the regulator unit is fixed to a rotating stator of a drive motor. This stator is driven by an auxilliary motor over a constantly variable transmission. The playback-head assembly is driven by the rotor of the drive motor through a gear transmission. Both motors are synchronous; therefore, the speed of the capstan, in relation to the speed of the playback head, remains constant.

Consider now, what actually determines the pitch. It depends on the speed of the head gap relative to that of the tape. If the tape is threaded in the standard recorder, as shown in Fig. 2-131B and the speed indicator dial set to 100 percent, the rotating head will be at rest, and the tape will playback normally with constant speed and constant pitch. If the head assembly is rotated in a direction opposite to the tape travel, the result will be an increase in the relative head gap to the tape speed with an increase in pitch. Rotating the head in the direction of the tape travel, the relative speed of the gap-to-tape speed is decreased and the pitch is *lowered*. As an example, if the rotational speed of the head-gap is increased to twice the gap-to-tape speed (30 ips), the pitch will be *raised* one full octave. To illustrate tempo change, it will be assumed that the pitch, as explained above, has been raised one octave. Now if the speed of the playback is changed to 7.5 ips, the pitch is brought back to normal, while the tempo has been cut in half. This the regulator accomplishes by linking the rotational speed of the head with the speed of the studio recorder capstan in such a manner as to maintain the pitch constant over a wide range of speeds.

To better understand the tempo regulator functions, expansion of the reproduction time takes place when the head is rotating in the opposite direction of the tape travel. When compressing the program material, the head rotates in the direction of the tape travel. The tape speed during reproduction, in relation to the original recording speed of 15 ips, is adjustable by a control on the regulator. For example, with the control at 120 percent, an increase in tape speed by 20 percent results in a reduction of reproducing time to $^{100}/_{120} \times 1\% = 83.33$ percent of the original recording time. A decrease of tape speed to 95 percent represents an increase of reproducing time to $^{100}/_{95} \times 1\% = 105.26$ percent of the original recording time. The tape speed may be varied from approximately 50 to 200 percent of the original recording time. Accurate adjustments to within 0.5 percent of the recording speeds are possible.

In Fig. 2-131C is shown the scale on a regulator unit for setting the speed of the rotating head for a given compression or expansion. The area between 80 to 120 percent is the normal operating band, where the minimum amount of distortion may be expected. Outside of these limits, the distortion will increase, depending largely on the type of recording.

The increase of reproducing time is basically an expansion of the recording time, obtained by repeating the reproduction time of certain individual sections. The decrease of time is obtained by omitting certain sections of the recording, and combining the remaining sections to obtain a continuous reproduction. At the same time, the speed of the recording medium in relation to the playback media (relative speed) is constant. This is achieved by the special motor assembly discussed previously.

Playback of a tape with an expansion ratio of 20 percent means the reproduction of every 5th section of tape is repeated again, as shown in Fig. 2-131D. The arrows above the numerals indicate the repeated sections. Using the compression ratio of 10 percent (Fig. 2-131E), every 10th section is omitted, and the 11th section follows immediately after the 9th section, the 21st after the 19th, etc. Using a compression ratio of 50 percent, every 2nd section is omitted (Fig. 2-131F).

To prevent the occurrence of audible distortion, it is necessary that during expansion no complete sounds are omitted, or during compression, no complete sounds are repeated. The additions or deletions are on the order of 30 milliseconds, and are always shorter than the shortest sound, in either music or speech. In use, the regulator unit may be installed permanently on a studio recorder, or set on a stand that is parallel with the transport system of the recorder. The output of the rotating head is connected in place of the normal playback head in the studio recorder. The regular unit contains no amplifiers or electronic components, except the special driving motor assembly.

Tempo regulators have been used quite successfully in the motion picture industry for correcting sound tracks where the sound and picture are not synchronized. The sound track is rerecorded at a speed that matches the action. If the out of sync conditions are such that the rate of change varies between action and sound, short sections of the sound track are rerecorded and during the editing are cut in at the proper positions.

Other uses for tempo regulators include training courses, slowed down

Fig. 2-132A. Universal Audio Inc., Model 962 Digital Metronome.

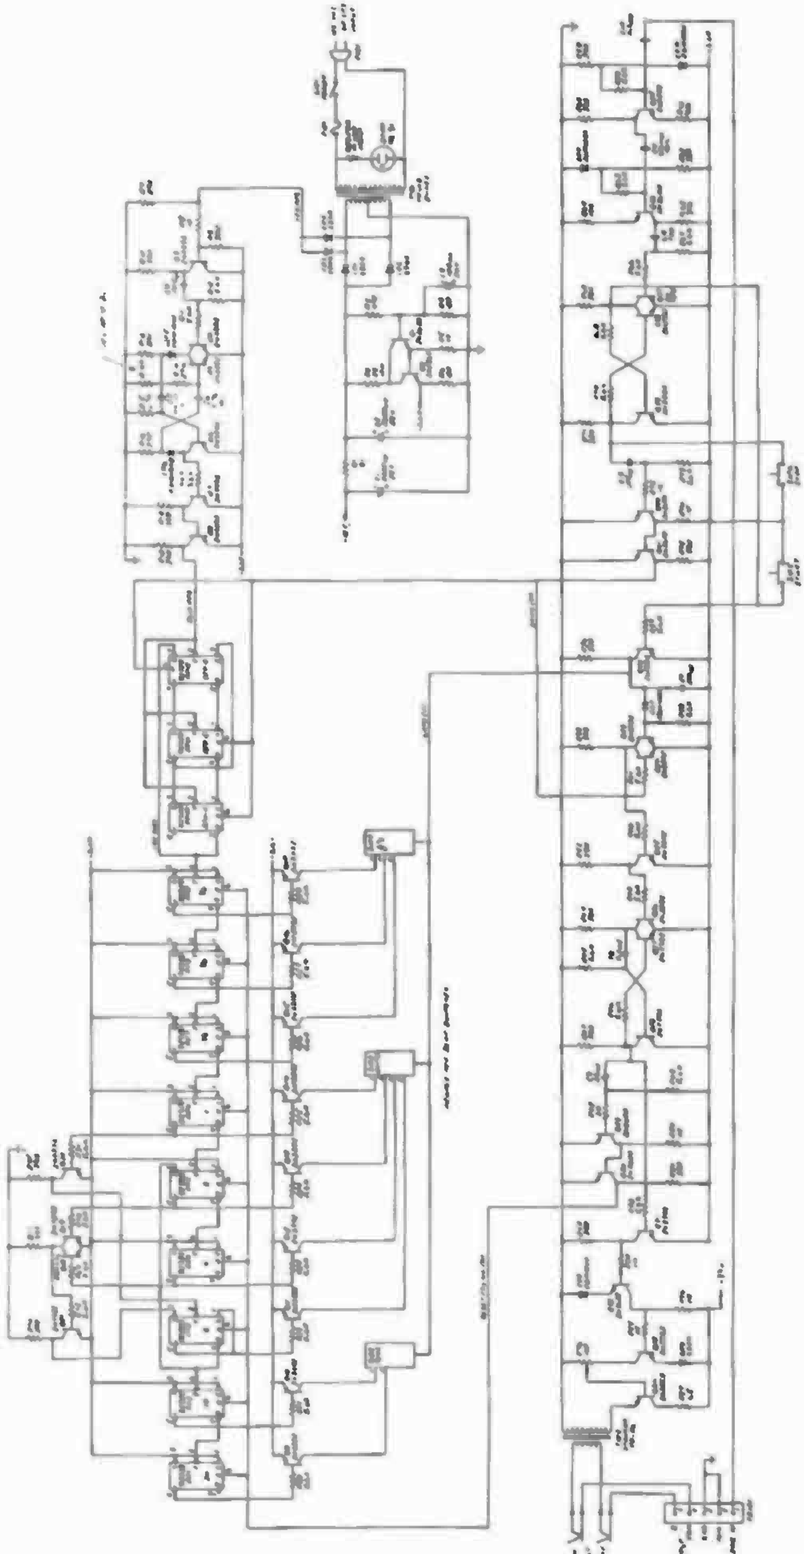

Fig. 2-132B. Schematic diagram for Universal Audio Inc. Model 962 digital metronome.

speech for language study, decreasing the time of commercials for radio, dictation speed reproduction, and many other uses. Speech compression is also possible using computer techniques. For details of this type compression the reader is referred to the appropriate literature.

2.132 ***Outline the principles of metronome design and operation.***—Metronomes are either a spring-driven or motor-driven mechanical device, with a moving pendulum, which produces a tick as it moves back and forth, for beating time. The rate of the beat is controlled by a movable bob that may be raised or lowered on the pendulum, to adjust for a fixed amount of beats per minute.

The Universal Audio Inc., Model 962 digital metronome (Fig. 2-132A) is a precision instrument capable of 312 different tempo beats with maximum deviation (nonaccumulative) on the order of ± 250 microseconds, and is used by motion picture studios for animation, sound effects, and with music scoring. The volume is adjustable, and low output impedance permits the use of a large number of headphones. The beat has a sharp and distinct wavefront, so that it may be easily heard over background noise usually present in film loops. Based on film speeds of 24 fps, tempo beats of 1 frame per beat to 40 frames per beat in ⅛ steps are available by selector switches.

An oscillator, synchronized to the 60-Hz line frequency generates the timing pulses. When the proper count of pulses is reached, an output click is produced, and the counter is reset. Two voltages, —3.6 and —16 Vdc, and a 120-Hz signal for oscillator synchronization, are generated in the power supply. The natural frequency of the oscillator is slightly slower than the required 960 Hz since it is a free-running (astable) *unsymmetrical multivibrator* so designed for ease in synchronization, which is accomplished by the 120 Hz derived from the transformer secondary and diodes CR3 and CR4. The schematic diagram is given in Fig. 2-132B.

2.133 ***How are film spool-banks and continuous film-feed mechanisms constructed?***—A film spool-bank is a group of 16-mm or 35-mm *ball-bearing* plastic rollers used in film processing machines, mounted on a metal pole with

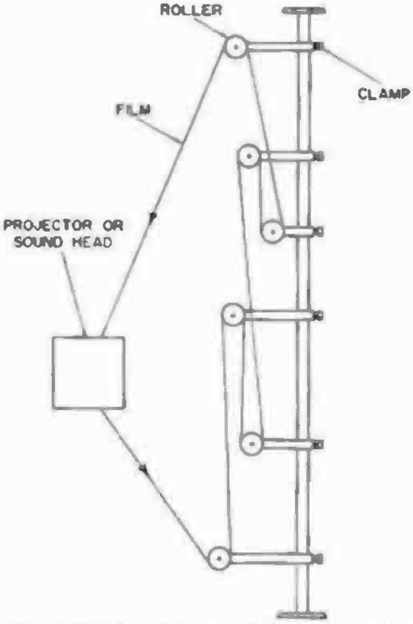

Fig. 2-133A. Film spool-bank with adjustable rollers.

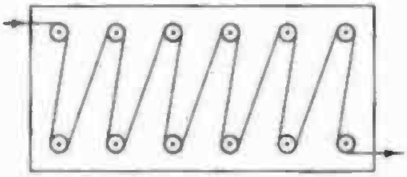

Fig. 2-133B. Film spool-bank using a plywood support.

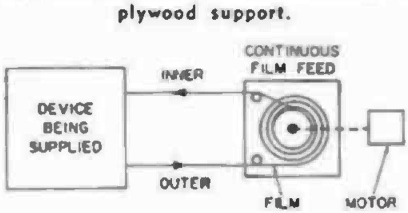

Fig. 2-133C. Continuous film-feed mechanism, for audio-visual devices

clamps for holding and separation of the rollers, as pictured in Fig. 2-133A. A portion of the rollers are mounted on short supporting arms to permit the film loops to clear each other as shown. Using several rollers will permit a rather large amount of film footage to be stored with little wear to the film surfaces.

A second method (Fig. 2-133B) employs a group of rollers mounted on a plywood board. This will also store considerable film. Both these methods of loop storage are used extensively in rerecording installations.

A third method is given in Fig. 2-133C, and consists of a *loosely wound* roll of film mounted on a motor-driven flange. The *inner end* of the film supplies the projector or sound head, while the *outer end* acts as a take-up. The driving-motor speed must be *constant* and compatible with the device being supplied. This system if not cleaned frequently may *abrade* the film surfaces.

The latter system is used quite frequently with audio-visual film display units, while the other two described may be used when looping dialogue and picture. (See Questions 17.208, 17.224 to 17.227, and 17.230.)

Section 3

Constant-Speed Devices, Motors, and Generators

The search for obtaining a constant linear speed is one that has been going on for years. The paper by Dr. E. W. Kellogg, "A Review of the Quest for Constant Speed," *Journal SMPTE*, April 1937, is a classic on this subject. For the recording and reproduction of sound, many drive systems have been developed, and ingenious new devices are still appearing. This section discusses the fundamental principles of constant-speed driving systems, single- and three-phase interlock systems, power-factor correction, motors, inverters, and general synchronization for both studio and location. Synchronization of camera and ¼-inch tape recorders by means of line frequency sync pulses are discussed as well as several different types of resolving systems.

3.1 What does the term constant speed mean?—A device which moves in a given direction without a change in velocity. The term constant speed is used in the recording industry to indicate devices used for driving recording and reproducing equipment.

3.2 What is the smallest change in the speed of a reproducing device which will be perceptible to a critical listener?—Approximately 0.30 percent at a frequency of 3000 Hz. The average person can detect about one percent.

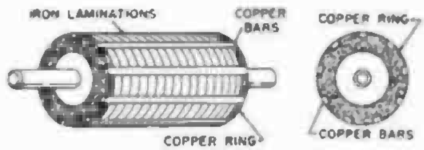
3.3 If the speed of a recording device is increased above normal, what is the effect on reproduction?—When the recorder material is played back at the correct speed, the pitch will be lowered and the playing time increased. The reverse is true if the recording speed is below normal.

3.4 What types of motors are used for driving studio recording and reproducing equipment?—Synchronous, multiduty (dual purpose) and selsyn-interlock motors, which may be used with either single- or three-phase power. The selsyn interlock motors are driven from a selsyn generator.

3.5 What controls the speed of a synchronous motor?—The frequency of the applied power source.

3.6 What is an induction motor?—Of all the motors used for alternating current operation, the induction motor enjoys the greatest use. Induction motors are a form of squirrel-cage motor, the armature consisting of a group of heavy copper bars welded to heavy copper rings at each end of the armature laminations. (See Fig. 3-6A.) The copper bars are short-circuited at each end by the copper rings, thus circulating currents will be induced in them by the field windings. The induced current reacts on the field, causing the armature to turn. The armature does not turn at the same speed as the rotating field, but runs somewhat slower. The difference between these two speeds is called "slip." Thus, if the rotor turns at 1750 rpm and the synchronous speed is 1800 rpm, the slip is 2.78 percent.

To understand how an induction motor functions, the action of the rotating field must be understood. Fig. 3-6B shows the field construction of a typical induction motor having six field poles. Each pole and its opposite member are energized by one of the 3-phase windings labeled phase A, B, and C. It will be noted that Pole 1 is connected in series with Pole 4, Pole 2 is in series



(a) *Side view.* (b) *End view.*

Fig. 3-6A. Rotor for a squirrel-cage motor.

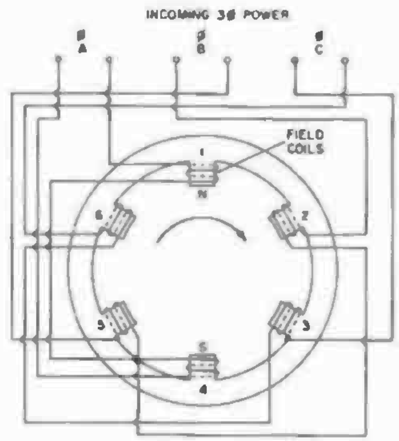


Fig. 3-6B. Field-coil connection of a three-phase induction motor.

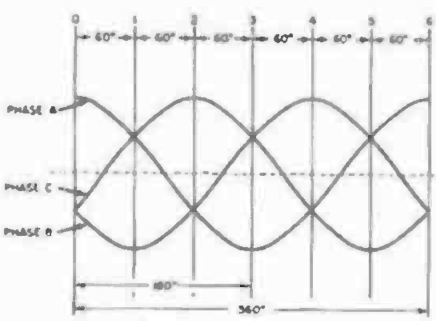

Fig. 3-6C. Rotating magnetic field of a three-phase induction motor.

with Pole 5, and Pole 3 is in series with Pole 6. The voltages applied to these poles are of equal magnitude but differ in phase, as shown in Fig. 3-6C.

Following the voltages as they are applied to the pole coils for a given instant, at zero degrees the magnetic field produced by the three voltages is at a maximum and extends from Poles 1 to 4. Under these conditions, it will be assumed that Pole 1 is North and Pole 4 South. At Position 1, or 60 degrees, the magnetic field has its greatest intensity extending from Pole 2 to Pole 5. At this instant, Pole 2 is North and Pole 5 South. At 120 degrees of rotation, at Position 2, the magnetic field is at maximum from Pole 3 to Pole 6 and it is apparent the field is rotating clockwise. At Position 3 or 180 degrees, Poles 4 and 1 are North and South, respectively, and the field has continued to rotate. This action is continued for each cycle. If the field current has a frequency of 60 Hz, the magnetic field rotates 60 times per second, or 3600 rpm. This is called the synchronous speed. However, the rotor does not rotate exactly at synchronous speed but turns slightly slower, inducing slip. Slip is discussed in Question 3.12.

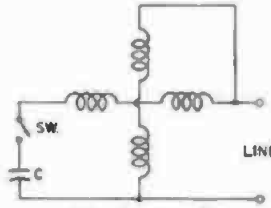
3.7 ***What controls the speed of an induction motor?***—The voltage of the applied power; however, induction motors are not absolute constant-speed devices and should not be used when a constant speed is essential.

3.8 ***What determines the speed of a direct-current motor, series connected?*** —The load and the applied voltage.

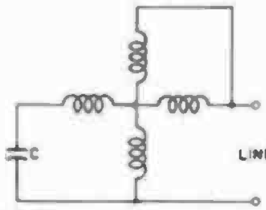
3.9 ***What is a capacitor-start motor and how does it function?***—A capacitor-start motor is similar in its construction to an induction motor, except for an added starting winding, a capacitor, and a centrifugally operated switch. The motor is started with the capacitor and the start winding in the circuit, which causes a phase shift between the windings, thus creating torque. When the motor obtains approximately 80 percent of its rated speed, the centrifugally operated switch opens and cuts out the capacitor and start winding. Typical circuits are shown in Fig. 3-9.

In some types of motors, the capacitor is left in the circuit after starting, as in (b) of Fig. 3-9. Others use a large capacitance when starting, then reduce its value, as in (c) of Fig. 3-9. A fourth method, part (d) Fig. 3-9, employs a transformer which transforms a small capacitor for starting, then either drops out of the circuit or is left in, depending on the service required of the motor. (See Question 8.34.)

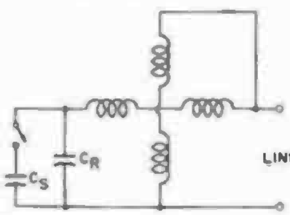
Capacitor-start motors are used quite extensively in magnetic tape recorders, record turntables, and similar devices. As a rule, the centrifugally operated switch is not used with sound equipment because there is a possibility of inducing noise when the switch is operated.



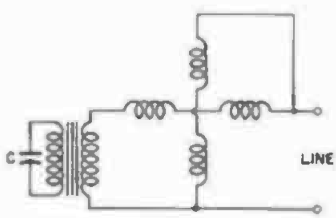
(a) *Start only.*



(B) *Permanently connected.*



(C) *Large capacitor start, small run.*



(D) *Transformer coupled.*

Fig. 3-9. Capacitor-start motor circuits.

3.10 How can an induction motor be altered to operate as a synchronous motor?—By cutting slots in the armature which are equal in number to the pole pieces, or a multiple thereof, and parallel to the shaft.

3.11 What is an induction generator?—A generator designed similar to an induction motor. To generate, it must be driven above synchronous speed and excited from the same ac supply system to which it is to deliver power.

3.12 What is slip in a synchronous motor?—The loss in rpm of a motor when the load is applied. Upon excitation of the primary windings, a rotating field is set up, causing the rotor to rotate. This is called synchronous speed. When the load is applied, the speed drops. The difference in the two speeds is called the slip and is stated in percentage of the synchronous speed. Thus, if the rotor turns 1750 rpm and the synchronous speed is 1800 rpm, the slip is equal to 2.78 percent.

3.13 How is the frequency of an alternator calculated?

$$F = P\left(\frac{S}{120}\right) \quad \text{or} \quad P = F\left(\frac{120}{S}\right)$$

where,

P is the number of poles,
S is the speed in rpm the machine is rotating.

The figure 120 is a constant for converting alternations per minute to hertz.

3.14 What is power-factor correction?—When a large number of electric motors are connected to a power source, the power factor drops. To correct this condition, capacitors are connected in parallel with the power source. (See Questions 3.58, 3.59, and 3.60.)

3.15 What is a shaded-pole motor?—A motor having a copper ring around a section of the pole piece in the direction of rotation, as shown in Fig. 3-15. This coil is called a shading coil and causes a phase difference between the flux from the larger portion of the pole piece and the flux emanating from the smaller portion of the pole piece. This produces a two-phase action in the armature and is sufficient to start the armature rotating.

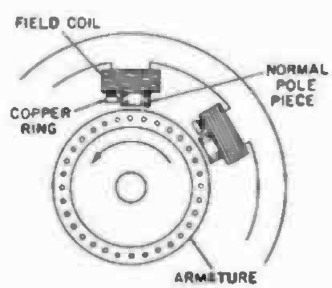


Fig. 3-15. A shaded-pole motor with a single-turn copper coil on a pole-piece.

3.16 What is torque?—A twisting motion in the operation of a machine. Torque is the product of force multiplied by the distance from the center of rotation. For example, a force of 20 pounds applied to the end of a two-foot pipe wrench would be equivalent to 40 foot pounds of torque. In motors, two types of torque must be considered, starting and pull-out. Excessive starting torque results in low efficiency, low power factor, and poor speed regulation. If the starting torque is low, the load cannot be started. High pull-out or stalling torque also means low power factor, with high starting current. If the pull-out torque is low, the motor may stall on small loads.

3.17 *What is a generator?*—A device for converting mechanical energy into electrical energy. The electrical energy may be either direct or alternating current.

3.18 *What is an alternator?*—An alternating-current generator.

3.19 *What is a dynamotor?*—A combination motor and generator, each having its own winding. Very often the motor section is of low-voltage direct current design and the generator section is of high-voltage direct current design.

3.20 *What is a dynamo?*—A generator.

3.21 *What is a genemotor?*—It is similar to a dynamotor.

3.22 *What is a rotary converter?*—A motor-generator consisting of a dc motor direct-coupled to an ac generator mounted on a common base. The motor is battery driven from a storage battery of 6, 12, or 32 volts. The ac generator section consists of a 250- or 500-watt, 115-volt unit. Both the dc and ac sides are filtered to prevent the brushes on the dc side and the slip rings on the ac side from transmitting noise to the equipment being driven by the converter.

A typical machine of this type, manufactured by the Carter Motor Co., is pictured in Fig. 3-22. It is especially designed for driving sound equipment, and will handle loads up to 250 watts having a power factor of 70 percent. The frequency of the ac voltage is controlled manually by a field rheostat in the case above the machine, and indicated on a vibrating-reed type frequency meter.

Fig. 3-22. Carter Motor Co., Model BR-1021CP converter, with manual frequency control and frequency meter.

Rotary converters are also manufactured using a common winding and armature for both the dc and ac sides of the machine. Such machines are not satisfactory for use with sound equipment because the common connection between the dc and ac sides of the circuit results in the transmission of brush noise to the sound equipment.

3.23 *What is an inverter?*—A device for changing direct current to alternating current. This is generally accomplished by means of vacuum tubes. (See Question 21.107.)

3.24 *What does the term electrical degrees mean when associated with a motor or generator?*—Electrical degrees are equivalent to mechanical degrees times the number of pairs of poles in the machine.

3.25 *What is ambient temperature?*—The temperature of the surrounding air or medium in which a device is operating. Motors are rated for a given rise in temperature. (See Question 25.136.)

3.26 *What is a delta connection?*—A winding connected in the form of the Greek letter delta, as shown in Fig. 3-26.

3.27 *What is a wye connection?*—A winding connected in the form of the letter Y, as shown in Fig. 3-27.

3.28 *What is a star connection?*—Windings connected as shown in Fig. 3-27.

3.29 *How may the direction of rotation of a three-phase motor be reversed?*—By reversing any two wires of the 3-phase power source.

3.30 *How may a single-phase motor be operated from a three-phase source?*

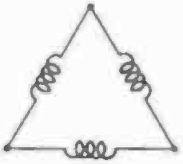

Fig. 3-26. Delta connection for motors, generators, and transformers.

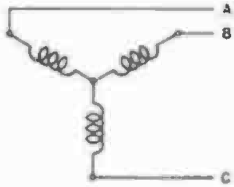

Fig. 3-27. Wye- or star-connected motor.

—By connecting a transformer of the correct voltage ratio between the motor and one pair of the 3-phase power source leads, as shown in Fig. 3-30. It is common practice in the motion picture industry to operate single-phase motors in conjunction with 3-phase motors using the described method.

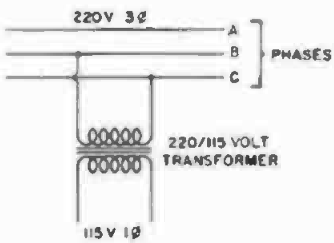

Fig. 3-30. Transformer connections for single-phase operation from a three-phase source.

3.31 ***Can a single-phase synchronous motor be operated in conjunction with a three-phase motor system and still maintain synchronization?***—Yes, provided it is operated from the same power source. Many times sound equipment using single-phase synchronous motors is operated with cameras driven by three-phase motors, during the shooting of motion pictures. The above system is only used when shooting the original picture and sound tracks. For rerecording, a selsyn interlock system is used. Fig. 3-30 shows how the single-phase motor is connected to the 3-phase power source. If the 3-phase and single-phase power are fed from the same source, the single-phase motor may be fed from any single-phase source of power.

3.32 ***Will a three-phase camera motor operate satisfactorily on either a three- or four-wire power system?***—Yes, provided the power characteristics of the motor are such that it will develop sufficient power when operating on the four-wire system. Three-phase, three-wire systems are generally of the order of 230 volts between phases. Four-wire systems are approximately 208 volts between phases. This means that when the motor is operating on a four-wire system, the power developed by the motor is considerably less than normal when operating from a three-wire system. A motion picture camera when cold requires considerably more power to operate; therefore, tests should be made to determine whether the camera can be brought up to speed before using it on production.

Generally, it is necessary to rewind a 3-phase motor designed for 230-volt operation, if it is to be used on a four-wire system. A four-wire, 3-phase, 208-volt power distribution system is shown in Fig. 3-32A. The voltage between any two phases at the load side is 208 volts. 120-volt single-phase power may be taken between ground and any one of the three phases.

The characteristics of a 220-volt, three-phase camera motor operating from a power source of 208 volts is shown in Fig. 3-32B, part (a). It will be noted that as the voltage is reduced below 208 volts, the motor speed starts to drop off because of the lack of power, which reduces the frames per second at a voltage of 200 volts. Part (b) is the power curve after rewinding the motor to operate at 208 volts. Here it may be seen the motor runs at its normal speed down to 200 volts and maintaining a speed of 24 frames per second.

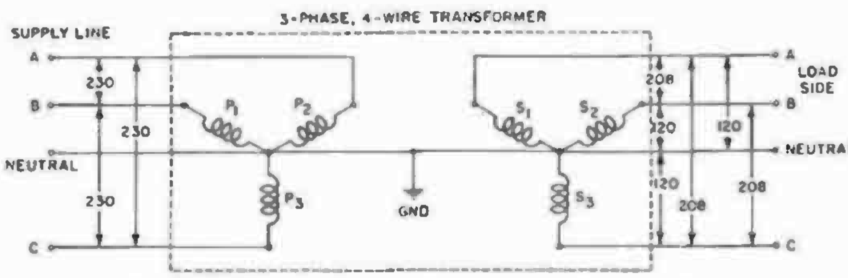

Fig. 3-32A. A three-phase, four-wire distribution system.

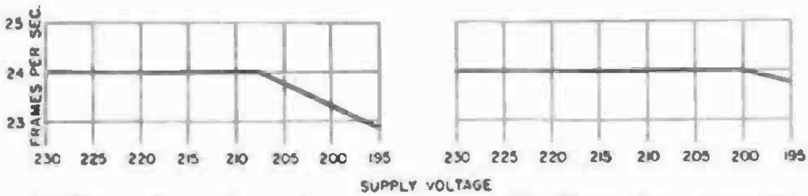

(a) *Three-phase, three-wire.* (b) *Three-phase, four-wire.*

Fig. 3-32B. Supply voltage versus sync drop-out of a three-phase synchronous camera motor.

The curves are actual curves made on a motor that is standard for 35-mm cameras and were made after running 3000 feet of film through the camera to warm up the motor. (See Question 8.22.)

3.33 ***What is an asynchronous motor?***—One in which the speed is not proportional to the frequency of the power source.

3.34 ***How many electrical watts are equal to one horsepower?***—746 watts.

3.35 ***How is the speed of a single-phase camera motor affected when the voltage source is lowered?***—Fig. 3-35 shows a test made on a typical single-phase camera motor plotted as line voltage versus frames per second for both warm and cold conditions of the motor. It will be observed that when the motor is warm the voltage may be dropped from 120 volts to 114 volts before the frames per second start to fall off. The condition is considerably worse when the motor is cold, as shown by the solid line.

This clearly indicates that the motor must be warmed up before using it, or that the voltage source must be maintained sufficiently high to maintain the correct speed. This may be accomplished by the use of a continuously variable autotransformer. (See Question 8.8.)

3.36 ***What is a prony brake?***—A friction device used for measuring the brake horsepower of a motor. The brake consists of an arm (Fig. 3-36) and a friction band clamped around a pulley mounted on the end of the motor shaft. The tension of the friction band may be adjusted by the wing nuts at the top of the band. A spring balance scale is connected to the end of the arm and secured overhead. The motor, in rotating, causes the friction band to move the arm downward and pull on the scale which is calibrated in either ounces or pounds. Knowing the speed of the motor, the length of the arm from the center of the motor shaft, and the pull on the scale, the brake horsepower may be calculated as follows:

$$B_{HP} = \frac{2\pi L \times rpm \times lbs}{33{,}000}$$

where,

L = Length of the brake arm in feet,
rpm = speed of motor,
lbs = the pull on scales, in lbs.

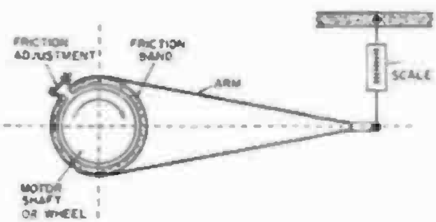

Fig. 3-36. Prony brake for measuring brake horsepower of a motor.

3.37 ***What is the formula for calculating the required size capacitor for a capacitor-start motor?***

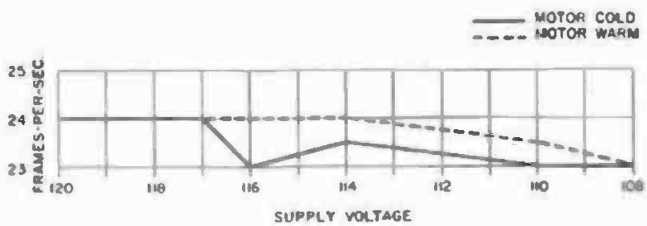

Fig. 3-35. Frames-per-second versus line voltage for a 120-volt synchronous, single-phase camera motor.

$$\mu F = \frac{2650 \times \text{amperes}}{\text{applied voltage}}$$

where,

amperes is the current drawn by the motor,
2650 is a constant,
the applied voltage is equal to the line voltage.

3.38 How is the efficiency of a motor calculated using a prony brake?

$$\text{Efficiency} = \frac{B_{HP}}{746}$$

where,

B_{HP} = brake horsepower,
746 = one horsepower in watts.

3.39 How can the torque of a motor be calculated using a prony brake?

$$\text{Torque (in ounce-inches)} = \frac{1352 \times \text{watts}}{\text{rpm}}$$

where,

watts is the power consumed by the motor,
rpm is the speed of the motor shaft,
1352 is a constant.

3.40 How is torque (in ounce-inches) converted to watts?

$$\text{Watts} = \frac{\text{oz-in} \times \text{rpm}}{1352}$$

3.41 How is torque (in ounce-inches) converted to horsepower?

$$\text{Hp} = \frac{\text{oz-in} \times \text{rpm}}{1{,}008{,}000}$$

3.42 State the equation for calculating the horsepower of a motor in watts.—The relationship of electrical horsepower to watts may be defined as follows:

One electrical watt is equivalent to one joule per second, or 60 joules per minute. Since one joule is equivalent to 0.7374 ft-lb, 60 joules will equal 44.244 ft-lb. Also, one horsepower is equivalent to 33,000 ft-lb per min. Therefore, the electrical equivalent of one horsepower is:

$$\frac{33{,}000}{44.244} \text{ or 746 electrical watts.}$$

The horsepower of a fractional horsepower motor may be expressed as a function of the torque and the revolutions per minute. For fractional horsepower motors, the approximate formula is:

$$\text{Hp} = (\text{in-oz}) \times 9.3 \times N \times 10^{-7}$$

where,

in-oz, is the torque in ounce-inches,
N is revolutions per minute.

3.43 How is the efficiency of an electric motor calculated?

$$\text{Efficiency} = \frac{\text{watts output}}{\text{watts input}}$$

3.44 How is synchronous speed calculated?

$$\text{Sync speed} = \frac{120 \times \text{line frequency}}{\text{number of poles}}$$

3.45 Define the term ounce-inches.—It is the weight in ounces that a motor will lift at a distance of one inch from the centerline of the motor shaft.

3.46 How can commutator noise be eliminated?—By the use of capacitors and chokes, as shown in Fig. 3-46. The most satisfactory method is by cut-and-try, as each source of noise presents an individual problem. As a rule, chokes will not be required unless radio-frequency interference is noted. The frequency of the interference will determine the value of the inductance. For large dc generators supplying several hundred amperes, such as used on motion picture sets with arc lights, a bank of 25 to 50,000 μF electrolytic capacitors is connected directly across the generator brushes. The capacitors are housed in a metal box, grounded to the frame of the generator. No smaller than a No. 10 gauge wire should be used for the capacitor connections. The voltage rating of the capacitors should be 25 to 50 volts greater than the maximum output voltage of the generator. (See Question 25.117.)

3.47 What is an electrical gearing system?—A name sometimes applied to a selsyn-interlock distributor system used for synchronous operation of recording equipment. (See Question 3.49.)

3.48 What is a selsyn-interlock distributor system?—A synchronous distributor system used for interlocking sound recording equipment with motion

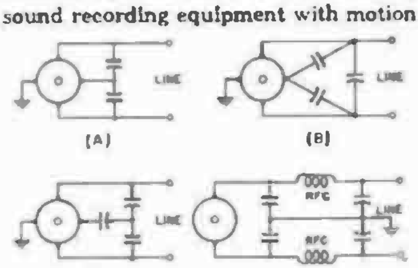

Fig. 3-46. Methods of filtering commutator ripple. The capacitor sizes from A to C vary 0.10 to 0.50 microfarad.

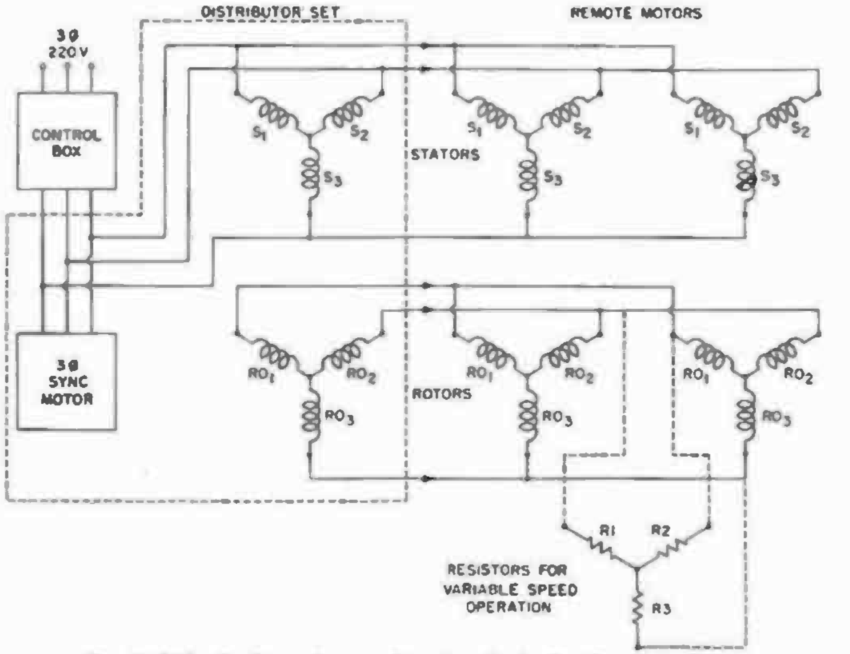

Fig. 3-49A. A three-phase selsyn-interlock distributor system.

picture cameras. Selsyn distributor systems are described in Question 3.49.

3.49 ***How does a three-phase selsyn-interlock distributor system function?***—The diagram for such a device appears in Fig. 3-49A. Starting at the left is a control box consisting of a group of relays, resistors, and three solenoids, one connected in each phase of the incoming power source. The solenoids have normally a low impedance; however, at the instant current flows through the coil, a soft iron plunger is pulled upward into the coil increasing its impedance. As the driving motor starts to rotate, the initial current drops and, as it does, the plunger falls out of the coil lowering its impedance to the original value. The pulling up of the plungers into the starting coils prevents the system from making a sudden start which might break film or damage equipment. When adjusted properly, a slow smooth start is obtained, even with 10 to 20 machines being driven simultaneously. The driving motor is a 3-phase, 220-volt, synchronous type turning 1200 rpm and is mechanically coupled

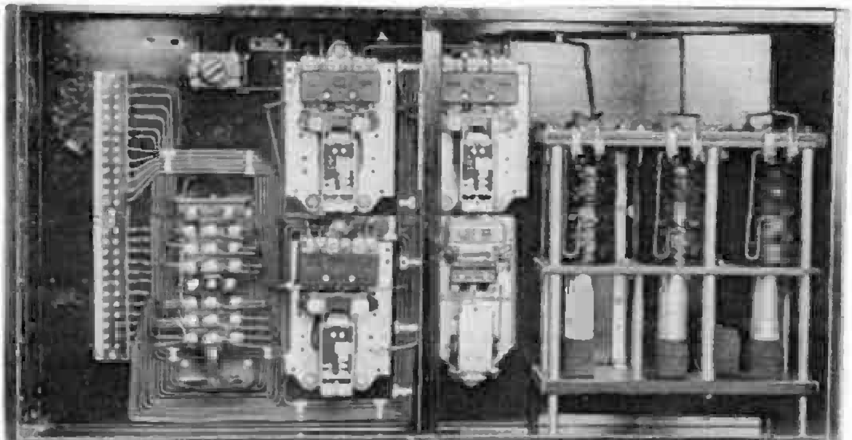

Fig. 3-49B. Control cabinet RCA selsyn distributor unit.

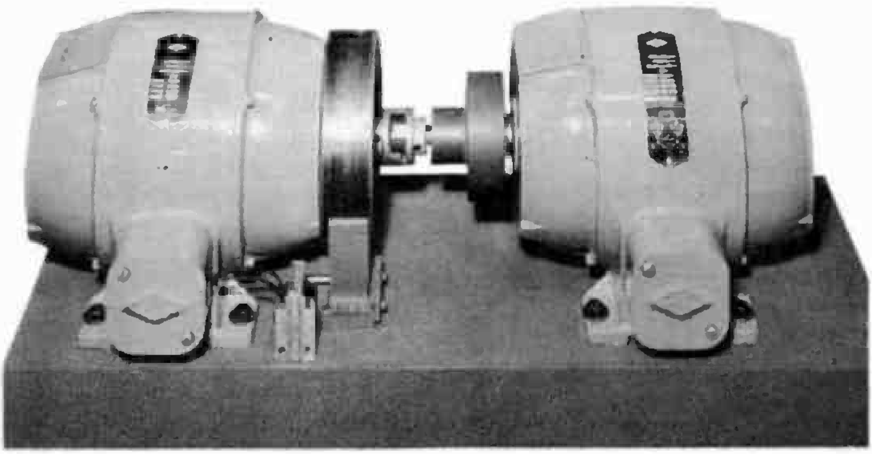

Fig. 3-49C. Selsyn interlock distributor set manufactured by Stancil-Hoffman. The electrically controlled brake may be seen at the front of the flywheel.

to the selsyn distributor unit. A heavy flywheel is mounted on the shaft to provide a large amount of inertia for a soft start and gradual slowdown. When running, it also helps to iron out small irregularities in the speed. An electrically controlled brake may be applied to the outer rim of the flywheel to bring the system to a gentle stop when the circuit to the drive motor is opened. When the circuit for running is closed, the brake is lifted automatically.

The sole purpose of an interlock system for rerecording and other purposes is that all the machines in the system, including the projection machine (which is the heaviest to start), must be brought up to speed in synchronism, from a standing start, in about 6 seconds. This must be accomplished in a smooth manner to avoid breaking film and sound track.

Selsyn distributors are sometimes referred to as rotary transformers, because of the 1:1 ratio of the two windings. As a rule, the internal windings of the distributor unit are star-connected. It will be noted the rotor windings of the distributor unit are connected in parallel, but not to the power source. The stator winding of the distributor and all other units being driven are also connected in parallel, but in this instance they are connected to the 3-phase power. Phasing of each unit is accomplished by connecting similar numbers of the windings together and to the same phase.

Because the distributor unit is always the largest unit in the system, it becomes the master and all other units become slaves. When properly phased, absolute synchronism is maintained as long as the frequency of the power source remains constant. Under these conditions the system may be termed as a constant-speed device.

In some distributor systems, the three solenoids shown in the control cabinet (Fig. 3-49B) are replaced by a group of resistors connected in the supply lines to the synchronous drive motor. The voltage drop across the resistors during the high inrush of current when the motor is at rest, holds the cutout relay open. When the system approaches its normal running speed the current through the resistors drops, and the relay closes, cutting out the resistors. A typical selsyn interlock distributor set is shown in Fig. 3-49C.

3.50 How may the selsyn distributor unit in Question 3.49 be made to operate at variable speed?—At times during the rerecording of a motion picture, a variable-speed distributor system is required to obtain a particular sound effect. If a separate distributor system is available, it may be made to run at variable speed by connecting three variable resistors, R1, R2, and R3, across the rotor windings as shown in Fig. 3-49A. If the values of the three resistors are varied the same amount and simultaneously, the speed of the system may be controlled. If the three resistors are shorted, the machine will run at 1800 rpm.

3.51 Is it possible to synchronize camera and sound with direct current

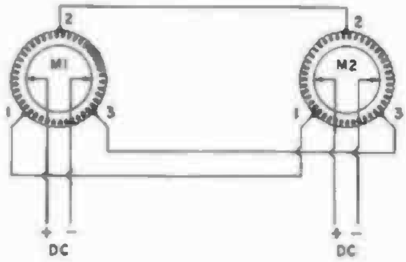

Fig. 3-51. A dc synchronous drive system for sound recorder and camera. The motor speed is set by means of a tachometer.

motors?—Yes. Special motors are available for this purpose. The connections for such a synchronizing system are shown in Fig. 3-51. It will be noted that the dc windings of the motors are tapped in three different places, 120 degrees apart. These taps are carried to each motor to be synchronized. Local batteries at each motor supply the necessary power for rotating the motors. A tachometer is used to set the initial speed.

3.52 ***How is frequency control obtained in other types of distributor systems?***—Other systems are available, similar to the one described in Question 3.49, except that vacuum-tube control circuits have been added to compensate for changes in the power frequency. Because present day power systems are controlled to hold the frequency within a fraction of one cycle, the system described in Question 3.49 is used in preference to the electronically controlled type.

3.53 ***Can single-phase selsyn motors be used to drive sound equipment?***—Yes, except that single-phase systems are not as efficient as 3-phase systems and are more subject to slipping out of lock. A diagram of a typical single-phase, 115-volt, ac interlock system is shown in Fig. 3-53. As a rule, single-phase selsyn motors are internally connected in delta. It will be noted the rotors have only one winding and are connected to the source of power and driven by a synchronous motor mechanically connected to the shaft.

3.54 ***Describe a simple interlock system.***—A simple but effective single three-phase interlock system can be devised by mounting an interlock motor on a motion picture projector and driving the interlock motor from the synchronous motor on the projector by means of a Gilmer belt and gears. Although this system is not suitable for rerecording, it may be used for running picture and sound track in synchronism. As a rule, the motor on the projector is around ⅙ to ⅓ horsepower, so no difficulties should be encountered. However, for rerecording, a selsyn interlock system is required. (See Question 3.49.)

3.55 ***Describe an interlock distributor system, using a differential generator for correcting out of phase conditions.***—At times, during the screening of a picture it will be discovered that the picture and sound are out of sync, because of improper splicing or threading of a machine. This necessitates stopping the system and correcting the fault and re-

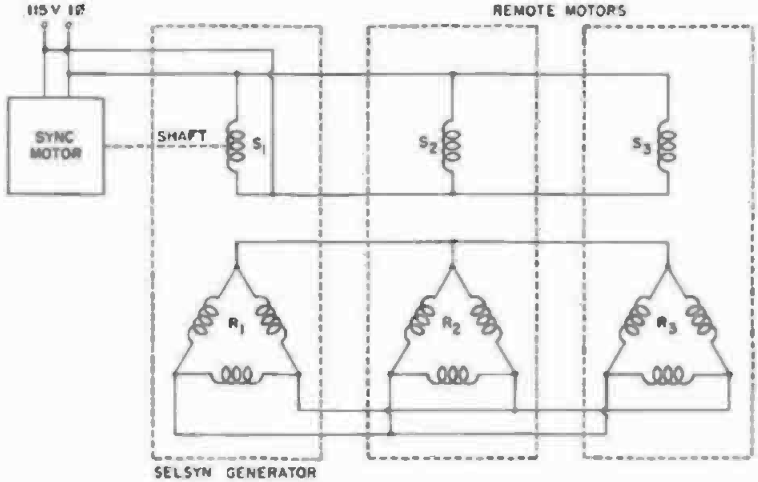

Fig. 3-53. A single-phase selsyn-interlock distributor system.

threading all machines. If several sound tracks are involved, this can become quite costly, plus the time lost. One of the major studios provided for this situation in its review rooms by installing differential generators in the interlock system feeding three sound reproducers and two projectors. If it becomes necessary to correct for an out of sync condition, the machine at fault,

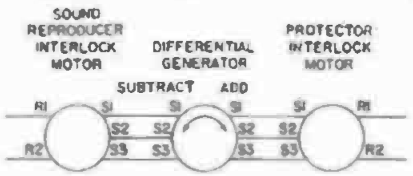

Fig. 3-55. Differential generator connected in the line feeding a sound reproducer and projection machine, using single-phase motors.

while running, can be advanced or retarded to correct the number of frames to bring it back into sync. The control dials for the differential generators are calibrated in frames per second to aid the editorial department in correcting the situation later. A footage counter indicates the exact footage of the out of sync condition.

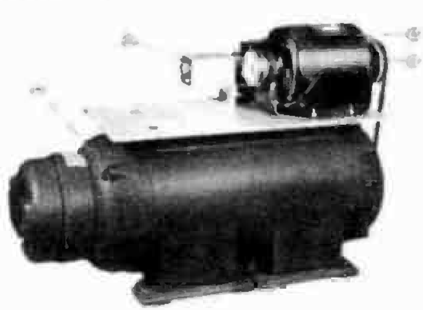

Fig. 3-56. Dual-speed selsyn generator made by Magna-Tech Electronic Co.

3.56 ***Describe a dual-speed selsyn-interlock distributor system.***—A dual-speed selsyn-interlock distributor system generator, manufactured by Magna-Tech Electronic Co., is shown in Fig. 3-56. This device consists of two selsyn generators. The smaller of the two (A) is mounted above the larger generator (B). The larger generator is driven by a 208/230-volt three-phase, 2½ horsepower synchronous speed motor at 1200 rpm. This generator is used to interlock and drive 35-mm machines running at 90 fpm (1200 rpm).

The smaller generator is driven from the larger generator by a Gilmer belt and gears (C), and is employed for interlocking and driving 16-mm machines at a speed of 36 fpm (600 rpm). A third generator (D) is provided for driving a remote footage counter in the dubbing stage. (See Question 18.339.) The larger generator also houses a braking system for bringing the system to a smooth stop. External cabinets house the control equipment.

If desired, the 16-mm generator (B) may be substituted for one turning at 45 fpm for driving machines using 17.5-mm magnetic film. Dual-interlock systems are very convenient in plants where both 16- and 35-mm recording equipment is in use, as this permits a 35-mm picture to be run with 16-mm recording and reproducing equipment or vice versa. Distributor systems of this design are often referred to as a *piggy-back* distributor system.

3.57 ***What is a pm generator?***—An alternator which uses permanent magnets rather than coils in the rotating member. In this respect, it differs from the conventional type alternator. The rotor consists of a nonmagnetic ring in which Alnico V magnets are embedded and equally spaced in such a manner that the magnetic axis of each magnet is perpendicular of the axis of the rotor shaft. The inner end of the magnet rests on an iron ring which acts as a return magnetic circuit. The number of magnets will depend on the speed and frequency of the machine. This type of construction eliminates arcing caused by slip rings.

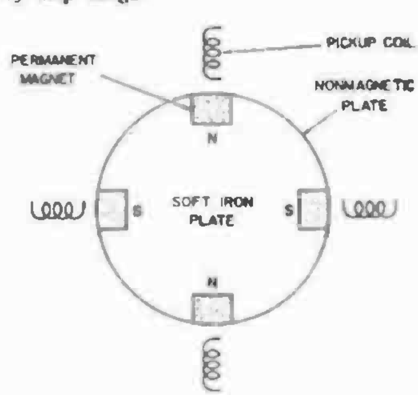

Fig. 3-57. Basic design of a permanent-magnet generator. Such design is used for sync-pulse generators mounted on the end of a camera motor shaft.

Small generators based on the above design are often used for generating sync pulses for one quarter inch magnetic recorders. Two types are in use, two-pole and four-pole. The construction of the rotating member is shown in Fig. 3-57. The number of magnets will depend on the desired frequency and the rotational speed of the motor shaft. The frequency used for sync-pulse recording is 60 Hz; however, in some instances where the generator is mounted on a camera shaft, turning at 1440 rpm, the frequency is 48 Hz. The frequency may be computed:

$$f = \text{rpm}/60 \times \text{the number of poles.}$$

Thus, for a motor turning at 1800 rpm, using two-poles:

$$f = 1800/60 = 30 \times 2 = 60 \text{ Hz.}$$

3.58 ***What is power factor and how is it measured?***—The power factor of an alternating current is the number by which the apparent power in the circuit (volts times current) must be multiplied to ascertain the true power. When an alternating-current circuit contains inductance, the current will lag behind the voltage. When the circuit contains capacitance, the current will lead the voltage. In each instance, the current and the voltage reach their maximum values at different instants and the product of the voltage and the current at any given time is less than it would be if the two were in phase. If the voltage and current are measured separately, the voltmeter and the ammeter will indicate the mean effective values. If the power in the circuit is measured using a wattmeter, the instrument indicates the combined efforts of the voltage and current synchronously, not the product of their effective values, which occur at different instants. Consequently, a wattmeter indication will be less than the product of separate voltmeter and ammeter readings.

The ratio of the power read by the wattmeter and the power read by the voltmeter and ammeter is the power factor of the circuit.

$$1\,\phi\,\text{PF} = \frac{\text{watts}}{\text{V} \times \text{A}}$$

where,

watts is the reading of the wattmeter,
volts and amperes are the readings on the individual meters.

The power factor for a two-phase circuit is expressed:

$$2\,\phi\,\text{PF} = \frac{\text{watts}}{2(\text{V} \times \text{A})}$$

and for a 3-phase circuit:

$$3\,\phi\,\text{PF} = \frac{\text{watts}}{\sqrt{3} \times \text{line to line volts} \times \text{line amps}}$$

A single-phase motor drawing 5 amperes at 220 volts, as shown by the voltmeter and ammeter, has a power factor of 80 percent. The true power is $5 \times 220 \times 0.80$, or 880 watts.

3.59 ***How is a synchronous motor used for power-factor correction?***—If the synchronous motor is driven from an external source of power and a variable dc voltage is applied to the rotor windings and set to a value which will be called, for the sake of illustration, 100 percent, no current will flow from the stator windings to the rotor windings. Under these conditions the voltage generated in the stator windings (counter emf) exactly balances the voltage applied to the stator from the external voltage source.

If the dc exciter voltage is now reduced to a value less than 100 percent, a reactive component is produced which will lag the applied voltage. The machine will now act as a capacitor. Thus, a synchronous motor may be used for correcting the power factor and, when so used, is called a synchronous capacitor or a rotary condenser.

When the motor is used as a capacitor, the motor is connected in parallel with the line to be corrected, and the dc excitation voltage is adjusted to produce a leading current which offsets the lagging line current. The result is unity power factor.

3.60 ***How may the power factor be corrected by the use of capacitors across the line, and how are their values calculated?***—Power factor may also be corrected by connecting capacitors in parallel with the line to be corrected. The approximate value of capacitance required may be calculated:

$$C_{\mu F} = \frac{I \times \text{Sin}\,\phi \times 10^6}{2\pi f E}$$

where,

E is the line voltage,
I is the current drawn by the load,
f is the frequency of the power source.

The value of the capacitance required for power-factor correction may also be determined experimentally by connecting a dynamometer-type voltmeter across the line and adding sufficient capacitance in parallel with the line until the voltage is brought up to normal.

If the value of capacitance is large, ac electrolytic capacitors may be used. Dc electrolytic capacitors must never be used as they will explode within a few minutes of being connected across the line. If practical, paper or oil-filled capacitors should be employed.

3.61 How can the power factor be estimated if measurements cannot be taken?—For regular lighting loads and no motors, 0.95; with lighting and motors, 0.85; and for motors only 0.80.

3.62 How may the current-per-phase of an electrical system be calculated?—For a single-phase system:

$$I = \frac{W}{E \times PF}.$$

For a two-phase system:

$$I = \frac{W}{E \times PF} \times 0.5.$$

For a three-phase system:

$$I = \frac{W}{E \times PF} \times 0.58.$$

where,

I is the line current,
W is the power delivered in watts,
E is the potential existing between the mains,
PF is the power factor.

3.63 What is the procedure for testing motor-starting capacitors?—For the proper starting and operation of a motor using a capacitor permanently or for starting only, the capacitor must maintain its power factor and capacitance, within fairly close limits. A high power factor is manifest by reduced starting torque and a prolonged starting period. To test a starting capacitor properly, it should be tested under the exact conditions in which it operates. A circuit for this purpose is shown in Fig. 3-63A. The power-factor wattmeter must be capable of reading quite low values, since the losses of a good capacitor are quite low, although the product of current and voltage as read on the voltmeter and ammeter is quite high. Therefore, it is desirable to have a power-factor wattmeter that will read about one fifth the watt volt-ampere capacity of the test circuit.

To find the capacitance and power factor of a capacitor, the voltage is adjusted to the rated value of the capacitance, and readings of the voltmeter and ammeter are taken. The capacitance may then be calculated:

$$C = \frac{1 \times 2650}{115}$$

The percent power factor is then found by dividing 100 times the power in watts, as read on the power-factor wattmeter, by the product of the current times the voltage. This is true only for 60 Hz. The problem may be somewhat simplified by the use of the nomograph in Fig. 3-63B.

Using the test circuit shown, assuming the capacitor draws 5.2 amperes, at 120 volts at 60 Hz, and dissipates 40 watts, the percentage power factor is found by

$$\text{Percent PF} = \frac{100 \times \text{Power in watts}}{\text{Current} \times \text{Voltage}}$$

or

$$\frac{100 \times 40}{5.2 \times 120} = 6.4 \text{ Percent}$$

To read this value on the nomograph connect 120 volts from the left of "A" to 5.2 amperes on the left of "C," with a straightedge. Note where the straightedge intersects "B." From this point on "B" connect the straightedge with 40 watts on the left edge of "A" and read

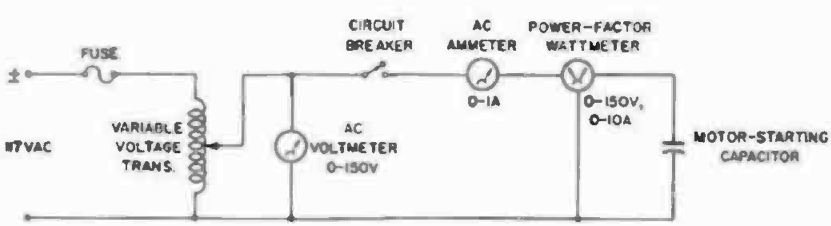

Fig. 3-63A. Circuit for testing motor-starting capacitors.

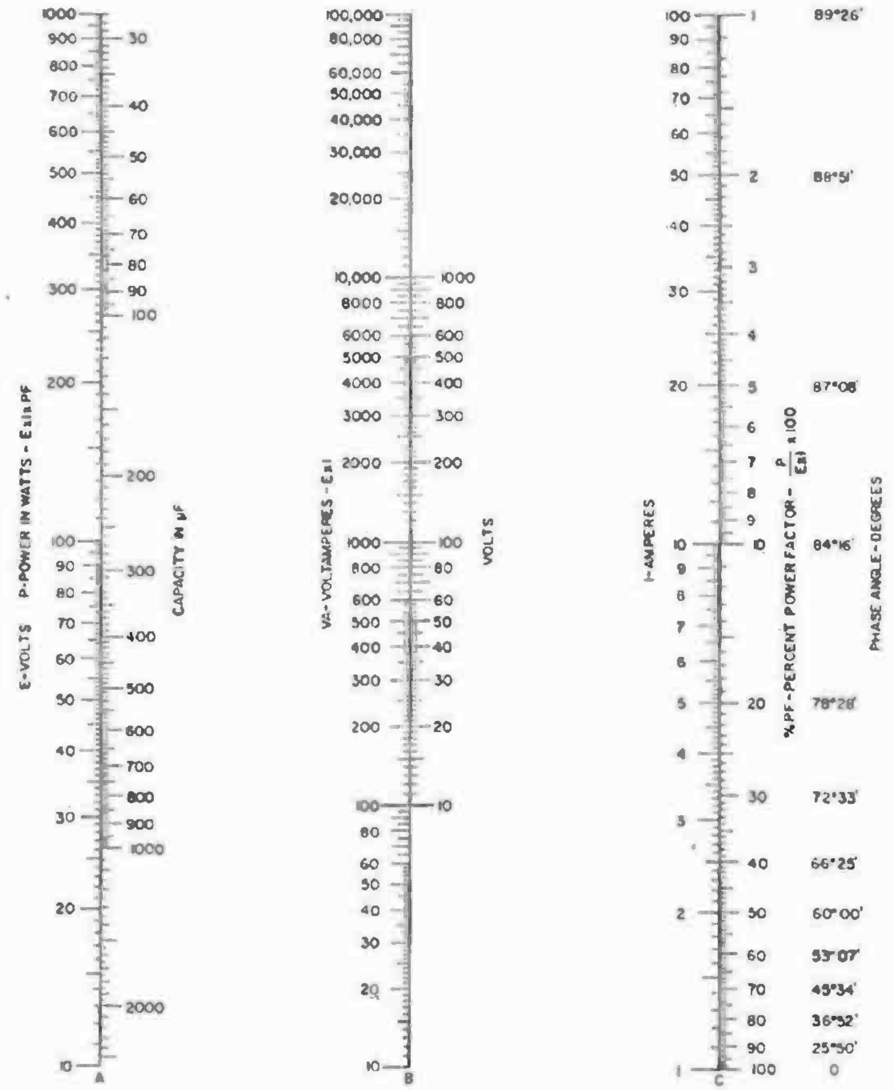

POWER-POWER FACTOR CHART

Fig. 3-63B. Nomograph for determining the power factor of motor-starting capacitors.

the power factor (6.5 percent) on the right edge of "C."

Capacitance may be determined from the nomograph by placing the straightedge at 5.2 amperes on the left of "C" to connect with 120-volts on the right edge of "B" and reading the capacitance on the right edge of "A."

Motor-starting capacitors may be of three different types, depending on the voltage and the required capacitance. If the required capacitance is small, either oil or paper dielectric may be used. If the needed capacitors are large, (10 microfarads or greater) they are generally of the ac or nonpolarized electrolytic type. The characteristics of motor-starting capacitors must remain stable, that is, they must hold their capacitance and power factor within fairly close limits. If they do not, the motor will have low starting torque and prolonged starting, resulting in the motor and capacitor overheating. *Dc polarized electrolytic capacitors must never be used as motor-starting capacitors.* (See Question 3.60.)

3.64 ***What is meant when it is said a motor-generator is hunting?***—A motor-generator is said to be hunting when it oscillates during the starting period or increases or decreases its speed when the load is changed.

3.65 ***Where are torque motors used?***—Manufacturers of professional (and some nonprofessional) magnetic recording and reproducing equipment make use of torque motors mounted on the spindles for the feed and take-up reels, to provide a constant tension on the film or tape, regardless of the diameter of the recording media on either reel. The motors may be of the induction type, or of the single-phase shaded-pole design. Resistors connected in the ac supply line are used to control the speed, and to provide an adjustment for the desired tension. The power drops off proportionally to the increase in speed, and develops maximum power at stall speeds. Therefore, this characteristic is used to an advantage to control the tension for the feed and take-up reels.

One advantage of using torque motors in the feed and take-up positions is that the tape or film may be rewound in either direction. During the rewind cycle, the circuitry of the motor system is such if the tape breaks or runs out the motors stop automatically. The motor on the feed reel always acts as a holdback. This subject is further discussed in Section 17.

3.66 ***How can the power factor of a dynamotor be corrected to operate with a low power factor motor?***—If the low power factor motor is connected across the ac side of a dynamotor, the dynamotor will speed up. Power correction may be applied by adding capacitance across the power source at the ac generator terminals in parallel with the load. A typical example of how the power factor may be corrected is given below.

A 0.5 kW dynamotor driven by a 12-volt battery, develops 115 volts ac, which is to be used to drive a portable recording channel and supply sufficient power to drive a 35-mm motion picture camera. When the camera was applied to the ac side of the dynamotor, the power factor, as measured with an ac ammeter and voltmeter, indicated a power factor of 32 percent and a power consumption of 190 watts.

Connecting a 20 μF oil-filled capacitor across the ac terminals increased the power factor to 40 percent, with 190 watts of power consumed. Increasing the capacitance to 70 μF increased the power consumption to 280 watts with a power factor of 92.5 percent.

Power factor may be calculated:

$$PF = \frac{W}{AC_v \times AC_i}$$

where,

AC_v is the voltage across the load,
AC_i is the current drawn by the load,
W is the watts consumed.

Capacitance is applied in parallel with the load until a power factor of at least 90 percent is obtained. The proper amount of capacitance is the point where the maximum power factor correction is obtained with a minimum of capacitance.

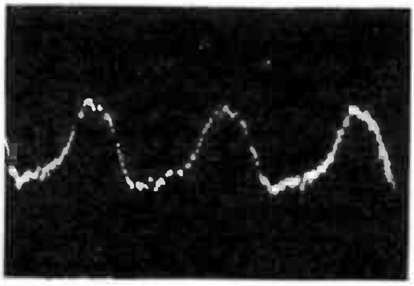

Fig. 3-67A. Waveform of dc generator with shorted turns in armature.

3.67 ***What is the appearance of the current waveform of a maladjusted dc generator?***—Malfunctioning of the generator because of bad brushes and commutator bars or shorted turns will produce a waveform at the ontput of the generator similar to the one shown in Fig. 3-67A. A well-adjusted and operating dc generator will, after the current has passed through a filter to remove commutator ripple, show practically a pure dc current when observed

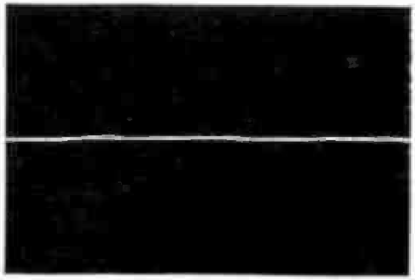

Fig. 3-67B. Waveform of dc voltage from a well adjusted dc generator.

Fig. 3-67C. Waveform of a properly adjusted dc generator before filtering.

on an oscilloscope (Fig. 3-67B). The waveform before passing through the filter is shown in Fig. 3-67C.

3.68 ***How are filter circuits connected in the input and output of a dc dynamotor?***—In the manner shown in Fig. 3-68. Large capacitors are connected in parallel with the battery side to remove the effects of motor commutator ripple and brush noise. An iron-core choke and two filter capacitors are connected to the load side to remove commutator ripple and radio-frequency interference. The capacitors and choke must be placed in a metal can and grounded to the frame of the machine.

3.69 ***How are filters connected in the input and output of a converter?***—In the manner shown in Fig. 3-69. Capacitors C1 and C2 at the ac output remove any noise due to sparking at the slip rings, and the small capacitor C3 at the output terminals removes radio-frequency interference. The frame of the machine should have a physical ground, if possible.

3.70 ***Describe the construction of an inside-out hysteresis synchronous motor.***—One such type motor is shown in Fig. 3-70A. This motor is often referred to as an inside-out motor, because the stator revolves rather than the armature. This type of motor is used extensively for the driving of ¼-inch magnetic-tape recorders, at speeds of 1⅞ to 30 inches per second. Such motors are available in dual- and triple-speed designs. Common speeds for the dual type are; 300/600, 360/720, 450/900, and 600/1200 rpm; and 300/600/900 for the triple speeds. A nonmagnetic puck or capstan is pressed on the motor spindle to obtain the desired linear speed for magnetic tape.

Hysteresis synchronous motors provide the exact constant-speed required for magnetic recorders, with high torque and constant angular velocity. The rotor (stator) is a dynamically balanced flywheel, which assures a constant speed under changing load conditions. A Mumetal shield is placed over the stator winding and rotor, to eliminate the high flux-torque from the region of the motor shaft. Impellers on the rotor circulate air to provide forced ventilation for the motor and associated equipment.

Fig. 3-70B shows the internal and external connections for a dual-speed motor, and Fig. 3-70C shows the connections for the triple-speed unit. The average power consumed hy this type motor is approximately 30 to 40 watts, at 117 volts, with a rotor torque of 7 to 10 ounces. The bearings may be ball-bearing or oilless sleeve type. The motor is single hole mounting, and uses a capacitor ranging from 1.5 to 3.0 μF.

3.71 ***How is speed reduction obtained for recording and reproducing equipment?***—Several methods used to obtain speed reduction in recording and

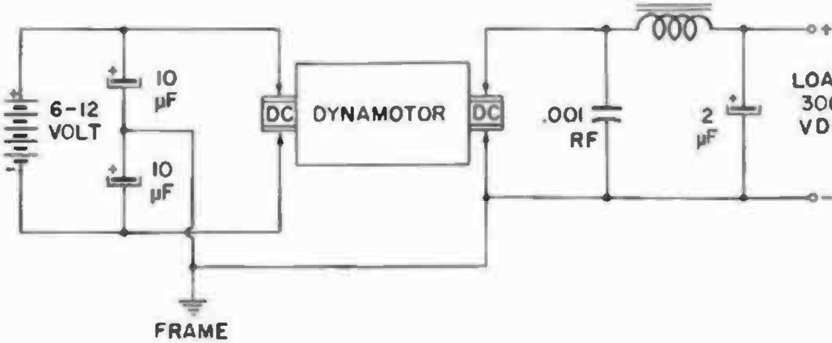

Fig. 3-68. Filter system used with a 6/12 volt dc to 3000 volt dc dynamotor.

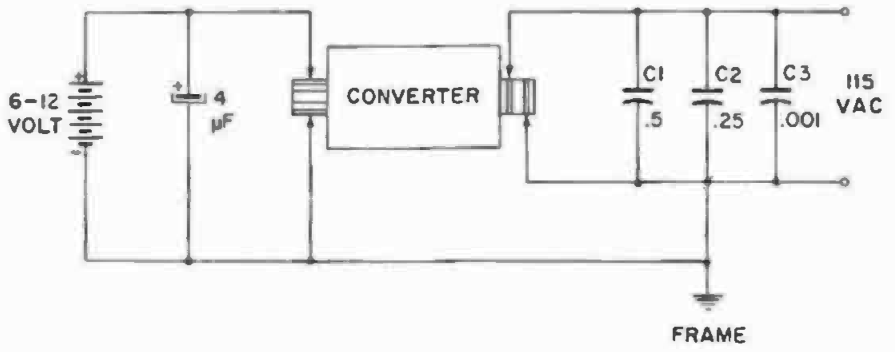

Fig. 3-69. Filter system used with a 6/12 volt dc to 115 volt ac converter.

reproducing equipment are shown in Fig. 3-71. Among these various systems will be found gear reducers, intermediate idler rollers, and belt drives. Fig. 3-71(a) shows three types of puck or idler drive systems. Fig. 3-71(b) illustrates two types of gear reducers, Fig. 3-71(c) shows two types of belt-speed reducers, and Fig. 3-71(d) shows a "Gilmer Timing Belt" drive system. For the sake of clarity in the drawings, decoupling devices (compliance) generally connected between the motor and the driven member have been left out.

Decoupling devices are generally of a loose coupling design; that is, the motor shaft is connected to the driven member through a piece of rubber, felt, leather, or adhesive tape, to reduce the transmission of vibration from the motor to the speed-reduction system. In some systems, a second decoupler is used to isolate the gearbox vibration from the driven system. Pucks, idlers, and belts serve as their own decoupling devices.

Intermediate rubber-covered idler roller drives are nsed in magnetic recorders and other types of recording equipment because of their low cost and smoothness of operation. Also, they serve as decoupling devices and prevent hunting in the drive system. The principal objection to their use is slippage, due to the deformation of the rubber at the point of surface contact. This slippage may be reduced to a minimum by the use of multiple pucks with narrow faces. Wide faces are not always best because the wide contact surface does not bear uniformly over the entire surface.

Rim drive or drives on the outer surface of a flywheel damp out the action the flywheel is intended to impart to the drive system, that of smoothing

Fig. 3-71. Drive systems used in recording and reproducing equipment.

out the rotational irregularities and surface imperfections of the idler or puck surfaces.

Gear drives have the advantage of positive nonslip drive between the motor and the driven members. However, rather elaborate decoupling devices are necessary between the gearbox and the driven member to eliminate vibrations from the gearbox, being transmitted to the driven system.

Single- and double-belt drives are quiet and require no lubrication, and also act as decoupling devices. Flat- or round-type belts may be used, but are subject to slippage. Belt-driven rim-drive devices, such as a recording or reproducing turntable, lose their flywheel effect when belt-driven, as the belt applies a damping effect to the drive system.

The best method of obtaining a positive drive with a belt is the "Gilmer Timing Belt Drive" shown in Fig. 3-71 (d), which incorporates a unique system of securing a positive speed reduction. Basically, it is a combination of a belt and a gear drive system, having the positive drive of a gear and the advantages of a belt.

The Gilmer belt drive is made of molded neoprene on a base of non-stretch cotton material. Precision teeth are molded into the belt which make contact with gear-type pulleys. Because of the characteristics of neoprene, there is a certain amount of natural compliance which eliminates the noise and ripple generally associated with gear driven systems. Also, no lubrication of any kind is required. Gilmer belt systems are used in many different types of recording and reproducing equipment where absolute synchronous speed is required. (See Sections 17 and 18.)

3.72 What is the relationship of frames per second to hertz?—Frequency meters on camera supply units are generally calibrated to read in both frames per second and hertz. This enables the recordist to increase or decrease the speed of the camera motor for special effects. If the camera is run overspeed, when the picture is projected later the action will be slowed-down; if the camera is run underspeed, the action will be speeded-up. In these instances, the camera is run wild, without sound. The relationship of frequency to frames per-second is:

40 Hz	16 frames per second
45 Hz	18 frames per second
50 Hz	20 frames per second
55 Hz	22 frames per second
60 Hz	24 frames per second
65 Hz	26 frames per second

When a change of frames per second is required and a calibrated scale is not readily available, the corresponding frequency may be determined by multiplying the desired frames per second by a factor of 2.5, which is derived by:

$$60/24 = 2.5$$

where,

24 is the frames per second for a standard frequency of 60 Hz. (See Question 22.37.)

3.73 Describe the different types of insulation used in motor windings.—Progressive advances in motor design, manufacturing techniques, and newly developed insulating materials have advanced to where a given size motor of a few years ago, is now considerably smaller and more efficient. The minimum physical size of a motor and its life expectancy are limited and determined by the destructive effects of internal operating temperature and winding insulation. The materials for a motor winding are divided into groups, and standardized by the Institute of Electrical and Electronic Engineers, (IEEE).

Class	*Maximum Spot Temperature*
O	90°C.
A	105°C.
B	130°C.
H	180°C.
C	No limit set

The electrical and mechanical properties of the insulated windings must not be impaired by the application of a permissible temperature for given classification. Cotton, silk, paper and similar materials may be used as a class-O insulation; however, if these materials are to be used as class-A it is necessary that they be impregnated or immersed in a liquid dielectric to afford greater insulation. Other class-A insulations are: molded and laminated materials with cellulose filler, phenolic and other similar resins, also films and sheets of cellulose acetate or other cellulose derivatives. Conductors are varnished. Class-B and class-H make use of materials such as mica, asbestos, Fiberglas, etc., with suitable binding substances. Where the temperature may be higher in class-C, materials such as mica, porcelain, quartz, and glass may be required.

3.74 Describe the operation of a centrifugal governor.—Centrifugal governors are used with both series and shunt ac or dc motors and generators. The governor consists of an insulated plate, mounted on one end of the armature shaft, with two stationary and two movable weighted contacts. The weighted contacts are adjusted to be opened by the centrifugal force acting on the movable contacts if the armature exceeds its rated speed by more than 5 percent. When the contacts are opened, a resistor is connected in the circuit, reducing the armature speed by the reduction of the line voltage. When the armature falls below the rated speed, the contacts close, shorting out the resistor. The voltage then rises as does the speed of the armature. The cutting in and out of the resistor is a continuous action as the armature speed varies. If the line voltage and the load are fairly constant, the governor is not too active, and the armature speed oscillates around the rated speed.

The disadvantage of a centrifugal governor is the high-frequency interference generated by the opening and closing of the contacts (with the possibility of generating noise), and the pitting of the contact surfaces. The contacts are normally shunted with a 0.25-μF high quality high-voltage capacitor. If this shunting capacitor opens, contact interference will be maximum. It may be desirable to connect a noise-suppression diode across the contacts and install a line-noise filter near the machine to prevent interference being fed back over the power line. This is particularly true if the device is installed near high-gain amplifying equipment. Noise-suppression devices are discussed in Question 24.67. The circuitry for connecting centrifugal governors is given in Fig. 3-74A and Fig. 3-74B.

3.75 Describe how dynamic braking is applied to a motor.—Dynamic braking can be applied to any motor circuit. However, as the motor increases in complexity, the switching circuitry becomes more involved. The braking effect to the motor is accomplished by disconnecting the power source and applying a direct current to one or more windings, thus reducing the rotation of the armature by magnetic drag until it comes to rest.

Several circuits are available for this purpose. Fig. 3-75A is the circuit for a shaded-pole motor. A dynamic braking circuit for split-phase start, capacitor start, or permanent split-capacitor motor is shown in Fig. 3-75B. Several oth-

ers shown in Figs. 3-75C to E are self-explanatory. The direct current is supplied from a half-wave rectifier. Extreme care must be exercised in the braking of geared motors to avoid shocking beyond their capabilities. This is especially true for loads having considerable inertia.

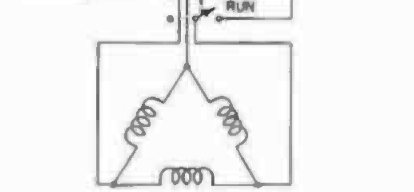

Fig. 3-75C. Dynamic braking circuit for three-phase motor. For delta connection only one phase of the stator is used. If star connected, two phases are used.

3.76 ***When certain motor data are known, how may other unknown related factors be determined?***—The nomograph in Fig. 3-76 provides a fast convenient way to determine factors of: Torque (in-oz) speed (rpm) frequency (Hz) horsepower and stator poles, as applied in the formulas:

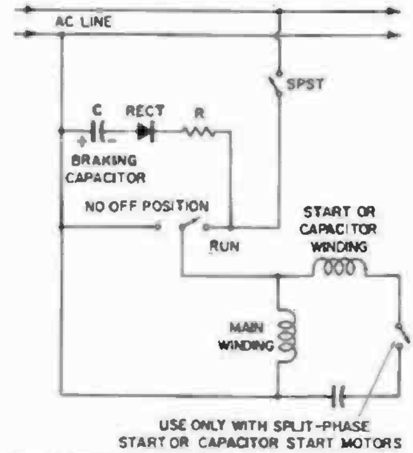

Fig. 3-75D. Dynamic braking circuit for split-phase start, capacitor start, or permanent split-capacitor motors.

$$\text{Speed} = \frac{120 \times \text{frequency}}{\text{Stator poles}}$$

Horsepower =

$$9.92 \times \text{Torque} \times \text{Speed} \times 10^{-7}$$

By connecting the points of known values on the nomograph, other values may be read. Example: To find the speed, given a frequency of 50 Hz, and 6 stator poles, the line connectiug these two values, intersects the speed scale

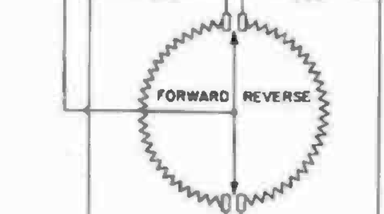

Fig. 3-75E. Dynamic brake and speed control of 3-wire reversible capacitor motor. Maximum speed will be obtained when the resistor shunted across the capacitor is minimum and will increase with an increase of resistance. Maximum speed is obtained when contact arm reaches the horizontal position and shunt circuit is open. Motor is braked when contact arm is vertical.

at 1000-rpm, line "A." When the horsepower is 0.250 and the speed is 1500-rpm what is the torque? The straight edge laid across the known values, torque is read at $1.68 \times 10^{x+2-y}$ ($x = 0$ $y = 0$) $= 1.68 \times 10^2 = 168$ in-oz, line "B." Given a horsepower of $\frac{1}{70}$ or 0.0143 or 0.143×10^{-1} then $x = -1$, with a speed of 3,600-rps or 360×10^1 then $y = 1$. The torque scale is intersected at $4 \times 10^{(x+2-y)}$ or $4 \times 10^{-1+2-1} = 4 \times 10^0$ $= 4$ inch ounces, line "C." (See Questions 25.116 and 25.136.)

3.77 ***Describe the characteristics of synchronous motors used for driving sound equipment.***—The synchronous motor employed for driving of recording and projection equipment is not the conventional synchronous motor generally found in an industrial plant. Motors for sound work are of special design and are of the variable reluctance type, using squirrel-cage construction for the armature, with salient poles milled in the armature laminations. Such armatures are constructed by using heavy copper bars running lengthwise of the armature, and shorted at each end by a heavy copper ring. Salient poles are milled the length of the armature laminations, at an angle of 7 to 10 degrees, using the armature shaft as reference (Fig. 3-77A.)

In the early days of sound, synchronous motors were not available and induction motors were made to run at synchronous speeds by cutting slots in the armature laminations. This was

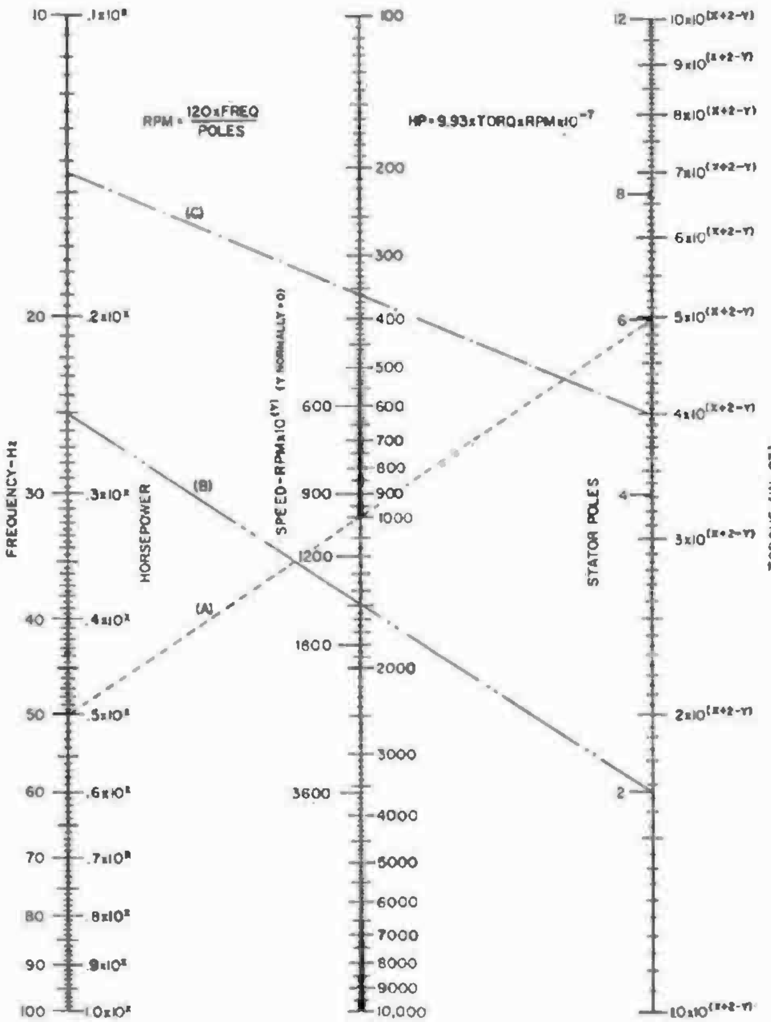

Fig. 3-76. Nomograph for determining the characteristics of motors. (Courtesy, Bodine Electric Co.)

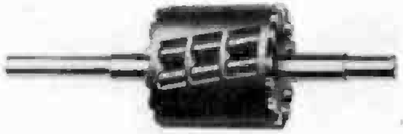

Fig. 3-77A. Squirrel-cage motor armature showing the copper rods, rings, and salient poles. (Courtesy, Bodine Electric Co.)

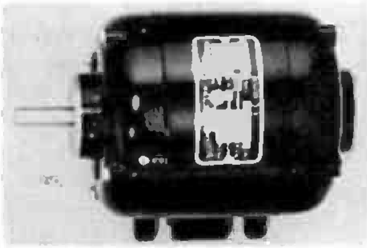

Fig. 3-77B. Fractional horsepower motor manufactured by Bodine Electric Co.

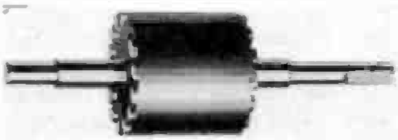

Fig. 3-77C. Armature of a standard induction motor. (Courtesy, Bodine Electric Co.)

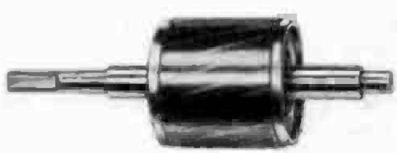

Fig. 3-77D. Armature of a permanent split-capacitor motor. (Courtesy, Bodine Electric Co.)

done by placing several hack-saw blades in a frame and cutting a slot about ⅛-inch in width, the length of the armature, at an angle of about 10 degrees; the armature was then rebalanced.

If the bars of the squirrel-cage rotor are of sufficient low resistance to bring the rotor to synchronous speed, the salient poles will pull the armature into step with the points of greatest flux density of the rotating field. As there are no windings, the armature requires no maintenance.

Synchronous motors may be designed to operate over a limited speed range by changing the frequency of the driving-power source. This usually requires a change in the supply voltage to maintain a satisfactory power input. Synchronous motors may also be provided with stator windings to produce a number of different pole combinations, and by using a suitable rotor, the motor may be made to operate at a number of different speeds. This is discussed in Question 3.70.

Because of the quick starting characteristics of squirrel-cage motors due to the copper bars, shorting rings, and salient poles, they have a high starting torque and are brought into synchronism very quickly. As this is somewhat of a disadvantage, particularly for the cameras and projection machines, some means must be taken to provide a soft start, such as putting resistors in the power source and cutting them out of the circuit as the motor comes up to speed.

Because such motors can not be interlocked at rest, a sync mark must be provided, to indicate when they reach synchronous speed. On production, this is accomplished by the use of clap-sticks held in front of the camera, and photographed while the sound is being recorded. Later, the picture of the clap-sticks and their sound is used by the editorial department to synchronize the picture with the sound track. (See Question 18.334.)

Motors of the above described type are characterized by their high starting torque, rapid acceleration, low power factor (because the exciting current is taken from the line through the stator winding), and efficiency. However, these factors are of little consequence as the power rating is low, generally on the order of 1/10 to 1/3 horsepower. Synchronous motors of this type cannot be used for background projection or rerecording purposes. In background projection, the shutter of the projector must be synchronized with the camera beforehand. If this were not done, the camera shutter might be opened while the projector shutter was closed, resulting in no exposure of the background projection. Selsyn interlock motors must be used to bring the camera and projector up to speed and in synchronization. When sync speed has been attained, clap-sticks are used to establish the synchronization of picture and sound. (See Question 19.59.)

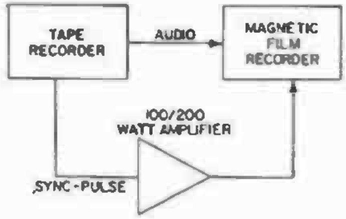

Fig. 3-78A. Basic resolver system using the sync pulse to drive the transfer machine motor.

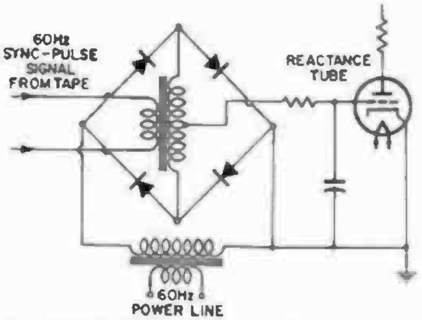

Fig. 3-78B. Bridge circuit with reactance tube for controlling the frequency of the 60-Hz oscillator driving the synchronous motor in the ¼-inch tape reproducer.

In rerecording installations, quite often certain machines are equipped with dual-purpose motors. These motors function as both selsyn interlock and a straight synchronous motor, which is quite convenient during a rerecording session, where a single track is wanted for listening purposes, and the balance of the machines are set for interlock running.

Transfers from one synchronous machine to another are permissible, provided a start mark is recorded on the new sound track when the machine has attained synchronous speed. It is quite common practice when transferring a magnetic sound track to a photographic sound track to start the photographic recorder first and then start the magnetic sound track. The machine carrying the magnetic track will settle down in a very short time, while the photographic recorder takes longer in comparison because of the transport-loop system. A fractional horsepower synchronous motor, manufactured by the Bodine Motor Co., appears in Fig. 3-77B. Figs. 3-77C and D show an armature for a standard induction motor and also one for permanent split-capacitor motor.

3.78 ***Describe the methods for recording a sync pulse on quarter-inch magnetic tape for synchronous operation with camera.***—Sync-pulse systems used for the synchronization of motion picture camera and ¼-inch tape recorders are quite common. Several different types of systems are in general usage. All these systems accomplish the same end result, but in a slightly different manner. Such systems are said to record magnetic sprocket holes, because they produce the same results as sprocket type machines. The first of these systems was developed by Col. H. B. Ranger, of the Rangertone Co. In this system, the sync pulse was the power-line frequency. A low level 60-Hz signal was recorded in the center of the tape, over the sound track, at an angle of approximately 87 degrees to the direction of the tape travel (Fig. 3-78C.) Later, when this track was transferred for editorial purposes, the sync-pulse signal on the tape was amplified by a power amplifier and used to drive the motor on the transfer machine (Fig. 3-78A). Any variation in the line frequency or camera during the original recording was transmitted to the transfer machine motor, duplicating the elec-

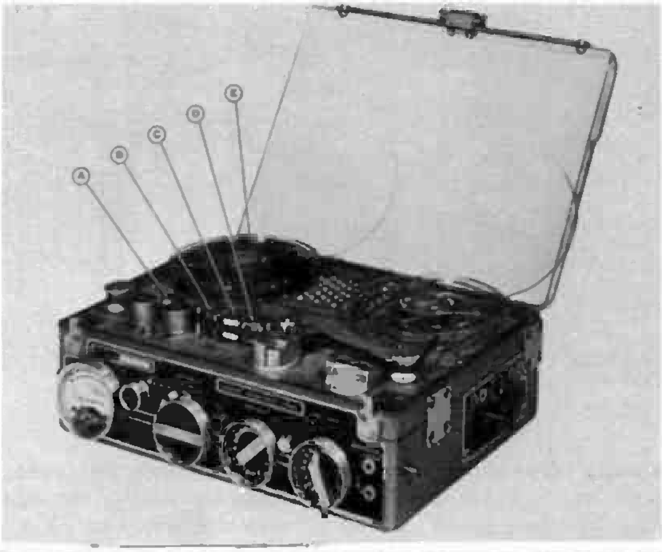

Fig. 3-78F. Nagra III ¼-inch magnetic recorder. (Courtesy, Magnetic Sales Corp.)

trical conditions prevailing at the time of the recording; thus, synchronization between the sound and picture was achieved.

A second system, developed by Ranger for transferring the original sound track, compares the sync-pulse signal on the tape to the 60-Hz power-line frequency driving the transfer machine motor. This comparison is made automatically by using a bridge circuit in which one arm is a reactance tube that controls the frequency of an oscillator, which is normally adjusted for 60 Hz (Fig. 3-78B). The oscillator drives the power amplifier which, in turn, drives the synchronous motor in the tape recorder now being used as a reproducer. If the sync-pulse signal at a given moment is exactly in step with the power frequency, the bridge circuit is in balance and the reactance tube is inactive. If the sync pulse on the tape gets ahead of the power frequency, the bridge becomes unbalanced and slows down the motor in the recorder until the sync pulse is again in step with the power-line frequency. If the sync pulse is slow, it is speeded up by the reverse process. Corrections to the speed of the tape must be made slowly, so as not to produce a noticeable change to the ear. Experience indicates that if the corrections are less than 1 cycle in two seconds, the variation in speed is not heard.

A third method of applying sync pulses to a tape recorder is termed the echelon system, used with Perfectone recorder, developed for location work by Ryder Sound Services. In the echelon method, the sync pulse is recorded

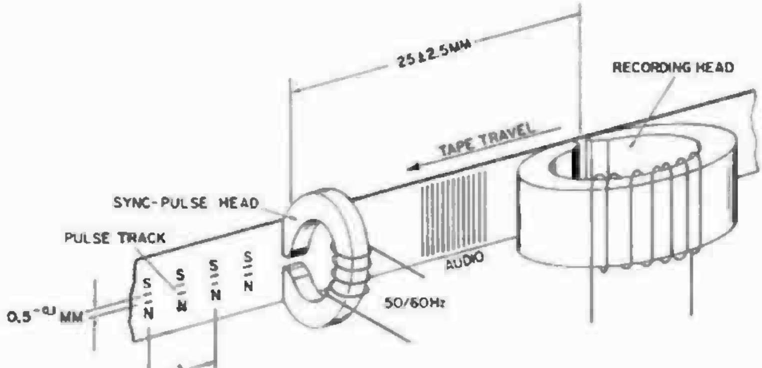

Fig. 3-78G. Rangertone transversal recording.

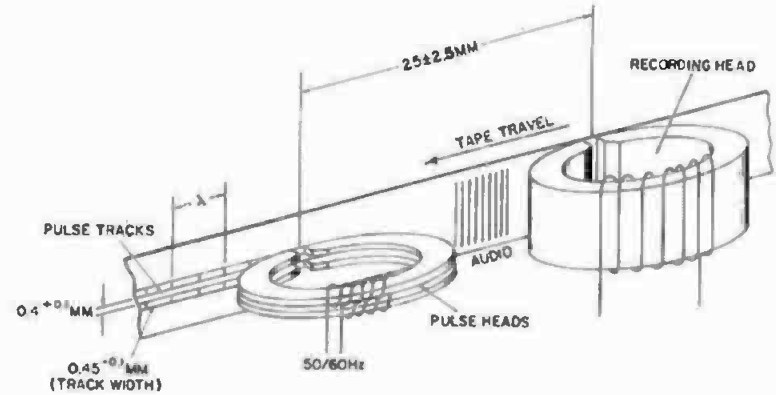

Fig. 3-78H. Nagra push-pull recording.

on the two outer edges of the tape at an angle of 90 degrees to the direction of tape travel. The pole pieces of the heads are staggered about one half wavelength of 60 Hz, running at a speed of 7.5-inches per second, or approximately 1/16 inch (Fig. 3-78D). The sync-pulse signal may be generated by a permanent-magnet generator mounted on the camera motor, or taken from the camera motor-supply voltage as discussed in Question 3.57.

A fourth method called the NeoPilot system, developed by Stefan Kudelski of Lausanne, Switzerland, is used with the well-known Nagra recorders. This system employs a sync-pulse head that records a 50- or 60-Hz push-pull signal in the center of the tape, at an angle of 90 degrees of the direction of tape travel (Fig. 3-78E). Although the construction of the NeoPilot head appears to be similar to the echelon type, it is not, since the pole pieces are in-line and staggered. The sync-pulse signal may be taken from the camera power source, or from a sync-pulse generator mounted on the camera motor. All of the systems that have been discussed employ approximately 1.25 Vac at the sync-pulse head.

A Nagra III recorder-reproducer is shown in Fig. 3-78F with the head placement indicated. At "A" is the erase head, "B" the sync-pulse head, "C" the record head, and "D" the playback head. The supply reel for the tape is shown at "E." This recorder is treated in detail in Question 17.177.

The positioning of the sync-pulse head for the Rangertone system is shown in Fig. 3-78G. Here, the sync-pulse head is mounted on the center line of the tape at a right angle to the audio signal after the tape has passed over the recording head. Some cross talk between the sync pulse and the audio signal may be expected using this system.

In Fig. 3-78H is shown the position of the sync-pulse head on a Nagra recorder using the NeoPilot system. Since in this system the sync-pulse head is of push-pull design, no cross-talk interference is observed between the sync pulse and the audio signal. All three systems are compatible except for the different methods used for taking off the sync-pulse signal. For the Ryder echelon head, it is placed in the same position as for the NeoPilot system.

In the absence of a recorder especially designed for sync-pulse operation, a stereophonic two-track recorder may be used. In this instance the sync-pulse signal is recorded on one track and the audio signal on the other. The sync-pulse signal is then reproduced and used to drive the transfer recorder, or interlock other machines as previously discussed. (See Question 3.80.)

3.79 *Can frequencies other than 60 Hz be used for sync-pulse signals?*—Yes, they may be operated at 50, 60, 100, 120, and, in some instances, 14,000 Hz. However, if the higher frequency is used, the recorder must be capable of recording a strong 14,000-Hz signal on the tape, and precautions taken to prevent leakage of the sync signal into the recording circuits and causing beats. Pictured in Fig. 3-79 is a resolver manufactured by Magna-Tech Electronic Co., Inc., Model 92B. This device is designed to operate at both 60 and 14,000 Hz. The sync-pulse head is mounted between

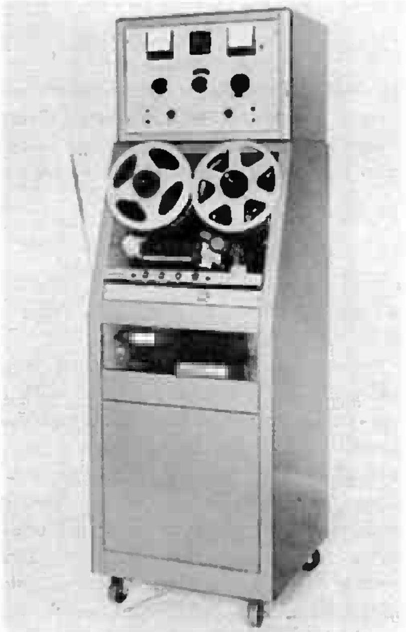

Fig. 3-79. Magna-Tech Electronic Co., Model 92B playback synchronizer operating in conjunction with an Ampex ¼-inch tape recorder.

the normal head assembly. The capstan and pinch-wheel are at the right.

3.80 Describe the methods used to connect a tape recorder and camera for sync-pulse operation.—Five different methods of connecting or operating a ¼-inch tape recorder and camera for sync-pulse operation are shown in Fig. 3-80A through E. In Fig. 3-80A the tape recorder is operated from its internal batteries and is fed a sync-pulse signal from a permanent-magnet generator (60 Hz) mounted on one end of the camera motor shaft. The power supply for the camera consists of a three-phase 220-Vac 60-Hz generator driven from batteries. With the sync-pulse voltage taken from the camera motor-driven generator, any change in camera speed is reflected in the frequency of the sync pulse and recorded on the tape, along with any small variations in the battery-driven motor in the recorder.

The system shown in Fig. 3-80B is similar, except that the sync-pulse voltage is taken from a step-down transformer connected across two phases of the three-phase voltage fed to the camera motor. Any change in the frequency of the camera-supply voltage is recorded on the tape. When shooting in a studio, the camera is generally supplied from the house mains, which also supply the sync pulse through a step-down transformer (Fig. 3-80C).

Systems are also available where the sync pulse is transmitted by a small radio transmitter to the recorder, as in Fig. 3-80D. Another system for driving the camera employs a transistorized inverter operated from batteries, and generating 117 Vac, at 60 Hz (Fig. 3-80E). The frequency of the generator is precision-controlled. The sync-pulse signal is taken from a small precision unit which generates 60 Hz with an accuracy of ±0.0005 percent. The manufacturer states the inverter and sync-pulse generator have an accuracy of 20 parts per million, over a temperature range of minus 20°C to plus 50°C (minus 40°F to plus 122°F); or 5 parts per million over a temperature range of plus 8°C to plus 34°C. Using this synchronization, several cameras can be used simultaneously without interconnecting cables. While there are other

variations of the described systems, those shown in Figs. 3-80A through C, are the most commonly employed. (See Question 3.78.)

3.81 Describe a system for interlocking nonsynchronous recorders and reproducers.—The problem of interlocking nonsynchronous sound equipment and picture has been one of the chief difficulties of the sound industry, because synchronous motors, although rated constant-speed, are only approximately so. They are subject to slight speed changes due to possible variation of the coupling angle between the rotating field and the rotor. The angular velocity may not be constant, but the average speed will be synchronous.

Nonsynchronous motors never operate at synchronous speeds, even at no load, and the difference between synchronous and actual speed will depend upon the design, power input, and torque requirements. They are also affected by the line voltage and the load. To overcome this difficulty, the Radio Corporation of America, has developed a system of interlocking synchronous and nonsynchronous machines, with a trade name of Unilock.

To explain its operation, in Fig. 3-81A is shown a tape recorder with a sync-pulse recorded on the tape (see Question 3.78), interlocked with a standard 35-mm or 16-mm projection machine. The only piece of equipment required at the projector is a rate-generator mounted in the film path. The moving film drives a drum containing holes that chop a light beam between a small lamp and photodiode, generating a 60-Hz signal at a frame rate of 24 frames per second. The output voltage of the rate generator is applied to the input of a Schmitt-trigger amplifier in channel "B" of the Unilock system. The output from the sync-pulse head on the tape recorder is applied to a second Schmitt-trigger in Channel "A." To operate, the tape and film are threaded at their respective start marks, and the system thrown to the interlock mode and the projector and tape transports started.

During the acceleration period, the tape will attain sync speed almost in-

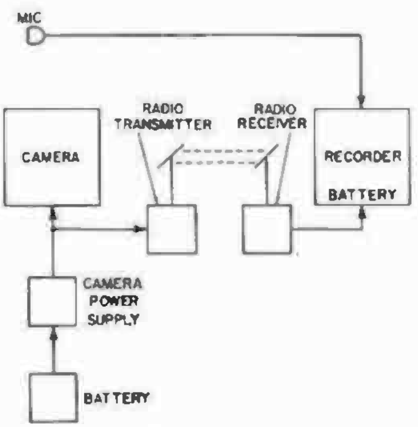

Fig. 3-80D. The camera is operated from a battery-operated generator. The sync-pulse is sent to the recorder by radio.

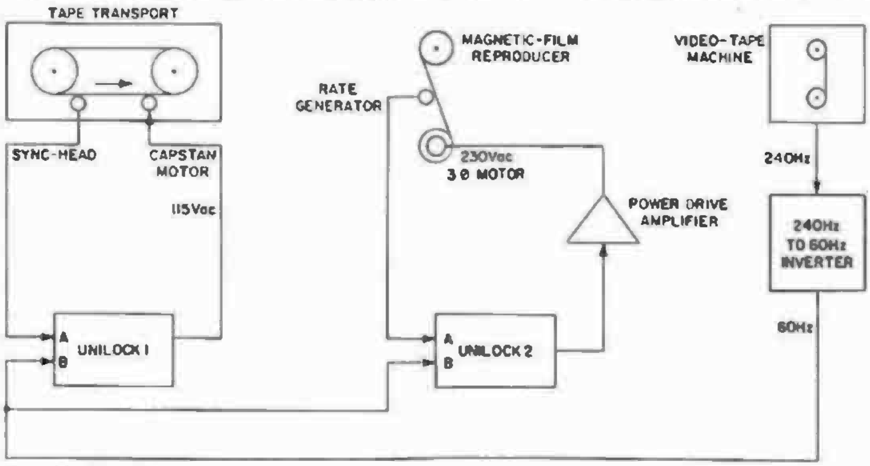

Fig. 3-81B. Tape recorder, 35- or 16-mm magnetic-film machine, and video-tape recorder interlocked using a Unilock system.

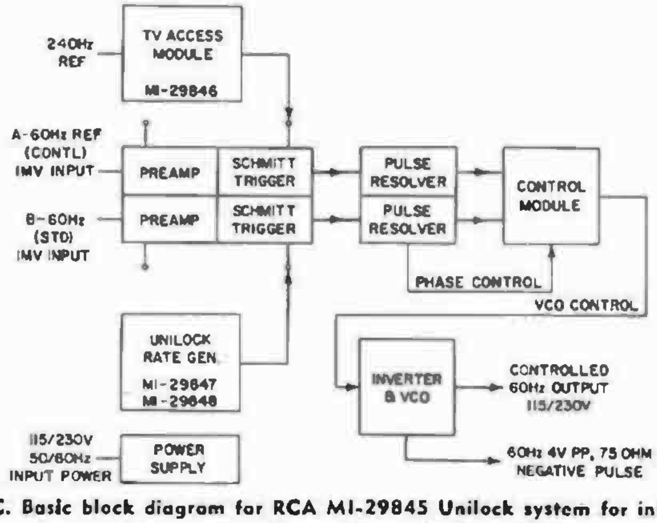

Fig. 3-81C. Basic block diagram for RCA MI-29845 Unilock system for interlocking nonsynchronous recording and reproducing equipment.

Fig. 3-81D. Unilock sync or pick-off head mounted on an RCA TP-66 16 mm projector.

stantaneously, while the projector accelerates more slowly. This produces a lower pulse rate in channel "B." As the pulse-count differential between the two channels builds up, the stepping motor turns potentiometer P1 so as to slow down the tape-transport capstan. As the projector attains full speed, the pulse rate from the rate generator approaches 60 Hz. The number of pulses in channel "B" will eventually catch up with the total pulses of Channel "A." In so doing, the stepping motor will bring potentiometer P1 back to the position where the capstan motor is driven at synchronous speed, thus synchronism is attained. The time required for the system to stabilize is approximately 5 seconds. Even if the system is stopped, it can be started again with both machines in synchronism.

To use the system with a video-tape recorder, a magnetic-film reproducer, or a projector, the equipment is connected as shown in Fig. 3-81B. The 240-Hz control-track signal from the video machine, after suitable amplification, is applied to a converter which reduces the 240 Hz to 60 Hz. The inverter output drives a 230 Vac three-phase power drive amplifier, which supplies the motive power for the magnetic-film reproducer. Many other combinations of this system are possible and any number of

Fig. 3-81E. Reference signal rate-generator mounted on RCA TP-66 16mm projector.

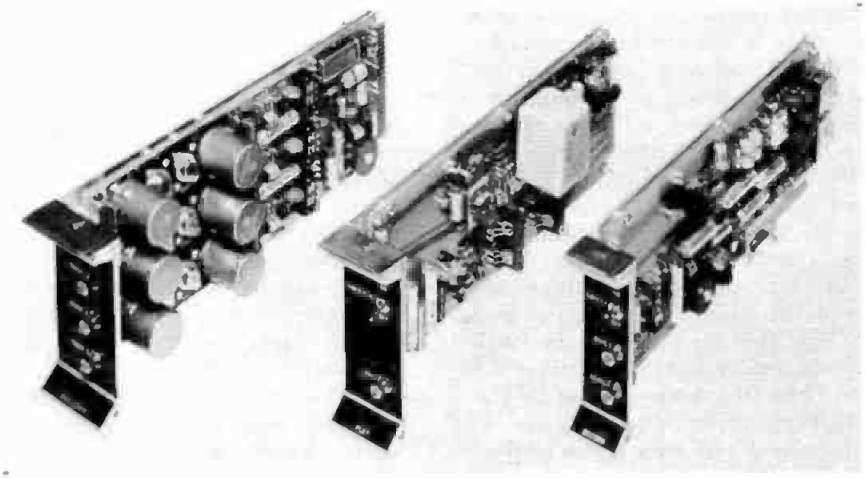

Fig. 3-81F. RCA Unilock control modules.

machines can be interlocked. Control equipment is available for either 50- or 60-Hz operation.

A basic block diagram in Fig. 3-81C is completely solid-state. The inverter unit will supply 30 watts at 117 Vac for driving the capstan motor of ¼-inch tape recorders, or 300 watts at 230 Vac for driving the motor of a magnetic-film recorder/reproducer. To operate a ¼-inch tape recorder, a sync or pick-off head is required, and is shown mounted on an RCA RT-21 tape recorder. A reference signal rate-generator is shown installed on an RCA TP-66 projector in Fig. 3-81E. Three modules associated with the control system are shown in Fig. 3-81F, with an inverter, preamplifier, pulse resolver, control, and power supply shown in Fig. 3-81G.

3.82 Describe the methods used for phasing a selsyn interlock system.—Assuming the system is designed for three-phase operation, the phasing is started at the synchronous motor driving the selsyn generator set. The driving motor is phased for the correct direction of rotation by connecting its leads to the three-phase power source, and noting the direction of the rotation, which should be clockwise when facing the shaft end driving the selsyn generator unit. If the rotation is counterclockwise, reverse two of the power leads. The generator unit will have 6 leads, numbers 1 to 3 being the stators, and 4 to 6 the rotors. These 6 leads are run to each machine to be driven, and the leads numbered similarly to the generator leads. The stators of all mo-

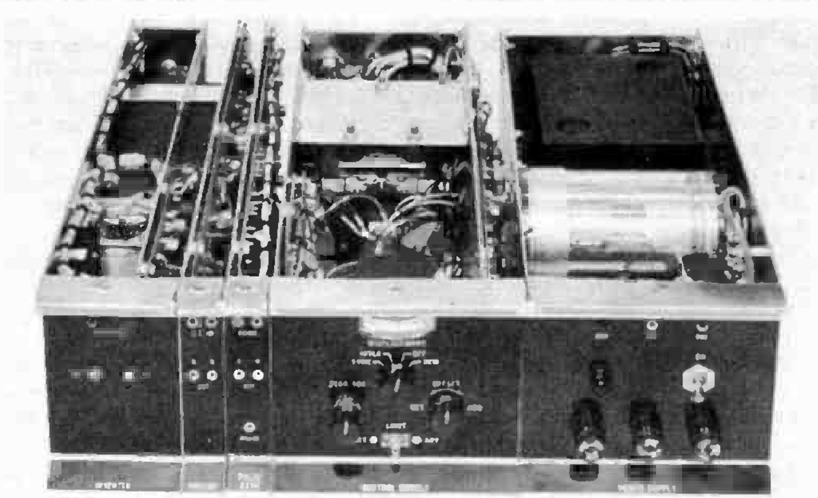

Fig. 3-81G. RCA Unilock control modules.

tors are connected to the stator lines from the selsyn generator, number for number. The selsyn generator is started and the rotors of each motor shorted together, without load, and the direction of rotation noted. If the motor rotates in the wrong direction, reverse the two stator leads. This procedure is followed through for the whole system. After phasing the motors, two phases of the power line (locking position) are closed. The rotors should then all pull into lock. Rocking the rotors by hand, the lock should feel firm. Closing the third phase, the motors should all run at 1200 rpm in the same direction.

It is possible in some selsyn systems to have what appears to be correct phasing, but one motor does not lock solid, and has a tendency to run away (1800 rpm). This condition must be corrected or the motor will overheat and run away frequently. This condition can be caused by the leads on the stator side not being properly phased, although about 90 percent of the time it operates normally.

Single-phase interlock systems are somewhat simpler to phase. The single-phase line is connected to the rotors, and two of the three stator leads are reversed for the correct direction of rotation. If the selsyn is a dual-purpose type (selsyn and synchronous) designed for three-phase operation, it will have 9 leads. Leads 7 to 9 are for synchronous operation. These leads are connected to a source of 230-volt three-phase power and reversed for the correct direction of operation. Care must be taken that the synchronous switch is never thrown when the system is operating as a selsyn motor.

3.83 ***What is the purpose of reversing a rerecording system?***—Reversible rerecording systems serve two important purposes; they save rehearsal time, and they afford the operating personnel greater convenience of operation. It is the current practice to rerecord a full reel of picture and sound track that may run from 940 to 980 feet in length. Many times a difficult cue or sound effect is encountered down in a reel 500 to 600 feet from the start. If the cue is such that it may require several rehearsals, this can become costly and time consuming, as all the sound tracks and picture must be rewound for each rehearsal. Interlock systems can be designed to hold the machines in sync, while reversing and running back to a portion to be again rehearsed. After reversing, they may be run forward again without loosing synchronization. This may be done as many times as required.

Interlock systems designed for reversal operation require special treatment. The picture gate in the projector must be suitable for running in reverse, or modified to do so. The modification will differ with each make of machine. Solenoids must be installed to lift the pad roller off the impedance drum in the sound head when running in reverse. Also, the fire shutter must be closed when the picture comes to a stop at the point of reversal. Most magnetic film machines will run reverse as they have torque motors on the feed and take-up spindles.

In some installations, the magnetic recorder is provided with an erasure system for erasing a portion of the sound track, while running in reverse, to permit recording that portion over again. Recorders are available that will permit a single word or musical note without a trace of the substitution.

Distributor systems can be reversed in several different ways. Two of the most common are the reversing of the power leads by a system of relays, and reversing the power circuits and rotating the distributor unit in reverse by means of a separate motor running at 120 feet per minute. Reversal systems are usually designed to fit a particular installation.

3.84 ***Describe a resolving system for transferring ¼-inch tape, using a sync-pulse to drive a sprocket-driven recorder.***—A resolver is a device used for transferring a ¼-inch magnetic tape sound track employing a sync-pulse signal, to a sprocket driven recorder, while maintaining absolute synchronization. Several different methods are available; they will be discussed in their proper order. The reader is referred to Question 3.78, before reading the following discussion.

Assume a motion picture is being shot, where the camera is being supplied with a three-phase 220-volt 60-Hz voltage from a battery-driven power supply, and the ¼-inch tape recorder is driven from internal batteries. The camera motor power supply does not generate a constant frequency, even with constant-frequency control, but will vary both above and below the nominal frequency. If the alternator is generating 61.0 Hz, the camera motor is turning 1.66 percent faster, and if the alternator is generating only 59 Hz; the rotor is 1.66 percent slower, with reference to 60 Hz.

In the first method of transfer that might be used, the battery-driven recorder is now used as a reproducer (Fig. 3-84A). The sync-pulse signal is amplified by a 60- to 100-watt amplifier, which drives the synchronous motor in the sprocket-driven transfer recorder. Since the power for the transfer recorder motor is the original pulse signal recorded during the shooting of the sound track now undergoing transfer, the sprocket-driven machine motor will increase and decrease its speed in

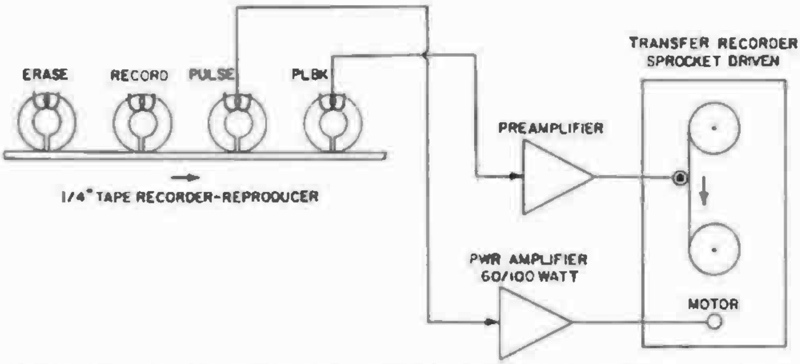

Fig. 3-84A. Direct method of transferring ¼-inch tape using a sync-pulse signal to a sprocket driven machine.

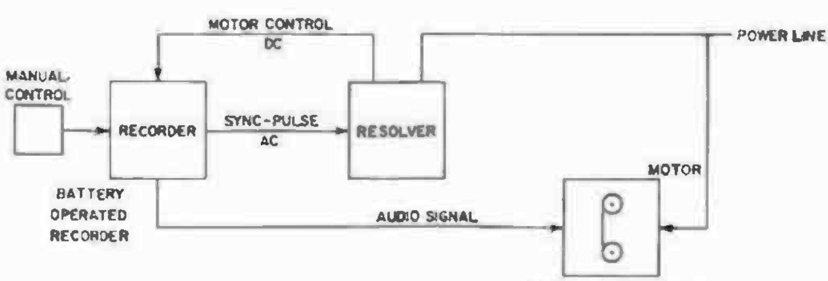

Fig. 3-84B. Kudelski Nagra III ¼-inch tape recorder connected to a sync-pulse resolver. The sync-pulse signal is fed to the resolver from the recorder. After correction, it is returned to the motor-control circuits in the recorder. The manual control extends the range normally outside the resolver range. The audio signal is fed from the recorder to the transfer machine in the usual manner.

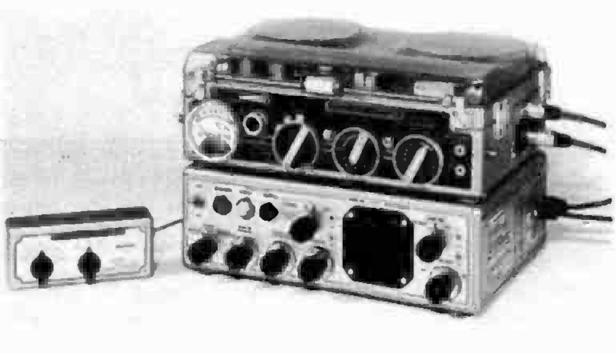

Fig. 3-84C. Kudelski Nagra III and Model SLO resolver, with Variator manual control at left.

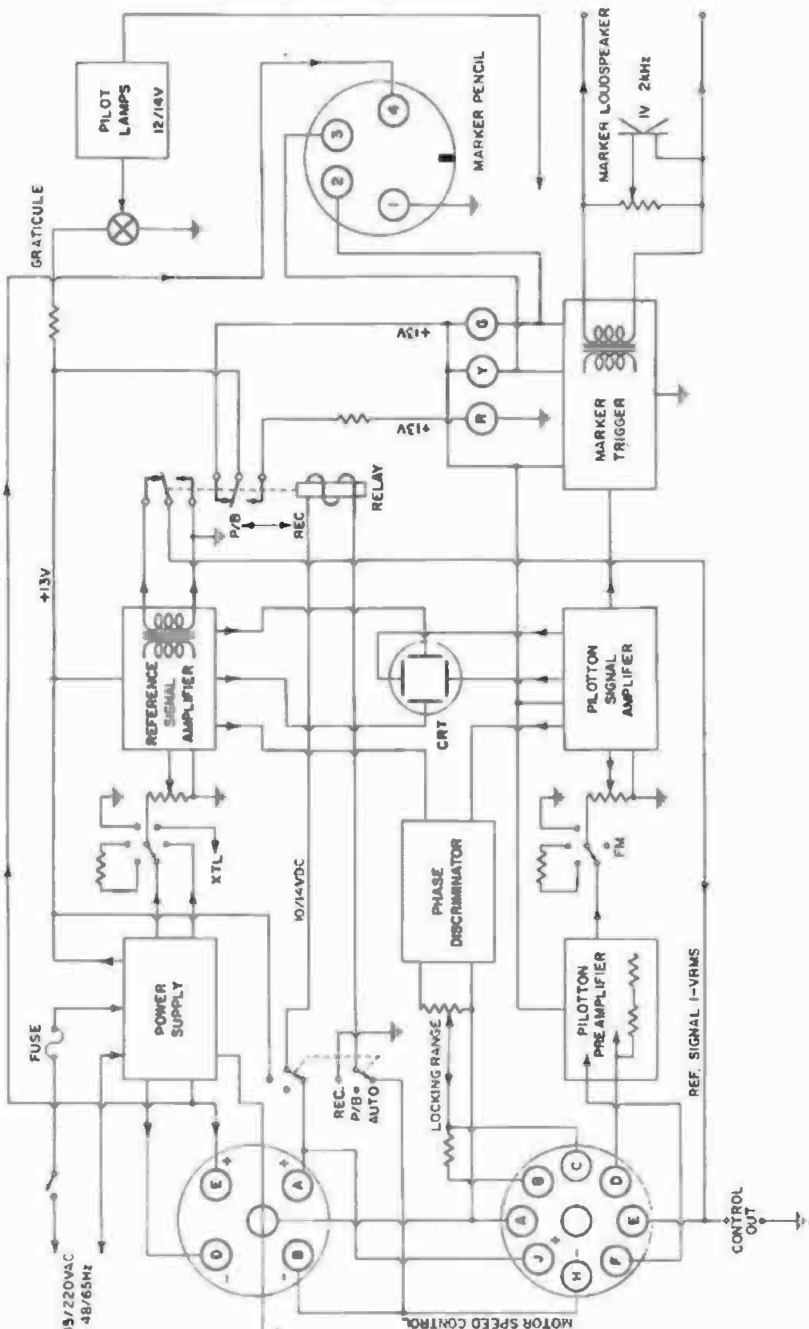

Fig. 3-84D. Block diagram for Kudelski Model SLO resolver for use with Nagra recorders or similar equipment. The two plugs at the left connect to the motor-control circuits in the recorder and the switch circuitry. The Variator control plugs into the recorder.

accordance with the record of the sync signal on the tape. Thus, the same result is obtained as if the original sound track had been recorded on the sprocket-driven machine. It will be observed that in this system and all others to be discussed, corrections are automatically made for variations in the speed of the tape recorder, elongation of the tape, and any other elements that disturbed the linear speed during the recording of the original tape. This method can be used with satisfactory results, when other methods of transfer are not available.

In the second method, the same results are obtained by reversing the procedure. Here, the sprocket-driven machine is powered from the studio power line, and the speed of the motor driving the tape recorder is controlled by a resolver to synchronize it with the studio power-line frequency. The advantage of this method over the first is that there are always slight discrepancies between the sync signal on the tape and the power line frequency, and in many instances it is next to impossible to avoid parastic oscillations, resulting in slow drifts and low frequency flutter. This second method eliminates these difficulties, and is the system used by Rangertone. (See Question 3.78.)

A third resolving system (Fig. 3-84B), developed by Kudelski of Lausanne, Switzerland for the Nagra line of recorders, is of different design. The principal component of the circuitry is a phase-discriminating circuit for comparing the frequency of the sync pulse on the tape to that of the studio line frequency. The phase difference is converted into a pseudodirect current which is used to correct the speed of the dc motor in the Nagra recorder as it reproduces the sync-pulse signal. Three types of reference signal may be employed: the internal line frequency (50 or 60 Hz), twice the line frequency (100 or 120 Hz) of any voltage up to 50 volts, or a signal generated from a quartz crystal clock for instrument use. Kudelski uses the name *NeoPilot* for the sync-pulse voltage. For normal transfer work, a cathode-ray tube displays the reference signal (line frequency) horizontally, and the sync signal from the tape vertically. When the reference and pulse signals are in absolute synchronization, the oscilloscope display is a steady oval nonmoving Lissajous pattern. The latitude of the speed control on the tape recorder motor circuit is ±2.5 percent, for a linear speed of 7.5 ips. If a greater spread is required, a manual control, called a Variator, is connected to the recorder by means of a cable, which permits the speed control operating range to be extended. There are also internal controls for extending the speed control range where a Variator is not available. If a malfunction occurred during the original recording, it may be necessary to control manually the motor speed correction. This is accomplished by slowly rotating the Variator. As a rule, most transfers will fall within the 1.5-percent range. If the power line was used for the sync signal during the recording of the original tape, the differences in speed will fall well within 0.5 percent.

Included in the resolver is a control for selecting either automatic or manual control of the tape recorder motor speed. If a tape is being transferred automatically and a dropout occurs, a marker trigger circuit becomes operative when the pulse signal drops to a predetermined level. The trigger circuit actuates an audible signal from a built-in loudspeaker, turns off a green sync-signal indicator light, turns on a yellow warning light, and actuates an external circuit which may be applied to a pencil-marking device on the transfer recorder. This latter device, however is not necessary, but is quite handy if the transfer operator cannot keep a steady watch on the operation, since it indicates dropouts in the original sound track and where they appear on the transfer track. The resolver may also be used to record a sync signal when a ¼-inch tape is being rerecorded from a sound track on a sprocket-driven machine for playback purposes.

A front view of a Kudelski type SLO resolver is shown in Fig. 3-84C, with a *Variator* manual control at the left. Above the resolver is a Nagra III ¼-inch tape recorder. A simplified block diagram for the internal circuitry of the resolver appears in Fig. 3-84D.

3.85 Show a block diagram for playing back ¼-inch tape on location using a resolver.—The Kudelski Type SLO resolver can be quite useful on location for making immediate playbacks after recording, or from tapes previously recorded in the studio. A block diagram of the connections appears in Fig. 3-85. Here is shown a Nagra recorder being used as a playback machine, in conjunction with the resolver, fed from a source of 50 or 60 Hz. The audio signal is fed to a power amplifier and loudspeaker.

If local power is not available, the equipment may be fed from the cam-

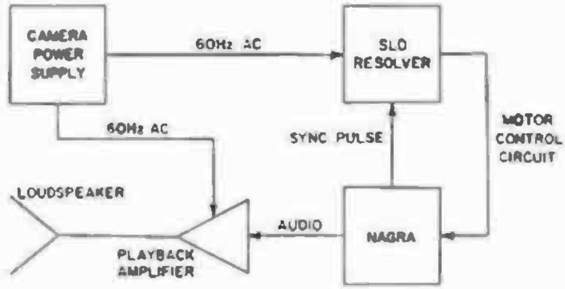

Fig. 3-85. Location playback system using a camera power supply unit for a source of 60-Hz power. The power supply must be adjusted carefully to hold the frequency as near 60 Hz as possible.

era-motor power supply system. In this latter instance, the camera power-supply frequency must be maintained as near to the line frequency of the studio as possible. A camera supply system with automatic frequency control is ideal for this purpose. Generally, for playbacks on location the tapes are prerecorded (using the studio mains) with the sync-pulse signal on the tape. This assures absolute synchronization of the picture with the playback.

3.86 Describe a synchronous resolver using a stroboscope lamp.—A unique method of obtaining synchronous sound transfer is by the use of a Strobelite resolver (Fig. 3-86A) developed and manufactured by Magnetic Sales Corp. Using this device, absolute synchronization can be obtained between any type of ¼-inch sync-pulse tape recorder and a synchronous sprocket-driven recorder. Synchronization is achieved by manual control of either machine, depending on the basic setup.

In Fig. 3-86B is shown a ¼-inch sync-pulse tape recorder reproducing an audio signal which is fed to a synchronous sprocket-driven machine, and recorded in the usual manner. The sync-pulse signal is fed to the resolver unit, amplified, then applied to a *stroboscopic* lamp in the resolver. This lamp

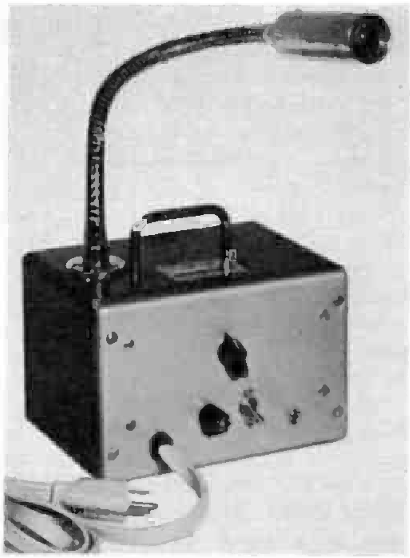

Fig. 3-86A. Strobelite resolver manufactured by Magnetic Sales Corp.

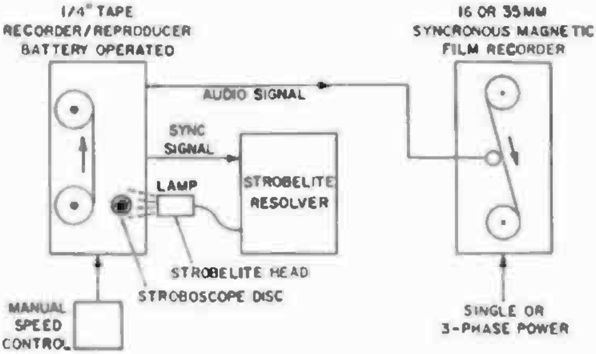

Fig. 3-86B. Block diagram for transferring ¼-inch sound track to magnetic film using a Strobelite resolver manufactured by Magnetic Sales Corp.

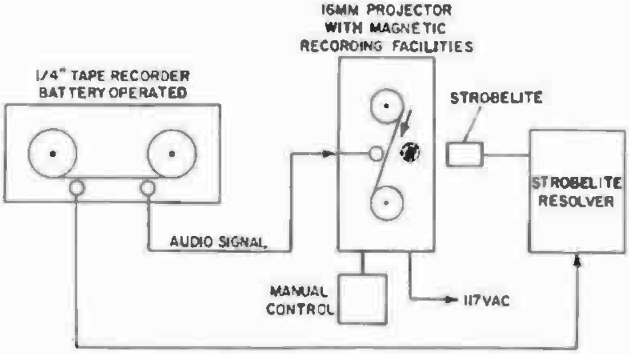

Fig. 3-86C. Basic setup for making synchronous sound transfers from a sync-pulse tape recorder to a 16-mm projector with sound recording facilities.

flashes once for each cycle of the synchronizing signal. The lamp flashes are employed to illuminate a *stroboscope* disc, mounted on the recorder (some recorders come factory equipped with these discs). When the image on the disc is brought to rest, the tape is running at the exact speed as when it was

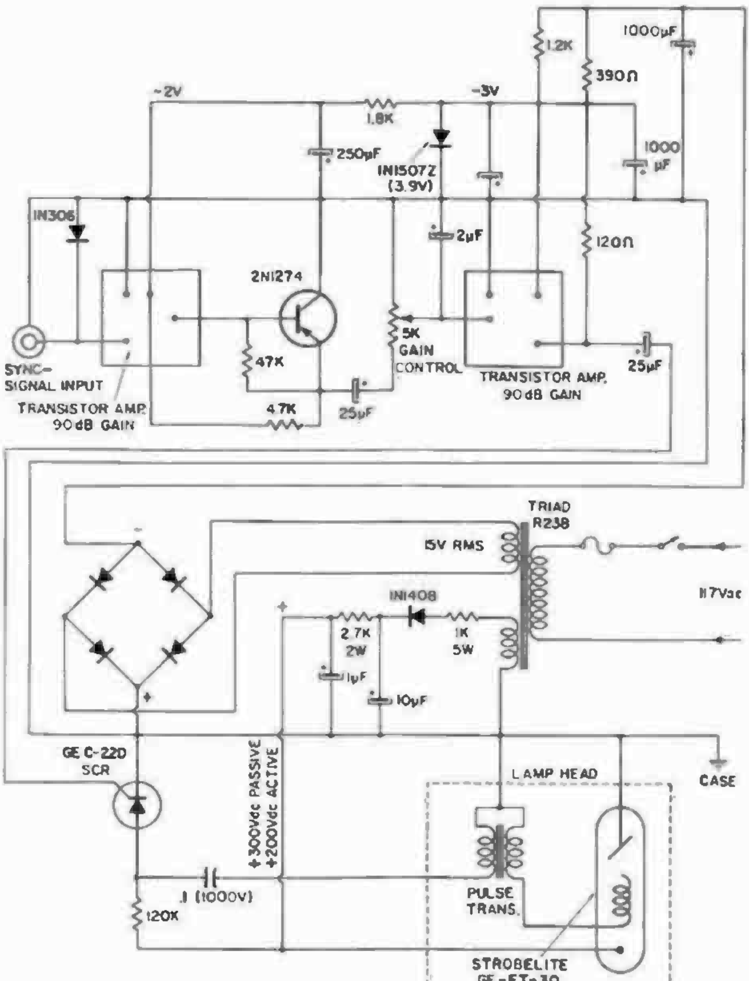

Fig. 3-86D. Schematic diagram for Magnetic Sales Corp. Strobelite resolver.

originally recorded with the picture. The external *manual* control for the tape recorder is adjusted to bring the tape recorder to the proper speed for stopping the image on the stroboscope disc.

A second method for using the Strobelite resolver is shown in block diagram in Fig. 3-86C. In this setup, the tape recorder is run at a fixed speed and the audio signal is applied to a 16-mm projector equipped with magnetic recording facilities. A stroboscope disc is mounted on one of the exposed rotating shafts. (See Question 3.87.)

The sync-pulse signal from the tape is applied to the resolver input, and the stroboscopic lamp placed in front of the stroboscope disc mounted on the projector. The speed of the projector is adjusted manually for a standing image on the disc by connecting a variable resistor (about 150 ohms, 50 watt) in place of the fixed resistor connected normally in the speed-governor control circuit (see Question 3.74). This will permit the speed of the projector/recorder to be varied above and below 24 frames per second.

To operate the system, the recorder is started and the speed of the projector/recorder adjusted for a *steady image* on the stroboscope disc, and thus maintained throughout the transfer. The sound may be recorded on a striped picture or on magnetic film.

The schematic diagram for the Strobelite resolver is shown in Fig. 3-86D. The sync-pulse signal is applied to a transistor amplifier, which feeds the signal to the gate of a silicon controlled rectifier (SCR). (See Question 11.150.) When the SCR fires, it applies a sharp pulse to a flash tube through a pulse transformer stepping up the voltage high enough to fire the stroboscopic lamp. The power supply provides 200 Vdc for the SCR tube, and low voltage for the transistors. (See Questions 3.81 and 3.84.)

3.87 Show a group of stroboscope discs suitable for use on a rotating shaft to indicate synchronous speed.—Several stroboscopic discs that may be duplicated and fastened to the end of a rotating shaft or sprocket, for checking synchronous speed, using a neon or regular lamp operated from the power mains, are shown in Fig. 3-87. For speeds other than those given they may be calculated as given in Question 13.117.

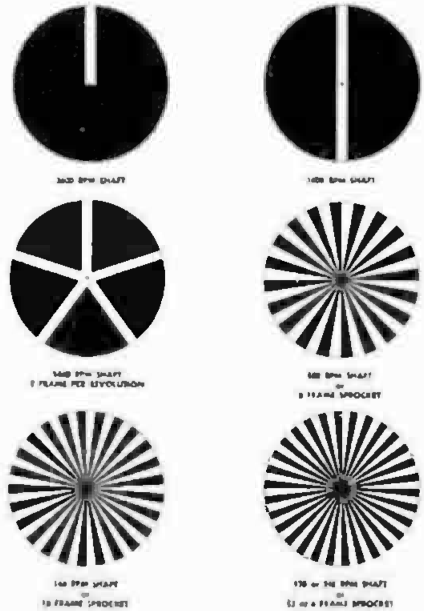

Fig. 3-87. Stroboscope discs. (Courtesy, Magnetic Sales Corp.)

For shaft speeds of 3600 rpm, only one bar is used to make it easier to distinguish. At speeds where the bars are large in number, they may be divided into even multiples of the basic number.

3.88 Describe a portable camera motor-drive unit for a constant source of 3-phase 60-Hz 230 Vac.—In the production of motion pictures, the demand for a portable synchronous motor-drive system has been going on for years, with many different systems having been proposed and developed. The basic requirement of such a system is a source of 230 Vac, 60-Hz three-phase power, that will interlock the camera with the sound equipment and hold the frequency to within a very small percent of the basic frequency (in USA it is 60 Hz), and yet be operated from batteries.

Since the advent of the battery-driven ¼-inch tape recorder for location work, the load of the sound equipment has been eliminated. Thus, the power-supply unit is now only required to supply power for the cameras and a low voltage (1.5 Vac) for the sync-pulse signal recorded on the tape recorder. (See Question 3.78.)

The schematic diagram for a camera control and generator unit, developed by F. G. Albin and manufactured by Magnetic Sales Corp., is shown in Fig. 3-88A. The system consists of a control cabinet and a soundproof case, which houses a 250 Vac 3-phase 500-watt (alternator) rotary inverter turning 3600 rpm driven from a 30-volt battery supply. The control cabinet supplies a means for manually or automatically controlling the frequency of the supply voltage. The control circuit consists of an elaborate network of transistors and diodes, which maintain the dc voltage constant at the motor terminals driving the alternator. In addition, the alternator is fitted with a centrifugal mechanical governor, which holds the dc voltage approximately constant to the driving motor, when the field current is adjusted for a given value. With the two methods of control, it is possible to hold the frequency to within less than ±½-cycle in 60 Hz. (See Question 3.74.) Provision is also made for manual control of the camera speed for special effects shots, where the camera must run faster or slower than 24 frames per second. Three meters are installed on the control unit for monitoring the dc driving voltage, generated 3-phase voltage, and frequency read in frames per second. (See Question 3.72.) The 1.5-Vac sync pulse for the tape recorder is supplied through a step-down transformer from one leg of the 230 Vac. Individual controls are provided for adjusting the field current for manual and automatic control modes.

When such a system is operated in the manual mode, the frequency must be continuously monitored to assure a constant frequency of 60 Hz. In the automatic mode as soon as the start switch is thrown (the generator settles down, in 1 to 2 seconds), the frequency is held constant at 60 Hz and requires no further adjustment, provided the field current has been adjusted for a particular camera load in advance of the shooting, since cameras vary in their load requirements. Operating in the automatic mode saves considerable camera film, and is an important factor, particularly if the picture is being shot in color. To prevent damage to the transistors, a fan in the control unit automatically starts if the internal temperature of the control cabinet rises above 100°F. The fan is automatically turned off during a take.

When more than one camera is used, it is generally necessary to add capacitance across each leg of the 3-phase alternator to provide power-factor correction. For convenience, external capacitor banks consisting of two banks of 10 and 20 uF each, are plugged into the power supply for switching across each leg of the alternator. The same value of capacitance is always used across each phase. The capacitors should be oil-filled. *Under no circumstances are conventional electrolytic capacitors permissible*, because of their internal leakage and the possibility of exploding. Nonpolarized electrolytic capacitors can be used; however, the paper or oil-filled type is preferred. In most portable alternator sets capacitors permanently connected across the three phases serve two purposes. First, they act as noise suppressors for the slip rings; second, they provide power-factor correction for a single camera.

When two or more cameras are to be driven, the cameras are run in advance and the capacitance adjusted for proper operation. In Fig. 3-88B, is shown a typical capacitor bank, consisting of six 10-uF banks, that may be connected for either 10- or 20-uF operation.

3.89 ***Describe a printed-circuit motor.***—The printed-circuit motor is a direct-current electrical machine, in which the conventional wire windings of a cylindrical armature have been replaced by printed circuits. Printed-circuit motors may be operated from one revolution per day up to several thousand revolutions per minute, and may be designed to deliver torques from a few ounce-inches to hundreds of pound-feet. Since the motor is basically of pancake form, it is well adapted to applications where the motor would be integral with the driven device. Because of its design, there is no magnetic attraction between the rotating armature and the stationary portion of the machine.

An exploded view of a motor, manufactured by Printed Motors, Inc., is shown in Fig. 3-89A. At the left is a flux plate, a portion of the housing supporting the brushes which make contact with the 132 segments shown in the center. A similar winding is printed on the reverse side, and connected to the front side by plated through holes. At the right is the opposite portion of the housing, with a permanent magnet stator.

An important aspect of the printed motor is the fact that the printed armature is a single-wave winding. As a result, the operating voltage is low in comparison to conventional motors. For an armature diameter of 3.5 to 8.5 inches, the terminal voltage will range from 6 to 150 volts dc. Consequently they are suited to control circuits employing semiconductor devices.

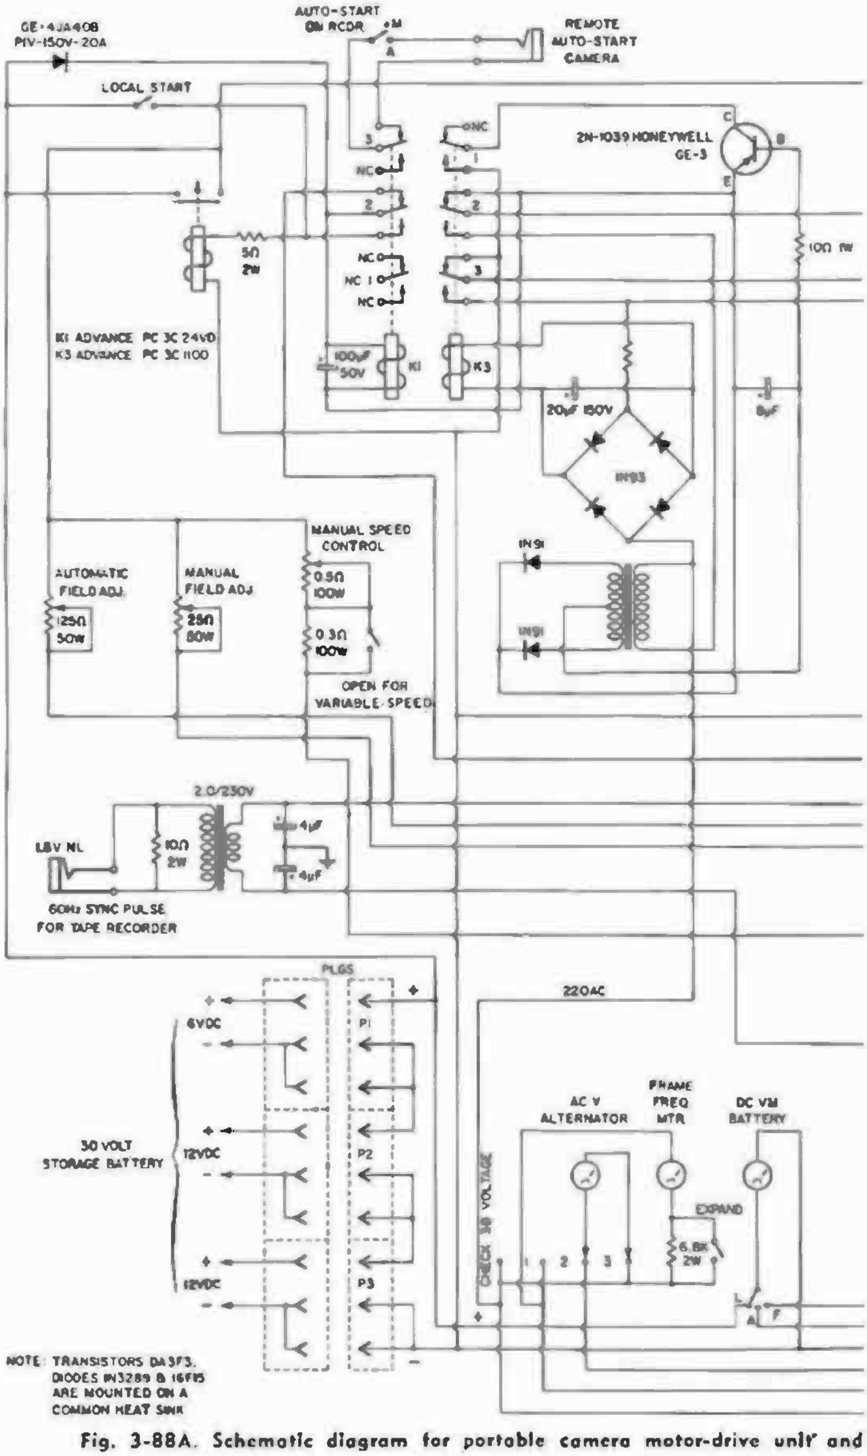

Fig. 3-88A. Schematic diagram for portable camera motor-drive unit and

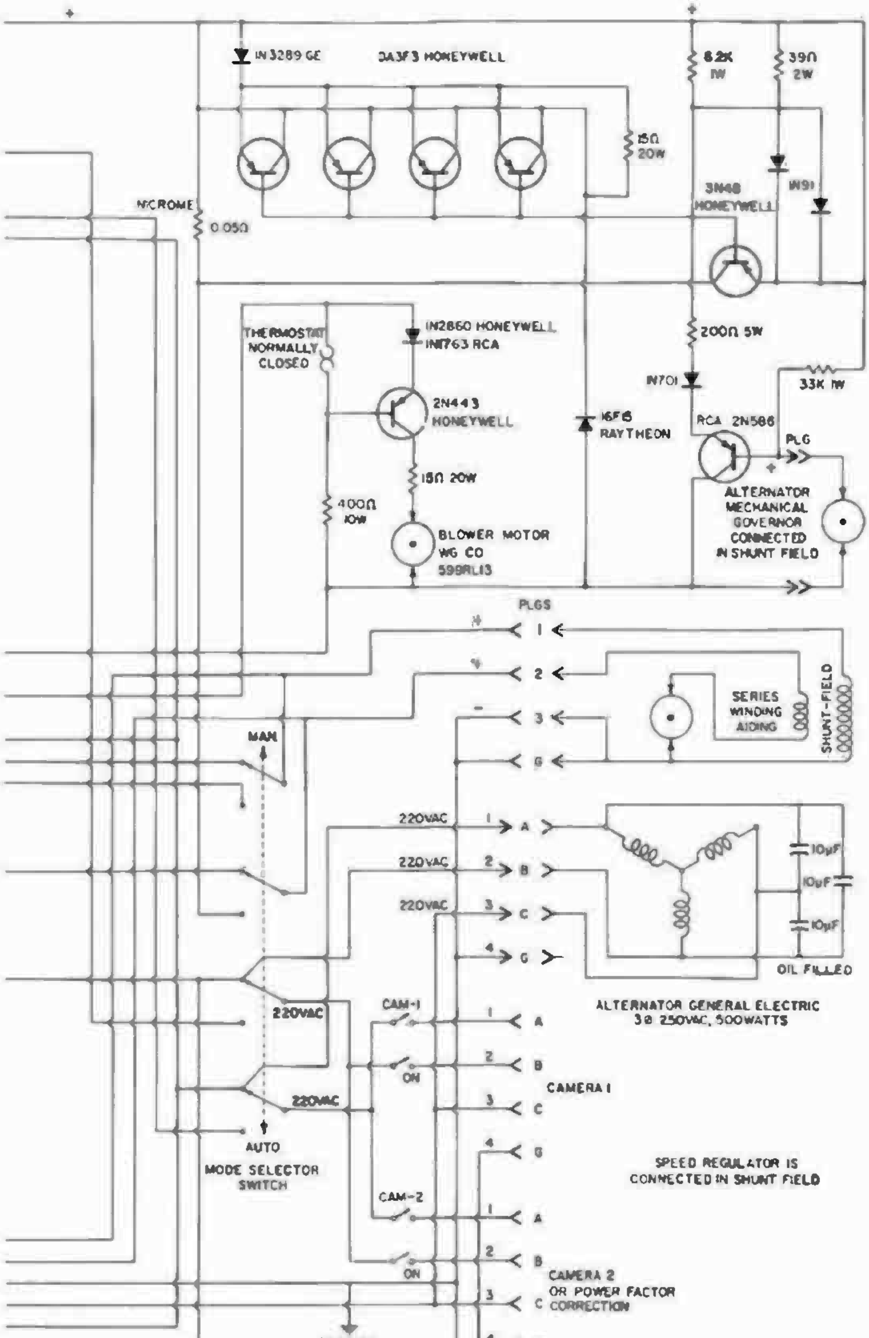
The armature consists of a disc printed and electroplated with the pattern of conductors rotating in a planar air gap permanent-magnet structure. Commutation is provided by the use of brushes bearing directly on the flat surfaces of the armature segments. Since the effective number of commutator bars is large and the rotating armature contains no iron, the motor provides a smooth modulation-free output torque in response to a constant input current.



250-volt, 3-phase 500-watt alternator. Manufactured by Magnetic Sales Corp.

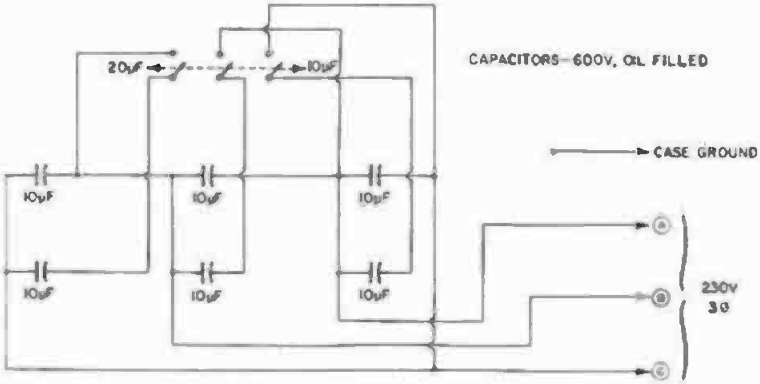


Fig. 3-88B. Camera motor power-supply capacitor bank for correcting power factor. Switch open, two cameras. Switch closed, three cameras. In some instances all the capacitance may be required for two cameras.

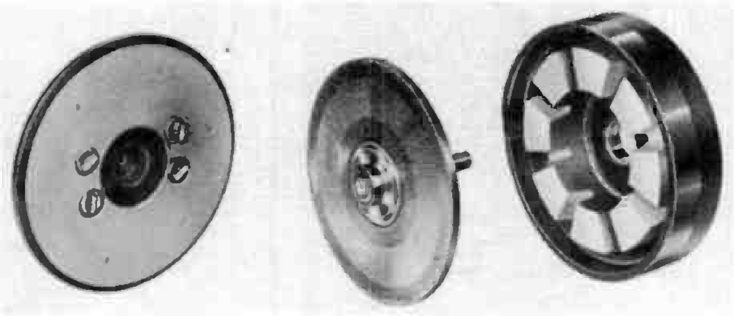

Fig. 3-89A. Exploded view of a printed-circuit motor. At the left is the housing cover with the brushes, armature, and permanent-magnet stator. (Courtesy, Printed Motors, Inc.)

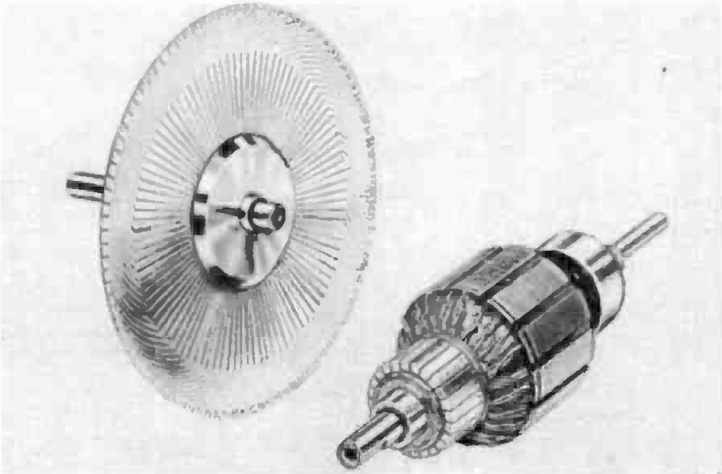

Fig. 3-89B. Printed-circuit motor armature at left and the conventional armature it replaces. (Courtesy, Printed Motors, Inc.)

A printed-circuit armature, compared to a conventional armature it replaces is shown in Fig. 3-89B. Since the magnetic field in a printed motor is supplied by a structure which does not rotate with the shaft, the rotation of the armature does not tend to modulate or vary the permeability of the magnetic path. Due to the design, cogging has been eliminated and there is the-

(b) *View of interior.*

Fig. 3-90. Model-700 portable dc generator for motion picture set lighting. Manufactured by Mole-Richardson. Generator is capable of developing 650 amperes at 120 Vdc.

oretically no limit on the angular accuracy.

The lack of armature inductance displayed by a printed motor is significant in applications where fast response is desired. If the mechanical time-constant is defined as the time for the machine to complete 63 percent of the velocity transition resulting from a step change in terminal voltage, printed motors lie between 0.010 and 0.050 second. Printed motors are best suited to applications involving direct drive of loads at speeds in the range from zero to several thousand rpm, where a premium is placed on the smoothness of generated torque, freedom from preferred armature position, fast response, and high accuracy.

3.90 Describe the construction of a portable dc generator, for motion picture set lighting.—Although portable lighting plants are under the jurisdiction of the electrical department in a motion-picture studio, in small organizations, very often the sound engineer is responsible for them; therefore, a basic knowledge of their design is useful.

Generating plants designed for motion picture use are generally portable either as a unit that may be loaded on a flat-bed truck, or built on a truck as an integral unit. Generally the plant consists of a gasoline motor driving a dc generator with automatic voltage control. A portable plant, manufactured by Mole-Richardson, is shown in Fig. 3-90. This plant is capable of generating 650 amperes at 120 Vdc. The generator is driven by a V-8 Cadillac gasoline engine. Depending on the electrical load demands, the output voltage may be controlled either manually by means of a rheostat, or automatically by a voltage regulator which controls the speed of the engine. The ripple voltage from the commutator is less than 0.5 percent; thus, the noise generated by arc lamps is at a minimum. Such power plants may be used for lighting either incandescent or arc lamps.

The silencing of a generator for motion picture use is a compromise between portability and the degree of noise reduction required. The housing wall of this particular plant consists of 20-gauge sheet metal outer skin, with 3M Co. undercoating applied to the inner surfaces. A fibrous asbestos is sprayed over the undercoating to form an additional sound absorbing layer about ¾-inch thick. This is protected by two coats of casein base paint and metal hardware cloth. The bottom of the plant is closed with covers consisting of ½-inch *Celotex* set between 18-gauge steel sheets. An acoustical partition within the housing, made of ½-inch *Celotex* faced on both sides by ⅛-inch *Transite*, prevents the engine noise from escaping through the radiator. All access doors are gasketed. A blanketed baffle spaced a short distance in front of the radiator reduces air and fan noises. The engine exhaust is muffled by a series-parallel system of silencers. One 3-pass muffler is connected to the exhaust of each 4-cylinder bank of engine, with the outputs of the mufflers joined at the input to a third muffler.

Section 4

Microphones

Since the invention of the microphone by Dr. Alexander Graham Bell, many types and designs of microphones have been developed over the years, each having served well until its replacement.

Microphones may be classified according to their physical design, such as carbon, capacitor, ribbon-velocity, moving-coil, semiconductor, crystal, and ceramic. They also may be classified according to their polar patterns as omnidirectional, bidirectional, directional, polydirectional, superdirectional, and cardioid. Nomenclature given to microphones designed for special use, such as wireless, dual-stereophonic, in-line, and high-intensity, might be considered yet another category. All of these microphones have been covered in this section, and also their electronics, phasing, and such ancillary equipment as cables, wind and rain screens, and concentrators are discussed in this section. In some instances, the description of a particular microphone is only basic since the design will vary with different manufacturers.

4.1 What is a microphone?—A transducing device which converts acoustical energy into electrical energy. Also called an electroacoustic transducer.

4.2 What are the basic principles of microphone operation?—Microphones are divided into two categories of operation, velocity and pressure. Pressure-operated microphones employ a diaphragm with only one surface exposed to the sound source. The displacement of the diaphragm is proportional to the instantaneous pressure of the sound wave. At lower frequencies such microphones are practically nondirectional.

A velocity microphone is one in which the electrical output substantially corresponds to the instantaneous particle velocity in the impressed sound wave. A velocity microphone is also referred to as a gradient microphone. A gradient microphone is a microphone in which the output corresponds to the gradient of the sound pressure. The quality of a microphone can be judged by the frequency response, sensitivity, distortion, internal noise, and field pattern.

4.3 What are the terms and equations associated with microphones?—Average threshold of the human ear $= 0$-dB SPL (sound pressure level) $= 0.0002$ dynes/cm^2 $= 0.0002$ microbar $= 10^{-16}$ watt/cm^2 (free field in air) $= 10^{-13}$ watts/ft^2.

$$1 \text{ microbar} = 1 \text{ dyne/cm}^2 = 10^{-6} \text{ bar} = 74\text{-dB SPL}$$

$$1 \text{ atmosphere} = 1 \text{ bar} = 14.5 \text{ lb/in}^2 = 10^6 \text{ dynes/cm}^2 = 194\text{-dB SPL.}$$

Microphone sensitivity is defined as output voltage in dB re: 1 volt for a sound pressure of 1 dyne/cm^2, or 74-dB SPL. As an example: the sensitivity rating for a given microphone of minus 85 dB re: 1 volt/dyne/cm^2 states; the output voltage is 85 dB below 1 volt for 74-dB SPL; for 174-dB SPL, the output voltage would be $174 - 74 + (-85) = +15$ dB re: 1 volt. An output voltage 15 dB above 1 volt equals 5.6 volts.

4.4 What types of microphones are classed as pressure operated?—The carbon, crystal, dynamic, pressure, capacitor, and frequency-modulated.

4.5 What type of microphone is classed as velocity operated?—The ribbon. The electrical response corresponds to the particle velocity.

4.6 What is a pressure gradient microphone?—A ribbon velocity microphone such as described in Question 4.50.

4.7 What is a polar field pattern?—It is a plot employing polar coordinates, to show the magnitude of a quality in some or all directions from a given point for three hundred sixty degrees. Polar plots are used to present the directional pattern of microphones, loudspeakers, and other devices having directional characteristics. The term field pattern is also used to denote directional qualities; however, either term may be used interchangeably. In some instances the term directional pattern or characteristic is used. The term free-field denotes the device under measurement is in space, in an area free from obstructions and reflections, such as would be found in open air or in an anechoic chamber. Polar plots are also used in the measurement of magnetic fields and many electrical devices not having acoustical properties. Typical polar plots or field patterns are shown in Fig. 4-57.

At (a) is an omnidirectional or circular or nondirectional field pattern for the crystal, dynamic (moving coil), capacitor (condenser), carbon, electronic, frequency modulated, and inductor type microphones.

At (b), a semidirectional pattern obtained with an adjustable field pattern microphone is illustrated. The microphone is directional at the higher frequencies but nondirectional at the low frequencies.

The bidirectional pattern obtained with a ribbon microphone is shown at (c). The microphone is essentially dead to pickup at the sides. This pattern is generally referred to as a figure-8 field pattern.

The pattern for a unidirectional microphone, called a cardioid pattern, is shown at (d). Microphones are available that will permit the field pattern to be varied to fit almost any situation and include all of the foregoing patterns in some form or other.

4.8 How is a carbon microphone constructed and what is its principle of operation?—Several hundred small carbon granules are held in close contact in a brass cup called a button, which is attached to the center of a metallic diaphragm. Sound waves striking the surface of the diaphragm disturb the carbon granules, thus changing the contact resistance between their surfaces. The change in contact causes a current from a battery connected in series with the carbon button and the primary of a transformer to vary in amplitude, resulting in a current waveform similar to the acoustic waveform striking the diaphragm. After leaving the secondary of the transformer, the minute changes of current through the transformer primary are amplified and reproduced in the conventional manner. The circuit diagram and construction of a carbon microphone are shown in Fig. 4-8. The output voltage from a carbon or pressure microphone is proportional to the displacement of the diaphragm. The field pattern is omnidirectional. This is shown in (a) of Fig. 4-7.

One of the principal disadvantages of the carbon microphone is that it has continuous high-frequency hiss caused

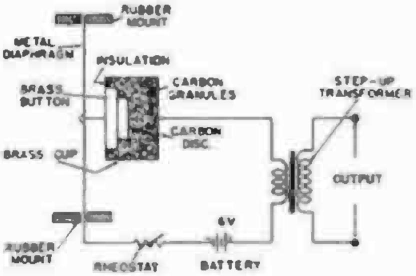

Fig. 4-8. Connection and construction of a single-button carbon microphone.

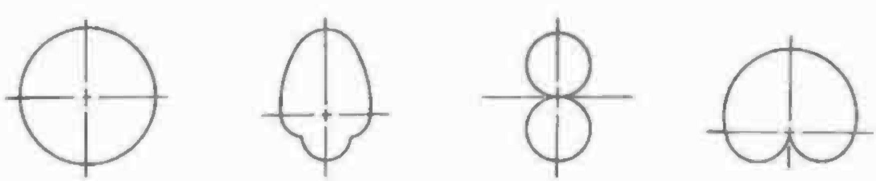

(a) Omnidirectional. *(b) Semidirectional.* *(c) Bidirectional.* *(d) Cardioid.*

Fig. 4-7. Basic microphone field patterns.

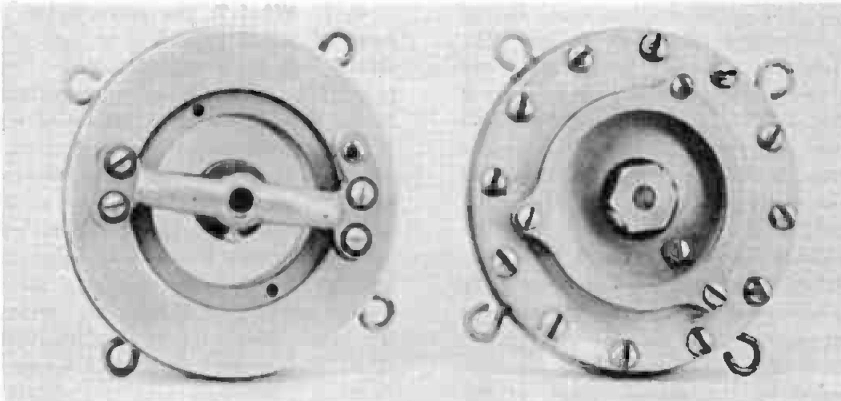

Fig. 4-9B. Early model Western Electric type 600A, double-button, stretched-diaphragm, carbon microphone.

by the changing contact resistance between the carbon granules. In addition, the frequency response is limited and the distortion is rather high.

4.9 ***What is a double-button carbon microphone and how does it function?***— The double-button microphone employs two carbon buttons similar to those used in the single-button type. One button is mounted on each side of the diaphragm. Pressure waves striking the surface of the stretched diaphragm cause it to move and disturb the contact resistance of the carbon granules in the buttons in a manner similar to the single-button microphone described in Question 4.8. As the diaphragm moves, the contact resistance of the granules in the button mounted on the pressure-wave side is reduced, while the resistance of the button on the opposite side is increased. When the pressure wave reverses itself, the reverse action takes place in the carbon buttons. Thus, the current through the buttons corresponds to each half of the pressure wave at the diaphragm. This action is somewhat similar to that of a push-pull amplifier stage. The circuit connections and construction are shown in Fig. 4-9A. The exterior appearance of an early model double-button carbon microphone, manufactured by Western Electric Co., is shown in Fig. 4-9B.

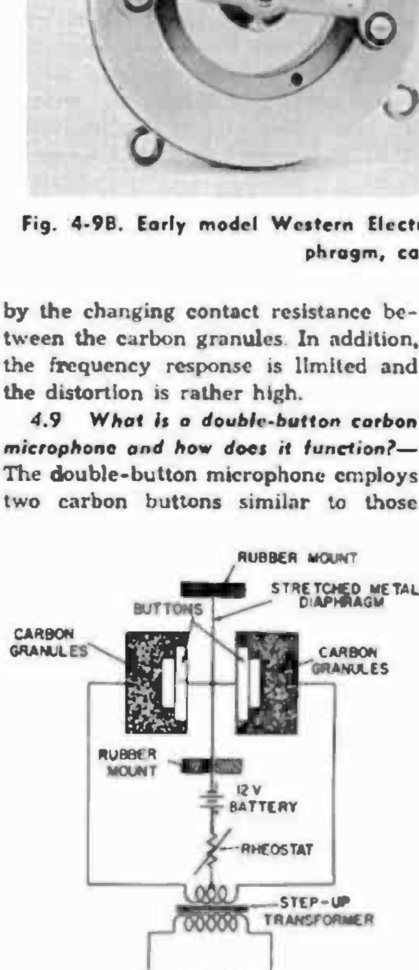

Fig. 4-9A. Connections and construction of a double-button carbon microphone.

The disadvantages of the double-button microphone are about the same

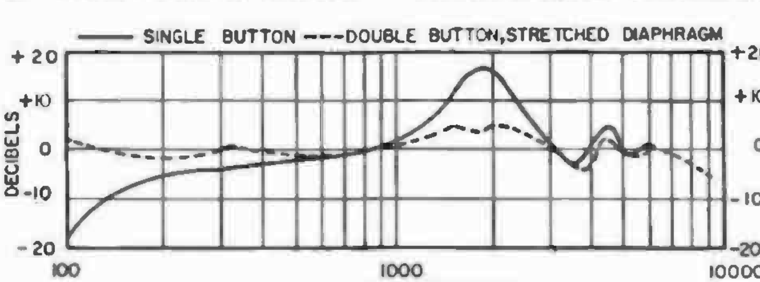

Fig. 4-9C. Frequency response of early model single- and double-button carbon microphones.

as for the single-button type, except the waveform distortion is less. The frequency responses for single- and double-button microphones are given in Fig. 4-9C. The solid line is the single button and the dotted line the double button. It will be noted the resonant peaks of the diaphragm have been reduced in the double-button type by stretching the diaphragm.

4.10 What precautions should be observed when using carbon button-type microphones?—The current through the buttons should not exceed that recommended by the manufacturer, or the carbon granules may be fused. If the microphone is of the double-button type, the currents through each button must be the same when the diaphragm is at rest. Carbon microphones should not be subjected to heavy jars when the current is flowing, unless they are designed for such service.

4.11 What causes packing of the carbon granules in a carbon microphone?—Excessive current through the buttons and moving the microphone when the current is flowing. However, carbon microphones used in communications work are designed to be moved while there is current through them.

4.12 Describe a crystal microphone.—A microphone employing one or more Rochelle salt crystals placed in such a manner that when their surfaces are struck by a pressure wave they are bent or twisted out of shape. This action results in the generation of an electrical current because of the piezoelectric effect of such crystals. A typical crystal microphone is shown in Fig. 4-12.

Fig. 4-12. A typical crystal microphone.

4.13 What is the piezoelectric effect?—When a crystal is subjected to strain, electrical polarization takes place. The polarization is proportional to the mechanical strain and sine with it. The inverse effect is produced when electrical current is applied to the crystal. The mechanical movement in this case is proportional to the applied current. Advantage is taken of this characteristic in the design of crystal microphones, pickups, speakers, and recording heads. The subject of piezoelectric effect is discussed further in Question 25.191.

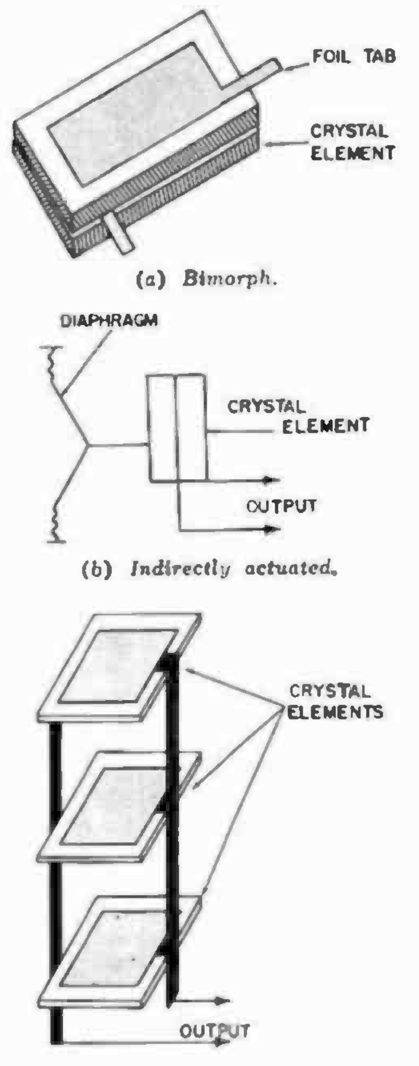
4.14 What type crystals are used in crystal microphones?—Rochelle salt crystals. They are grown from a supersaturated solution of sodium potassium tartrate tetrahydrate by cooling at a temperature of 40°C. Such crystals should not be operated or stored in temperatures exceeding 140° F. Crystals of this nature should not be confused with the quartz crystals used in radio transmitters. (See Questions 25.102 and 25.103.)

4.15 What type crystal microphones are in general use?—The direct-actuated, Fig. 4-15, part (a) and the indirectly actuated, Fig. 4-15, part (b). In the former type, the sound waves strike the surfaces of the crystals creating mechanical strain. In the latter, the sound waves impinge on a diaphragm attached mechanically to the crystal elements.

4.16 What is a sound-cell crystal microphone?—One in which a number of crystal elements are stacked in a pile, as shown in Fig. 4-15, part (c).

4.17 What is a Bimorph crystal?—A type of construction used in crystal microphones to increase their sensitivity. The crystal consists of two slabs cut on axes which determine whether they are to be benders or twisters. The two slabs are separated by a thin piece of foil which connects to one side of the external circuit. The outer surfaces of the crystal slabs are covered with foil and connected to the other side of the external circuit as shown in Fig. 4-15, part (a). The name *Bimorph* is a trade name of the Clevite Corp., Piezoelectric Div.

4.18 What is a bender element?—A crystal element cut on an axis which results in a piezoelectric effect only as a result of bending.



(a) *Bimorph.*

(b) *Indirectly actuated.*

(c) *Sound cell.*

Fig. 4-15. Direct and indirect actuated crystal elements used in microphone construction.

4.19 What is a twister element?—A crystal element cut on an axis which results in a piezoelectric effect only as a result of twisting.

4.20 What is the field pattern for a crystal microphone?—Circular, as for all pressure microphones. See Fig. 4-7, part (a).

4.21 What is the output impedance of a crystal microphone?—Generally on the order of 60,000 to 100,000 ohms.

4.22 Which type crystal microphone has the greatest output, the diaphragm or the sound cell?—The diaphragm type has the greatest output voltage, but the frequency response is limited because of the construction. The sound cell, Fig. 4-15, part (c) has the best frequency response but the lowest output level.

4.23 How is the greatest output voltage obtained from a crystal microphone with the lowest output impedance?—By connecting the crystal elements in series-parallel.

4.24 What is the maximum length of cable that may be used with a crystal microphone?—Approximately 50 feet. Because of the high impedance, a crystal microphone must not be separated too far from the input of the amplifier. The capacity of the cable acts as a capacitor in parallel with the crystal elements. A long cable attenuates the over-all level but has little effect on the frequency response.

4.24 What is the internal capacitance of a crystal microphone?—Generally on the order of 0.03 uF, for the diaphragm-actuated type. For the sound-cell type, 0.0005 to 0.015 uF.

4.26 What is the frequency response of a crystal microphone?—About 80 to 6500 Hz for the diaphragm type, with a peak occurring around 3500 Hz. High-quality crystal microphones will respond up to 16,000 Hz; however, they show a rise in the higher frequencies necessitating equalization to obtain a uniform frequency response. The frequency response of a typical high-quality crystal microphone of the sound-cell type is shown in Fig. 4-26.

4.27 What type amplifier input circuit is recommended for crystal microphones?—Resistance-coupled similar to that shown in Fig. 4-27. Because a crystal microphone appears as a capacitance, it may be considered to be in series with the grid resistance of the input stage. The grid resistance (R_g) should be from 3 to 5 megohms for a microphone of the sound-cell type and from 1 to 5 megohms for the diaphragm type. Lowering the resistance in the grid circuit attenuates the low frequencies.

4.28 What types of microphones are considered to be high impedance?—Crystal, ceramic and the head of a capacitor microphone (condenser) are included in this category. The ceramic microphone may be considered from an impedance standpoint to be similar to the crystal microphone. The head of a capacitor microphone is of extremely

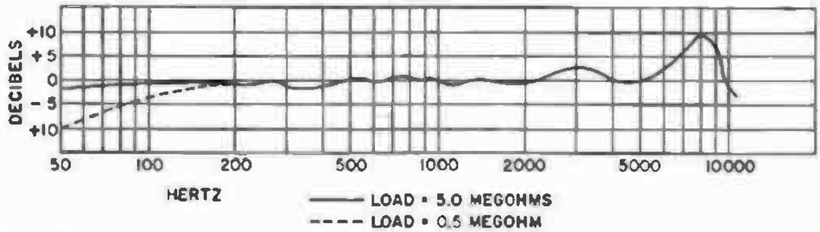


Fig. 4-26. Frequency response of a high-quality sound-cell type crystal microphone.

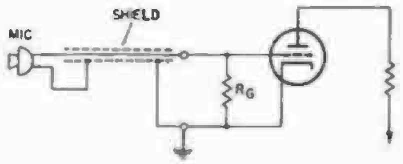

Fig. 4-27. Method of coupling a crystal microphone to the input of an amplier.

high impedance, running into several megohms; therefore, it must be operated adjacent to a preamplifier. An output transformer in the amplifier supplies a low output impedance, ranging from 50 to 250 ohms. Dynamic microphones may be obtained, with impedance ranging from 50 to 40,000-ohms.

4.29 Describe a ceramic microphone?—A microphone similar in characteristics to the crystal, except that it employs a barium-titanate slab in the form of a ceramic. It has piezoelectric characteristics and may be operated in higher temperatures and humidity. Generally speaking a ceramic microphone may be used wherever a crystal microphone is employed; however, the equalization may have to be revised slightly. Ceramic microphones, like the crystal microphone, must be operated into an input impedance from 1 to 5 megohms. Such microphones are ideal for walkie-talkies, hearing aids, dictating machines, public-address systems, and many other services. Typical output levels are minus 59 to 50 dB, where zero dB equals 1 volt/microbar, with an output impedance of 100,000 ohms.

4.30 Describe the construction and characteristics of a dynamic microphone.—A dynamic microphone employs a small diaphragm and a voice coil, similar to a dynamic loudspeaker, moving in an intense permanent magnetic field. Sound waves striking the surface of the diaphragm cause the coil to be moved in the magnetic field, thus generating a voltage proportional to the sound pressure at the surface of the diaphragm. This microphone is also referred to as a pressure or moving-coil microphone (nicknamed "eight ball" because of its appearance). Typical examples of this design are the Western Electric 630B, shown in Fig. 4-30A, and the Altec-Lansing Model 633a/c (nicknamed "salt shaker"), shown in Fig. 4-30B. Due to their similarities, the following explanation will suffice for both types, although the case and frequency response of the Atlec-Lansing 633a/c is somewhat different than the Western Electric 630B.

Shown in Fig. 4-30C is a cross-sectional view of the 630B. The diaphragm (A) is of Dural, approximately 0.5-mil in thickness, and it weighs 25 milligrams. Cemented to the rear of the diaphragm is a voice coil (B) constructed of edge-wound Dural ribbon 8 mils thick × 8 mils wide. The body of the microphone (C) consists of a molded spherical housing, containing a permanent magnet (D) with a center pole piece over which the voice coil is centered. The edge of the diaphragm is hinged and supported at the edges by the housing. The outer surface of the diaphragm is protected from mechanical injury by a perforated grid (E). A two-layer 16-mesh circular screen baffle (F) with layers of silk between the screens is placed in front of the diaphragm. The perforated grid and screen act as acoustical equalizers to improve the omnidirectional characteristics. At the lower left is a small metal tube (G) termed an acoustical equalizer. Its function is to release air pressure behind the diaphragm to prevent distortion of the diaphragm during its inward travel. Working in conjunction with this tube are two air-release vents (H) under the voice coil, to provide acoustical resistance. External pins (I) provide connections to the voice-coil leads (J).

Fig. 4-30A. Western Electric 630B dynamic (moving-coil) microphone.

Microphones of this type do not employ an output transformer; the output voltage is taken directly from the voice-coil winding. The frequency response of this microphone is little affected by the angle of incidence up to 120 degrees as may be seen in Fig. 4-30D. The output impedance is 20 ohms, but is operated into a 30- to 50-ohm preamplifier. The polar pattern is omnidirectional, with a frequency response as shown in Fig. 4-30D. The output level is minus 55 db/10 dynes/cm².

Fig. 4-30B. Altec-Lansing Model 633a/c dynamic (moving-coil) microphone. The 8b baffle is used to assist in achieving a directional characteristic.

4.31 What is a pressure microphone?—It is a dynamic microphone

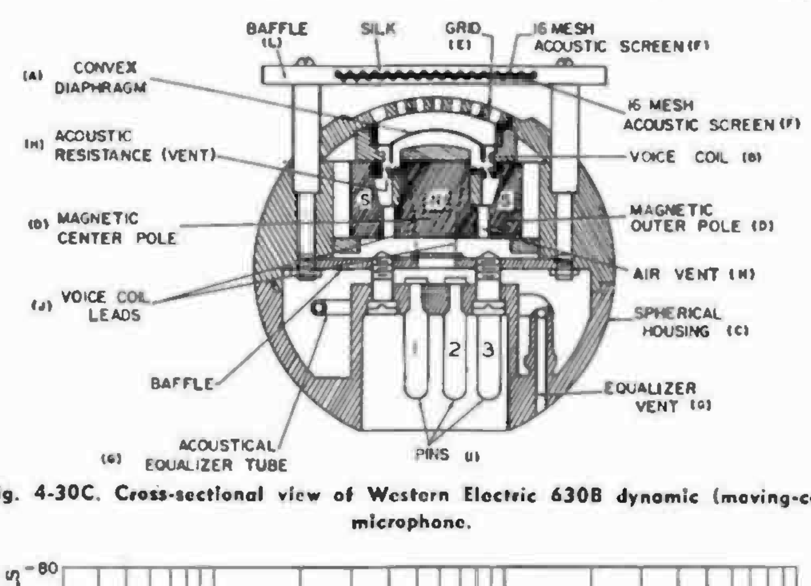

Fig. 4-30C. Cross-sectional view of Western Electric 630B dynamic (moving-coil) microphone.

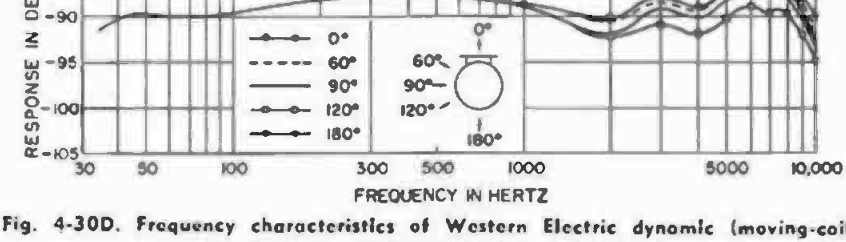

Fig. 4-30D. Frequency characteristics of Western Electric dynamic (moving-coil) microphone for different angles of incidence.

Fig. 4-31. American Microphone Co., type D-22 pressure (moving-coil) microphone with windscreen and boom hanger.

similar to that described in Question 4.30. A typical pressure microphone manufactured by American Microphone is pictured in Fig. 4-31, with a wind screen and hanger for fish-pole operation. The construction of the wind screen is discussed in Question 4.90.

4.32 What is a moving-coil microphone?—A dynamic or pressure microphone such as the ones described in Questions 4.30 and 4.31.

4.33 What is an acoustical equalizer?—A small metal tube located at the rear of a dynamic microphone to release the pressure behind the diaphragm and thus prevent distortion of the diaphragm. The acoustic equalizer (see Fig. 4-30) also tends to smooth out the frequency characteristic of a dynamic microphone.

4.34 What is the field pattern of a dynamic microphone?—Omnidirectional. Some directional effect may be obtained by hanging the microphone overhead with the diaphragm downward; however, this will attenuate the high frequencies to some extent.

4.35 Show an exploded view of a dynamic microphone. — An exploded view of an Electro-Voice Model 635A dynamic microphone is shown in Fig. 4-35. Starting at the left, is a protective screen (A) which combined with elements (B) and (C) compromises a four-stage pop-filter for close talking. Element (B) consists of a special *Acoustifoam* material developed by the manufacturer. Element (D) is a fine screen of magnetic material for attracting metal dust particles to prevent them from falling on the diaphragm and its associated magnetic assembly (F) and (G). The plate (E), with the diaphragm assembly, forms a Helmholtz resonator in front of the diaphragm (F). The inertance of the holes in the plate resonate with the compliance of the air between the retainer and the diaphragm. The moving elements consist of an *Acousticalloy* diaphragm (a special material developed by Electro-Voice) which is quite stable to pressure and temperature changes. A voice coil mounted at the rear of the diaphragm is centered in a strong permanent magnetic field (G).

As this microphone is designed to be hand-held if desired, mechanical shock must be reduced to an absolute minimum by isolating the voltage-generating elements from the case. This is accomplished by the use of a low-durometer plastisol sleeve (H). If the isolation between the case and the moving

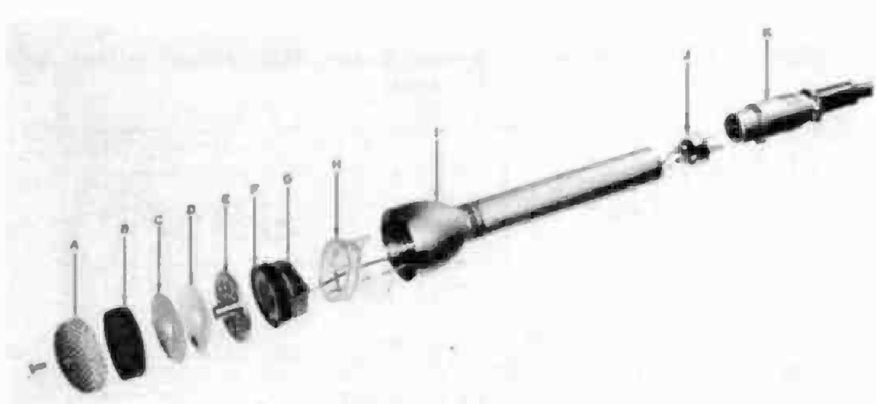

Fig. 4-35. Exploded view of Electro-Voice Model 635A dynamic microphone.

elements is not sufficient, vibrations will be transmitted to the moving coil and diaphragm assembly, resulting in unwanted noise.

The diaphragm is ⅞ inch in diameter and 0.0015 inch in thickness. No output transformer is used, as the moving coil is wound using a number 48 copper wire for an impedance of 150 ohms. Since there is only one opening to the diaphragm, the polar pattern is omnidirectional. This system of controlled leakage allows for pressure equalization on both sides of the diaphragm. The high-frequency response is held up by the use of the Helmholtz resonator (E).

The last three elements are the case (I), the three-pin male connector (J), and the female cable plug (K). The frequency response is 60 to 15,000 Hz, with an output level of minus 55 dB re: 1 mw/10 dynes/cm^2. Microphones of this type are used for professional and public-address work, and in television and broadcast studios.

Since the advent of rock and roll recording where the artist sings or shouts directly into the microphone one or two inches from the mouth, special blast-type microphones have been developed. This has been necessary because of the extremely high sound-pressure levels (SPL) distorting the diaphragm. Special precautions must also be taken to prevent the overloading of the microphone preamplifier input circuit. (See Question 9.51.)

4.36 What precautions must be taken when using pressure-type microphones with an omnidirectional polar pattern?—A characteristic of pressure microphones is their lack of discrimination to low-frequency sounds arriving from random directions. Sounds which originate at the rear of the microphone will be bent around the microphone housing and actuate the diaphragm as if they had arrived from the front. This is especially true of sounds whose wavelengths approach the dimensions of the microphone housing. At the higher frequencies, for sounds originating at its rear, the frequency response will drop off due to diffraction. When recording dialogue with this type of microphone, it may be desirable to increase the directional qualities by the use of a small baffle on the front of the microphone in place of the small screen baffle normally employed. The center hole of the substitute baffle is covered with a single layer of thin silk. The use of a baffle with this type of microphone not only increases its directional qualities, but also increases the response at the lower frequencies. The increase in low-frequency response may be desirable for certain types of pickups but not for dialogue. Therefore, the low-frequency attenuation normally used for dialogue recording may have to be increased.

4.37 How should a pressure microphone be used suspended from a boom?—The diaphragm is tilted downward with the diaphragm almost parallel to the floor. One reason for this suspension is that pressure-type microphones are highly efficient at the higher frequencies and any small loss of high frequency response is not detrimental to the pickup. A second reason is that for large angles of incidence, the directional response changes less rapidly than for small angles of incidence. Thus, a more uniform quality of pickup may be maintained.

4.38 What size baffle is recommended for use with the microphone discussed in question 4.30?—The baffle should be 3⅛ inches in diameter with a 1-inch hole in the center. The material may be ⅛-inch *Bakelite* or Dural.

4.39 Describe a dynamic microphone with cardioid characteristics and a variable-frequency response. — Many times it is necessary to intermix microphones, which generally poses a problem because of the difference in frequency response. The ideal microphone would be one that would permit its frequency response to be varied so as to match other microphones, while retaining its directional characteristics. The

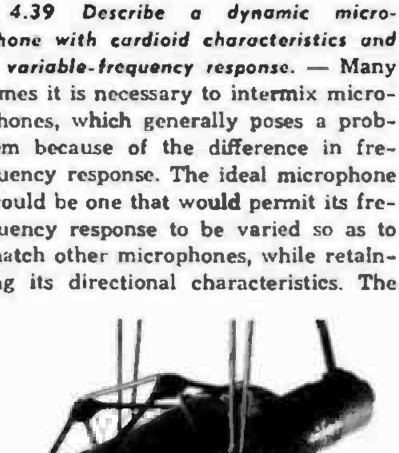

Fig. 4-39A. Electro-Voice Model 668 dynamic cardioid microphone mounted in its wind screen and boom hanger.

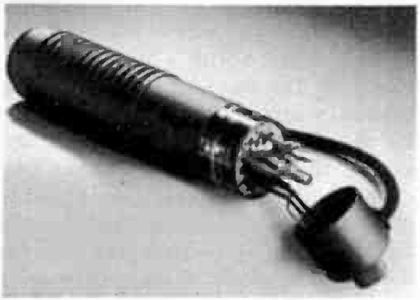

Fig. 4-39B. Electro-Voice dynamic cardioid microphone Model 668. The basic design is of the in-line type. Thirty-six different frequency-response curves are possible by the connections in the base.

microphone to be described is of the in-line family, and has been developed especially for this purpose by Electro-Voice. Complete with wind screen and boom hanger (Fig. 4-39A), it is light enough to be "fish-poled." The microphone proper is shown in Fig. 4-39B, with a cross-sectional view of the wind-screen and hanger construction given in Fig. 4-39C.

Basically the microphone is an in-line type, with two slotted tubes coupled to the back of the diaphragm. The acoustic length of the tube varies inversely with the frequency of the sound source, permitting the phasing-out of unwanted sound from all portions of the spectrum for a maximum front to back ratio. The transducer consists of a single moving-coil element. Contained in the base is a passive equalizer network, which provides a choice of three variations in the high-frequency response (A) (B) and (C) in Fig. 4-39D, and a choice of three variations in low-frequency response identified as (1) (2) and (3). A filter network for reduction of the response above 8000 Hz and below 80 Hz, having a 50 dB per octave cutoff rate, is also provided. The output level is minus 51 dB re: 1 mw/10

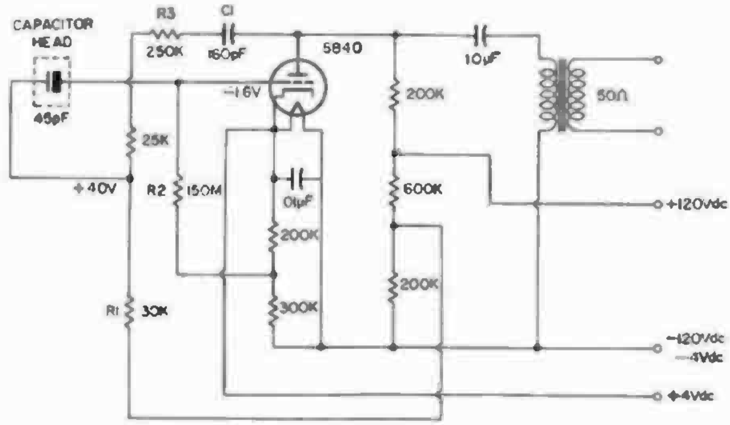

Fig. 4-40A. Typical preamplifier circuit for a capacitor microphone using a single vacuum tube.

dynes/cm². The polar pattern, Fig. 4-39E, is unaffected by the frequency response changes.

Referring back to Fig. 4-39C, at (A) is the microphone. The in-line port may be seen at (B), and the three sections of the wind screen at (C) (E) and (F), held in place by shock-rings (D). A cover (G) encloses a group of terminals for setting the desired frequency response and output impedance. Plate (H) shows graphically the frequency response possible by the plugging-in of the phone tips seen in Fig. 4-39B. The whole assembly is supported by rubber cords (J), held in place by steel rings (K). The hanger is suspended from a boom turret-head by a thumbscrew.

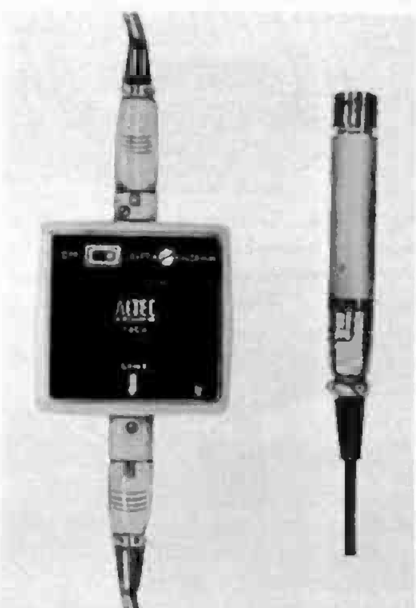

Fig. 4-40B. Altec Model 29B solid-state microphone system.

4.40 Describe the basic principles of a capacitor (condenser) microphone.—The head of a capacitor microphone consists of a small two-plate capacitor, about 40 to 50 pF in capacitance. One of the two plates is a stretched diaphragm; the other is a heavy back plate or center terminal (Fig. 4-41A). The back plate is insulated from the diaphragm and spaced approximately 0.001 inch from, and parallel to, the rear surface of the diaphragm. Mathematically, the output from the head may be calculated:

$$\frac{E_{oc}}{P} = \frac{E_o a^2}{8\,dt}$$

where,

P is the pressure in dynes per square centimeter,
t is the diaphragm tension in dynes per centimeter,
a is the radius of active area of the diaphragm in centimeters,
d is the spacing between the back plate and diaphragm in centimeters,
E_o is the dc polarizing voltage in volts.

If referred to a reference level of 1 volt:

$$dB = 20\text{Log}_{10}\frac{P}{E_{o}C} = 20\text{Log}_{10}\frac{8\,dt}{E_o a^2}$$

Fig. 4-40A is a schematic diagram of a typical preamplifier used with a capacitor microphone. Here, the back plate is connected to the control grid of the tube, and the diaphragm polarized at 40 Vdc, through a 30k resistor, R1. Thus a fixed charge accumulates on the diaphragm. As sound waves enter the head cavity through the side openings, the pressure causes minute changes in the spacing of the two head members, thereby varying the internal capacitance. The resulting signal voltage, which is proportional to the pressure wave, is applied to the control grid of the tube, amplified, and passed on through the output transformer.

It will be observed, the lower end of the 150-megohm resistor R2 is returned to a position of plus 2.4Vdc above ground. Also, the cathode is connected to the plus 4 Vdc of the heater circuit. This makes the control-grid minus 1.6 Vdc with respect to the cathode. Negative-feedback elements R3 and C1 reduce the distortion, and aid in the control of the frequency response. In some capacitor-microphone amplifiers, the grid resistor R2 is omitted, since the microphone head is a capacitor, and to obtain a good low-frequency response the shunt resistance must be as high as possible. The source impedance, as seen by the control grid of the tube, consists of capacitance and resistance in parallel. The thermal noise is least when the resistance is the highest. The effective grid resistance is established by the tube itself.

A microphone system, manufactured by Altec-Lansing and illustrated in Fig. 4-40B, consists of a single diaphragm; the directional (cardioid) head is of small size and low mass, for good high frequency and transient response. The cardioid characteristic is obtained by controlling the relative phase of the sound pressure reaching the back side of the diaphragm. This method provides the greatest front-to-back discrimination over a wide frequency range.

The microphone head is mounted on a base containing a field-effect transistor (FET) and the necessary components. The FET converts the extremely high impedance of the microphone capacitor head to a low impedance suitable for connection to a standard two-conductor cable. One conductor of the cable carries both signal current and the direct current for the FET, while the second provides a microphone polarizing potential of 64 volts. The output from the microphone amplifier is unbalanced until it joins the power supply unit which also contains an output transformer.

The power-supply unit is provided with both male and female cable plugs, to permit it to be inserted at any point in the microphone line when long cable runs are being used, thus increasing the signal-to-noise ratio of the signal in the cable. Power is supplied by two 4.2-volt and three 21-volt mercury batteries, with an expected life of about 2500 hours. A meter is provided on the rear of the power supply case for monitoring the batteries. The frequency range of this microphone is 20 to 20,000 Hz, with output level of minus 53 dB re: 1 mw/10 dynes/cm².

4.41 Describe the construction of a capacitor microphone head. — In earlier types of this microphone (Fig. 4-40A), the internal capacity of the head varied from 200 to 400 picofarads, for a diaphragm diameter of 1¾ inches. Present day capacitor microphone heads have an internal capacity of 40 to 50 picofarads with a diaphragm diameter of 0.5 inch. The impedance of such a head is approximately 30 megohms; therefore, it must be operated within a few inches of the amplifier input. Generally, the head and amplifier are assembled as a unit. A cross-sectional view of a head assembly manufactured by Altec-Lansing, is shown in Fig. 4-41A. Capacitor microphones may be designed to have omni, bi, or unidirectional (cardioid) polar characteristics. A capacitor

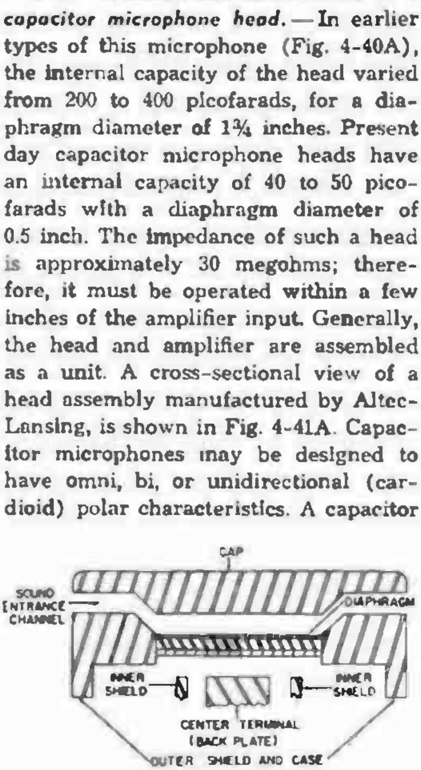

Fig. 4-41A. Cross-sectional view of a capacitor microphone head used with the Altec capacitor microphone pictured in Fig. 4-40B.

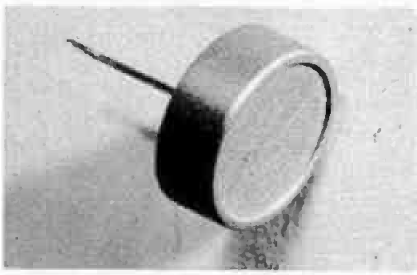

Fig. 4-41B. Capacitor head for Neumann Model U-64 capacitor microphone. (Courtesy, Gotham Audio Corp.)

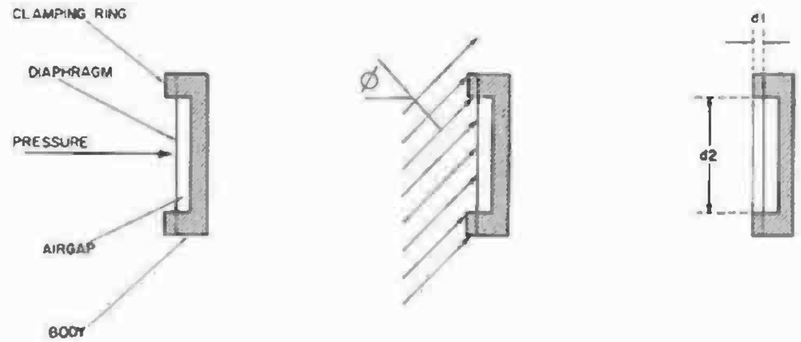
head for the Neumann Model U-64 capacitor microphone is shown in Fig. 4-41B. The diaphragm consists of an extremely thin mylar base, gold plated, less than ¾ inch in diameter. Although the head shown has only a single diaphragm and back plate, capacitor microphone heads designed for directional characteristics employ two diaphragms, with a common polarized back plate centered between the two. (See Question 4.115.)

4.42 ***What is the output level of a capacitor microphone head?***—Approximately minus 90 dBm.

4.43 ***What is pressure doubling in a capacitor microphone?***—It is the result of pressure waves, which are small in comparison to the diaphragm dimensions, coming to a complete stop at the face of the diaphragm. Pressure doubling in earlier types of microphones often caused a peak of 4 to 6 dB in the midrange frequencies. This peak caused extreme sibilance and high-frequency distortion. This defect has been eliminated in present day designs by reducing the physical size of the capacitor head. (See Question 4.41.)

4.44 ***Describe the effects of cavity resonance in a capacitor microphone.***—In the older model capacitor microphones, cavity resonance was quite common because of the large diaphragm (about 2 inches), the design of the case, and the method of stretching the diaphragm. Most of these effects have been eliminated in modern microphones by the reduction in size of the diaphragm to diameters of ¾ inch or less, and by improved methods of stretching the diaphragm. Three common causes of cavity resonance are given in Fig. 4-44. In part (a) are shown the effects of diffraction, which result when the reflected component of the sound-wave incidence upon the surface of the diaphragm causes a standing wave sufficient enough to produce pressure doubling and tripling. Part (b) shows the phase-difference effect, which is caused when the wavelength of the sound wave is comparable to the diameter of the diaphragm and occurs when the incident wave front strikes the diaphragm at an angle theta (θ) to cause pressure variations across the surface of the diaphragm. Part (c) shows cavity resonance caused when the wavelength of the sound wave is comparable to the inside dimensions of the diaphragm assembly. This causes an increase in the sound pressure in proportion to the ratio of the diaphragm d1 to the dimension of the cavity depth d2 (d1/d2).

4.45 ***What are the general characteristics of a capacitor microphone?***—Capacitor microphones have wide frequency response, low distortion, and little internal noise. Although the earlier models were omnidirectional, they may now be obtained with omni, bi, and unidirectional characteristics. A typical frequency response for a capacitor microphone, using an omnidirectional polar pattern is shown in Fig. 4-45. Capacitor microphones require a preamplifier as an integral part of the housing and a source of polarizing voltage for the head, plus a source of power



(a) Diffraction effect causing frequency doubling or tripling.

(b) Phase-differences caused by pressure differences across the face of the diaphragm.

(c) Pressure increases because of the resonance of the cavity area at certain wavelengths.

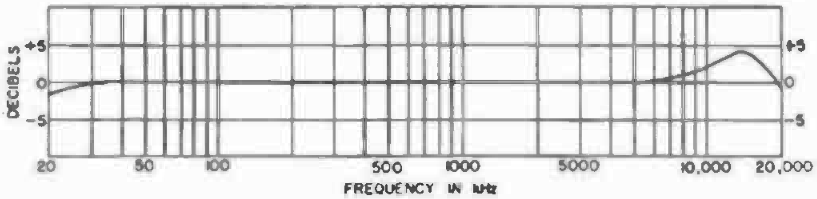

Fig. 4-45. Typical frequency response for a capacitor microphone using a transistor amplifier. Omidirectional pattern.

for the amplifier section, which may be either transistor or vacuum tube. Such microphones, if operated in a high humidity, may develop noise due to moisture getting into the head, and cause arcing between the diaphragm and back plate; however, in present day microphones, this has been almost completely eliminated. If the device is being operated in high humidity, the head should be stored in a desiccator jar when not in use.

4.46 Describe a completely self-contained capacitor microphone.—The microphone shown in Fig. 4-46A, Model S-10, manufactured by Syncron Corp., is completely self-contained and employs a field-effect transistor (FET), operated from a 8.4-volt mercury battery. Fig. 4-46B shows a cross-sectional view of the internal construction. The capacitor head is at (A) with a series of portholes (B) to permit the sound to enter the rear of the capacitor head, thus producing a cardioid pattern. The solid-state amplifier (C) consists of an FET, capacitors, resistors, and an output transformer (D). A solid-electrolyte polarizer (E) supplies a permanent polarizing potential of 62 volts to the capacitor head. This polarizing system has a capacity of 15,000 microampere hours, and because of careful control of leakage, the expected life is around 20 years. At (F) is a Type TS-126 8.4-volt mercury battery with an expected life of 1000 hours. The output transformer supplies a balanced output, with a nominal impedance of 200 ohms.

One of the interesting features of this microphone is its transient re-

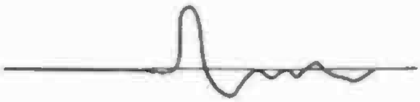

Fig. 4-46C. Rise time oscillograph for Syncron S-10 capacitor microphone.

sponse, as seen in Fig. 4-46C. The oscilloscope display shown was made with a shock-wave having a rise time of 1 microsecond, followed by a small amount of ringing and overshoot. The frequency response for three angles of incidence is shown in Fig. 4-46D, and the polar pattern appears in Fig. 4-46E.

The total harmonic distortion is less than 0.5 percent for an SPL up to 124 dB. The outpnt level is minus 53 dB re: 1 mv/10 dynes/cm². The nominal outpnt impedance is 200 ohms; however, it is unaffected by loading from 30 ohms to infinity.

4.47 What is a unidirectional microphone?—One having a greater sensitivity to sound pickup in one direction than another. The average unidirectional microphone has a back-to-front picknp of 20 to 26 dB; that is, it has 26 dB greater sensitivity to sound waves approaching from the front than from the rear. Directional characteristics may be obtained by using capacitor, dynamic, or ribbon-velocity design. Unidirectional microphones are used extensively for motion picture and television work.

4.48 Describe a dual-type microphone for stereophonic recording.—Microphones of the dual type are especially designed for the recording of stereophonic sound and may be of the capacitor or ribbon-velocity type. The first type to be discussed is the Neumann Model SM-2, manufactured in West Germany by George Neumann, previously known under the name, Telefnnken (Fig. 4-84A). An interior view of its construction is shown in

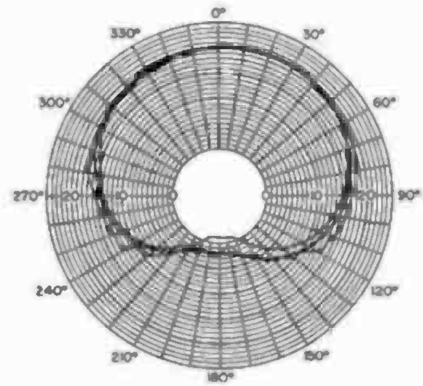

Fig. 4-46E. Polar pattern for microphone shown in Fig. 4-46A.

Fig. 4-48B. The microphone consists of two completely independent but similar capacitor microphones in a single case, one above the other (A) and (B). The upper unit may be rotated to achieve the MS (midscale) method of stereophonic recording technique, discovered by Lauridson, and sometimes termed the intensity system.

Each microphone system is of the pressure-gradient type head, employing two diaphragms (A and AA) and (B and BB), monnted on either side of two fixed-polarized electrodes. Each half of the system, (A) and (B), can be combined in a different manner, in order to obtain three different polar patterns: omnidirectional, cardioid, and bidirectional (figure-8). Below the capacitor head assembly are two preamplifiers, each employing a single AC-701K vacuum tube (C and CC). The second amplifier, not shown, is opposite (C). The polar pattern of each microphone can be independently and remotely adjusted for the three polar patterns and six intermediate patterns by changing the value of the polarizing voltage. This permits great flexibility and the variation of the polar patterns for optimum results.

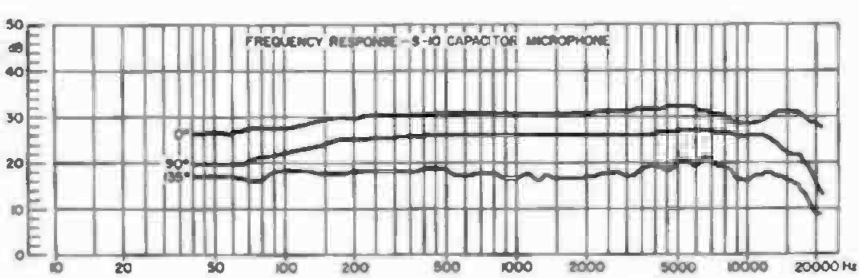

Fig. 4-46D. Frequency response for three angles of incidence.

Fig. 4-48A. Neuman Model SM-2 stereophonic microphone in its case. (Courtesy, Gotham Audio Corp.)

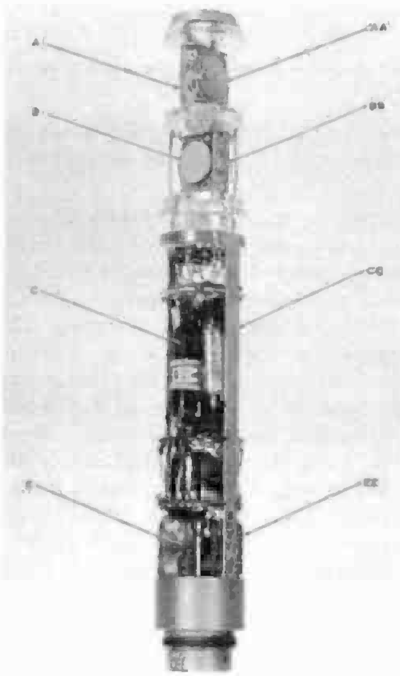

Fig. 4-48B. Interior view of Neumann Model SM-2 stereophonic microphone. The two capacitor heads may be seen at the top. (Courtesy, Gotham Audio Corp.)

Because of the small diameters of the microphone capsule (less than ¾ inch) the directional properties are almost independent of frequency; thus, the rear rejection ratio does not increase at the higher frequencies, relative to the middle or lower frequencies. This permits the microphone to be used close up in a more reverberant sound field. The high frequency rise which is generally required to compensate for the narrower pickup angle is unnecessary. The frequency response as measured in a linear sound field shows only a small rise at the high frequencies.

The frequency response for the three polar patterns is shown in Fig. 4-48C. Harmonic distortion is less than 0.4 percent over the entire frequency range, up to an SPL of 110 dB. The output impedance may be set for either 50 or 200 ohms, with an effective output level of minus 43 dBm. An external power supply model NSM supplies the operating voltages for the preamplifiers, and polarizing voltage for the capacitor heads. The output transformer is wound hum-bucking, to eliminate magnetic fields. The schematic diagram for a single side is shown in Fig. 4-48D.

A second dual-type microphone to be discussed is Model-200 stereophonic

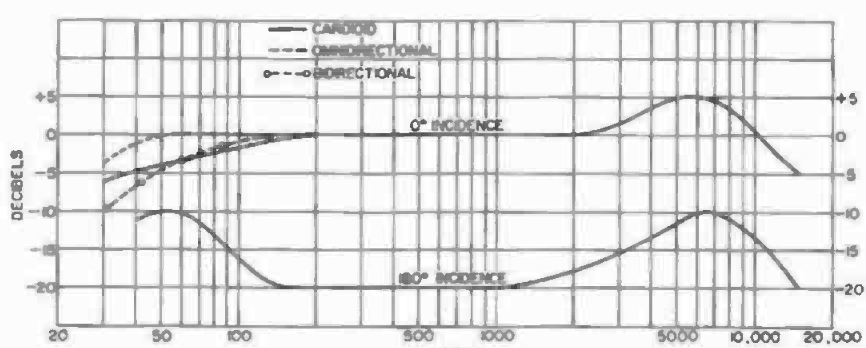

Fig. 4-48C. Frequency response for Neumann Model SM-2 stereophonic capacitor microphone, for three polar patterns.

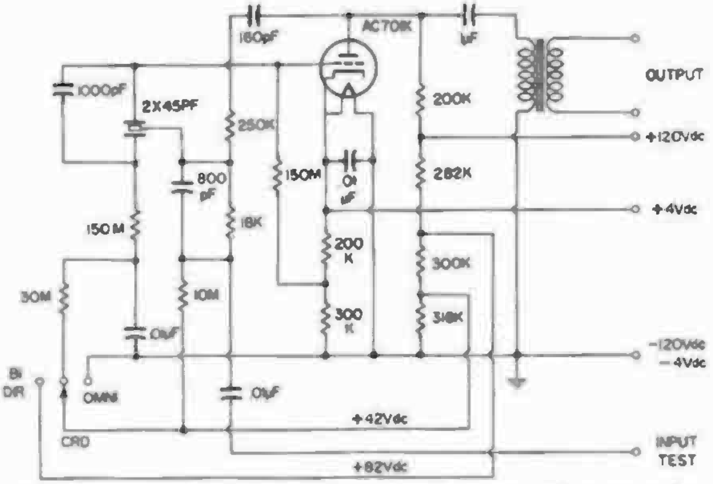

Fig. 4-48D. Schematic circuit for one side of Neuman SM-2 stereophonic capacitor microphone.

microphone, manufactured by Bang and Olufsen of Denmark (Fig. 4-48E). The device consists of two individual monophonic pressure-gradient bidirectional ribbon-velocity microphones, arranged one above the other, with provisions for rotating the upper unit 100 degrees.

The lower section is converted to stereophonic by plugging a second monophonic microphone in the top of the lower element. Such a design reduces phasing problems, since for practical purposes, both microphones occupy nearly the same space with respect to the source of sound pickup. The lower section includes a three-position switch (T) for talking, in which the low frequencies are rolled off at the rate of 3 dB per octave, whereby 125 Hz is minus 9 dB with respect to 1000 Hz. This is accomplished by muting the upper section and connecting a small inductance in parallel with a portion of the output transformer, making the microphone suitable for dialogue recording at distances of 8 to 20 inches. The polar pattern appears in Fig. 4-48F, and as can be observed, is quite constant from 200 to 10,000 Hz. The frequency response in music position is shown in Fig. 4-48G. The output level is minus 60 dB re: 1 volt/microbar. The output impedance is 150 and 250 ohms.

The moving element of each individual element consists of a dural ribbon, 0.0001 inch in thickness and weighing 1.3 milligrams. The ribbon, because of its weight, eliminates resonance in the normal operating frequency range. The magnetic structure consists of an anisotropic permanent Ticonal-E magnet in a magnetic circuit having negligible leakage. To obtain a smooth frequency response, the microphone must be hung on a soft suspension rather than on a stand; otherwise, a rise in frequency response below 50 Hz may be noted.

In stereophonic recording it is of extreme importance that the electrical

outputs from both microphone systems be in phase.

4.49 What is a bidirectional microphone?—A microphone which picks up at the front and back equally well, with little or no pickup at the sides. The field pattern is a figure-8. (See Fig. 4-7, part c.) Ribbon-velocity microphones have this characteristic.

4.50 What is a ribbon-velocity microphone?—A microphone in which a very light metallic ribbon is suspended in a strong magnetic field. Pressure waves cause the ribbon to vibrate in the magnetic field generating a voltage corresponding to the particle velocity of the pressure wave. Velocity microphones may be designed to have a wide frequency range, good sensitivity, low distortion, and low internal noise. Typical examples are the RCA 77DX and the MI-10001-C ribbon-velocity micro-

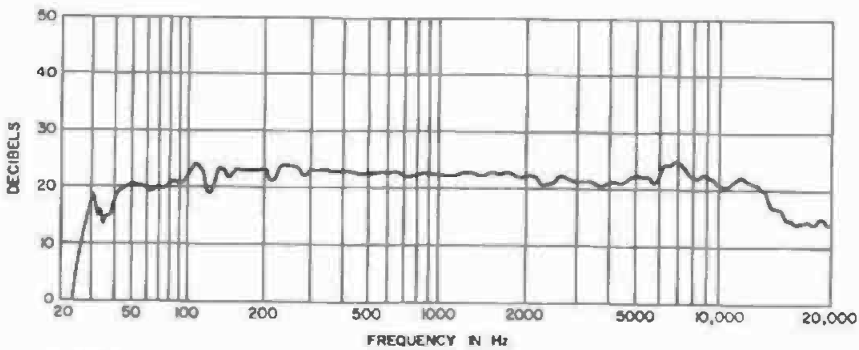

Fig. 4-48G. Frequency response for Bang and Olufsen Model 200 stereophonic microphone. (Courtesy, Dynaco Inc.)

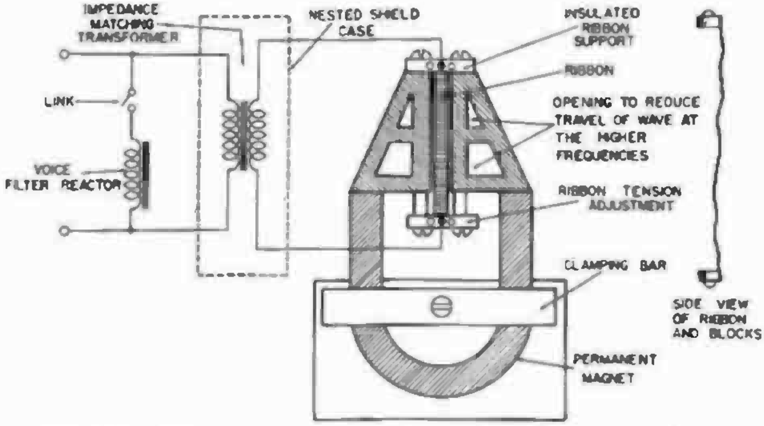

Fig. 4-51. Internal construction of a ribbon-velocity microphone.

phones discussed in Questions 4.59 and 4.77 respectively.

4.51 Describe the construction of a ribbon-velocity microphone.—Referring to Fig. 4-51, the magnetic structure consists of a horseshoe magnet with extended tapered pole pieces. A ribbon made of aluminum foil approximately 0.001 inch in thickness and corrugated throughout its full length for greater flexibility is suspended between the pole pieces on insulated supports.

4.52 Why are the pole pieces of a ribbon microphone tapered?—Because of the mechanical design, the magnetic structure acts similar to a baffle at the sides, obstructing the sound waves in their travel from the front to the rear surfaces of the ribbon. When a pressure wave passes, the ribbon is actuated by the variations in pressure and a voltage is generated by the movement of the ribbon in the magnetic field. This voltage is applied to the primary of an impedance-matching transformer and then to the input of a preamplifier. The ribbon in a velocity microphone may be looked upon as an inductive reactance. The higher the frequency, the higher the reactance of the ribbon. This causes the ribbon velocity to vary with frequency; however, the pressure on the ribbon surfaces will also increase with frequency and will continue to do so up to a point where the baffle dimensions equal one quarter the wavelength of the pressure wave frequency.

The greater the baffle dimensions (distance from front to rear surfaces of the ribbon) the greater will be the pressure; hence, a greater output results at the lower frequencies. At the higher frequencies the baffle affects the frequency response by reducing the output as the wavelengths of the pressure wave approach the baffle dimensions. When this situation occurs, the pressure is at a minimum for both surfaces of the ribbon. Holes are provided in the upper section of the magnetic pole pieces to reduce the length of travel for the higher frequencies. As a result, a greater output is obtained at the higher frequencies with a smoothing out of the frequency response.

When sounds originate at the side of the microphone in the same plane with the ribbon, a cancellation effect will take place, since the pressure on both the front and rear surfaces of the ribbon is equal. This cancellation action causes the field pattern to take the form of a figure-8, as shown in Fig. 4-7, part (c).

4.53 What is the impedance of the ribbon in a ribbon-velocity microphone?—Approximately 0.10 ohm, a value almost eqnivalent to its dc resistance. An impedance-matching transformer brings this low impedance up to the line impedance.

4.54 What is the resonant frequency of the ribbon in a ribbon-velocity microphone?—The ribbon is generally tuned so that the resonant frequency falls between 30 and 40 Hz. For microphones with a higher cutoff frequency, the resonant frequency is generally made higher.

4.55 What is a voice filter used with a ribbon-velocity microphone?—A small reactor connected in parallel with the output of the microphone to reduce the low-frequency response for speech.

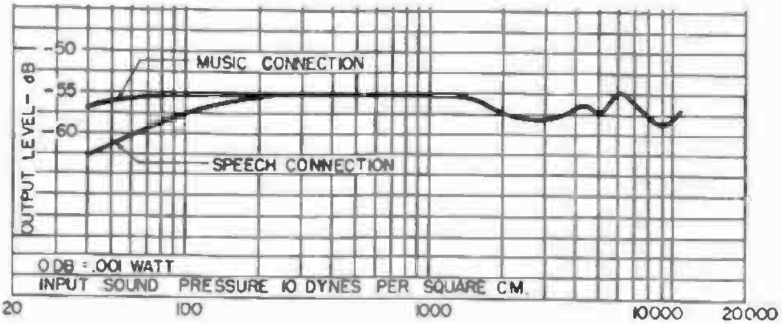

Fig. 4-56A. A typical frequency response for a bidirectional ribbon-velocity microphone.

At frequencies above 200 Hz, the reactor has little or no effect. Below this frequency, the response is slowly tapered off to the point where 40 Hz is attenuated 7.5 dB with respect to 1000 Hz. This is shown graphically in Fig. 4-56A. When recording music, the reactor is not nsed. Connections for the voice filter are shown in Fig. 4-51.

4.56 Show the frequency response and polar pattern for a bidirectional, ribbon-velocity microphone.—The frequency response for a typical bidirectional ribbon-velocity microphone is shown in Fig. 4-56A, with and without a voice filter. The polar pattern is shown in Fig. 4-56B. It will be noted that the response at 90 degrees is zero. This is caused by the pole-piece construction as described in Question 4.52.

4.57 Show the relationship of frequency to distance of a sound source for a bidirectional ribbon-velocity microphone.—As the distance between the sound source and the microphone is de-

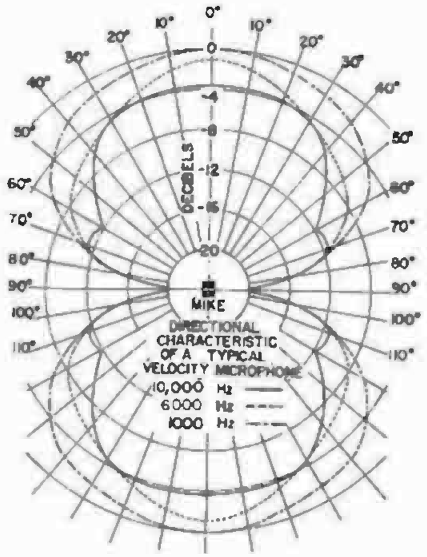

Fig. 4-56B. Polar pattern showing the bi-directional characteristics, of a typical ribbon-velocity microphone.

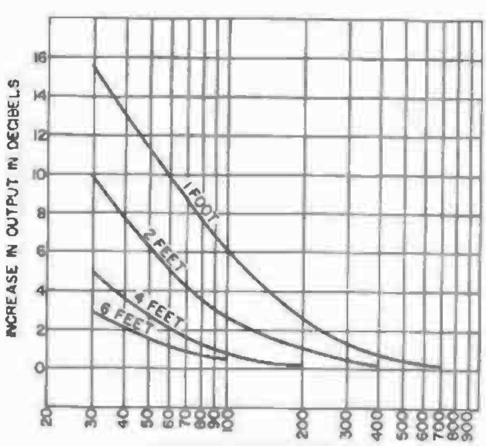

Fig. 4-57. Typical relationship of microphone distance to frequency response for ribbon-velocity bidirectional microphone.

creased, the low-frequency response will rise, as shown in Fig. 4-57. If the microphone is being used for dialogue pickup, the low-frequency response below 200 Hz must be rolled off, otherwise the reproduction at the low end will be excessive and tubby. The rolloff may be accomplished by the use of a voice filter, generally installed as an integral part of the microphone, or by the use of one of several dialogue equalizers discussed in Section 6.

Ribbon-velocity microphones should not be used closer than 4 feet from the sound source without a low-frequency rolloff. With the rolloff they may be used to within a few inches of the sound source. The increase in low-frequency response is characteristic of this type microphone. Ribbon-velocity microphones employing a directional characteristic give considerably less increase at the low frequencies for a given distance from the sound source, as illustrated in Fig. 4-57. This effect is referred to as the proximity effect.

4.58 What type microphones are generally used for motion-picture and television recording?—Capacitor or dynamic or ribbon-velocity microphones may be used if they provide a directional pattern and are suitable for boom operation. Typical types are the Altec-Lansing M-30 system and the 689BX, Electro-Voice 642 and 6681, and RCA MI-11010-A. Choice is not limited to the above microphones, but they do represent typical microphones developed for these express purposes.

4.59 Describe the construction of a unidirectional ribbon-velocity microphone.—A typical example of a unidirectional cardioid microphone designed for motion picture and television production recording, and broadcasting, is the RCA MI-10001C, shown in Fig. 4-59A, with its boom-suspension mechanism. The internal magnetic structure is similar to that of the bidirectional ribbon-velocity type, discussed in Question 4.51, with the exception of the added mechanism for obtaining the directional characteristics (Fig. 4-59B). The moving element is a single extremely light corrugated dural ribbon, suspended in an air gap, between the poles of a very highly charged permanent magnet (A). Thus, the ribbon can vibrate freely with the motion of the air particles of the sound wave. The voltage generated due to the movement of the ribbon cutting the magnetic field of force is the electrical equivalent of the velocity of the air particles. An acoustical labyriuth in the cylindrical section below the magnetic structure is filled with hair-

felt and terminates at the rear of the magnetic air gap by a tubular connector (C). The tubular connector is sealed to the rear of the air-gap, and contains a small silk covered opening, facing toward the ribbon (see Fig. 4-65). The area of the opening is of suitable dimensions to provide a cardioid or unidirectional polar pattern.

The ribbon and magnetic assembly are enclosed in a circular silk-lined grill, to provide protection to the mechanism and prevent metallic dust particles from entering the air gap. The hemispherical shell (B) also contains an impedance-matching transformer, with taps at 30, 150, and 250 ohms. The output signal is taken through a standard 3-pin male connector. Such microphones have a quite uniform frequency response for sound incidence at the zero axis (front of microphone), with output decreasing as the angle of the sound source with zero axis increases. The pickup angle is approximately plus or minus 50 degrees from the zero axis, with less than 1-dB difference in the output level, and approximately plus or minus 90 degrees before the output level decreases 6 dB over the frequency range normally employed. The broad angle of relativity equalizes the response, thereby reducing and simplifying "panning" the microphone, where two or more persons are concerned. The polar patterns in Fig. 4-59C and Fig. 4-59D are based on a plane-wave sound incidence. Referring to the plot in Fig.

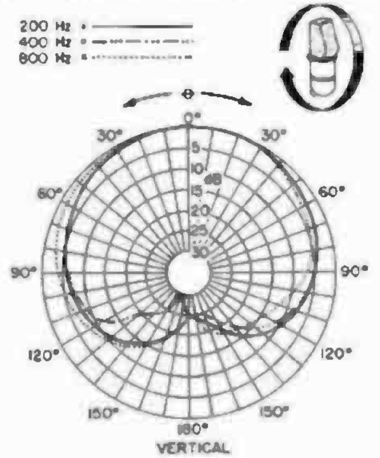

Fig. 4-59E. Vertical polar pattern for RCA MI-10001C ribbon-velocity unidirectional microphone—200 to 800 Hz.

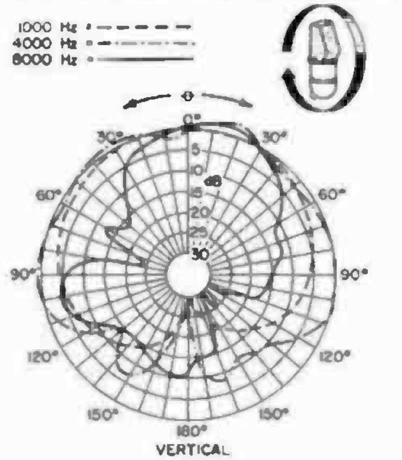

Fig. 4-59F. Vertical polar pattern for RCA MI-10001C ribbon-velocity unidirectional microphone—1000 to 8000 Hz.

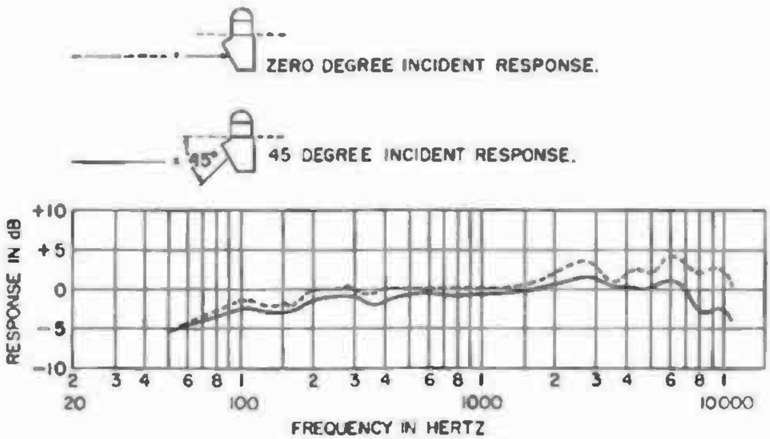

Fig. 4-59G. Frequency response of the RCA MI-10001C unidirectional microphone.

4-59C, cancellation for a plane wave at the rear is such that the cancellation is 20 dB or more at 180 degrees incident angle over a broad band of frequencies. As the distance between the microphone and sound source is decreased and the wavefront becomes increasingly curved, cancellation at the lower frequencies is reduced.

A loss of directional characteristic at the lower frequencies and short distances is such that the output level at a distance of 1 foot from the sound source is very nearly the same at the back and the front. As an example, the 80-Hz output is approximately plus 1.5 dB at 180-degree incident angle, re to zero dB at 1000-Hz for a zero-degree incident wavefront at one-foot distance. The 80-Hz zero axis output is accentuated approximately plus 3 dB, due to the low frequency tip-up characteristic of a velocity microphone.

It can be observed from Fig. 4-59G that the frequency response is relatively uniform over a range of 50 to 10,000 Hz. However, when the microphone is operated close to the sound source, the response will exhibit to a certain extent the low-frequency accentuation of a velocity microphone, although to a lesser degree than the conventional bidirectional ribbon microphone discussed in Questions 4.51 and 4.56. Under normal conditions the microphone under discussion should not be worked closer than 3 feet from the sound source, and preferably 4 feet, as shown in the curves of Fig. 4-59H.

As a rule, the RCA MI-10001C microphone is suspended at an angle of 45 degrees to the floor, with the microphone just outside the camera angle. The zero-degree axis (perpendicular to the front of the ribbon) should be directed toward the sound source, with the back facing unwanted sound sources, such as noises from camera, lights, traffic, and reflections from hard walls of a set. Referring to Fig. 4-59G, again the response changes as the angle of incident sound varies from zero to 45 degrees, and as the distance between the sound source and microphone is decreased (approaching the minimum of 3 feet), the lower frequencies are accentuated. Vertical polar patterns are shown in Fig. 4-59E and Fig. 4-59F for frequencies ranging between 200 and 800 Hz. Sensitivity to extraneous magnetic fields is quite low. For an exciting field of 0.001

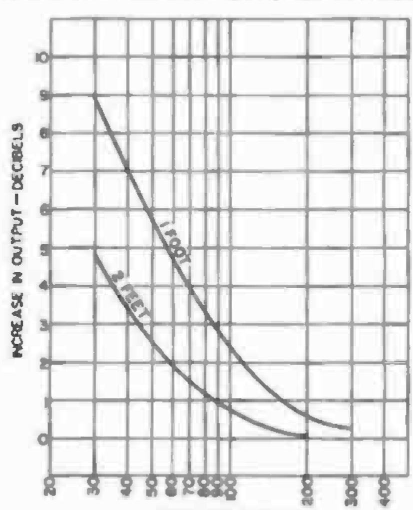

Fig. 4-59H. Relationship of microphone distance to frequency response for ribbon-velocity, unidirectional microphone.

gauss, the output level is minus 128 dBm. The signal output at 1000 Hz for a pressure of 10 dynes/cm² at the ribbon is minus 49 dB, using the 30-ohm output impedance.

Since random energy response of a unidirectional or cardioid microphone is one-third that of a nondirectional microphone, for the same permissible reverberation it may be used 1.7 times the distance of a nondirectional microphone, for a given set of conditions. The characteristics discussed were obtained operating the microphone into a preamplifier, using an unterminated input transformer. (See Questions 4.76 and 12.170.)

The hanger mechanism is designed for boom operation. The housing is clamped by two rings, supported by heavy rubber bands from a larger ring supported by the hanger arms, and hung from a boom turret-head by a single wing nut. Although the grill with the silk covering acts somewhat as a wind screen, it is not satisfactory for outside work if the wind is blowing more than 7 miles per hour. A large ball type wind screen that slips over the outside is generally employed.

As the distortion is quite low for this type microphone, it may be used for either dialogue or music recording. For dialogue, the low end is rolled off starting at 800 Hz to where it is down 8 to 12 dB at 100 Hz. This is the standard dialogue characteristic used by most motion picture studios. (See Questions 2.109, 6.80, and 18.81.)

4.60 Describe an early model unidirectional microphone.—One of the original unidirectional microphones developed for motion picture sound recording was the Western Electric RA-1142A. The magnetic structure of this microphone was quite similar to the 639A microphone used for broadcasting work. However, certain modifications were necessary to meet the requirements for sound recording and boom operation. The perforated metal case was added to improve the high frequency response and a boom hanger added with a shock mounting to protect the magnetic structure. Although this microphone has been obsolete for many years, its design is still of interest. The frequency response is given in Fig. 4-60B. (See Question 4.66.)

4.61 Describe the construction of a unidirectional microphone using two dynamic units.—The construction of the model D-202es unidirectional microphone, manufactured by AKG G.M.B.H. of Vienna, Austria, is shown in Fig. 4-61A. It employs two independent dynamic-unit (moving-coil) microphones, placed one above the other in a single

Fig. 4-60A. Interior view of an early (1935) Western Electric RA-1142A unidirectional microphone for motion-picture sound recording. Now obsolete, but it is still of historical interest.

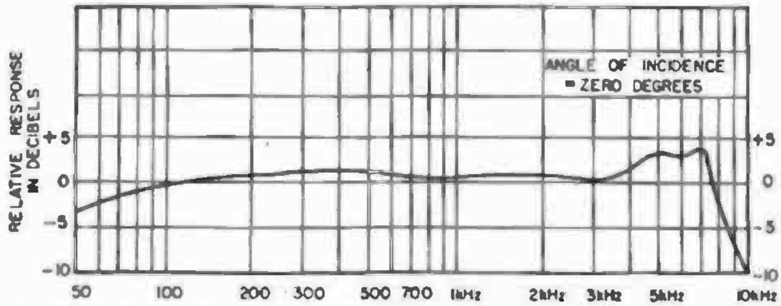

Fig. 4-60B. Frequency response of Western Electric RA-1142A unidirectional microphone.

housing, and connected electrically by a phase-correcting, dividing network. The frequency response of each dynamic unit is adjusted for optimum response at the low and high frequencies, crossing over at 500 Hz.

Referring to the cross-sectional view of the interior in Fig. 4-61B, at (A) is shown the high-frequency unit, employing a domed diaphragm (B) with a compensating coil (C) for eliminating the effect of extraneous magnetic fields. The high-frequency unit is mounted above the low-frequency unit by mounting plate (G). The domed diaphragm and its moving coil may be seen at (D), its magnets at (E), supported on shock mounts (F) and (H). A mass tube (I) projects into the low frequency microphone unit and connects with a smoothing chamber communicating with the outside sound field by means of a series of slotted openings (O), covered with a damping material to the lower end of housing (P). Because of the long sound-bypass distance (approximately 5½ inches) afforded by the mass tube and the subdividing of the frequency response between the high- and low-frequency units, it is possible to achieve a reduction on the distance effect or change in frequency response as a function of distance to the sound source.

The high-frequency diaphragm has a diameter of approximately ¾ inch and a sound bypass of ½ inch. A phase-correcting network, consisting of an RC network combined with an LC network, corrects the phase and frequency response at the higher frequencies. At (J) is a central screw for holding the assembly together, at (K) the crossover network, (L) an off-on switch, and at (M) a low-frequency attenuation switch and control that permits the low-frequency response at 50 Hz to be rolled off continuously to minus 20 dB, with reference to 1000 Hz. Item (N) is a standard 3-pin male connector. The upper end of the microphone housing (P) is covered with a sintered bronze cap (R) attached by a mounting ring (Q).

The frequency response is 30 to 15,000 Hz plus or minus 2 dB, with an output level of minus 53 dB re 0.2mv/microbar. The output impedance of 200 ohms is practically independent of frequency. The polar pattern is cardioid with a front-to-back ratio of 20 dB minimum over the entire frequency range. The off-axis response (90 degrees) is parallel with the on-axis (zero degrees) front curve. The microphone is designed for either boom or stand operation.

4.62 Describe the basic methods used for recording stereophonic sound.—The so-called *classical* method of recording stereophonic sound (sometimes called the AB or XY method) involves the use of two bidirectional microphones with identical characteristics.

Fig. 4-61A. Unidirectional microphone Model D-200es manufactured by AKG G.M.B.H, Vienna, Austria. (Courtesy, Sonocraft Corp.)

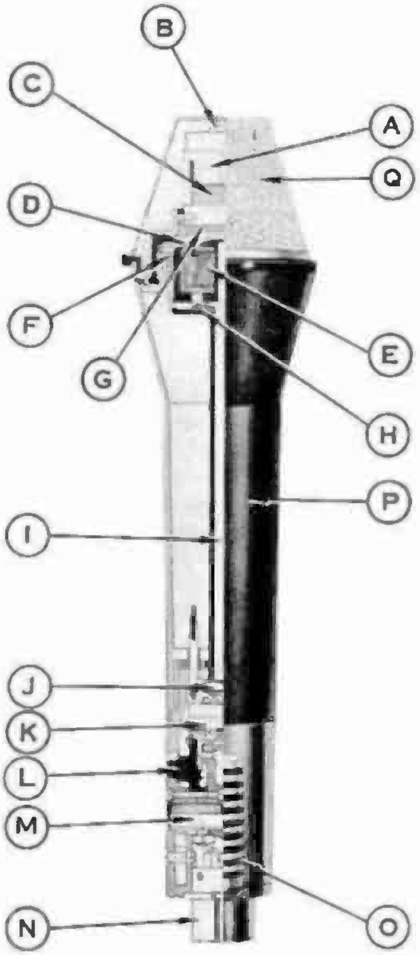

Fig. 4-61B. Cut-away view of unidirectional microphone Model D202-es manufactured by AKG, G.M.B.H. Vienna, Austria. (Courtesy, Sonocraft Corp.)

The microphones are placed side by side, spaced 12 to 48 inches apart, the exact distance depending on the desired working angle, relative to the source of sound. The microphones are connected as given in Fig. 4-62A. If additional vocal or solo microphones are required, they should consist of pairs placed fairly close together. An additional control (P5) is connected across the output from the vocal or solo microphones to provide a leakage path for reducing the effects of movement by the vocalist and the possibility of apparent movement when reproduced from one loudspeaker to the other.

For the listener to locate the sound source from the two loudspeakers, the speakers must be in the same position as were the microphones, to avoid differences in the distance from the sound source to the microphones. This may be accomplished in two different manners. The first method is by placing two microphones of similar electrical characteristics on a support as shown in Fig. 4-26B, suggested by Madsen, 12 to 20 inches apart, separated by a small baffle or sphere, thus creating a dummy head to enhance the left-to-right impressions. The use of the dummy head or baffle causes laterally displaced sound sources to be shadowed, resulting in a more uniform sound reproduction. The baffle has the effect of reducing the crowding of the sound source. Diffraction of the sound around the dummy head or baffle causes attenuation of the high frequencies on the far side. The resulting field pattern is shown in Fig. 4-62C.

The second method requires the mounting of the two microphones by a support, as shown in Fig. 4-62D. Here two capacitor-type microphones are placed one above the other as suggested by Lauridsen. The microphones must have similar electrical characteristics and their physical size must be small enough that they do not distort the sound field when they are placed in close proximity. They are rotated to a position where each microphone picks up the sound from half the studio.

The German (MS) method, also developed by Lauridsen, eliminates many of the drawbacks to the intensity system developed above. In the MS method (midside stereophony), one cardioid microphone supplies a complete pickup, similar to a single microphone pickup for monophonic recording. The second microphone having a bidirectional polar pattern is placed either above or below the cardioid and rotated to where its null point (x) meets the axis in the polar pattern of the cardioid microphone (Fig. 4-62E). Referring to Fig. 4-62F, if the output from the two microphones (A) and (B) in Fig. 4-62E are interconnected by means of differential transformers (S) and (M) to form an (A + B) and an (A — B) signal, two channels will result. In each channel one half the pickup area is preferentially received, relying on the fact the two principal axes of the pressure gradient microphone correspond to voltages of opposite polarity. Again

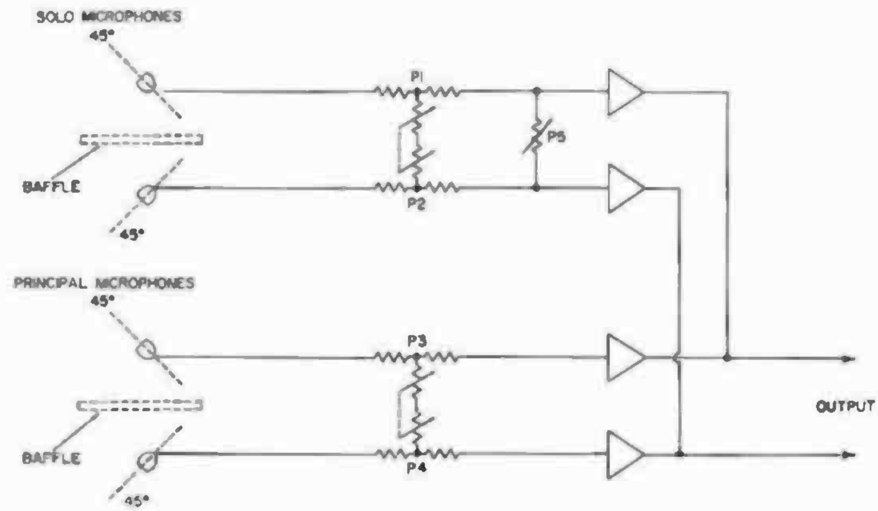

Fig. 4-62A. Classical two-channel method of recording stereophonic sound.

referring to Fig. 4-62E, and assuming the instantaneous value of the sound from the left microphone produces an instantaneous positive voltage (B) in the bidirectional microphone, the sound source on the central axis (M) will rise to the voltage (A) in only the cardioid

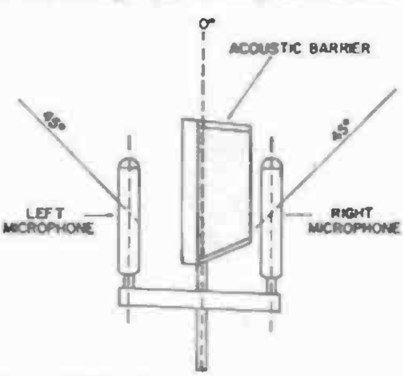

Fig. 4-62B. Stereophonic microphone placement using two ribbon-velocity bidirectional microphones set at an angle of 45-degrees each side of zero. (After Madsen.)

microphone, thus creating a central impression. Sound sources making angle (A1) with the central axis, give rise to a voltage (A + B) at the left loudspeaker, and (A − B) at the right loudspeaker. In a condition where (A = B) only the left loudspeaker is operative, and to the listener, the source is from the left. For sound sources at angle (A2) the sound appears to be coming from the right loudspeaker. For smaller angles in the recording studio, they correspond to the apparent direction. The size of the angle (A1 + A2) may be varied by changing the relative gain of the microphone channels. Experience indicates that sound sources lying outside angle (A1 + A2) will be more centralized, because the output from the bidirectional microphone predominates, causing the loudspeakers to be driven in opposite phase, resulting in a loss of direction to persons listening in a central position. This indicates that an individual microphone is necessary for a vocalist.

The advantages gained by the use of the MS method lie in the fact that one channel, namely the midchannel, produces a satisfactory single channel transmission; thus, the recording may be reproduced stereophonically or monophonically. To satisfactorily record stereophonically using the MS method requires dual microphones (see Question 4.48) or two individual microphones placed as near as possible to the same position (Fig. 4-62D). Dual-type microphones, when added for vocal or solo position, may be connected as shown in Fig. 4-62H.

The British E.M.I. system employs two bidirectional ribbon microphones (figure-8 pattern) placed at a 45-degree angle to the source of sound. The field patterns of the two bidirectional microphones create a pattern similar to a four-leaf clover (Fig. 4-62G). Since both microphones have equal sound pickup in the designated areas, A1 and A2, they may be connected in or out of

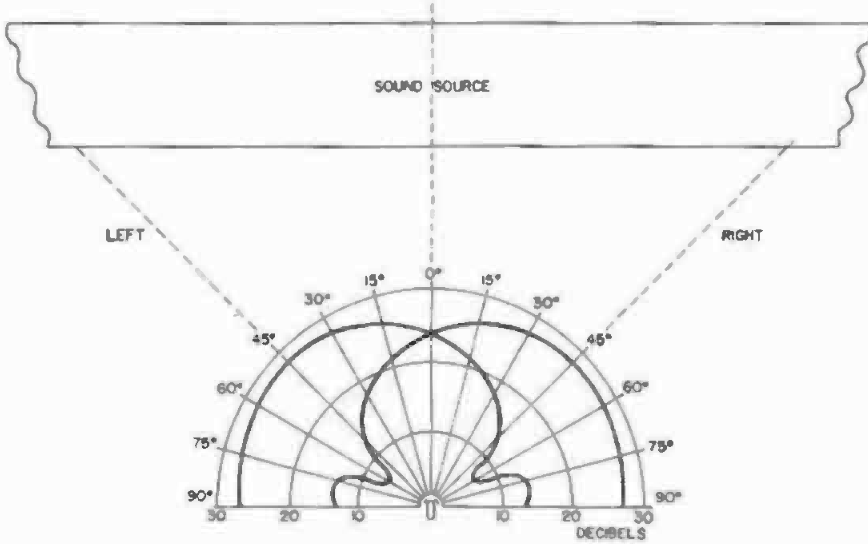

Fig. 4-62C. Polar pattern for two bidirectional ribbon-velocity microphones using an acoustic barrier between the microphones. Each microphone is turned 45 degrees from the zero point. (After Madsen.)

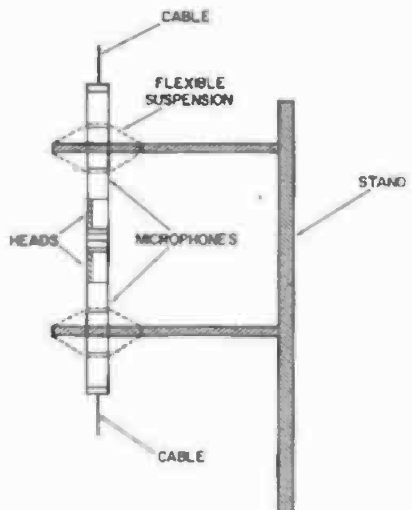

Fig. 4-62D. Two cardioid capacitor microphones mounted vertically head-to-head for stereophonic recording.

phase to produce a given signal at the cutting-head coils.

Connecting the output of the microphones in phase produces a lateral signal component equivalent to the (M) component in the German MS system (Fig. 4-62E). If the outputs are connected out of phase, the resulting field pattern is that of the (S) or vertical component of the German system. For

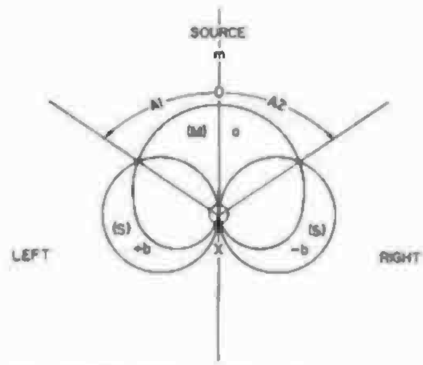

Fig. 4-62E. Polar pattern for a microphone combination using cardioid and bidirectional microphones.

signals of random differences, the resulting signal at the cutting head is a complex one, a combination of both lateral and vertical motion.

In the United States and Europe, many variations of the methods of sound pickup described above as used in combination with the 45/45 degree system of disc recording developed by Davis and Frayne of the Westrex Corp., (USA). Reproducing characteristic in the United States is that standardized by the Record Industry Association of America (RIAA), Fig. 13-95. As a rule, each recording activity develops a system of microphone placement and method of operation which is peculiar to itself.

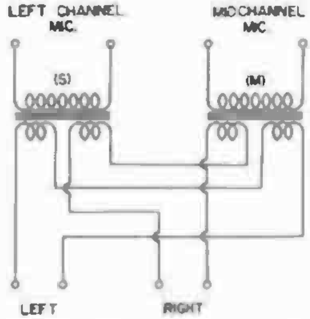

Fig. 4-62F. Differential transformers connected at the output of two microphones to obtain sum and difference voltages for MS stereophonic recording.

4.63 How does the transient response of a dynamic microphone compare to a capacitor microphone?—The transient responses of a dynamic and capacitor microphone are compared graphically in Fig. 4-63. It can be observed that the capacitor microphone has a much faster rise time than the dynamic microphone. The dynamic microphone has a longer rise time because of the diaphragm and the inductance of the moving coil. Although the capacitor microphone *appears* to have better transient response, in both instances *the rise time amounts to microseconds;* the capacitor rising from 10 percent of its rise time to 90 percent in approximately 15 microseconds, while the rise time for the dynamic microphone is on the order of 40 microseconds. The measurement of rise time is discussed in Question 22.74.

4.64 Show the methods used for grounding microphones and microphone cables.—The grounding of microphones and their interconnecting cables is of extreme importance, since any hum frequencies or noise picked up by the cables will be amplified along with the audio signal. Professional systems gen-

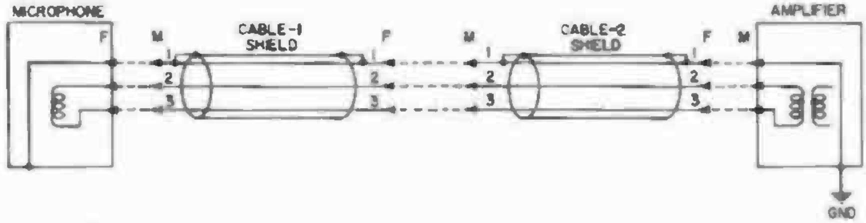

Fig. 4-64A. Grounding method for 3-conductor microphone cables. The physical ground connection is made at the amplifier or mixer console.

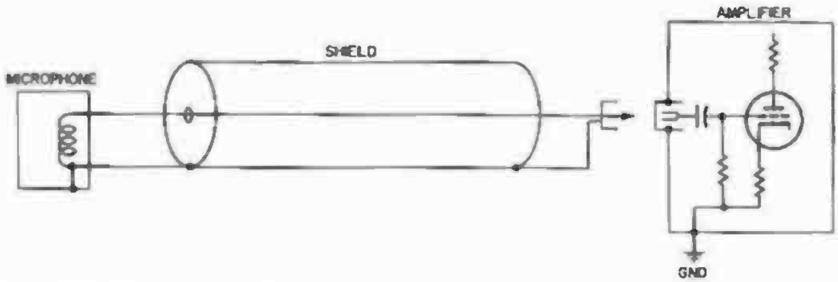

Fig. 4-64B. Grounding method used for 3-connector microphone cables using pin-plugs. The physical ground is connected at the amplifier end only.

erally use the method shown in Fig. 4-64A. Here the signal is passed through a three-conductor cable to the input transformer of a preamplifier. It should be observed, that the cable shield is connected to conductor and pin number 1, and the audio signal is carried by conductors and pins 2 and 3. The actual physical ground is connected at the preamplifier chassis, and carried to the microphone case over conductor number 1. In no instance is a second ground ever connected to the far end of the cable, as to do this will cause the flow of ground currents between two points of grounding. The grounding of electronic circuits and their associated equipment is discussed in Section 24.

In the making up of microphone cables, precautions must be taken to establish a color code and follow it through all cables. The pin count shown is that used by RCA. The plus or minus side of the audio signal (hot side) is connected to pin number 2.

In systems designed for semiprofessional and home use, the method in Fig. 4-64B is used. It will be noted that one side of the audio signal is carried over the cable shield to a piu-type connector. The bodies of both the male and female connector are grounded, the female to the amplifier case and the male to the cable shield. The microphone end is connected in a similar manner; here again the physical ground is connected only at the preamplifier chassis. Pin counts are also discussed in Questions 24.42 and 24.100.

4.65 ***Describe how a cardioid polar pattern is obtained with a ribbon-velocity microphone.***—The basic principles of securing a directional patteru with a ribbon-velocity microphone are shown in Fig. 4-65. The dural ribbon is suspended in a strong magnetic field, as described for the ribbon-velocity microphone in Questions 4.51 and 4.52. The ribbon is anchored at its mechanical center and grounded to the case. This effectively divides the ribbon into two separate parts. Directly behind the upper ribbon is a metal tube which connects to an acoustical labyrinth located in the base of the microphone case. The labyrinth is filled with hair felt and dissipates sound waves traveling down the pipe in the form of heat. With this type construction, the upper portion of the microphone becomes a pressure-operated device, while the lower section operates as a normal ribbon-velocity microphone. The overall device now becomes a combination of a pressure and a velocity microphone. The extreme ends of the ribbon are connected to a transformer.

Pressure waves striking the front of the ribbons cause voltages, which are in series and in phase, to be generated

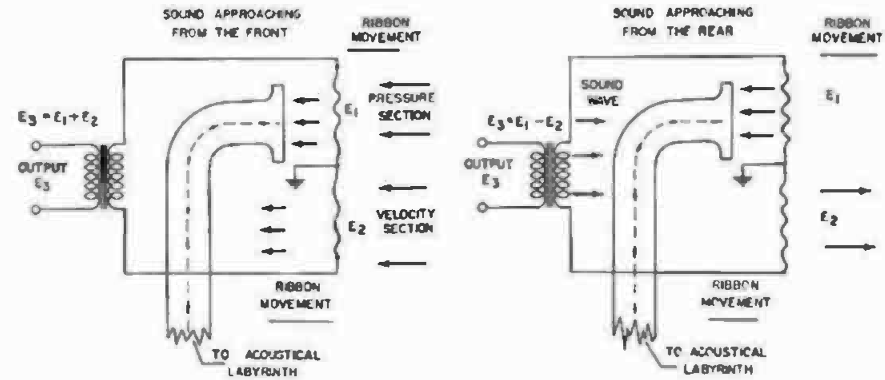

Fig. 4-65. Basic principles of operation of a unidirectional ribbon-velocity microphone.

simultaneously in both the upper and lower ribbon sections. Hence, these voltages are additive. However, pressure waves, either reflected or direct, which strike the ribbons from the rear will have little effect, since they generate voltages which are in series, but out of phase. Furthermore, it is difficult for waves approaching from the rear to strike the upper ribbon, due by the mechanical interference offered by the pipe connecting to the acoustical labyrinth below. Thus, the effect of waves approaching from the rear is minimized, since the waves are able to actuate only the lower half of the ribbon and have little or no effect on the voltages generated by waves striking the front of the ribbous. (See Question 4.59.)

4.66 Describe the construction of a directional microphone employing both a ribbon-velocity and pressure unit.—Microphones of this design (Fig. 4-66A) make use of both a pressure and ribbon-velocity unit to obtain a cardioid omnidirectional or bidirectional polar patterns. The output voltages from the two microphones are used independently, or combined in various proportions to obtain a variety of polar patterns. Six different patterns are available by means of a switch at the rear of the microphone housing. The pressure uuit is a moving-coil dynamic unit microphone, similar to the Altec-Lansing 633a/c, described in Question 4.30, and when used alone, has an omnidirectional polar pattern. The ribbon-velocity section has a bidirectional pattern. Combining the output voltages of these two units results in the phasing of the voltages in such a manner to produce a cardioid polar pattern. The output impedance is approximately 35 ohms and is operated into a 30- to 50-ohm input. The output level is minus 52 dB, re: 10 dynes/cm².

Fig. 4-66A. Altec-Lansing Model 639B microphone. Six different field patterns are made available by means of a switch at the rear of the housing.

4.67 Show the frequency response and angle of incidence for the microphone discussed in Question 4.66.—Both the frequency response and field patterns for this microphone are shown in Fig. 4-67. The single letter at the top of each characteristic may be interpreted as follows: R-ribbon, D-dynamic, C-cardioid. Numbers 1, 2, and 3 are variations of C.

4.68 What is a polydirectional microphone?—A microphone in which the polar pattern may be changed from omnidirectional to a bidirectional, a cardioid, or a combination of the three.

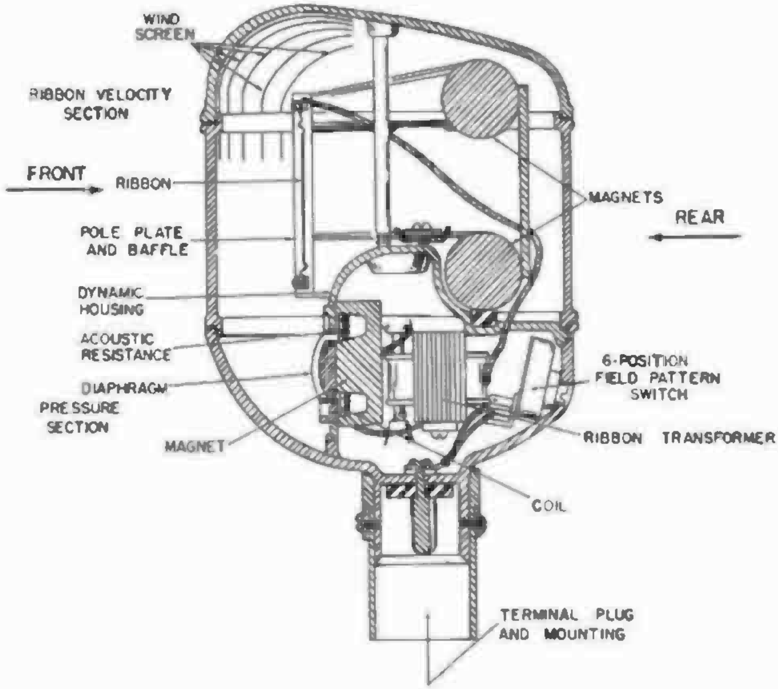

Fig. 4-66B. A cross-sectional view of Altec-Lansing Model 639B microphone.

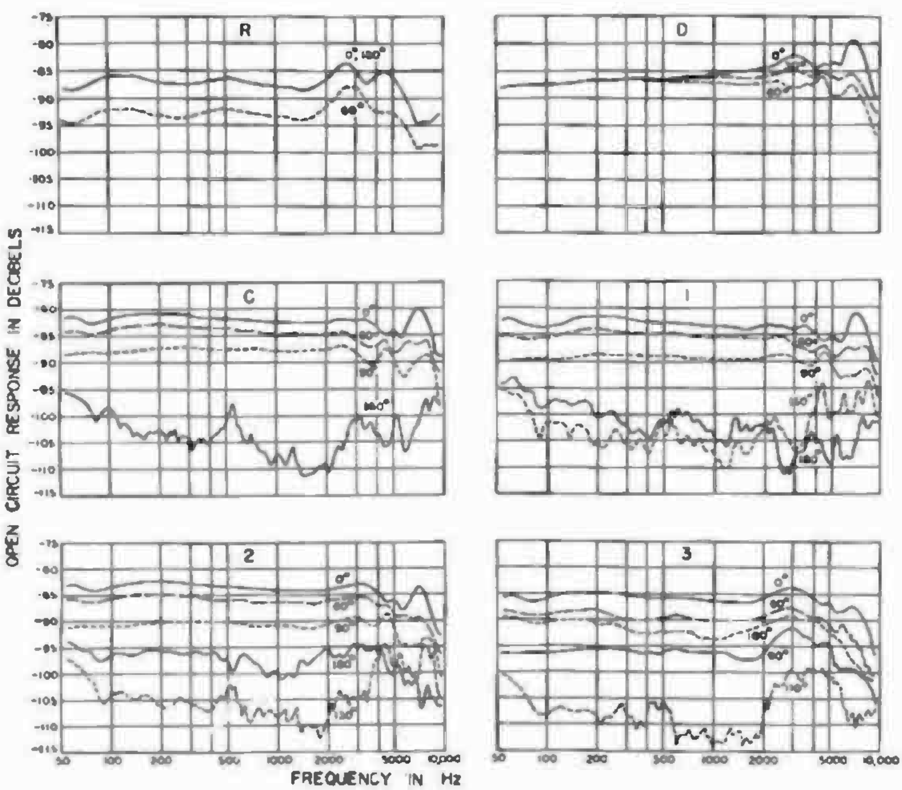

Fig. 4-67. Frequency response for Altec-Lansing 639B microphone, for various angles of Incidence.

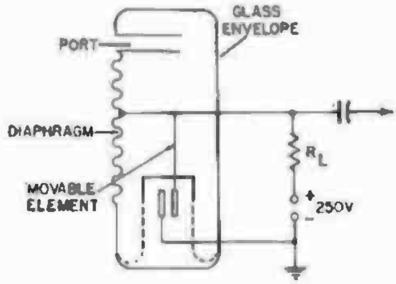

Fig. 4-69. The RCA type 5734 mechano-electronic transducer. This device is a vacuum-tube type microphone.

Such a microphone is discussed in Question 4.77.

4.69 What is an electronic microphone?—A microphone constructed in much the same manner as a vacuum tube. One of the internal elements is connected to an external diaphragm. Pressure waves striking the diaphragm move the internal element causing it to be displaced. This action causes a change in plate current proportional to the diaphragm displacement. The output voltage is amplified in the usual manner. Since the device is pressure operated, its field pattern is circular. A cross-sectional drawing of its construction is shown in Fig. 4-69. It is sometimes referred to as a mechano-electronic microphone. It was developed by RCA but is not used commercially.

4.70 What is a frequency-modulated microphone?—A capacitor microphone which is connected to a radio-frequency oscillator. Pressure waves striking the diaphragm cause variations in the capacity of the microphone head, which frequency-modulates the oscillator. The output of the modulated oscillator is passed to a discriminator aud amplified in the usual manner.

4.71 Describe a capacitor microphone using a radio frequency oscillator.—Capacitor microphones using a radio-frequency oscillator are not entirely new to the recording profession, but since the advent of the transistor considerable improvement has been achieved in design and characteristics. An interesting microphone of this design is the Schoeps Model CMT26U (Fig. 4-71A) manufactured in West Germany by Schall-Technik, and named after Dr. Carl Schoeps, the designer.

The basic circuitry is shown in Fig. 4-71B. By means of a single transistor, two oscillatory circuits are excited and tuned to the exact same frequency of 3.7 MHz. The output voltage from these circuits is rectified by a phase-bridge detector circuit, which operates over a large linear modulation range with very small radio-frequency voltages from the oscillator. The amplitude and polarity of the ontput voltage from the bridge depends on the phase angle between the two high-frequency voltages. The microphone capsule (head) acts as a variable capacitance in one of the oscillator circuits. When a sound wave impinges on the surface of the diaphragm of the microphone head, the vibrations of the diaphragm are detected by the phase curve of the oscillator circuit, and an audio frequency voltage is developed at the output of the bridge circuit. The microphone-head diaphragm is of metal to guarantee a large constant capacitance. An automatic frequency control (afc) with a large range of operation is provided by means of capacitance diodes to preclude any influence caused by aging or temperature changes on the frequency-determining elements, which might throw the circuitry out of balance.

The internal output resistance is 200 ohms, fed directly from the bridge circuit through two capacitors and delivering an output level of minus 51 to 49

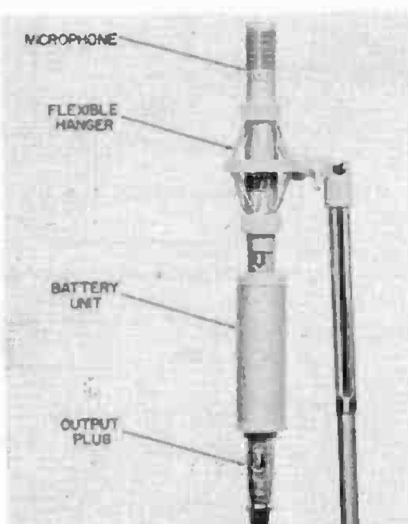

Fig. 4-71A. Schoeps (West Germany) Model CMT26U radio-frequency capacitor microphone, with BZ02 battery supply unit. (Courtesy, International Electroacoustics Inc.)

dB (depending on the polar pattern used), into a 200-ohm load for an SPL of 10 dynes/cm². The signal-to-noise ratio and the distortion are independent of the load because of the bridge circuit; therefore, the microphone may be operated into load impedances ranging from 30 to 200 ohms. The manufacturer suggests that no output transformer be used; however, this will be determined by the mixer input circuits employed. The audio signal and a dc operating potential of 8.5 volts are carried over a two conductor cable; the battery volt-

age is fed across the center point of the output circuit and the cable shield. The center or neutral point is created by the two resistors across the output of the microphone bridge circuit, and the two resistors on the input side of the battery unit (Fig. 4-71C).

The advantage of supplying the operating voltage in this manner is that since the modulation voltage is not superimposed on the supply voltage, the crosstalk damping is around 100 dB, even when operating several microphones from the same supply source. The internal noise voltage when terminated in 1000 ohms ranges from 0.30 to 0.44 microvolt, depending on the polar pattern used. Hum pickup is negligible

because interference superimposed on the supply voltage does not directly reach the modulation. The phase of the output voltage may be reversed without modification to the power-supply source. A resistive network for supplying the operating voltage from an existing power supply is shown in Fig. 4-71D. Frequency response and polar patterns for three methods of operation are shown in Figs. 4-71E, F, and G.

A second microphone of the capacitor type, developed by Stephens, utilizes the advantages of the capacitor microphone in a circuit that does not require the use of a preamplifier at the capacitor head, as it differs in the manner in which the minute changes of capac-

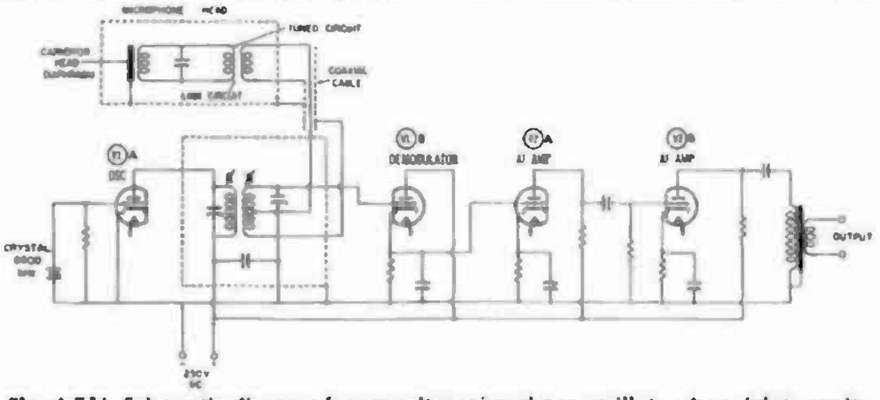

Fig. 4-71I. Schematic diagram for capacitor microphone oscillator-demodulator unit. (After Stephens.)

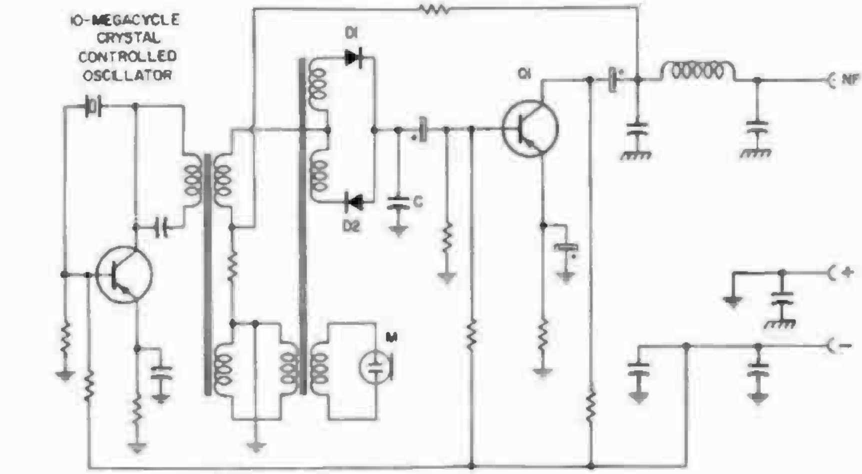

Fig. 4-71K. Basic circuitry for Sennheiser capacitor microphone Model 404 employing an rf oscillator.

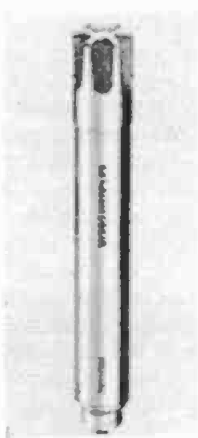

Fig. 4-71J. External appearance of Sennheiser Models MKH404 and MKH405 capacitor microphones having cardioid directional characteristics.

itance are used. No polarizing voltage is required, as in the conventional capacitance microphone. The head assembly, Fig. 4-71H, contains a *resonant* circuit link-coupled by a coaxial cable to a crystal-controlled oscillator. Tuning of the circuit to a frequency that is approximately that of the crystal oscillator is provided by the capacitance of the head (Fig. 4-71I). Sound waves at the diaphragm cause small changes in the head capacitance and shift the frequency of the oscillator either above or below the nominal operating frequency. A demodulator (detector) converts the rf changes into audio frequencies, which are amplified in the usual manner. Typical operating frequencies for the crystal are: 8.6 kHz and 8.725 kHz. The cable length between the capacitor head

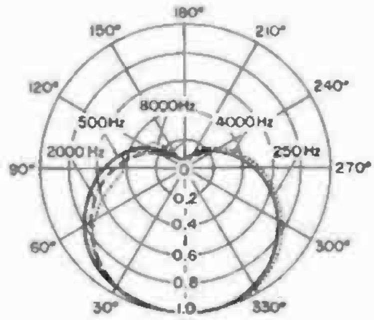

Fig. 4-17N. Field pattern for Sennheiser Model MKH405 capacitor microphone.

and the oscillator is quite critical, and is cut in lengths of 37.5 inches. The oscillator-modulator may be placed up to 400 feet from the capacitor head.

A capacitor microphone of somewhat different design, manufactured by Sennheiser of West Germany and also employing a crystal-controlled oscillator, is shown in Fig. 4-71J. In the conventional capacitor microphone (without oscillator) the input impedance of the preamplifier is on the order of 100 megohms; therefore, it is necessary to place the capacitor head and preamplifier in close proximity. In the Sennheiser microphone, the capacitive element (head) used with the rf circuitry is of lower impedance, since the effect of a small change in capacitance at rf frequencies is considerably greater than at audio frequencies. Instead of the capacitor head being subjected to a high dc polarizing potential, the head in this microphone is subjected to an rf voltage of only a few volts.

Since the preamplifier and crystal-controlled oscillator are of transistor design, they are assembled in an integral unit. An external power supply of 12 Vdc is required. The circuitry for a Model MKH404 microphone is shown in Fig. 4-71K, with the circuitry for a Model MKH405 shown in Fig. 4-71L.

Referring to Fig. 4-71K, the output voltage of the 10-MHz oscillator is periodically switched by diodes D1 and D2 to capacitor C. The switching phase is shifted 90 degrees from that of the oscillator by means of loose coupling, and aligning the resonance of the microphone circuit M under a no-sound condition. As a result, the voltage across capacitor C is zero. When a sound impinges on the diaphragm, the switching phase changes proportional to the sound pressure, and a corresponding audio voltage appears across capacitor C. The output of the switching diodes is di-

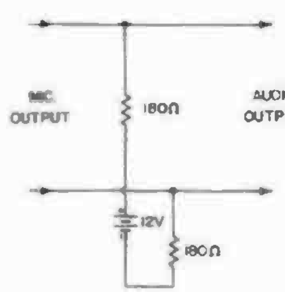

Fig. 4-71O. Duplexing the operating voltage for a microphone over an audio line.

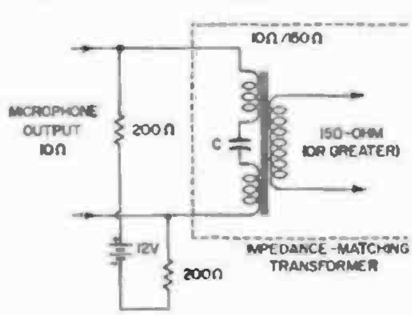

Fig. 4-71P. Impedance-matching transformer connected in the output of a microphone, with the operating voltage duplexed over the audio line.

rectly connected to the transistor-amplifier stage, whose gain is limited to 12 dB by the use of negative feedback.

To eliminate the effects of rf oscillator noise, the oscillator circuit is crystal controlled. Noise in an oscillatory circuit is inversely proportional to the "Q" of the circuit, and because of the high "Q" of the crystal and of its stability, compensating circuits are not required, resulting in extremely low internal noise. In Model MKH404 microphone, only one stage of amplification is employed. For model MKH405 and 805 two stages are used as shown in Fig. 4-71L.

The output stage is in reality an impedance-matching transformer. In the Model MKH404, the output is adjusted for 100-ohms, and for the MKH 405 and 805, 10 ohms. With proper precautions, they may be operated into a balanced, symmetrical, or unbalanced input circuit. For an output impedance of 100 ohms, the load impedance must be 2000 ohms or greater; and for the 10-ohm output, 150 ohms or greater. Using an output impedance of 10 ohms permits long cable runs without an appreciable loss of the high frequencies. Radio-frequency chokes are connected in the output circuit to prevent rf interference and also to prevent external rf fields from being induced into the microphone circuitry. Shown in Fig. 4-71M is the frequency response, with manufacturing tolerances shown by the dashed lines; the polar response is shown in Fig. 4-71N. Two types of power supplies are available, mercury battery and ac operated. The battery supply will provide 50 to 60 hours of operation on one set of batteries. The operating voltage (12 Vdc) is duplexed over the audio lines. This is accomplished by connecting the battery across the audio line through two series resistors of 180 ohms each (Fig. 4-71O). With impedance-matching transformers, the circuit shown in Fig. 4-71P is used. Here a capacitor (C) is connected in series with the *split primary* of the input transformer to prevent the flow of current through the windings. If the transformer does not have a split primary, a capacitor is connected in each side of the line.

The schematic diagram for an ac power supply appears in Fig. 4-71Q. This supply is capable of operating up to six microphones simultaneously. The voltages are well stabilized, using zener diodes for each microphone supply circuit. The output level for the Model MKH405 is minus 27.5 dB re: 1 mw/ 10 dynes/cm^2. Frequency response is 40 to 20,000 Hz; THD distortion 0.5 percent; EIA rating 121.5 dB. Mode of operation is pressure gradient, with a cardioid directional characteristic.

4.72 What is a wireless microphone? —It is a miniature microphone attached to a frequency-modulated radio transmitter and is worn on the body of the user. For motion picture and television use, the microphone and transmitter are concealed. Two systems are in use. One system uses a small transmitter worn on a coat lapel or mounted on the housing of a miniature frequency-modulated radio transmitter. The second system employs a hand-held or lavalier microphone housing a transistor radio transmitter (Fig. 4-72A); this is the system to be discussed. The antenna is wrapped around the body of the user and he becomes a part of the antenna system. Or, in the instance of the hand-held microphone, the antenna is attached to the microphone-transmitter or it may be built into a helmet. The transmitted signal is picked up by a remote receiver. The maximum transmitting distance is about one half mile, depending on the frequency used and the antenna system. As a rule, the distance between the transmitter and the receiver is kept to within 200 feet or less. When several microphones are required, such as might be used with several characters in a play, a separate receiver is required for each microphone, each receiver tuned to a different frequency. The transmitter may be tuned from 25 to 45 MHz, with a signal-to-noise ratio of 60 dB, or better, for a plus-minus 20-kHz modulation swing.

The receiver consists of 11 tubes, including radio-frequency amplifiers, limiters, automatic frequency control (afc), intermediate amplifiers, audio stages, and an adjustable squelch control for reducing background noise. The unit also contains a built-in 36-inch collapsible antenna, or it may be used with a 72-ohm remote transmission line and antenna. A tuning eye is provided for setting the receiver to the exact frequency of the transmitter. The sensitivity is 1.5 microvolts for 20-dB quieting. The audio frequency response is 20 to 20,000 Hz. The output has an impedance of 150 or 600 ohms designed to operate directly into a mixer console. A loudspeaker is also included for monitoring purposes. The schematic diagram for the receiver portion is shown in Fig. 4-72B.

The microphone with its transmitter is completely transistorized. Its schematic diagram appears in Fig. 4-72C, and consists of a dynamic microphone element, with a frequency range of 80 to 14,000 Hz. The transmitter has a swing of 20 kHz at normal voice levels, with a power output of 40 milliwatts to the final amplifier, depending on the frequency and the antenna system used. The battery is a 6.5-volt mercury type, with an expected life of 20 hours. The whip antenna, shown on the side of the microphone in Fig. 4-72A, is used for personal interviews or when walk-

ing around in a crowd, and may be extended to 23 inches. Frequencies for wireless microphone operation in the United States are under the jurisdiction of the Federal Communications Commission, and such devices are operated in the general business frequencies, 33.14, 35.02 and 42.98 megahertz, or 26.25 for radio and television relay operation. Permission must be obtained from the

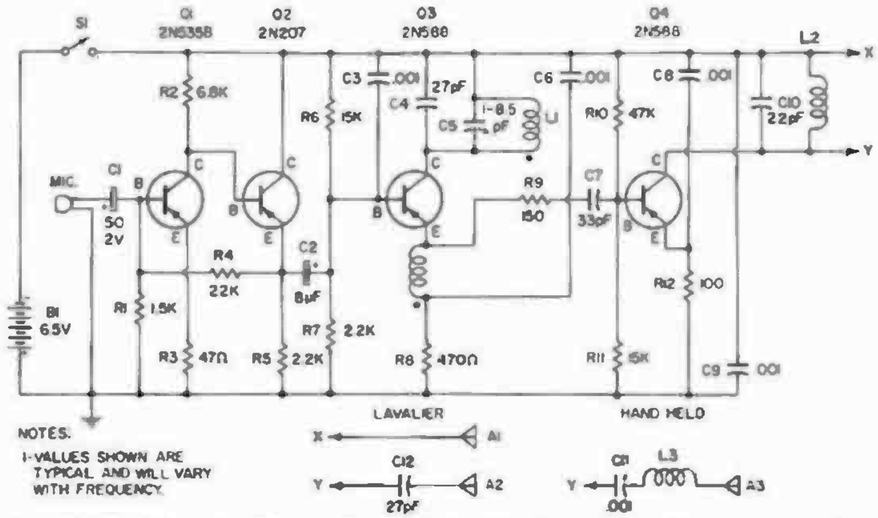

Fig. 4-72C. Schematic diagram for wireless microphone transmitter unit manufactured by Vega Electronics Corp.

FCC in advance, before any type of wireless microphone can be operated.

4.73 How far can a low-impedance microphone cable be run without a preamplifier?—Microphones with an output impedance ranging from 30 to 200 ohms can be run to a distance of 200 feet without seriously affecting the frequency response. It is a fairly safe rule to follow, that the lower the impedance of the line, the greater the distance it can be run. However, unless the cable is well shielded, the signal-to-noise ratio may be seriously affected. Also for such long runs, the cable must be kept clear of all ac lines and equipment. A good practice to follow when long runs are necessary is to insert a preamplifier in the cable run at about 100 feet. This preamplifier may be of transistor design with a gain of 40 to 60 dB adjustable in steps of 20 dB. (See Question 4.76.)

4.74 If an oscilloscope is connected to the output of a microphone, what is the relationship between the pressure wave and the image?—The vertical deflection will be proportional to the amplitude of the pressure wave at the diaphragm of the microphone.

4.75 What does the term open-circuit voltage mean?—It is the voltage measured with a high impedance vacuum-tube voltmeter at the output of an unterminated microphone. As a rule, preamplifiers designed to be used with microphones do not use a termination across the secondary of the input transformer. This method of operation increases the voltage at the control grid of the first tube in the preamplifier 6 dB or a voltage gain of 50 percent, which results in a substantial increase in the signal-to-noise ratio. Open-circuit operation is discussed in detail in Question 12.170.

4.76 What effect does the terminating impedance have on microphone characteristics? — Microphone specifications relative to their frequency-response characteristics and output level are based on an *open-circuit voltage* measurement. Such measurements are made using a high-impedance voltmeter, connected directly across the microphone output terminals (Fig. 4-76). However, in actual practice the microphone is fed into a preamplifier with an input transformer using an *unterminated* secondary. (See Question 12.170.)

If the microphone characteristic is measured using a load impedance approaching the microphone internal output impedance, the performance characteristics will differ from those specified for an unloaded measurement. A typical example of a *loaded* condition is operating the microphone into a low-

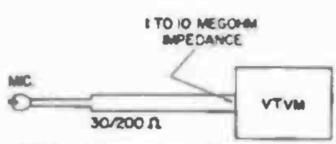

Fig. 4-76. Measuring the open-circuit voltage of a microphone.

level mixing circuit, a transistor preamplifier with a low input impedance, or into an input transformer with a terminated secondary. (See Question 9.2.)

If the microphone is terminated in a *resistive* load equal to its own impedance, only a drop in level will be experienced with no appreciable change in the characteristics. If the load varies with frequency, the overall response will be affected. This can easily occur if the interconnecting cables have an appreciable amount of capacitance such as might be encountered with a high-impedance microphone. The greater the cable capacitance per foot, the more the high frequencies will be attenuated. This is particulary true for microphones having an output impedance of 10,000 to 20,000 ohms. Generally about 18 to 20 feet is the maximum distance that can be run.

Mass-controlled microphones, such as the bidirectional and cardioid types, generally have an impedance curve that decreases sharply as the frequency is increased in the range of 100 to 2000 Hz. Connection of these microphones to a resistive load causes a change in both the output level and the frequency response, particulary at the low frequencies. For professional usage, microphones are fed into an open circuit preamplifier; thus, the problem of loading is eliminated. They are also operated at an impedance of 50 ohms, therefore cable lengths may be up to 600 feet with about a 1-dB loss at 10,000 Hz. (See Question 4.73) Operating a 50-ohm impedance into a 250-ohm input results in a 7-dB loss of output level, but no appreciable change in the frequency response. (See Question 4.98)

4.77 Describe a ribbon-velocity microphone with variable polar patterns.—A variable polar pattern microphone can sometimes be quite useful and convenient as it may be changed from a directional to a bidirectional or omnidirectional polar pattern by a simple adjustment. The microphone to be discussed is the RCA 77-DX MI-4045-F ribbon-velocity microphone (Fig. 4-77A). The general design of this microphone is similar to the unidirectional ribbon-velocity microphone discussed in Questions 4.59 and 4.65. As in the RCA MI-10001-C, the 77DX ribbon is divided into two sections, with the center grounded and the upper portion terminated in an acoustic impedance consisting of a small tube sealed at the back of the ribbon and connected with an acoustic labyrinth situated in the lower portion of the housing. An aperture in the back of the tube near the top is made variable by a rotating plate controlled from the exterior at the rear of the housing. Controlling the size of the aperture determines the types of polar pattern. When the aperture is completely open, the ribbon is not terminated by the acoustic labyrinth; therefore, both sides of the ribbon are exposed to the sound source. Under these conditions, the microphone operates as a ribbon-velocity microphone with a bidirectional polar pattern (Fig. 4-77B).

Closing the aperture to about half size, one half of the ribbon has both surfaces exposed to the sound pickup and therefore operates as a ribbon-velocity microphone; however, the other half of the ribbon is terminated in the acoustic labyrinth and operates as a pressure unit. Operating under these conditions, the voltages generated by the upper and lower sections of the ribbon, tend to reinforce each other for sounds arriving from the front, but tend to cancel each other for sounds arriving from the rear, resulting in a cardioid polar pattern (Fig. 4-77B). By closing the aperture completely, the two sections of the ribbon are terminated in the acoustic labyrinth and the polar

Fig. 4-77A. RCA Model 77DXMI-4045-F polydirectional microphone.

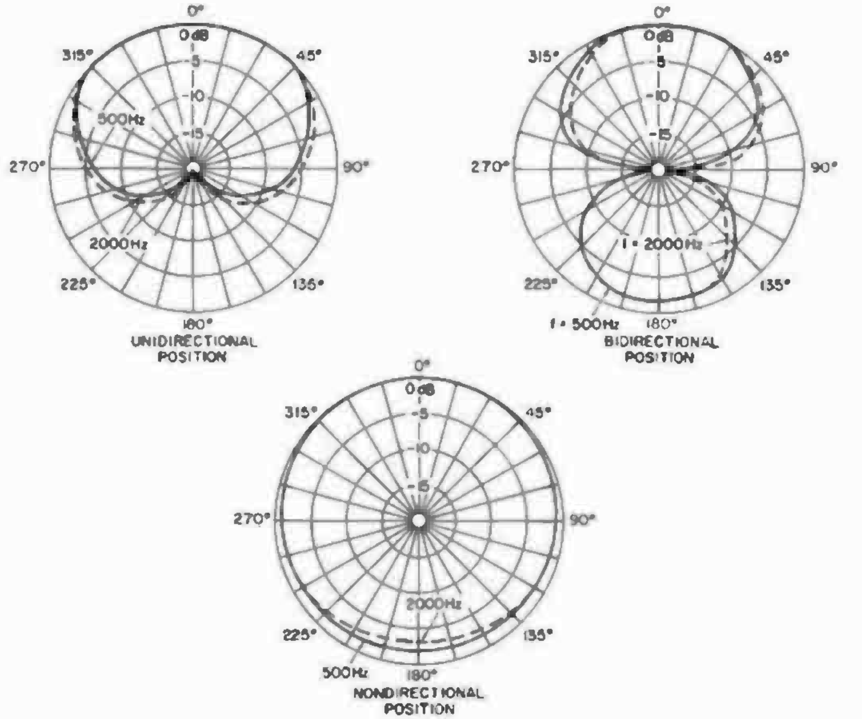

Fig. 4-77B. Polar patterns for RCA 77DXMI-4045-F polydirectional ribbon-velocity microphone.

pattern becomes omnidirectional (Fig. 4-77B). Because the aperture is variable, six polar patterns are possible. In the unidirectional position, the attenuation between front and rear is approximately 20 dB, or a ratio of 10:1.

The bottom of the housing contains an impedance-matching transformer, and a switch for selecting two types of low-frequency rolloff for voice, and a flat position for music. Position V1 is used for sound pickups within 1 foot of the microphone, aud V2 for distances greater than 1 foot (see Fig. 4-59H). Low-frequency attenuation is accomplished by connecting a reactor across the output of the microphone. The smaller the value of the reactor, the greater the attenuation will be.

The frequency response is shown in Fig. 4-77C. In the flat position the response is 30 to 20,000 Hz, within plus-minus 5 dB at the low and high ends, with output impedances of 30, 150 and 250 ohms. The output level ranges from 56 dBm (omnidirectional) to minus 50 dBm for the bidirectional position, for sound pressures of 10 dynes/cm². Hum level is minus 128 dB, referred to a field of 0.001 gauss. Microphones of this type, offering adjustable polar patterns are often termed polydirectional.

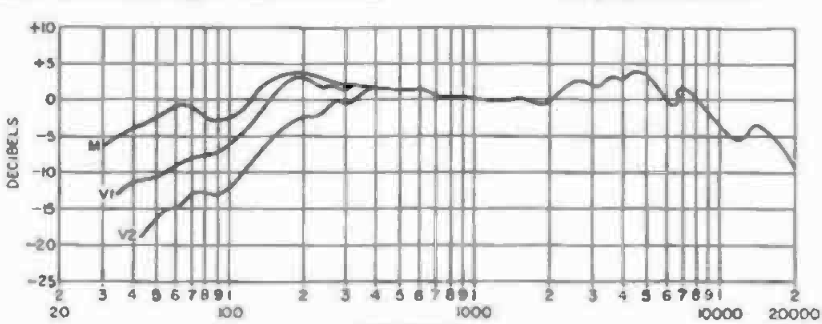

Fig. 4-77C. Frequency response for RCA 77DXMI-4045-F polydirectional microphone.

4.78 What is the impedance of a so-called high-impedance dynamic microphone?—The term high impedance is generally associated with crystal or ceramic microphones and will range from 100,000 ohms to 1 megohm. However, dynamic microphones rated high impedance are usually 40,000 ohms output impedance, although the moving-coil element may be on the order of 1.5 to 50 ohms. An output transformer of 40,000-ohms impedance with taps at 250, 150, and 50 ohms is included in the microphone housing.

4.79 What is a uniaxial microphone?—A unidirectional microphone in which the maximum response is in the principal cylindrical axis.

4.80 What is a cephloid microphone?—A mannikin head with microphones mounted in the head at the normal ear level to create a diffraction pattern and simulate human hearing. Such microphones are used in acoustical laboratories for binaural work.

4.81 What is a lavalier microphone?—A small dynamic microphone worn around the neck as a lavalier. A typical microphone of this type is the RCA BK-6B shown in Fig. 4-81A.

This microphone has been especially designed for correct speech balance when used informally in television broadcasting interviews and public address applications. The frequency response and directional qualities are engineered to complement human speech so that a correct frequency balance is maintained when the speaker is talking off mike.

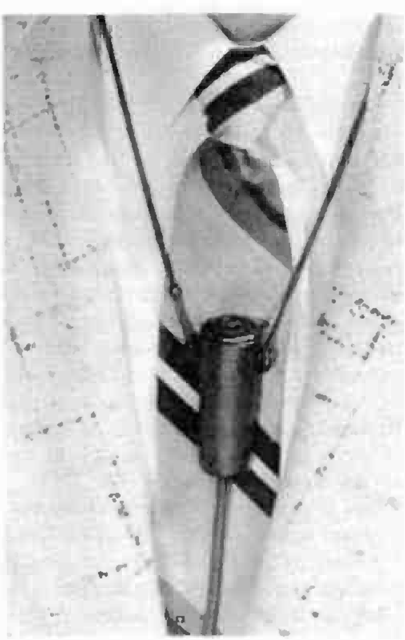

Fig. 4-81A. RCA BK-6B dynamic lavalier microphone, designed to be worn around the neck.

An internal resonator placed in front of the diaphragm reduces the high frequency emphasis while extending the upper frequency limit.

The output impedance may be set for 30, 150, or 250 ohms. The output level is minus 67 dB, for a pressure of 10 dynes/cm². The polar pattern is shown in Fig. 4-81B and the frequency response is shown in Fig. 4-81C.

4.82 What is a throat microphone?—One in which the diaphragm is actuated by being directly in contact with the external portions of the throat. Such microphones are widely used in aircraft for radio and internal intercommunication, or where the ambient noise level is high.

To obtain the maximum intelligibility, the high frequencies are attenuated. The unit may be of the moving coil or button design.

4.83 What is a sound-powered microphone?—A microphone constructed similarly to a dynamic microphone, with the exception that it generates considerably more output power and may be used without amplification over a con-

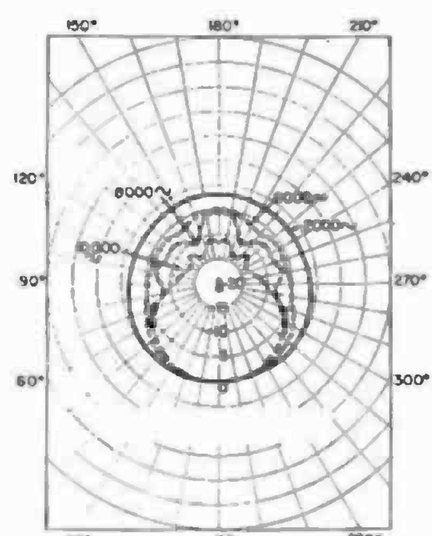

Fig. 4-81B. Polar pattern for RCA BK-6B lavalier microphone.

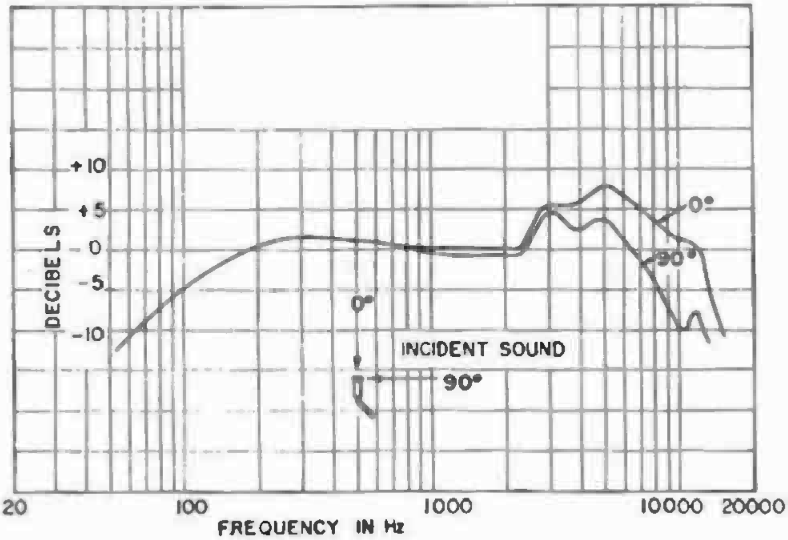

Fig. 4-81C. Frequency response of RCA 8K-68 lavalier microphone.

siderable distance. It is frequently used in intercommunication systems. The frequency response is limited to the voice frequency range.

4.84 How important is the phasing of microphones when making a multiple microphone pickup?—When two or more microphones are being used on the same channel and they are within ten feet of each other, they should be electrically in phase. If they are not, serious distortion may take place due to cancellation.

4.85 How are microphones phased? —The microphones to be phased are placed alongside each other and connected to their respective preamplifiers and mixer inputs. While someone speaks into the microphones, one mixer pot is adjusted for a normal output level as indicated on a VU meter. The setting is noted aud the pot closed. The same adjustment is made for the second microphone and the setting of that pot noted. Now both pots are opened to the above settings and, if the microphones are out of phase, the quality of reproduction will be distorted and there will be a distinct drop in level. Reversing the electrical connections to one microphone will bring them into phase. A second test is then made similar to the first. If the microphones are in phase, the output level will be greater and undistorted.

If the microphone is of the bidirectional type (figure-8) it may be reversed 180 degrees to bring it into phase, and later corrected electrically. If the microphones are of the directional type, only the output or cable connections can be reversed. After phasing a bidirectional microphone, the rear should be marked with a white stripe for future reference.

4.86 Describe the methods used for calibrating microphones.—Generally a microphone is calibrated using one or more of four calibrating instruments—the pistonphone, thermophone, electrostatic actuator, or a reciprocity calibrator.

Pistonphones are used for calibrating below 150 Hz, and consist of a pressure chamber, tightly sealed to the front of the microphone housing to be calibrated (Fig. 4-86A). The voltage developed at the output of the microphone for a given pressure at the diaphragm is noted. The pistonphone is then disconnected, and a voltage of the same frequency is connected in series with the microphone head and adjusted for the same output level as developed by the pistonphone. The response E_o/P is then the ratio of the second voltage to the applied pressure.

Two practical applications of the pistonphone are shown in Figs. 4-86G and H. Referring to Fig. 4-86G, the pistonphone consists of a sealed glass jar, with a mechanically driven piston in the base, which produces known sinusoidal fluctuations in air pressure. The actual pressure is calculated from the volume of the chamber, the dimensions of the

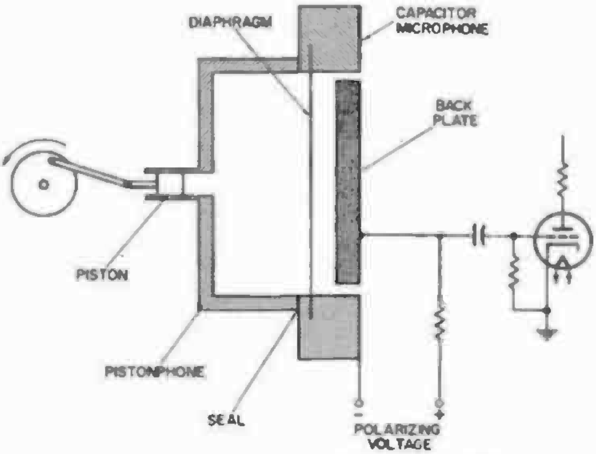

Fig. 4-86A. Pistonphone microphone calibrator.

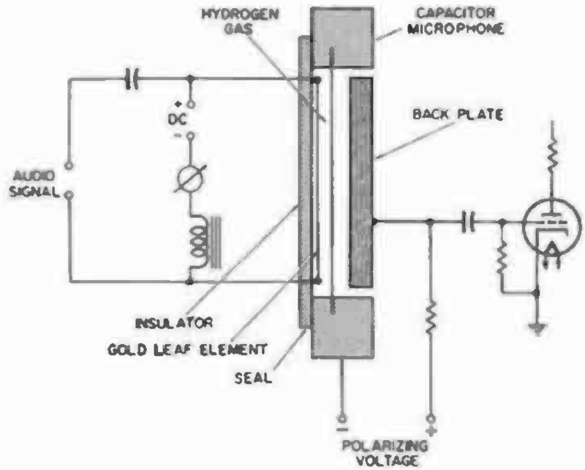

Fig. 4-86B. Thermophone microphone calibrator.

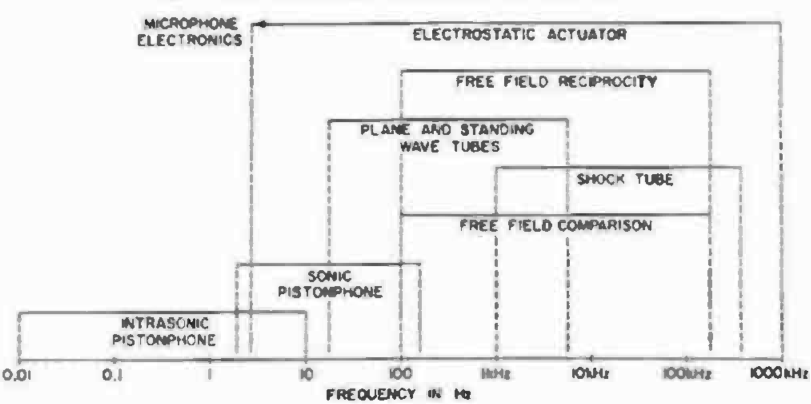

Fig. 4-86C. Frequency range of instruments used in the calibration of microphones.

piston, its stroke, and the constants of the air. With devices of this type, frequencies of a fraction of a cycle are possible, with sound-pressure levels of 94 to 115 dB, re: 0.0002 dyne/cm².

A second design appears in Fig. 4-86H, and is somewhat similar to a dynamic-loudspeaker mechanism. The small piston in the chamber at the left produces the pressure for the measurement. A calibrated eyepiece and a marker on the piston shaft permit the calibration of the piston movement. A capacitor microphone is shown under measurement, with its electronics and case mounted at the right end of the pressure chamber. Noise contributed by the electronics may be measured by replacing the microphone head with a low-leakage capacitor of the same value capacitance as the head, or the microphone may be placed in an acoustic chamber constructed of two lead cases, one inside the other, separated by acoustic absorbent. The noise level is then measured at the output, using a vacuum-tube voltmeter.

The thermophone, shown in Fig. 4-86B, is constructed of one or more very thin gold-leaf strips, supported on insulated blocks in front of the microphone diaphragm. A measured, steady direct current is passed through the gold-foil strips with the audio fre-

(Courtesy, LTV Research Center Western Division) quency signal superimposed on the dc. The cavity of the thermophone is filled with hydrogen gas to shift standing waves in the cavity beyond the range of measurement. Thus, the variation of pressure in the cavity occurs at the applied frequencies.

Microphones designed for use in space require frequency calibrating ranges from 0.01 to 1 MHz per second, with sound pressures up to 195 dB, re: 0.0002 dyne/cm², also at extremely high and low temperatures, with low static pressures equivalent to those found in high altitudes. The various methods used for microphone measurements and their frequency range is given in the tabulations in Fig. 4-86C. Both the reciprocity and pistonphone techniques provide a high degree of accuracy, the pistonphone being capable of measurements down to 0.01 Hz, with an upper limit of 15,000 Hz, using a closed coupler, and up to 100 kHz in a free field. Calibrations at high pressure levels are performed in standing and progressive wave tubes, the high-intensity pistonphone, and shock tube. However, the above instruments are difficult to apply to calibrations at environmental conditions similar to that experienced in the field. These difficulties have been overcome to a great extent by further development of the electrostatic actuator (Fig. 4-86D) which is used primarily for the calibration of capacitor microphones.

The electrostatic actuator was described by Olson in 1931, by Ballantine in 1932, and further developed by Brown and Dahlke. The actuator consists of a slotted perforated flat metal plate, which is insulated and placed parallel to the diaphragm of the microphone at a known distance. A direct-current voltage applied between the actuator plate and the diaphragm of the microphone to be calibrated generates an electrostatic force, simulating a sound pressure, at the surface of the diaphragm. The sound pressure thus generated is the function of the product of the applied voltage, the square of the effective spacing, the permittivity of the vacuum, and the dielectric constant of the gas between the plates. Since the influence of temperature and static pressure on the dielectric constant is considerably less thau the accuracy in determining the pressure, the simulated

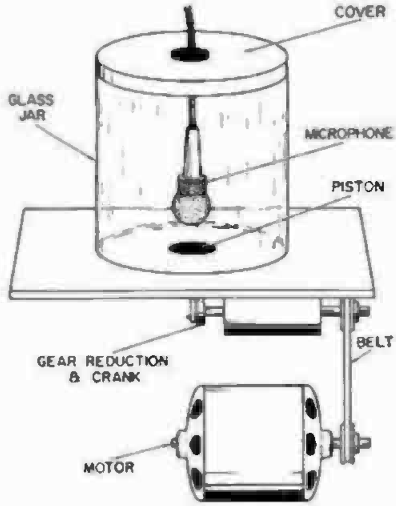

Fig. 4-86G. Pistonphone for calibrating microphones. A piston in the bottom of the glass jar is driven by crank and gear reduction, from the motor at the floor level. The microphone to be calibrated is suspended in the jar over the piston.

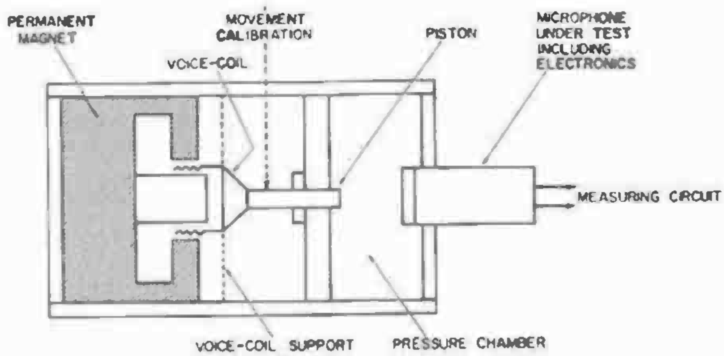

Fig. 4-86H. Pistonphone built along the lines of a dynamic loudspeaker. The piston is actuated by the movement of the voice coil, creating a sinusodial pressure in the chamber containing the head of the microphone (after Glover and Baumzweiger).

sound pressure is not affected by the environmental conditions. In addition, the sound pressure is not a function of the applied frequency.

The effect of the actuator plate and its geometry is shown in Fig. 4-86E. If the effective spacing of the slot D_e, which is not identical to the actual spacing, can be determined, the effective sound pressure can be expressed:

$$P_e = \frac{KE_o}{d^2} E_{oe}$$

where (D) is the effective spacing between plates, E_o permittivity of free-space and equals 8.85×10^{-12} farads/m, K the dielectric constant of the insulator between the plates, and E the dc potential between the plates. For a complete mathematical treatment pertaining to the actuator, the reader is referred to the reference.

Since the simulated sound pressure is produced by an electrostatic force, the signal driving the system will determine the low-frequency response of the electrostatically driven diaphragm. If the driving system cutoff frequency is low enough, the output voltage of the microphone system will be the response of the microphone electronics. To obtain the low-frequency response, the front to back vent of the microphone must be present in the sound field. The electrostatic actuator does not fulfill this requirement.

The schematic diagram for the actuator driving system is shown in Fig. 4-86F. The maximum sound pressure level (SPL) for 5-mil spacing of the actuator and the microphone diaphragm, and a 20-percent safety factor in breakdown voltage is 127 dB. For 2-mil spacing, the SPL rises to 134 dB. However, for this spacing, some difficulty may be experienced in keeping the actuator and diaphragm parallel. To reduce harmonic distortion below 2.5 percent, the ratio of the dc polarizing voltage to the ac signal voltage must be greater than 10:1; as 150 volts of signal is a reasonable value, the dc voltage will be on the order of 1500 volts. Frequency measurements, using this device, are possible to within plus or minus 1 dB. Microphone calibration using the reciprocity method is discussed in Section 23.

Considerable work has also been done in the testing of microphones, termed real voice testing. In this test, a person speaking in a normal tone of voice replaces the usual sound pressure generating device. As the speaker talks, a frequency analysis is made and the average output level established. Thus, the average output for a number of speakers is the real voice calibration. The test equipment consists of the microphone to be tested, preamplifier, and a magnetic tape recorder. Portions of the recording are made into a loop, and the output fed to an octave-band analyzer and graphic level recorder. The result of this test is the average power output from the microphone. It has been found for some types of research, the real voice test is more satisfactory than the usual pressure calibration.

4.87 Describe how the linearity of a capacity microphone is determined at high intensities.—It is tested by measuring its linear response to a step function generated by the use of a shock tube at pressure levels equivalent to 5 pounds per square inch. The linearity of an Altec-Lansing Model 21-BR-200 high-intensity microphone is shown in Fig. 4-87A, for SPL of 140 to 180 dB, re: 0.0002 dyne/cm² at a frequency of 400 Hz. To provide a primary calibration, the sensitivity of a group of eight microphones was measured, using a pistonphone at an SPL of 124 dB at frequencies up to 400 Hz. Sound pressures are then generated in a standing-wave tube to provide nearly undistorted sinusoidal pressures at extremely high levels.

Essentially, a standing-wave tube consists of two cylindrical tubes having lengths which are nonharmonically related. The tube is driven by an electrodynamic driver, which produces a somewhat distorted signal at the amplitudes necessary to generate sound pressures at the desired levels. This distortion is suppressed by the design of the standing wave tube, which acts similar to an acoustic bandpass filter. The standing-wave tube measurements are performed at a single frequency associated with the tube resonance. To verify the microphone linearity at the higher frequencies, shock-tube techniques are employed.

A microphone is placed at the end of the shock tube. A shock is generated by bursting a diaphragm which isolates the drive section of the tube. The mi-

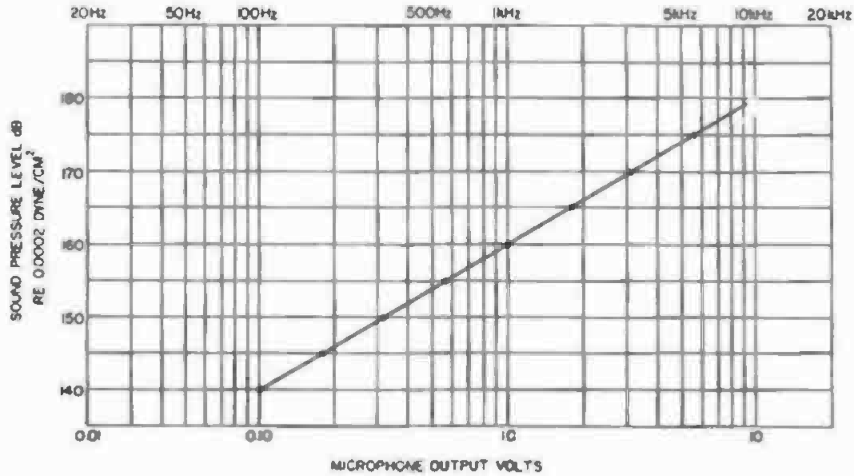

Fig. 4-87A. Standing-wave tube linearity calibration of Altec-Lansing capacitor microphone Model 21-BR-200. Sensitivity −86 dB re: 1 volt/dyne/cm².

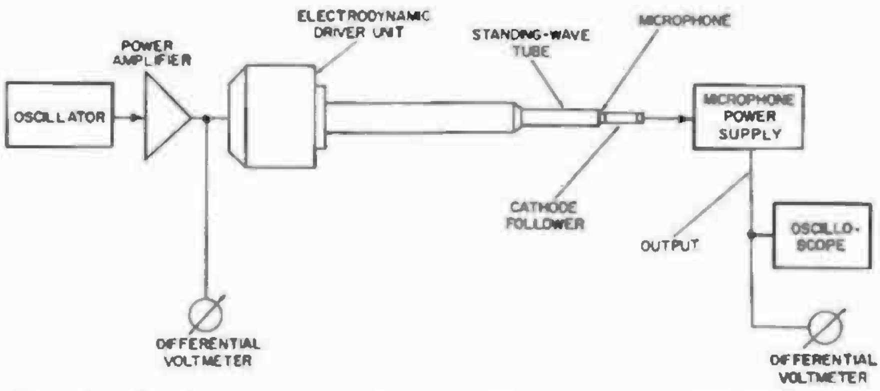

Fig. 4-87B. Standing-wave tube and its associated equipment used in the linearity measurement of microphones. (Courtesy, LTV Research Center Western Division)

crophone experiences a sudden rise in pressure associated with the reflection of the shock wave at the end of the driven section of the tube. The rise-time, overshoot, and decay time of this response exhibit the linear characteristics of a simple system transient response. The system resonance and damping constant are established from this transient response to yield the steady-state response characteristics. The basic test setup for using a standing-wave tube is shown in Fig. 4-87B. A cross-sectional view of a high intensity microphone head is given in Fig. 4-115A. Details for the use of standing-wave and shock-tube devices are given in the reference.

4.88 What does the term "gunning a microphone" mean?—To point the microphone at the source of sound. If the microphone is suspended from a boom on a turret head, it is turned towards the actors as they speak, to secure a uniform sound quality. As the microphone is generally moved quite rapidly, it is referred to as "gunning."

4.89 What happens when a ribbon-velocity microphone is moved rapidly through the air?—A low-frequency flutter is generated due to the passage of air between the ribbon and the pole pieces. It is not practical to use standard ribbon microphones on a boom and attempt to gun them. Ribbon-velocity type microphones used for motion pictures and television are especially designed to be used on a boom and may be gunned without producing noise.

4.90 Describe a microphone wind screen, its construction, and effectiveness.—A wind screen is a device placed over the exterior of a microphone for the purpose of reducing the effects of

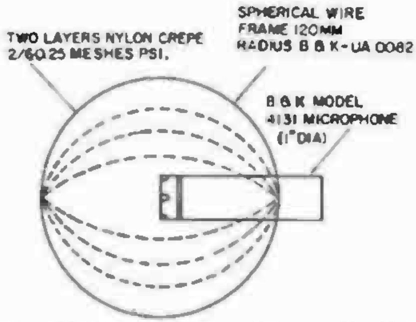

Fig. 4-90A. Typical silk-covered wind screen and microphone. (Courtesy, B and K Technical Review.)

wind noise when recording out of doors, or when panning or gunning a microphone. The screen consists of a wire frame covered with silk or a special type foam-rubber composition. Microphones designed for television and motion picture recording are generally constructed with the wind screen as an integral part of the microphone. (Wind screens are also referred to as wind gags.)

With a properly designed wind screen, a reduction of 20 to 30 dB in wind noise can be expected, depending on the sound pressure level at the time, wind velocity, and the frequency of the sound pickup. Wind screens may be used with any type microphone and they vary in their size and shape. Two types of wind screens employing a special type foam-rubber manufactured by Electro-Voice, and marketed under the trade name *Acoustifoam* are shown in Figs. 4-39A and 4-97E. This material has no effect on the high frequency response of the microphone because of its porous nature. *Standard styrofoam is not satisfactory for wind screen construction because of its homogenous nature.*

A cross-sectional view of a typical wind screen employing a wire frame covered with nylon crepe for mounting on a one inch diameter microphone is shown in Fig. 4-90A. The effectiveness of this screen as measured by Dr. V. Brüel of Brüel and Kjaer is given in Figs 4-90B, C, D, and E. When recording dialogue using a wind screen, its effectiviness is increased if dialogue equalization is used as discussed in Questions 4.114, 6.122, and 18.81.

4.91 What is a rain screen and how is it constructed?—During the filming of rain and snow scenes, a protective covering called a rain screen is placed over the microphone, as shown in Fig. 4-91, to protect the microphone and reduce the sound of the raindrops. The screen consists of an inverted shell approximately 18 inches in diameter. The exterior is covered with hair felt and metal fly screen, to break the raindrops into fine particles. The interior is cov-

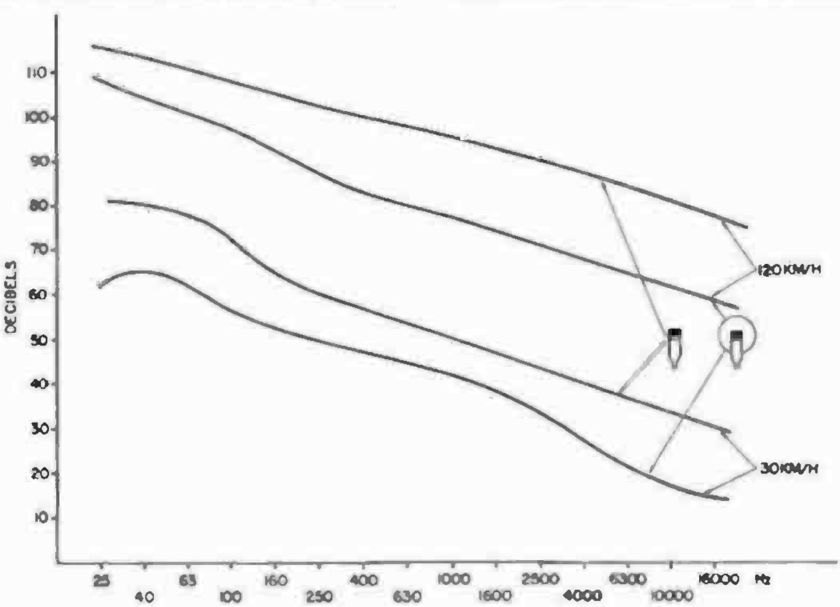

Fig. 4-90B. Wind noise as a function of frequency, measured in ⅓ octaves, but with the wind direction parallel to the membrane. (Courtesy, B and K Technical Review.)

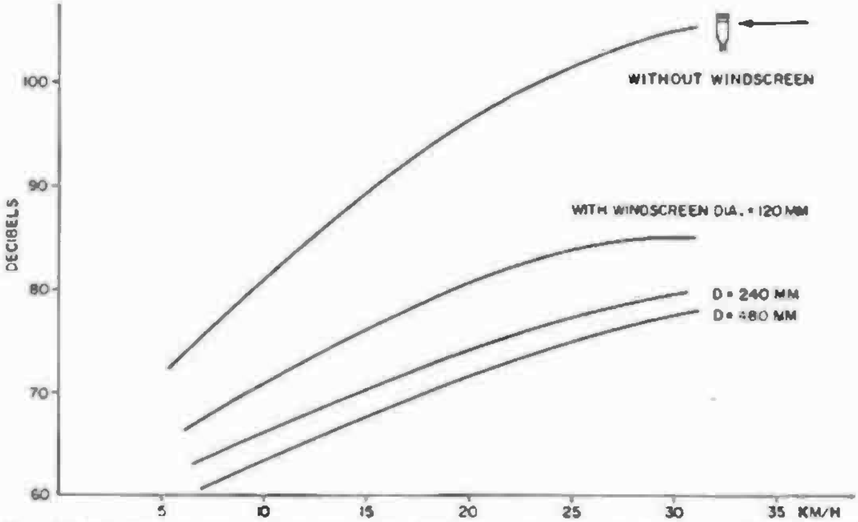

Fig. 4-90C. Wind noise measured with different sizes of windscreens. (Courtesy, B and K Technical Review)

ered with oilcloth and a layer of fly screen. The microphone is suspended inside the screen on a flexible support.

4.92 What type of microphone is recommended for dialogue recording?— It is the practice in the professional field to use either dynamic, capacitor, or ribbon-velocity microphones having *directional characteristics*. This is an absolute necessity to reduce unwanted noise pickup at the sides and rear of the pickup area. Bidirectional microphones should *not* be used, if the microphone is to be suspended from a boom. It is common practice in the broadcast field to mount bidirectional microphones on a floor stand, placing one person on each side of the microphone. Dialogue equalization should always be used for voice pickup, or the microphone should be connected with the internal *voice-filter* in the circuit. Dialogue equalization is discussed in Questions 4.114, 6.122, and 18.81.

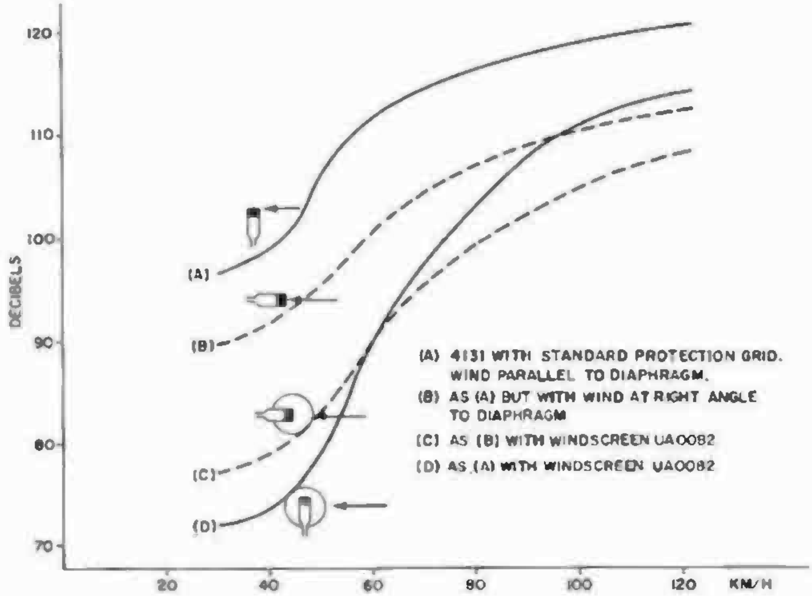

Fig. 4-90D. Wind noise as a function of wind speed in the range 20 Hz to 20kHz. (Courtesy, B and K Technical Review)

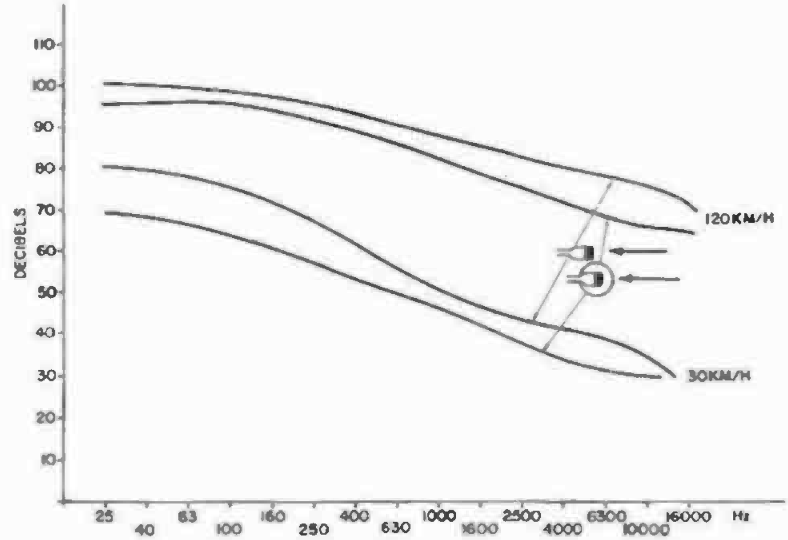

Fig. 4-90E. Wind noise as a function of frequency, measured in ⅓ octaves, with the wind direction at right angles to the membrane. (Courtesy, B and K Technical Review)

4.93 What types of microphones are recommended for music recording?—Capacitor, ribbon-velocity, and dynamic types. Similar types of microphones employing directional characteristics are preferred to aid in the separation of various sections of the orchestra. For stereophonic recording, the dual-type microphone similar to those discussed in Question 4.48 is used.

4.94 How close may two microphones be placed when feeding the same recording channel?—As close as their physical dimensions will permit, provided they are in phase electrically with each other. If they are not in phase, the output will be distorted and show a decided loss in output level. (See Questions 4.84 and 4.85.)

4.95 What is the standard pin count for microphone plugs? — It is standard practice to employ a recessed male plug on the microphone. Microphone cables are then made up using a female plug on one end and a male plng on the other. The pin count may be either of the two that are shown in Fig. 4-95. The pin count should be determined before attempting to put the microphone in service. *Under no circumstances is a volt-ohmmeter or buzzer ever to be applied to the output connections of a microphone.* To do so will severely damage the internal strncture. (See Question 24.100.)

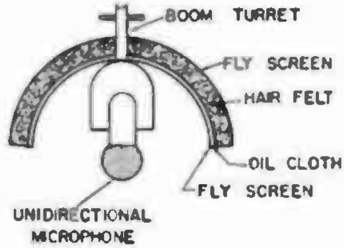

Fig. 4-91. A microphone rain screen.

Fig. 4-95. Pin count used on microphone cables.

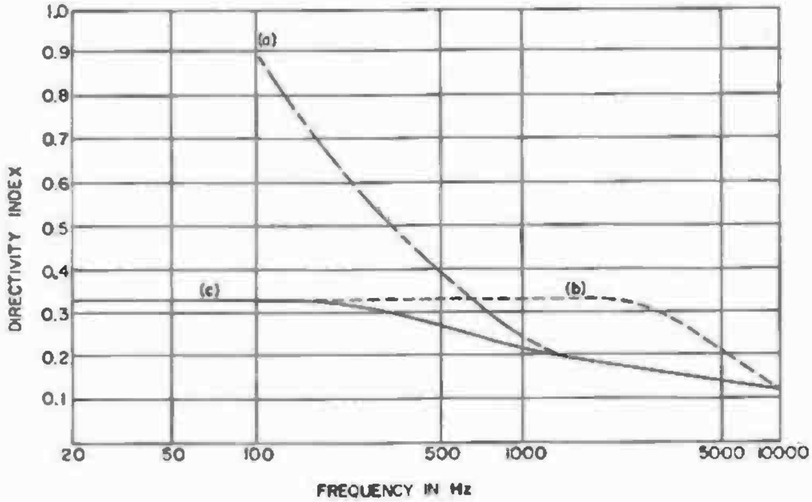

Fig. 4-97A. Directivity index for: (a) 11-inch line microphone, (b) cardioid microphone, (c) Electro-Voice Model 642 Cardiline dynamic microphone.

4.96 How may the signal-to-noise ratio be increased on a long microphone cable run?—See Question 4.73.

4.97 Describe the basic principles of a cardioid in-line directional microphone.—Both television and motion picture production have suffered greatly from the fact that to pick up good sound, the microphone must be reasonably close to the person speaking. On a motion picture set, this causes difficulties for both the camera man and the sound man. Also, getting in close restricts the movement of the microphone boom and is often the cause of poor pickup and excessive camera noise. These problems have been overcome to a great extent by the development and introduction of the cardioid in-line directional microphone, described by Olson in 1938.

Two of the most important characteristics of any microphone are its sensitivity and directional qualities. Assuming a constant sound pressure source, increasing the distance of the microphone from the source requires an increase in the gain of the amplifying system after the microphone. This is accompanied with a decrease in signal-to-noise ratio and an increase in environmental noises, such as reverberation and background noise, to where the indirect sound may equal the direct sound. The pickup then deteriorates to where it is unusable. Distance limitations can be overcome by increasing

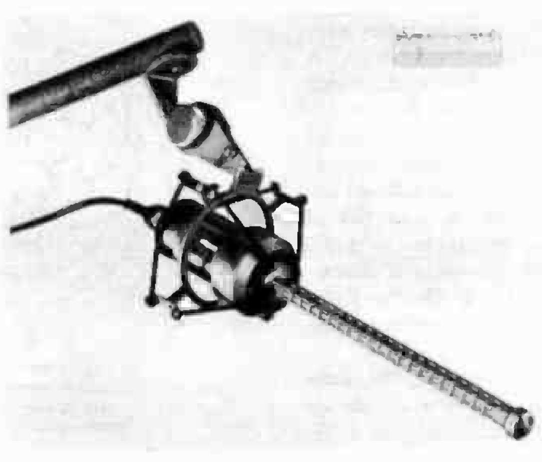

Fig. 4-97B. Electro-Voice Model 642 Cardiline (in-line) directional microphone, with boom hanger.

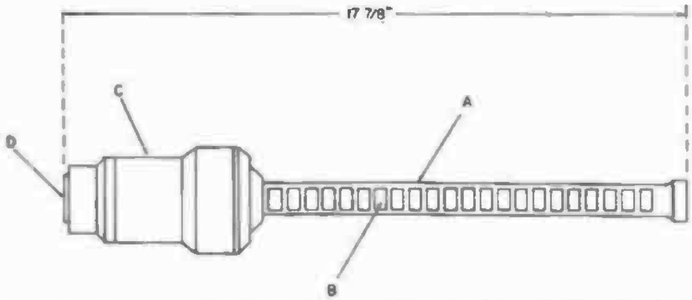

Fig. 4-97C. Basic components of the Electro-Voice Model 642 Cardiline directional microphone.

the sensitivity of the microphone, and the effect of reverberation can be lessened by increasing the directivity of the pattern. The in-line microphone has these two desirable qualities.

Over the years, the most commonly used microphone for boom operation and the recording of dialogue has been a gradient microphone with a cardioid directional polar pattern, as shown in Fig. 4-7, (c) and (d). In addition to the polar plot, the directional characteristics of a microphone may be described by a ratio termed directivity index. Directivity index is a ratio of output voltage from a microphone in a sound field that arrives at the microphone from all directions, to the output voltage of an omnidirectional microphone (with equal axial sensitivity) in the same sound field. The directivity index is a measure of nonaxial response; the lower the directivity index the sharper the polar response.

For microphones of the bidirectional and cardioid type, the index is 3:1; because of baffle effects (see Question 4.52), the polar response becomes narrower at the higher frequencies. A graphical plot of the directivity index versus frequency response for an 11-inch cardioid line microphone, and for a 1½-inch dynamic gradient microphone with a cardioid polar pattern are shown by the curves (a) and (b) of Fig. 4-97A. Curve (c) is for a Model 642 cardioid in-line directional microphone, manufactured by Electro-Voice under the trade name *Cardiline*, pictured in Fig. 4-97B.

The basic components of the construction of this microphone are shown in Fig. 4-97C. Line-tube (A) has a ⅛-inch slot milled its entire length and a group of ports which act as a linear tapering acoustic resistance; they are equally sensitive to equal sound pressures, and will cause equal voltages to be generated at the output of the dynamic transducer unit (C). Since the ports are acoustically connected to the transducer unit by the common tube, acoustic delays are introduced ahead of the transducer element. When placed in a plane-wave sound field, this equally sensitive line with variable delay produces wave interference in the common cavity at the front of the transducer unit. The magnitude of this interference will depend on the angle between the plane wave and the axis of the tube. The directivity of a line microphone is a function of frequency; the lower the frequency, the broader the polar pattern (Fig. 4-97D). Sensitivity is achieved by a rather heavy magnetic structure consisting of an Indox V and Armco magnetic iron, approximately 2½ inches in diameter. Dimensions of this size can be used; because of the in-line tube no baffle effects occur, the directivity being controlled by the

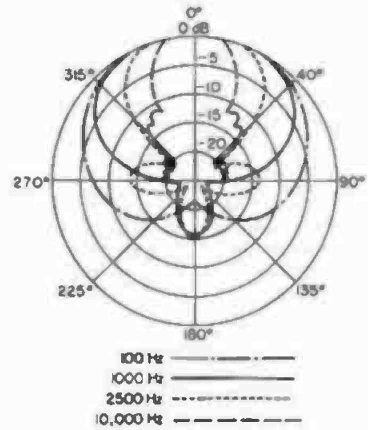

Fig. 4-97D. Polar response pattern for Electro-Voice Model 642 Cardiline directional in-line microphone.

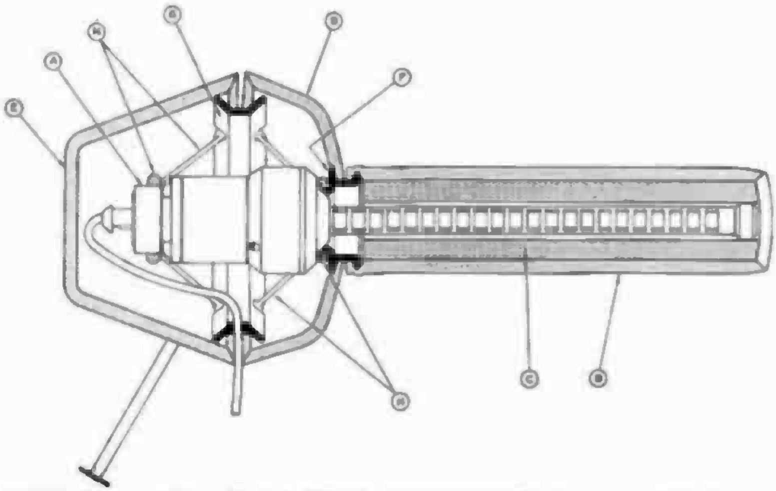

Fig. 4-97E. Electro-Voice Model 642 Cardiline microphone mounted in its support hanger and Acoustifoam wind screen.

openings in the tube structure. The diaphragm of the dynamic unit is 1¼ inches in diameter with a ¾-inch voice coil.

The drawing in Fig. 4-97E shows the microphone with its *Acoustifoam* wind screen attached. The microphone is supported at (A) by two rubber rings and arms (H) in a metal ring (G). A second ring (F) seals the front and rear wind screens (B) and (D). The third wind screen (E) encloses the rear of the microphone assembly. Experience indicates the rear wind screen must be in place to achieve the maximum effect of the wind screen assembly. The *Acoustifoam* wind screen has no effect on either the frequency response or the polar pattern. Since the screen is quite porous, air may be blown through quite easily. Dirty screens may be washed in clear water.

The frequency response is shown in Fig. 4-97F. Three positions are available for adjusting the low-end frequency response; flat, minus 5 dB, and minus 10 dB at 100 Hz, with reference to 1000 Hz. The output level is minus 48 dB re: 1 milliwatt/10 dynes/cm². Hum level is minus 120 dB re: 0.001 gauss. The directivity index is 6:1 with an included angle of pickup of 80 degrees. The output impedance may be adjusted for 50, 150 or 250 ohms. Because of the directional characteristics and sensitivity, this microphone may be operated from 2 to 4 feet farther from the sound source than the conventional microphone.

4.98 What is the effect of a long microphone cable on frequencies above 1000 Hz?—The high frequencies will be attenuated. Assume a microphone with an output impedance of 20,000 ohms is

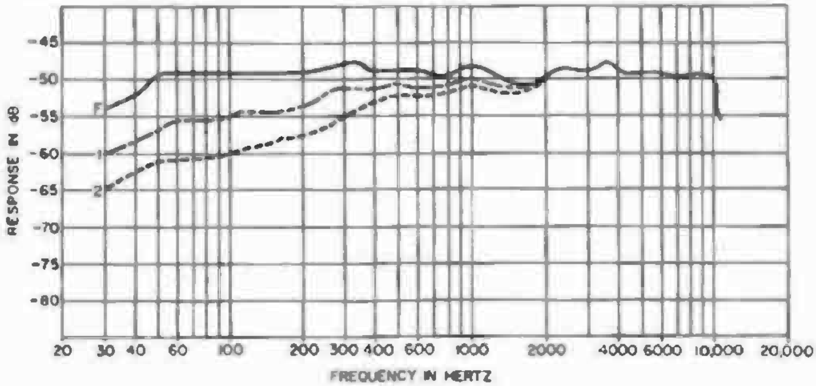

Fig. 4-97F. Frequency response for Electro-Voice Model 642 Cardiline directional in-line microphone.

connected to a line 30 feet long. The loss at 10,000 Hz compared to 1000 Hz is approximately 3 dB. Increasing the line to 100 feet will increase the loss at 10,000 Hz to 16 dB. Decreasing the impedance to 250 ohms or less, the loss at 10,000 Hz is negligible. For long runs an impedance of 50 to 150 ohms maximum is recommended.

4.99 How can microphone cables on a stage be prevented from picking up ac hum?—The microphone cables should be kept as far away as possible from ac circuits. If it is necessary to cross an ac line, do so at right angles, not parallel to it, or support the microphone cable a few feet above the cables carrying the alternating current. Microphone cables should be kept at least 6 feet from arc lights and similar equipment. Arc lights will also create mechanical noise due to the feed mechanism. Therefore, it is desirable that unidirectional microphones be used. The treatment of arc lamp noise and generator ripple is discussed in Question 25.117.

4.100 What is a sound concentrator?—A wooden parabolic reflector used with a microphone to obtain a highly directive pickup response. The microphone is mounted in the center of the reflector, as shown in Fig. 4-100A, forward of the dish center. The microphone is focused by moving it in or out of the reflector for maximum pickup. This type concentrator is often used to pick up a horse race or a group of people in a crowd.

The greatest gain in sound pressure is obtained when the reflector is *large* compared to the wavelength of the incident sound. With the microphone in focus, the gain is the greatest at the midfrequency range. The loss of high frequencies may be improved somewhat by defocusing the microphone a slight amount, which also tends to broaden the sharp directional characteristics at the higher frequencies. A bowl 3 feet in diameter is practically nondirectional below 200 Hz, but very sharp at 8000

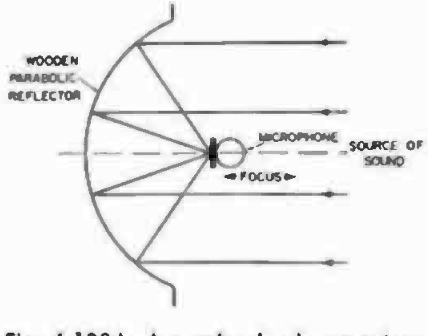

Fig. 4-100A. A wooden bowl concentrator for directional microphone pickup.

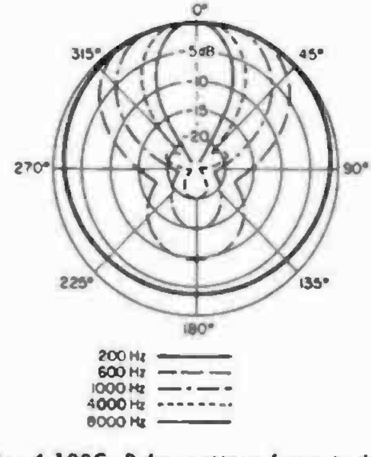

Fig. 4-100C. Polar pattern for a typical parabolic wooden bowl concentrator.

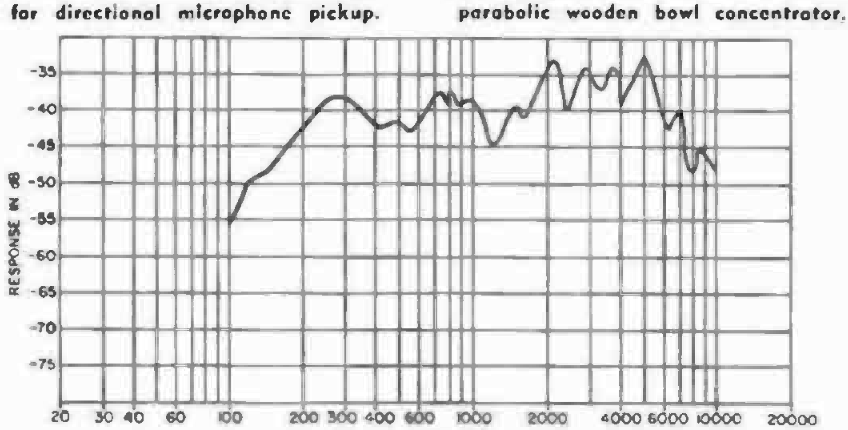

Fig. 4-100B. Frequency response of microphone and parabolic wooden concentrator.

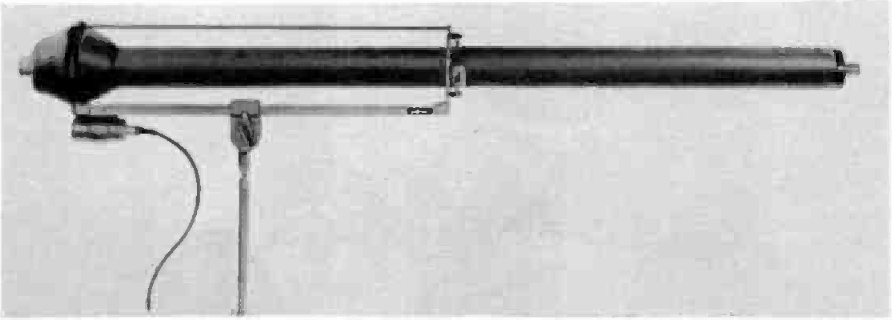

Fig. 4-101A. Electro-Voice Model 643 long range pickup, highly directional Cardiline dynamic microphone, with Acoustifoam wind screen.

Hz. For a diameter of 3 feet, the gain over the microphone without the bowl is about 10 dB, and for a 6-foot diameter, approximately 16 dB. The frequency response for a typical wooden concentrator bowl is shown in Fig. 4-100B, and its polar pattern in Fig. 4-100C.

4.101 Describe a highly directional microphone suitable for long range pickup.—In Question 4.97 the basic principles of an in-line type microphone and a commercial model with such characteristics were discussed. This question will deal with a commercial model of a super in-line microphone used for picking up a group of persons in a crowd from the roof of a nearby building, following a horse around a race track, picking up a band in a parade, and other hard-to-get distant pickups.

The Electro-Voice Model 642 microphone discussed previously has a directivity index ratio of 6:1 with an included pickup angle of 80 degrees. The microphone to be discussed here is the Electro-Voice Model 643 (Fig. 4-101A) which has an included pickup angle of 40 degrees, with a 30:1 directivity index ratio. The basic design is the same as that for the Model 642, except for its much sharper angle of pickup, as it has a longer in-line tube with a greater number of in-line ports.

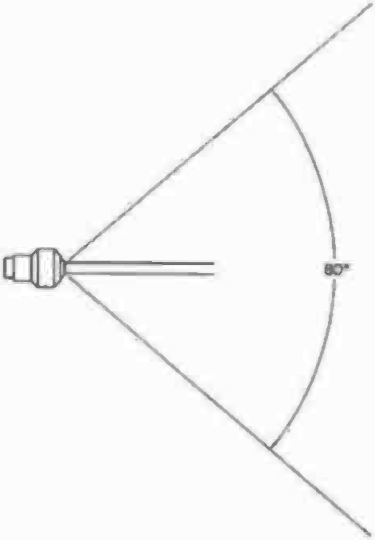

Fig. 4-101C. The included angles of an in-line microphone.

For a better understanding of Model 643, the included angles of pickup for both models, 642 and 643, are compared with that of an omnidirectional microphone having an included angle of pickup of 300 degrees, in Figs. 4-101B, 4-101C and 4-101D. The cone of pickup

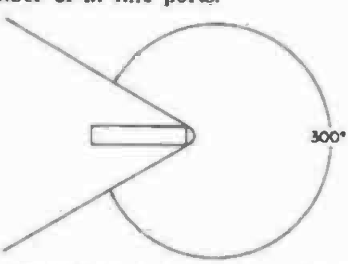

Fig. 4-101B. Included angles of omnidirectional microphone.

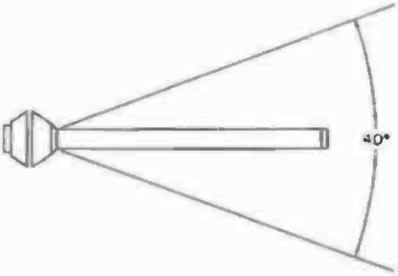

Fig. 4-101D. Included angles of super in-line microphone.

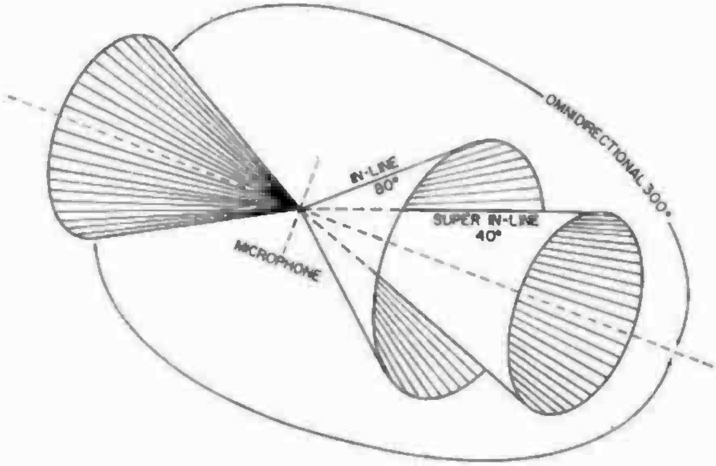

Fig. 4-101E. Included angles in the form of cones showing the range of pickup for an omnidirectional, in line, and super in-line microphone.

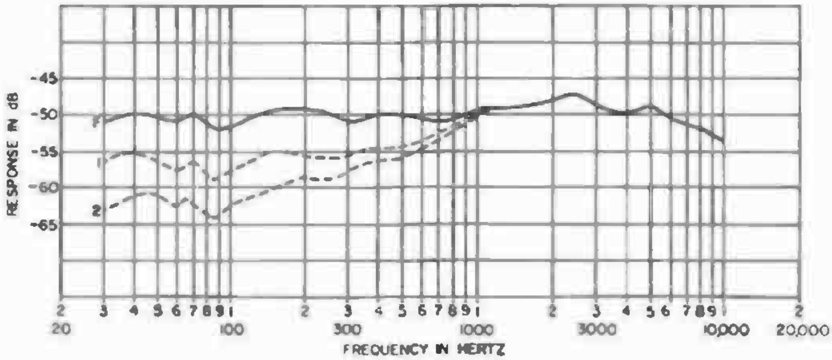

Fig. 4-101G. Frequency response for Electro-Voice Model 643 Cardiline super-directional microphone.

on axis for these microphones is shown in Fig. 4-101E.

The characteristics shown are the ideal and will not always be obtained under practical operating conditions, because of reflections from nearby walls or other objects on axis. It might be mentioned, at the present time there is no known microphone that will exclude completely all sounds originating at the sides or back. The characteristics for the Model 643 provide a cardioid polar pattern up to 100 Hz, and then a highly directional one, as the polar plot of Fig. 4-101F indicates.

The base of the microphone includes an integral two-position, low-frequency rolloff, and a high-pass filter (Figs. 4-101G and 4-101H.) The high-pass filter suppresses room reverberation, while maintaining the presence for dialogue. For comparison with the Model 642 microphone, the overall mechanical dimensions for the Model 643 are given in Fig. 4-101I. Except for the high-pass filter and the slightly different frequency response, the transducer unit, wind screen, output impedances, and sensitivity are similar to the Model 642. This microphone has been used quite successfully by both the television and motion picture industry.

Pictured in Fig. 4-101J is another in-line type microphone with extremely

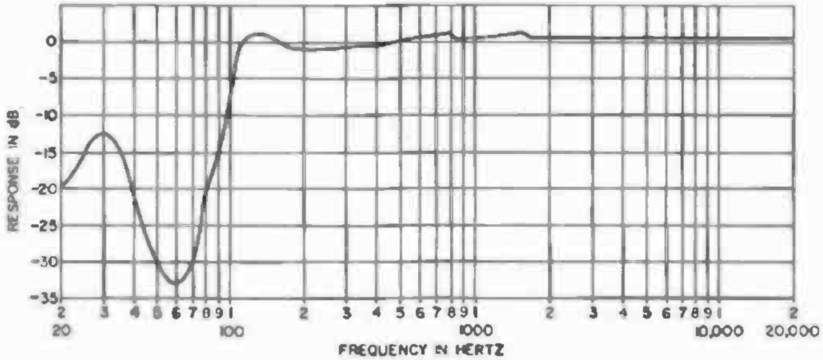

Fig. 4-101H. Frequency response of internal 100-Hz high-pass filter.

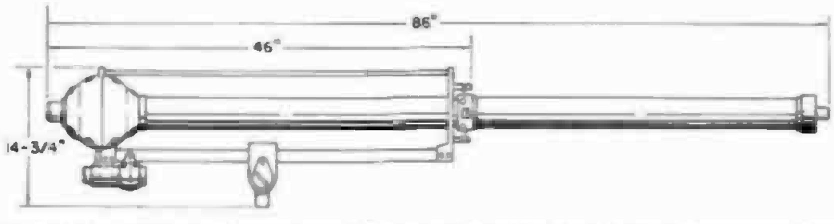

Fig. 4-101I. Cross-sectional view of Electro-Voice Model 643 Cardiline super-directional microphone, which is in reality a 7-foot version of the Model 642.

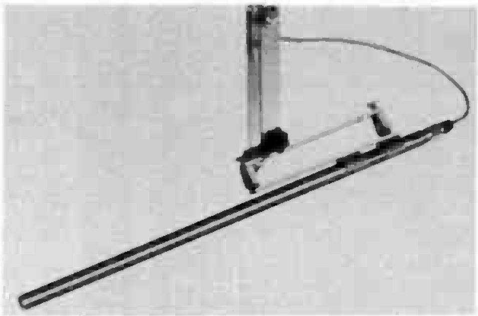

Fig. 4-101J. Sennheiser Electronic, Model MKH-805 capacitor in-line long-range pickup microphone.

narrow pickup characteristics, manufactured by Sennheiser Electronic of West Germany. This microphone uses a radio-frequency oscillator, and a two-stage transistor amplifier mounted in the end of the assembly. The basic principles of operation are discussed in Question 4.71. Insofar as the in-line tube design is concerned, it is quite similar to that described in Question 4.97.

The internal output impedance is 10 ohms and is designed to operate into a load impedance of 150 ohms. Power for the preamplifier is duplexed over the audio lines. Power requirements are 10 volts at 5 milliamperes. Frequency response is 50 to 20,000 Hz. The output level is minus 21.5 dB re: 1 mw/1 dyne/cm², with an EIA rating of minus 115 dB. This microphone like the one previously described, is suitable for long range pickup. (See Question 4.104.)

4.102 What precautions should be taken when using the microphone discussed in Question 4.101?—This particular microphone has an included angle of 40 degrees on axis and appears as a cone, as shown in Fig. 4-101E, which is the starting point for cancellation, but it should not be interpreted that no sound will be picked outside this cone. As the microphone is rotated from an on-axis position to a 180-degree off-axis position, there will be a progressive drop in level. Sounds originating at angles of 90 to 180 degrees off-axis will cancel by 20 dB or more, as indicated by the polar plot of 4-101F. However, the amount of cancellation depends on the level and distance of the microphone from the sound source. As an example, if an on-axis sound originated at a distance of 20 feet, a 90- to 180-degree off-axis sound occurring at the same distance and intensity will be reduced by 20 dB or more, providing none of the off-axis sound is reflected into the front of the microphone by walls, ceilings, etc. On the other hand, should the off-axis sound originate at a distance of 2 feet at the same level, it will be reproduced at the same level as the on-axis sound. The reason for this behavior is that the microphone is still cancelling the unwanted sound as much as 20 dB, but due to the difference in the distances of the two sounds, the off-axis sound is 20 dB louder than the axial sound and they are reproduced at the same level. For a pickup in an area where random noise and reverberation is a problem, the mi-

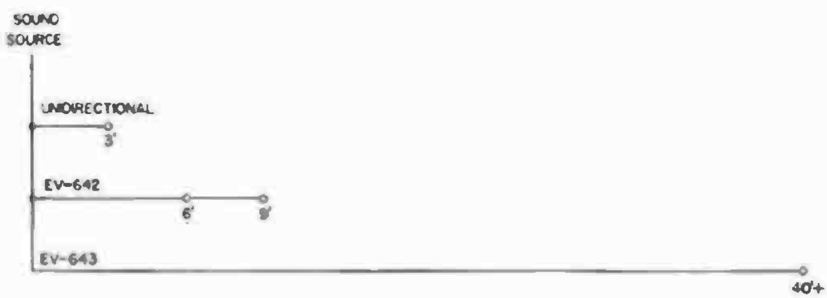

Fig. 4-102. Comparison of standard unidirectional microphone and Electro-Voice Models 642 Cardiline, and 643 long-range pickup.

crophone should be located with the *back end* to the source of unwanted sound and away from the disturbance at the greatest possible distance.

If the microphone is being used inside a truck and pointing out a rear door, poor pickup may be experienced for the following reason. All sounds, both wanted and unwanted arrive at the microphone on-axis. Since the only entrance is through the truck door, no cancellation occurs because the truck walls inhibit the sound from entering the sides of the microphone. In this instance, the microphone will be operating as an omnidirectional microphone. Due to the reflected sound from the walls the same condition will prevail in a room where the microphone is pointed through a window, or when operating in a long hallway. For good pickup, *the microphone should be operated in the open and not in closely confined quarters.*

Because of the narrow included angle of the pickup, random noise is reduced considerably, and the distance to the sound source may be increased without a loss of presence. *It should be understood that this microphone cannot be compared to a zoom lens; the focus does not vary nor does it reach out to gather in the sound.* What the narrow polar pattern and high rate of cancellation does is to reduce the random sound energy and to permit the raising of the amplifier gain *following* the microphone, without seriously decreasing the signal-to-noise ratio. This permits the pickup of voices at a distance that cannot be understood to be reproduced with intelligibility.

Difficulties may also be encountered using this microphone on stage and picking out a speaker in the audience, particularly where the voice is 75 to 100 feet distant and fed back through a reinforcement system for the audience to hear. Under these circumstances, only about 30 to 50 feet is possible without acoustic feedback; even then the system must be balanced very carefully.

If the pickup is being made in a wind of 20 miles per hour or more, the 100-Hz high-pass filter in conjunction with the *Acoustifoam* wind screen will eliminate the low-frequency distortion caused by the wind. Switching in one of the low-frequency rolloffs, as shown in Fig. 4-101G, may also be helpful. If the pickup is only dialogue, the 100-Hz filter may be left in, and the number 1 rolloff used, as most male voices may be attenuated below 120 Hz. (See Question 18.81.) The filter and rolloff characteristics are of exceptional help when reverberation is a problem in a hard-walled room.

A comparison of a standard cardioid microphone with the Electro-Voice 642 and 643 relative to increased distance pickup, is shown in Fig. 4-102. Normally pickups at a distance of 50 feet or greater, using the above precautions, are possible; however, quite satisfactory pickups have been made at distances of 150 feet. Only through *experience* will its full capabilities be realized.

4.103 What is a rifle microphone? —The rifle microphone consists of a microphone transducer with a series of tubes of varied length mounted in front of the transducer diaphragm (Fig. 4-103A). The transducer may be either a capacitor or dynamic type. The tubes are cut in lengths from 2 to 60 inches, and bound together. The bundling of the tubes in front of the transducer diaphragm creates a distributed sound entrance and the omnidirectional transducer becomes highly directional.

Sound originating on the axis of the tubes first enters the longest tube and as the wave front advances, it enters successively shorter tubes in normal progression until the diaphragm is reached. Sounds reaching the diaphragm from the source travel the same distance, regardless of the tube entered; thus, all sounds arriving on-axis are in phase when they reach the diaphragm. However, sounds originating 90 degrees off-axis enter all tubes simultaneously. A sound entering a longer tube may travel 18 inches to reach the diaphragm, while the same sound traveling through the shortest tube will travel only 3 inches, with other differences for the varied length of tubing, thus causing an out of phase signal at the diaphragm. Under these conditions, a large portion of the sound originatiug at 90 degrees is canceled; from 180 degrees an even greater phase difference occurs, and cancellation is increased considerably.

The RCA MI-10006A *Vari-directional* microphone (Fig. 4-103A) consists of nineteen $\frac{5}{16}$-inch plastic tubes, ranging from 3 inches to 18 inches in length. Each tube is damped to prevent reso-

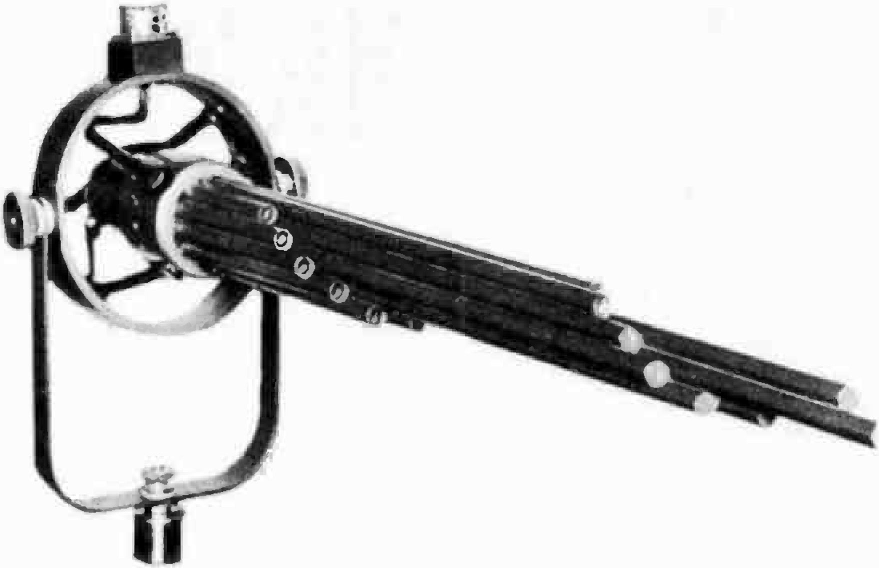

Fig. 4-103A. RCA MI-10006A Vari-directional microphone.

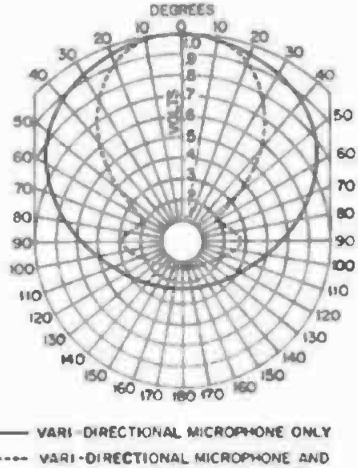

Fig. 4-103B. Polar plot for RCA MI-10006A Vari-directional microphone.

nant effects. The tubes are bundled and mounted in front of an omnidirectional capacitor-microphone head. An amplifier contained in the transducer housing is supplied from a small battery pack, having a life of several months. The polar and frequency response are shown in Figs. 4-103B and 4-103C. Two positions for reducing low-frequency response are provided at the transducer and are indicated by the dotted lines in Fig. 4-103C.

4.104 How is the effective output level of a microphone rate?—The EIA standard defines the system rating (G_m) as the ratio in decibels relative to 0.001 watt per 0.0002 dyne per square centimeter of the maximum electrical output from the microphone to the square of the undisturbed sound field pressure in a plane progressive wave at the microphone. Expressed mathematically:

$$G_m = (20\text{Log}_{10}\frac{E_o}{P} - 10\text{Log}_{10} Z_o) - 50 \text{ dB}$$

where,

E_o is the open circuit voltage of the microphone,

P is the undisturbed sound field pressure,

and Z_o is the microphone rated output impedance.

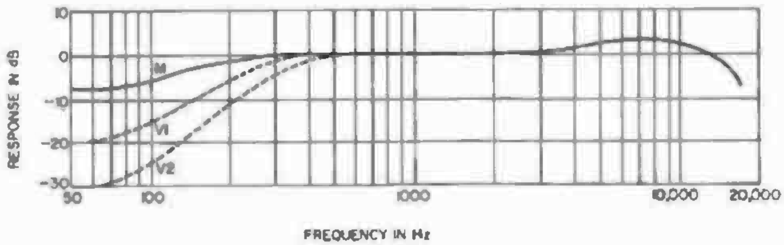

Fig. 4-103C. Frequency response for RCA MI-10006A Vari-directional microphone.

For all practical purposes, the output level of the microphone can be obtained by adding to G_m the sound pressure level, relative to 0.0002 dyne per square centimeter.

The sound pressure level (SPL) is measured with a sound level meter (see Question 22.94). The sensitivity to extraneous magnetic fields is referred to 1 milliwatt and calculated in the same manner as for the effective output level, using as the output voltage, the voltage produced by an arbitrary 60-Hz magnetic field of 0.001 gauss. This subject is discussed in detail in Question 23.81.

4.105 Show the relationship between air-particle amplitude, frequency, and sound pressure in microbars.—By referring to the graph in Fig. 4-105, the air-particle amplitude for frequencies ranging from 10 to 10,000 Hz, may be read directly in microinches for sound pressures between 0.0001 microbar and 100 microbars. As an example: What is the air-particle amplitude for 1000 Hz at an SPL of 0.01 microbar? Enter the graph at 1000 Hz at the left and follow the horizontal line to where it intersects the diagonal line for 0.01 microbar. Follow the intersecting vertical line downward to the lower margin, and read 0.015 microinch. For 10,000 Hz, the amplitude is 0.0015 microinch. Dropping down 10 Hz, the amplitude increases to 1.15 microinches. Taking the amplitude of 10,000 Hz at 0.01 microbar and 100 Hz at 100 microbars (which equals 1500 microinches) the ratio is 1,000,000:1.

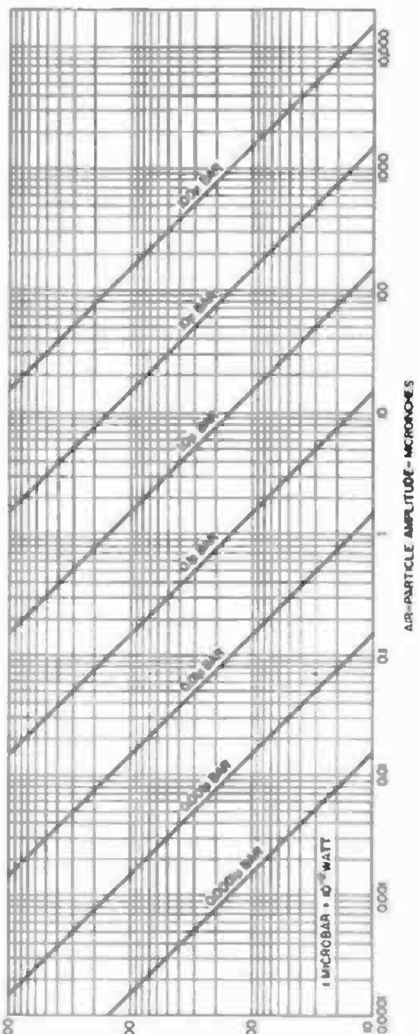

Fig. 4-105. Amplitude of vibrating air-particle versus frequency.

4.106 What is the average output level of different type microphones, taking into consideration the basic design?—The majority of microphones manufactured in the United States rate their microphone level in accordance with the EIA formula, discussed in Question 4.104. However, some European manufacturers rate their output level in volts for a given impedance. Using the EIA standard output rating, the average output levels for several different type microphones are:

Carbon-button (communication type)	−60 to −50 dB, −20 to −10 dB
Crystal	−50 to −41 dB
Ceramic	−50 to −40 dB
Dynamic (moving coil)	−53 to −48 dB
Capacitor (internal amplifier)	−51 to −37 dB
Ribbon-velocity	−51 to −48 dB (up to 0 dBm)
Lavaliers (dynamic moving-coil)	−67 to −60 dB
Transistor (communications)	−60 to −53 dB
Sound power (moving-coil)	−32 to −20 dB

Microphones are also rated by stating the output impedance and output level relative to 1 milliwatt/10 dynes/cm².

4.107 Show a nomograph for determining the output level of a microphone, both open-circuit and terminated.—For low-impedance type microphones (250 ohms or less) the output level is given

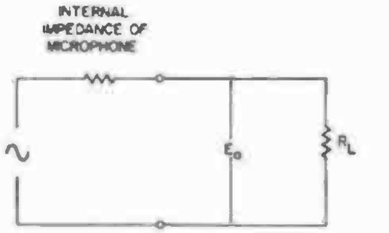

Fig. 4-107A. Equivalent circuit for a microphone output circuit.

in dB, with reference to 1 milliwatt/10 dynes/cm² sound pressure. For carbon and high-impedance microphones (above 250 ohms) the output level is referenced in dB to 1 volt, for 1 dyne/cm² sound pressure. It will be noted that both the acoustical pressure at the face of the microphone and the electrical output are given. Therefore, the microphone may be considered to be an acoustical generator, with a voltage or power output.

The specified output level is taken at 250 Hz for high quality wide-range professional microphones, while for communication types which have considerably less bandwidth, it is taken at 1000 Hz. For low-impedance microphones, the power output is specified. Since the output impedance of these microphones is low, it is customary to transform them to a higher impedance for application to the input circuit of an amplifier. The output is given in power, which does not change with the transformation, except for a small insertion loss of the transformer, which is generally less than 1 dB. As an example: For a low-impedance microphone with a sensitivity rating of minus 60 dB, re: 1 milliwatt/10 dynes/cm², what is the input voltage at the grid of the amplifier? Visualizing the microphone as a generator (Fig. 4-107A), the sensitivity rating of minus 60 dB means that for an acoustic pressure of 10 dynes/cm² at the diaphragm, the microphone will deliver into a resistive load (equal to its own impedance) a power of 10^{-9} watt. Therefore:

$$E_o^2 = 10^{-9} \quad E_o = 3.18 \times 10^{-4} \times R_L$$

For an impedance at the grid of the first stage of 40,000 ohms, the output voltage will be:

$$E_o = 3.18 \times 10^{-4} \times 40{,}000 \text{ ohms}$$
$$= 0.0637 \text{ volts}$$
(for 10 dynes/cm² sound pressure).

If the microphone is operated open-circuit, the output voltage will be doubled. A nomograph for determining the output voltage for various sensitivities is given in Fig. 4-107B. (See Question 12.170.)

High-impedance microphones are not transformed, as they are already 20,000 to 40,000-ohms impedance (internal transformer), and may be directly connected to the input of an amplifier, and

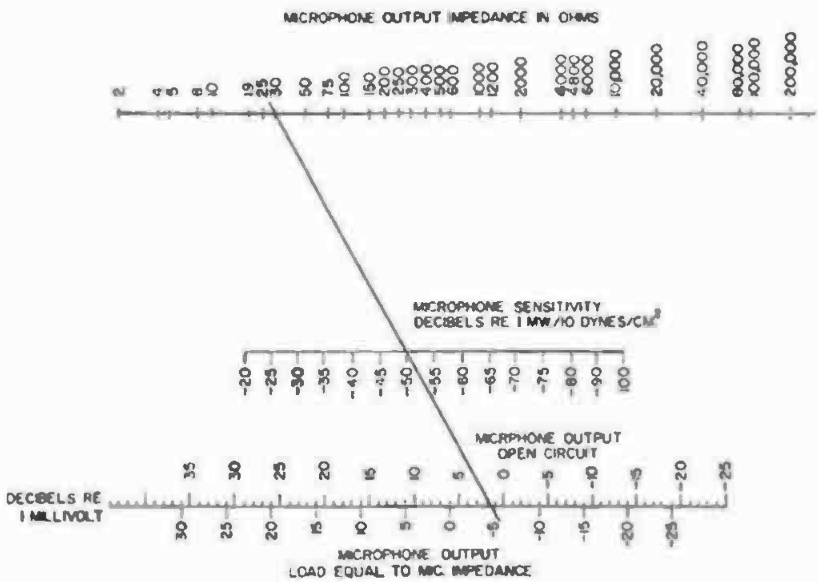

Fig. 4-107B. Nomograph for determining the output level of a microphone in decibels or voltage, both open-circuit and terminated.

the sensitivity is given as an open-circuit voltage, for a given sound pressure. A high-impedance microphone, with a sensitivity of minus 55 dB re: 1 volt/1 dyne/cm² will produce an open-circuit voltage of 0.0018 volt, with a sound pressure of 1 dyne/cm². The sensitivity rating determines the output voltage at only one sound pressure. However, since nearly all microphones are linear over all pressures encountered, the voltage output is a direct function of the sound pressure. If the pressure is increased by a factor of 10, the electrical output will increase by a factor of 10. Thus, knowing the sound pressure and sensitivity, the output voltage may be determined.

Sound pressure is generally given in reference to 0.0002 dyne/cm², and is considered to be zero sound pressure, and is approximately equal to the threshold of hearing. Typical sound pressures are:

Speech, ¼-inch from microphone front, 107 dB (peaks may add another 12 dB)

15-piece orchestra, 72 dB (with another 20 dB on peaks)

Threshold of pain, 130 dB

Acoustic noise in very quiet studio, 10 dB

Thus it can be seen that the first stage of a microphone preamplifier is required to operate over a wide range of input voltage.

To use the nomograph, two factors must be known in advance—the output relative to 1 milliwatt/10 dynes/cm², and the impedance. For example, to find the open-circuit output level for a microphone of 30-ohms impedance, rated minus 50 dB (RCA 77-DX, Question 4.77), a straight edge is laid from the 30-ohm impedance on the upper scale to a minus 50 dB on the center scale. The output level is read on the open-circuit values on the lower scale, which for this example is 1.5 dB above 1 millivolt. Terminating the microphone in its own impedance, the output voltage level drops to 4.5 dB below a reference level of 1 millivolt.

4.108 Give the equation for calculating the ribbon-deflection amplitude in a ribbon-velocity microphone.—Of the various types of microphones developed through the years, the ribbon-velocity microphone has, by far, the greatest deflection amplitude, approaching within a few percent the amplitude of the vibrating air particles. The amplitude of the ribbon deflection may be calculated:

$$d = \frac{e10^{8}}{LB2\pi f}$$

where,

d is the deflection amplitude,
e is the open circuit voltage,
L is the length of the ribbon in centimeters,
B is the flux density in the air-gap in gauss,
and f the frequency in Hz.

As an example, if the ribbon length is 5 centimeters, the flux density 10,000 gauss, the frequency 1000 Hz and the open circuit voltage 0.001 volt, for a sound pressure of 1 microbar, the ribbon-deflection amplitude is 1.2-microinches. As the frequency decreases, the ribbon deflection increases. For an *increase* in frequency, the ribbon deflection decreases.

4.109 What does the term dBV mean?—This term is used with a microphone when the output level is rated with reference to a one-volt reference level. (See Question 10.36.)

4.110 How is the transformer in a microphone designed to prevent pickup from extraneous fields?—The coils are wound hum-bucking and the whole assembly is encased in a triple-shielded case as shown in Fig. 8-50. The efficiency of transformer shields may be measured as described in Question 23.162.

4.111 How are unidirectional ribbon-velocity microphones operated from a boom? — For an example, the RCA MI-10001C microphone (Question 4.59) is suspended from a turret head on the boom, tilted at an angle of 45 degrees relative to the floor, about 4 feet from the sound source. For dialogue, the voice filter is used or dialogue equalization in the mixing panel (one or the other, but not both). For a normal pickup at this angle, the response changes less than 1.5 dB at any frequency. The ribbon should never be placed parallel to the floor, because of the directional nature of the human voice at the higher frequencies. (See Question 4.114.)

4.112 How should microphones be placed on a stage for the best results?—Several microphones spaced about 10 feet apart should be placed in the footlight trough, in an enclosure made of wire screen and covered on the outside with 2 inches of rock wool and a thin layer of felt on the inside surface (Fig. 4-112). This enclosure is designed to reduce or eliminate pickup from the orchestra pit. Unidirectional microphones with rather broad polar patterns should be used; they can be capacitor, dynamic, or ribbon-velocity types. Microphones should also be hung from overhead when possible, in areas where the players are likely to move, to assure an even sound pickup. This is particularly true if the actors turn their backs to the audience.

For small band combinations with a vocalist, it may be necessary to hang a loudspeaker 10 to 15 feet above and slightly behind the performers, and play back the program material at a level that cannot be heard by the audience or fed back to the microphones. This gives the musicians and the vocalist a feeling of the reproduction in the auditorium, and reduces the dead feeling due to the acoustic damping of the stage equipment.

Each microphone output is brought to a separate mixer control at the console. It is of extreme importance that all microphones be in electrical phase with each other, or dead spots may occur between microphones, as the actors walk in front of the microphones. Phasing is discussed in Question 4.85. For the most satisfactory sound pickup, the operator should attempt to follow the action, using only the necessary microphones. Separate microphones are used for the orchestra pickup.

If loudspeakers are used in the auditorium for sound reinforcement, the reproduced level should be just loud enough to get a good coverage, and of such a level that the audience is not aware that reinforcement is being used.

4.113 How is a sound pickup made from an outdoor band shell?—Because of its design, the shell acts as a huge concentrator making it difficult to obtain a pickup with good orchestra balance. This undesirable effect may be overcome by the use of polycylindrical diffusers, as explained in Question 2.76. The use of polycylindrical diffusers will also permit a better balance between the instruments and eliminate resonant peaks that go with a band shell.

4.114 What are the general rules pertaining to the placement of microphones for recording dialogue, music and sound effects, and lecterns?—A single microphone pickup should be used whenever possible. When two or more microphones are used simultaneously for recording either dialogue or music, they should be placed at least 10 feet apart. Also, their levels should not differ by more than 2 dB, have similar frequency characteristics, and be in phase electrically if the final result is to be uniform. An exception to the foregoing occurs when solo microphones are used.

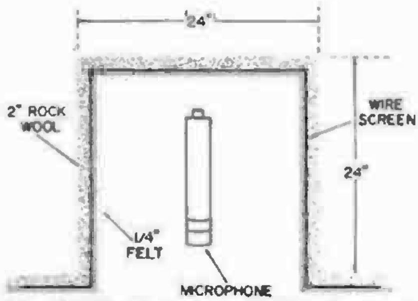

Fig. 4-112. Plan view of microphone enclosure for use in a footlight trough.

When multiple microphones are placed relatively close to the source of the pickup for either dialogue or music, and the sound source is directional, it becomes more important than ever to observe the distance the microphones are separated, their signal levels to one another, and the phasing.

Microphones should not be placed near highly reflective surfaces and must be suspended by resilient supports from either a boom or stand. For television and motion picture recording, the distance the microphone is placed from the source of sound will depend on the scene being photographed. Obviously, long-shot quality with reverberation cannot be used with a close-up and vice versa, as neither would sound natural.

The boom man should not be confused about the position of the camera or its distance from the subject as close-ups and medium-long shots are often made without moving the camera, only the lenses are changed. This is particularly true if a zoom lens is employed.

For a medium shot, the microphone is moved a little farther away from the subject than for a close-up. For a long shot the microphone is left at a distance comparable with the picture composition. However, this is not always done when making motion pictures for television viewing exclusively, as it is important that the dialogue have a high rate of intelligibility.

It is the practice to employ a fixed amount of midrange high-frequency equalization and rolloff at the low frequencies in the production mixer panel. The midrange high-frequency equalization adds presence to the voice, and the low-frequency rolloff attenuates the tubbiness in male voices and reduces low-frequency noise picked up on the set. The same type microphone should be used throughout a production, if possible; if it is not, a noticeable change of quality will be apparent and difficult to correct later in rerecording. After the correct equalization has been selected for a given type microphone, it should not be changed. If different type microphones are employed, *their frequency response must be matched to that of the original microphone*. Any further corrections as to presence and low-frequency attenuation should be left to rerecording. Twelve dB of low-frequency attenuation is maximum, but less than 6 dB (100 Hz) should not be used.

A microphone suspended from a boom should not be panned with too great a rapidity if it can be avoided, as noises may be generated by the movement of the boom mechanism and the swishing of the air as it passes over the face of the microphone.

Recording outdoors is not too different from recording indoors. If an outdoor scene is being shot indoors, the microphone must be kept close to the source of sound to prevent picking up an undue amount of reflected sound and thus lose the outdoor effect. If the indoor scene is being shot outdoors, reverberation can be introduced later during rerecording to simulate the indoor scene.

As most recording systems provide headphones for the boom man, it is his responsibility as well as that of the mixer to maintain a uniform quality of pickup by keeping the microphone at a fixed position in front of the actors although he is required to move the microphone over a considerable area of the set. If the actors are spaced a considerable distance from each other and it is not practicable to pick them up with one microphone, two microphones are used; however, it is highly important that the microphones be phased. The phasing of microphones is discussed in Questions 4.84 and 4.85.

Unidirectional capacitor-dynamic, or ribbon-velocity microphones are used for motion picture recording and television, because of the high ratio of back-to-front pickup. The microphone is maintained within a distance of four feet forward of and not less than three feet above the person speaking. This is illustrated in Fig. 4-114A.

Microphone booms designed for motion picture recording are equipped with a rotatable turret head for gunning the microphone rapidly from one source of pickup to another. This keeps the pickup quality uniform. In some instances a tilting mechanism is also

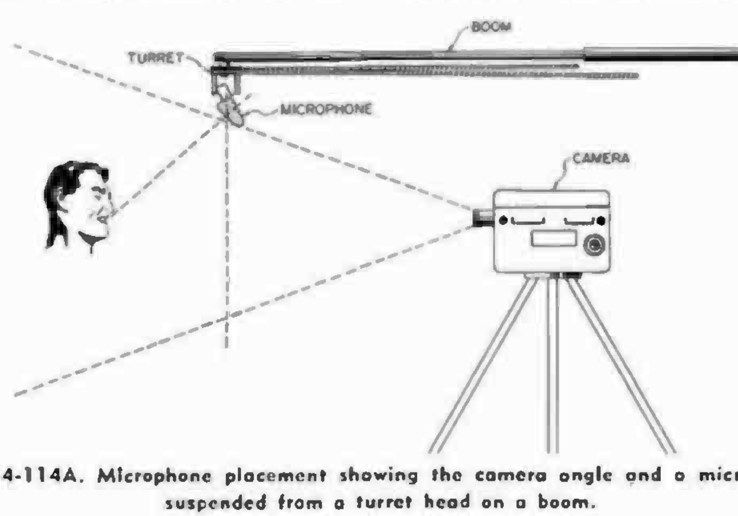

Fig. 4-114A. Microphone placement showing the camera angle and a microphone suspended from a turret head on a boom.

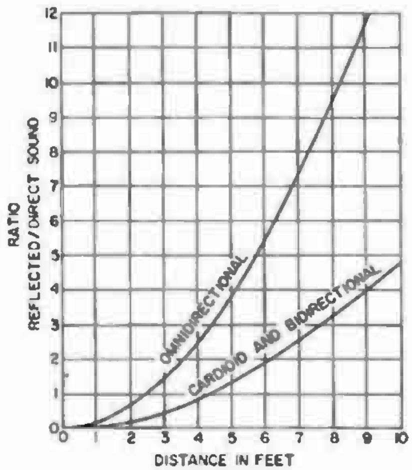

Fig. 4-114B. Ratio of reflected sound to direct sound.

mounted on the turret head to permit the microphone to be moved in a vertical direction. Rotating a unidirectional microphone such as the RCA MI-10001 (Fig. 4-59A), only varies the sensitivity about 1.5 dB when rotated 45 degrees either side of the center plane of the ribbon. The closer these type microphones are placed to the subject, the greater will be the increase of low-frequency response. (See Question 4.127.)

For dialogue recording, low-frequency attenuation is introduced starting at 800 Hz and slowly tapering off to a point where 100 Hz is down 8 to 12 dB with respect to 1000 Hz. This characteristic is discussed in Question 18.81. Dialogue should never be recorded flat because of the increase of tubbiness of the human voice due to set conditions and also to microphone characteristics. If more than one microphone is being used, the voice filters or equalizers must be set to achieve as near similar frequency-response characteristics as possible. If dialogue equalization is used in the mixer, the microphone is set for a flat frequency response. *Dialogue equalization and the voice-filter are never used in combination.*

If a bidirectional ribbon-velocity microphone (Fig. 4-50) is used, it must be kept from 4 to 5 feet away from the subject to prevent a tubby response. If the microphone is rotated, it must be done in such a manner that the dead side of the field pattern (Fig. 4-7C) does not face the sound source. Panning

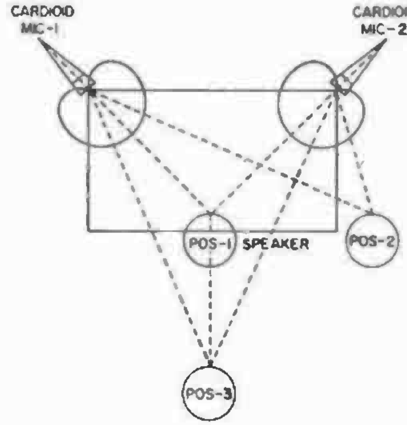

Fig. 4-114C. Usual microphone placement on lectern.

must be smooth without overshooting the subject. Although this microphone is satisfactory for fixed shots, it is not recommended for boom operation.

Microphones are expected to operate under adverse conditions. To facilitate their operation and increase their usefulness, several devices have been devised. Among these are the wind screen and the rain screen. In the early days of sound recording, several layers of thin silk were wrapped around the outside of the microphone to reduce the effects of wind. The many layers of silk also served to reduce the high-frequency response and affected the quality of the recording. Later, manufacturers of microphones developed special wind screens that could be easily attached to the microphones when required. The design of these screens is such that wind noise is reduced without affecting the sound quality. A typical wind screen is shown on the microphone in Fig. 4-31.

Special effects such as creating the illusion of a large auditorium may be obtained by placing the microphone in such a relationship to the sound source that a greater part of the pickup is reflected rather than direct sound. If this is not satisfactory, the sound is reverberated by the use of an echo chamber or reverberation unit, described in Question 2.80. The ratio of direct sound to reflected sound for an omnidirectional microphone, compared to a cardioid and a bidirectional ribbon-velocity microphone is given in Fig. 4-114C.

Microphones used for production recording should have frequent checks of their sensitivity, frequency response, phasing, and overall sound quality to determine whether any internal noise is being generated. These tests may be made using the techniques described in Question 23.80.

Microphone placements for large orchestra setups are discussed in Questions 2.118, and 2.120. Although there are some basic rules for such pickups, each mixer has his own preference as to microphone placement, because he must consider the characteristics of the stage, the number of pieces in the orchestra, and the type of music being recorded, also if it is monophonic or stereophonic. All of these factors affect the placement of the microphones and only actual listening tests will determine the best locations.

In some instances where it is not practical to use a microphone on a boom, a wireless microphone, as described in Question 4.72, may be used. Microphones may also be concealed on the set; however, they are seldom in the correct relationship to the source of sound. If the shot is a fixed one and the characters do not move out of the field of the microphone, it may be hung permanently overhead or concealed on a table or in some other object near the source of the pickup. (See Questions 6.122 and 18.81.) For long range pickups, such as race tracks, parades, groups of people in a crowd, etc., a long range microphone or sound concentrator may be employed, as described in Questions 4.100 and 4.101.

Placement of microphones may appear at first glance to be quite simple; however if certain precautions are not observed, a radical change in the quality of the pickup can occur quite easily. The usual manner of setting up microphones on a lectern is shown in Fig. 4-114B. If the speaker stands at position 1 and does not move, the pickup could be satisfactory. However, speakers do not always stand in one place, and it is not uncommon for them to step completely out of the area of pickup. At position 2, the sound originates off axis from microphone 2, but is fairly on axis of microphone 1. Any movement by the speaker in this area is manifest by a considerable change in the quality of the sound, because of phase differences between the two microphones due to spatial relationship to the sound source. Major dips in the frequency range of 800 Hz and higher will be quite noticeable, resulting in a lack of presence. If the placement of the microphones is changed to where the microphones are rotated 15 to 25 degrees from center (included angle of 30 to 50 degrees) with about 12 to 20 inches between, better results may be expected. Greater angles will permit the speaker more latitude of movement, and the smaller distances between the microphones reduces both the acoustic feedback and background noise. One of the most important points to remember is the *microphones must be in phase electrically* as discussed in Question 4.84. Also, the output levels should be within plus or minus 2 dB, with similar frequency characteristics.

Although omnidirectional or bidirectional microphones can be used for a single microphone pickup, they are generally unsatisfactory because noise picked up from the audience side is mixed with the speaker's voice and when sound reinforcement is in use, serious acoustic feedback can occur. If an omnidirectional microphone is used, the speaker must work as close to the microphone as possible, and the gain of the system must be continuously monitored to prevent feedback. For a single microphone pickup, it is much more satisfactory to use a lavalier type microphone, as discussed in Question 4.81. If a bidirectional microphone is used, (figure-8 polar pattern) the waist of the polar pattern is turned toward the audience at an angle of about 30 to 45 degrees, to reduce the pickup from that direction. Microphone placement for several different type pickups is discussed in Questions 2.124 and 2.127.

Recording of sound effects is rather simple, as only two rules are important. The first is to record as much level on the sound track as practicable, keeping in mind the scene in which it is to be used. The second rule is to keep the background noise to an *absolute minimum*. Equalization should be adjusted to bring out any special effects at the low- and high-frequency end of the spectrum. This will result in good solid sound tracks that can be again equalized during rerecording to suit the scene. Many times a good sound effect is unusable because the level is too low, and in trying to bring it up to a useable level, the background noise becomes excessive. Therefore, the same care must be exercised for recording sound effects as when recording dialogue.

4.115 Describe the construction of a high-intensity capacitor microphone head.—High-intensity capacitor microphone heads are especially designed for measuring high-level sound pressures of jet engines, explosions, acoustic wave shocks, and atomic blasts. A typical example of such design is the Altec-Lansing type 21-BR, shown in Fig. 4-115A. The general theory of its operation is the same as that explained in Question 4.41. Except for the stiffness of the diaphragm, and the internal capacitance being less, the heads follow the same general design.

In the Altec-Lansing capacitor-microphone preamplifier the conventional grid resistance is omitted. Since the microphone head is capacitive, extended low-frequency response dictates that the shunt resistance of its load must be as high as possible. The source impedance viewed from the preamplifier control grid consists of resistance and capacitance in parallel. Also, over the useful frequency range the thermal noise is least when the resistance is the highest. For these reasons no physical grid resistor is employed, the effective resistance between the control grid and cathode being that established by the input of the tube itself. Thus, the load resistance is extremely high and the self-established bias is steadily maintained at approximately 1 volt negative. Consequently, the polarizing voltage applied between the electrodes of the microphone head is approximately 1 volt less than the dc voltage drop across the cathode resistance. The voltages required for operating the amplifier are supplied from an external power supply.

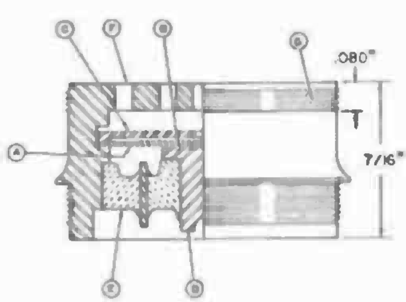

Fig. 4-115A. Cross-sectional view of Altec-Lansing 21-BR high-intensity capacitor microphone head.

The cross-sectional view in Fig. 4-115A is of a typical high-intensity microphone head. Such heads may be obtained for measuring SPL's up to 200 dB, over a frequency range of 5 to 15,000 Hz. The selection of the proper head depends on the device to be measured, its frequency range, and the maximum SPL expected. The diaphragm (A) is 0.5 inch in diameter, made of glass ground optically flat to the thickness of 0.002 to 0.013 inch, depending on the required sensitivity. One surface (B) is gold plated, which makes contact with the outer shell. A damping plate (C) is placed over the diaphragm. The fixed electrode (D) is ungrounded and is a machined part extending through a Mycalex dielectric (E). The dielectric is provided with annular corrugations between the fixed electrode and the outer sleeve to extend the length of the surface leakage paths. To maintain the highest surface resis-

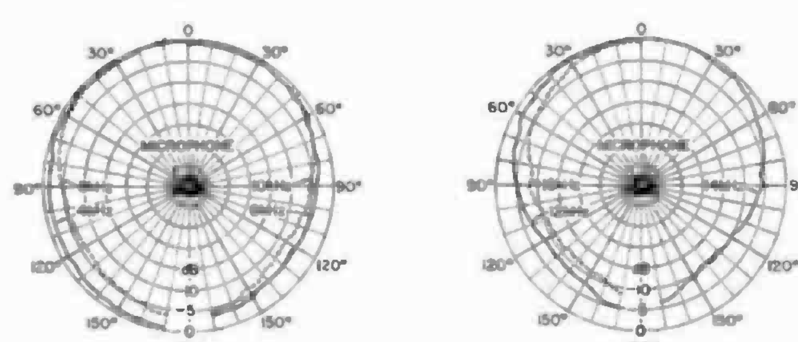

Fig. 4-115B. Polar diagrams for Altec-Lansing 21-BR high-intensity capacitor microphone.

tivity and prevent moisture-film globules, the surface of the dielectric is treated with a silicone compound. The critical elements are made of either glass compounds or stainless steel which have nearly identical coefficients of thermal expansion, to assure the maintenance of the close spacing.

Holes (F) at the top admit the sound pressure to the interior. Threads (G) are for screwing on a protective cap when the microphone is not in use.

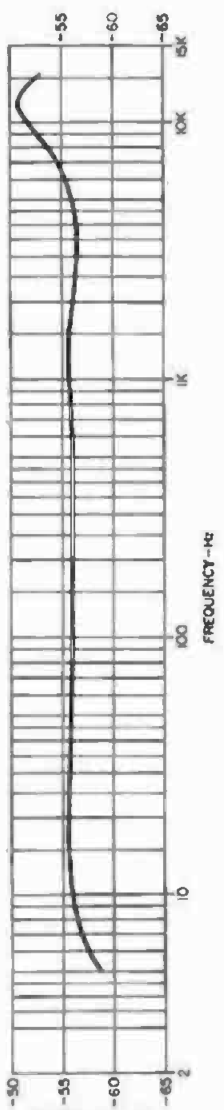

Fig. 4-115C. Typical free-field calibration for Altec-Lansing 21-BR-150 high-intensity microphone, parallel incidence. The output level is the open circuit voltage in dB re: 1 volt/dyne cm².

The axial acceleration of the mass of the diaphragm causes it to deflect to an extent proportional to its density, and inversely proportional to the square of the thickness. Since the diameter of the 21-BR microphone head is $^{11}/_{16}$ inch, or 1 wavelength at 17,000 Hz, variation with the angle of incidence is limited to the highest frequency, as may be seen by inspection of the polar diagrams in Fig. 4-115B. Microphone heads are available for measuring sound pressures ranging from 50 dB to 200 dB re: 0.0002 dyne/cm². The difference in construction is the thickness of the diaphragm. In the low-intensity types, diaphragm resonance is damped principally by means of a narrow air film between the diaphragm and the back-plate. However, in the high-intensity designs the rear diaphragm space is connected to the free air by a vent of sufficiently high impedance to support the frequency response to 5 Hz, and fast enough to prevent the development of static pressure differences when used in aircraft. If the head is exposed to moisture for any length of time, it may be dried out by placing it in a desiccator, or by heating it to 300 degrees Fahrenheit.

A typical free-field calibration for an Altec-Lansing Model 21-BR-150 head capable of linear measurement to 158 dB, made at parallel incidence, is shown in Fig. 4-115C. It will be noted the resonant frequency occurs at 11,000 Hz, with maximum peaks of 4 dB. The polar pattern is omnidirectional. The 165-A base to which the capacitor head attaches contains a preamplifier that uses a 5840 vacuum tube connected as a pentode cathode follower (Fig. 4-115D). The output from the cathode follower and the operating voltages are carried over a 6-conductor cable to the power supply. The polarizing voltage for the head is 200 volts. The cathode current for the 5840 tube is 5 milliamperes. Although the internal output impedance of the cathode follower is 640 ohms, it must not be loaded with less than 50,000 ohms, which is substantially an open circuit. Lower impedances will affect the linearity of the cathode follower. A plug-in transformer may be used for providing a number of output impedances.

Linear limit is the SPL that produces an open circuit output voltage of 20 volts; this is the level that causes the cathode follower to depart 1 dB from a linear input-output response at 10,000 Hz when the output is loaded with its regular cable. The average noise threshold is an SPL that produces a signal-to-noise ratio of unity and a noise output of 0.2 mV. The total noise is primarily the thermal noise of the input circuit of the microphone, with contributions from tube and leakage currents across insulating materials.

4.116 ***What is a filter microphone?*** — A microphone used to simulate a telephone conversation during a radio broadcast. A normal microphone is used with a telephone equalizer or filter in the circuit as described in Question 7.73.

The actors, when required to carry on a conversation over a telephone, step

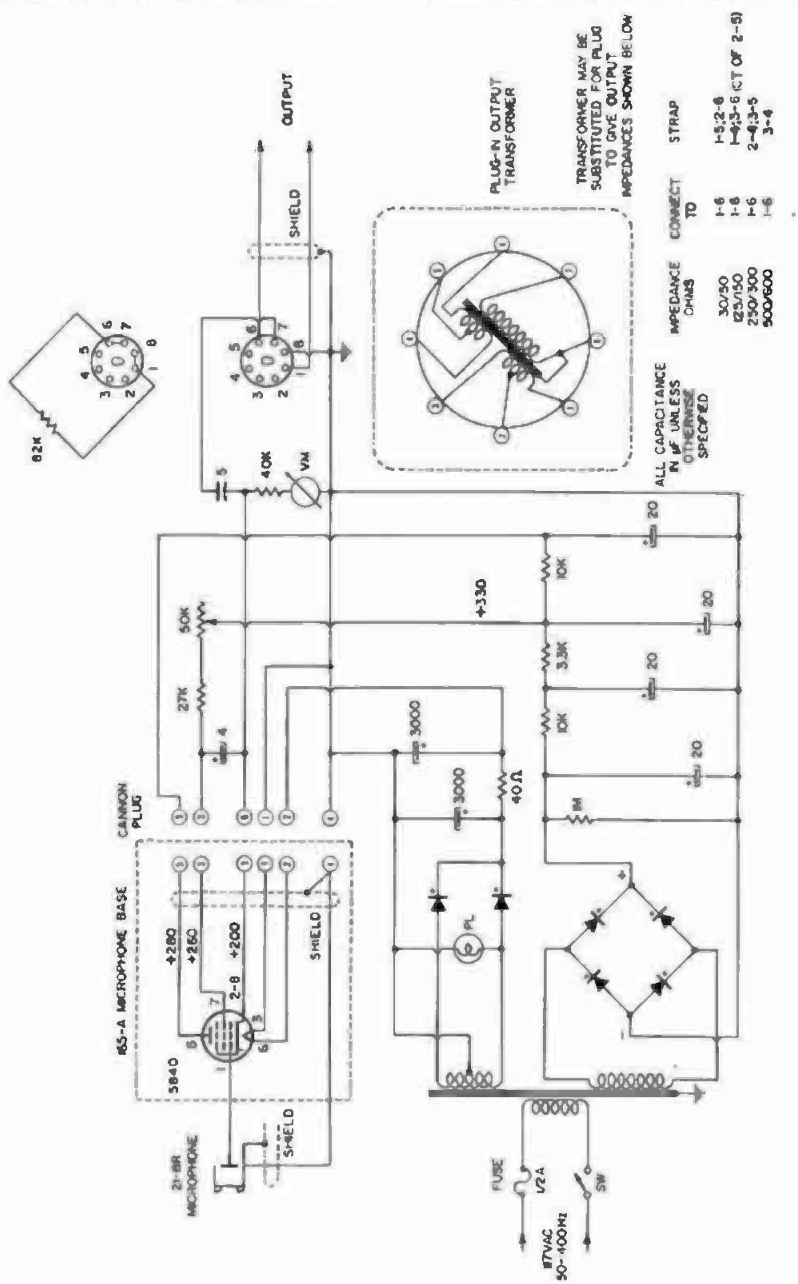

Fig. 4-115D. Schematic diagram for Altec-Lansing 21-BR capacitor microphone, 165-A base, and 526-B power supply.

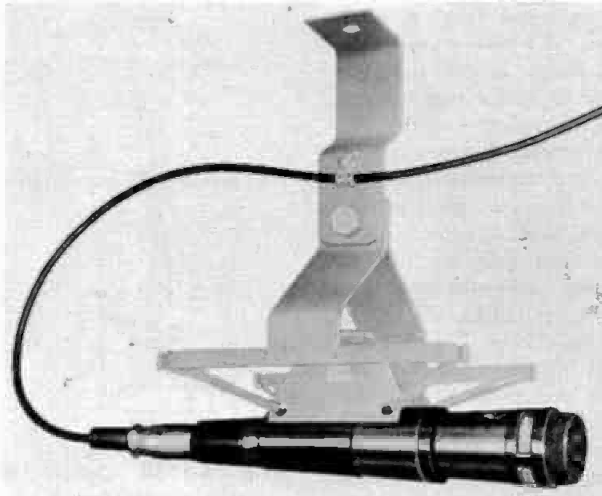

Fig. 4-117A. Altec-Lansing Model 689BX dynamic cardioid microphone and Model 181A hanger.

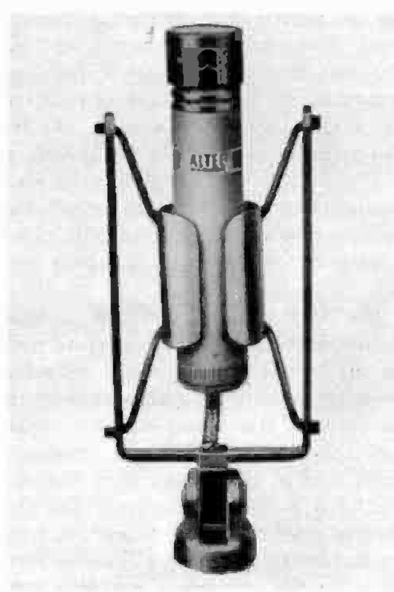

Fig. 4-117B. Altec-Lansing Model M30 capacitor cardioid microphone and Model 169A hanger.

to the filter microphone and use it, rather than having the mixer cut-in a telephone equalizer or filter each time it is required.

4.117 How are microphone hangers constructed?—Each type microphone as a rule requires an individually designed hanger because of the microphone body contour. However, all the microphone hangers have one thing in common, the microphone is supported by a metal holder which is in turn supported by a rubber mounting of some sort.

The purpose of the hanger (besides holding the microphone) is to isolate the microphone from vibrations transmitted by the microphone boom and its mechanism. The hanger should also be designed that when attached to a boom, it can be turned toward the actors for the best sound pickup. (See Question 2.101.)

The hanger used to support the RCA MI-10001C microphone from a boom is shown in Fig. 4-59A. It will be noted in this hanger two metal rings are clamped around the microphone body, and are supported by a group of heavy rubber bands fastened to a larger ring supported by a vertical bracket held by the turret head of the microphone boom. Wing nuts at the lower end of the vertical bracket permit the microphone to be tilted at various angles with respect to the sound source. Several different type hangers may be seen in Figs. 4-31, 4-39, 4-46, 4-59, 4-97, and 4-117A and 4-117B. A special hanger, including a tilting mechanism has been developed by the Fisher Boom Co. for the microphone boom pictured in Fig. 2-101A, which will permit the boom man to change the angle of incidence with respect to the persons speaking, as well as, "gunning" or "panning," from person to person.

4.118 Describe the construction of an optical microphone.—In an optical microphone, the sound waves modulate a light beam reflected from a small mirror mounted on a ribbon or a diaphragm. This design is one that has been under discussion for many years, and to date no microphones of this design have been produced commercially. It has been proven mathematically that it is not feasible to build such a microphone, although several patents have been issued for such a design.

The first design to be discussed was patented in 1938, by Banks, US Patent 2,259,511, and appears in Fig. 4-118A. The assembly is housed in a metal container (A) with an opening on one side. A thin metal diaphragm (B) is mounted below this opening, and the front face is exposed to incident sound, while the rear face is highly polished to function as an optical mirror. The diaphragm is suspended a short distance in front of a fixed reflector (C), with the two mirror surfaces parallel to each other. A suitable light source and slit (D) and lens (E) project a beam of light through the aperture (F) at one end of the second reflector (C) onto the rear reflector side of the diaphragm, at an angle of 45 degrees which, in turn, is rereflected back onto the second diaphragm, and so on for a predetermined number of reflections, in a zigzag pattern.

The light is finally brought to focus on one edge of a second aperture near the other end of the second reflector; however, some light passes through to the cathode (G) of an electron-multiplier tube (H). In the static condition, about half of the light passes into the multiplier cathode; therefore, if the diaphragm is vibrated, the reflections from the diaphragm reflector will cause variations in the amount of incident light falling on the cathode of the electron-multiplier tube. If the diaphragm reflector moves through a distance (D),

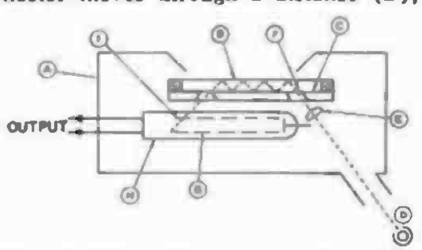

Fig. 4-118A. Optical microphone invented by Banks. A light beam is modulated by a diaphragm and projected on an electron-multiplier tube.

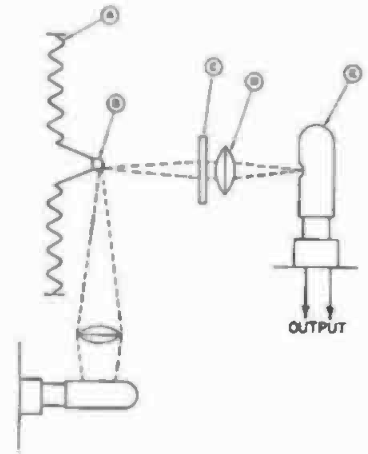

Fig. 4-118B. Optical microphone invented by MacDonell. A light beam is focused on a cylindrical mirror mounted on a diaphragm. The beam is projected through a grating to a photocell.

the lateral movement of the light image at the focus will be (nD), where n is the number of reflections of the light in its passage. The field electrode (I) opposite the cathode must be light permeable (mesh form). The generated signal is taken from the output electrode of the electron multiplier.

A second US Patent (2,666,650) issued to MacDonell is for a different design shown in Fig. 4-118B. This device consists of a diaphragm (A) with a small mirror (B) mounted at the apex of the diaphragm. A beam of light from an exciter lamp is focused on the mirror and is reflected to a grid (C) and lens (D), onto the cathode of a phototube (E). Sound waves striking the diaphragm set it in motion, causing the front-surfaced mirror (B) to vibrate. The condensed light from the exciter lamp focused on the mirror is refracted to the grid (C), where modulation occurs, then to the lens (D) and onto the cathode of the phototube. As the light beam is modulated by the mirror, it is reflected to the grid (C) at an angle which increases and decreases because of the cylindrical shape of the mirror. The grating consists of a piece of quartz or glass, divided into parallel lines equally spaced and equal in width. Each alternate space in the grid is opaque, and the intervening clear spaces are left more or less transmittive as dictated by the type phototube employed. The output signal is taken from

Fig. 4-119A. Euphonics Model C-47M semiconductor close-talking communications microphone.

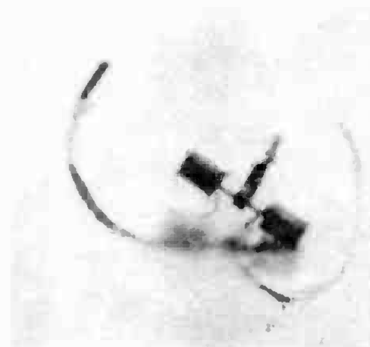

Fig. 4-119C. Semiconductor twister element, twister yoke, and supporting pads with output leads of the Euphonics Model C-47M semiconductor microphone.

the phototube and amplified in the usual manner.

4.119 Describe a semiconductor close-talking communication microphone.—The microphone to be discussed is a Model C-47M, semiconductor microphone (Fig. 4-119A), developed by John F. Wood and George Grover of the Euphonics Corp., Guaynabo, Puerto Rico. The device consists of a highly doped silicon semiconductor element, manufactured by the Endevco Corp., to which a source of dc voltage is applied. The silicon element is coupled to a diaphragm through a flexible yoke. Sound waves impinging on the surface of the diaphragm cause the coupling yoke to transmit a twisting action to the silicon element, changing its internal resistance. This modulates the dc voltage applied to the silicon element; thus, an end audio-frequency signal that is proportional to the sound wave striking the diaphragm is produced. The output signal is then amplified in the conventional manner. It should be understood that the semiconductor does *not* generate a signal, but *modulates* the applied dc voltage, thus producing the audio-frequency signal.

Referring to Fig. 4-119B, here is shown a cross-section view of the semiconductor element and its components. Element (A) is a laminated epoxy beam, with the upper surface (B) gold plated, and a brass strip (C) on the

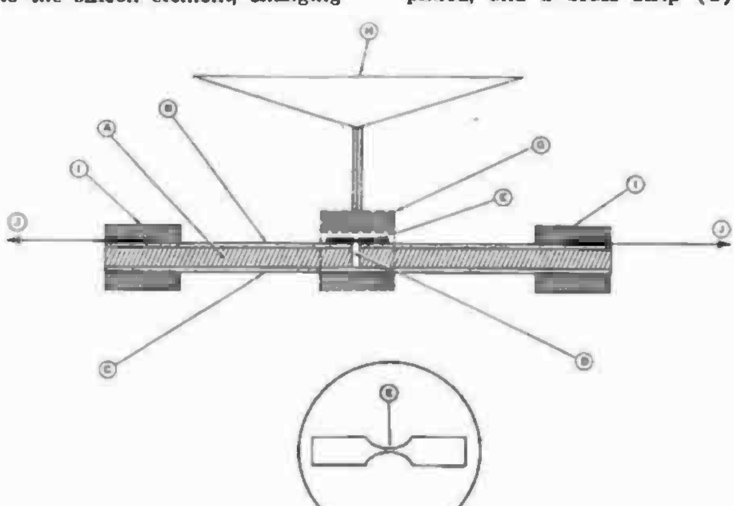

Fig. 4-119B. Cross-sectional view of Euphonics Corp. Model C-47M semiconductor communications microphone.

Fig. 4-119D. Semiconductor element assembly for Euphonics Model C-47M semiconductor close-talking communications microphone.

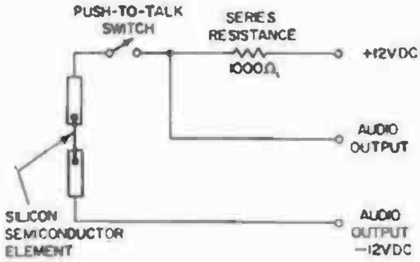

Fig. 4-119F. Internal and external connections for Euphonics Corp. Model C-47M semiconductor close-talking communications microphone.

lower surface. A notch (D) is cut through the epoxy to the inside surface of the lower strip (C), leaving a hinge for stress concentration. There is no electrical connection between the upper surface (B) and the lower surface strip (C). Above the notch is soldered a silicon semiconductor element (E) shaped in the form of a letter H, shown in the enlarged drawing at (F). The silicon fiber (E) is about 0.005 inch in thickness, and connects to the two larger end portions. A flexible yoke (G) is slipped over the silicon element, and connects to a 2-inch conical diaphragm (H) made of *Lexan*, a metal similar to aluminum but more durable. Two resilient pads (I) are used to support the ends of the epoxy beam, and to isolate it from shock and vibration. Contact is made to the two ends of the silicon element by low-resistance leads (J), held in place by the pressure of the pads (I).

The assembled semiconductor element and its modulating yoke is shown in Fig. 4-119C, and mounted in its supporting structure as seen in Fig. 4-119D. The semiconductor element has a frequency range from dc to 50,000 Hz; however, for this application the frequency range is limited from 100 to 6000 Hz, with a peak in the midrange high frequencies (Fig. 4-119E). The output impedance is 500 ohms. With 12 volts dc in series with 1000 ohms applied to the silicon element, the output level is minus 52 dB re: 1 mW/10 dynes/cm^2. The open-circuit voltage for close speech work is approximately 10 volts. A higher output level may be obtained by increasing the dc voltage. However, increasing the dc voltage requires that the series resistance also be increased to limit the current through the silicon element to a maximum current of 13 mA or less. With 20 volts dc and a series resistance of 2000 ohms, the output level is increased to minus 46 dB re: 1 mW/10 dynes/cm^2. A diagram of the internal and external connections is given in Fig. 4-119F.

4.120 What is a differential noise-cancelling microphone? — Differential noise-cancelling microphones are essentially designed for use in automo-

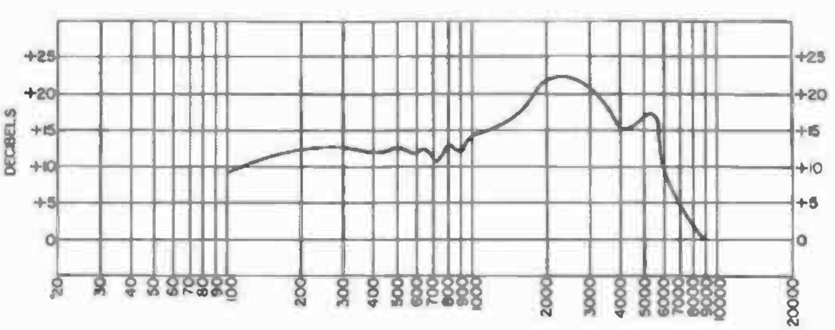

Fig. 4-119E. Frequency response of Euphonics Model C-47M close-talking communications semiconductor microphone.

biles, aircraft, boats, tanks, public-address systems, and industrial plants, or for any service where the ambient noise level is 100 dB or greater, and the microphone is hand-held. Two different designs of noise-cancelling microphones, manufactured by Electro-Voice, are given in Figs. 4-120A and B. The microphone in Fig. 4-120A is the Model 602F, of the dynamic type. Discrimination is afforded against all sounds originating more than ¼-inch from the front of the microphone. The noise-cancelling characteristic is achieved through the use of a balanced port opening, which conducts the unwanted sound to the rear of the dynamic unit diaphragm, and is out-of-phase with the sound arriving at the front of the microphone. The noise cancelling is most effective for frequencies above 2000 Hz. Only the speech originating within ¼ inch of the aperture is fully reproduced. The average discrimination between speech and noise is 20 dB or a ratio of 100:1 in intensity. The frequency response is 200 to 5000 Hz, with an output level of minus 60 dB. The impedance may be either high or 150 ohms. The polar pattern is bidirectional, pressure gradient.

A single-button carbon-granule microphone, Model 205KK is shown in Fig. 4-120B. The ambient noise is fed into two apertures, one above the other in such phase relationship to provide almost complete cancellation. Speech sounds originating ¼ inch from one of the two apertures is fully reproduced. Articulation is 97 percent under quiet conditions and 87 percent in an ambient noise level of 115 dB. The frequency response is 100 to 4000 Hz, with an output level of minus 50 dB re: 1 volt/dyne/cm², or 0.31 volt into 100 ohms. The internal resistance is 100 ohms and requires 10 to 50 mA of button current. The polar pattern is bidirectional, pressure gradient.

4.121 Describe the construction of an electrostatic-velocity microphone.—This microphone was developed about the same time as the first ribbon-velocity microphones. The structure is somewhat similar to an electrostatic loudspeaker. The sensitive elements consist of a flat insulated perforated plate, covered with a group of eight dural ribbons, about ¼ by 4 inches, and approximately 0.0002 inch in thickness. The perforated plate has about 80 holes per square inch. A polarizing voltage of 100 to 350 Vdc is applied between the ribbons and the back plate. Displacement of the ribbons results in the greater or lesser charge across the ribbons and back plate, which is applied to the control grid of an amplifier tube. In general, it may be considered to be a capacitor microphone. The frequency response is surprisingly good, being fairly constant from 40 to 5000 Hz; however, the harmonic distortion is rather high.

4.122 Describe the operating principles of a controlled-reluctance microphone.—This microphone operates on the principle that an electrical current is induced in a coil, located in a changing magnetic field. A magnetic armature is attached to a diaphragm suspended inside a coil. The diaphragm,

Fig. 4-120A. Electro-Voice Model 602F dynamic microphone.

Fig. 4-120B. Electro-Voice Model 205KK carbon-button microphone.

when disturbed by a sound wave, moves the armature and induces a corresponding *varying voltage* in the coil. High output with fairly good frequency response is typical of this type microphone.

4.123 Describe an inductor microphone.—An inductor microphone is a moving-coil type microphone employing a coil consisting of one turn of wire, suspended at the rear of a *parchment* diaphragm. The coil, because of the diaphragm movement, is caused to move in a strong magnetic field generating minute voltages. An impedance-matching transformer matches the low impedance of the coil to the transmission line. The field pattern is omnidirectional. The inductor microphone is now *obsolete*.

4.124 What is the standard for phasing microphones? — Microphones may be phased against a microphone known to be in phase, by the method discussed in Question 4.85. The standard method as recommended by the EIA for manufacturers, specifies that the polarity of the microphone or a transducer element refers to in-phase or out-of-phase conditions of voltage developed at the microphone terminals, with respect to the sound pressure of a sound wave causing the voltage. Exact in-phase relationship can be taken to mean that the phase of the voltage is coincident with the phase of the sound-pressure wave causing the voltage. In practice, this relationship may not always be obtainable.

It is important to keep in mind that if a preamplifier is connected between the transducer element and the output terminals, it may cause a *phase reversal*. For capacitor microphones, the inward motion of the diaphragm, because of a positive increment of pressure by the sound wave, produces an increase in capacitance. Since the charge ($Q = CE$) remains constant, an increase in capacitance will cause a decrease in voltage across the electrodes. Therefore, in a pressure-operated capacitor transducer, the in-phase terminal is the terminal to be connected to the negatively charged electrode.

For a piezoelectric microphone, the phasing is determined by the orientation of the molecules in the element, which may not be known beforehand. This may be ascertained by a slight pressure applied to the sensitive element, and the polarity of the resulting voltage, determined by observing the motion of the trace on an oscilloscope, connected at the output of the microphone. In this instance, the phasing of the oscilloscope must be established beforehand, by use of a battery. (See Question 23.218.)

Magnetic, dynamic, and ribbon microphones may be phased by the application of a low-voltage direct current of known polarity, applied to the termi-

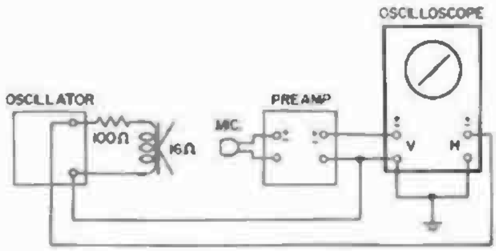

Fig. 4-124A. Test setup for checking the phase of a microphone per the EIA standards.

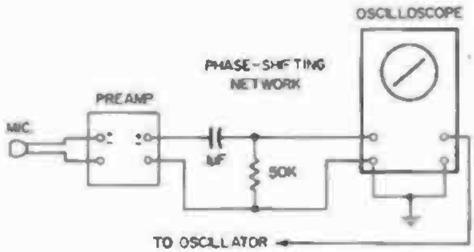

Fig. 4-124B. Phase-shift network for use with a velocity microphone.

nals of the transducer element, which will cause a motion of the element. The in-phase terminal is the terminal which, when the positive polarity is applied to the transducer element, moves *away* from the observer facing the front of the microphone. Great care must be exercised when performing the described measurements, as the moving element can be very easily damaged.

A microphone-phasing test setup is shown in Fig. 4-124A, using a loudspeaker for the sound source, and an oscilloscope for observing the phase conditions. To establish the proper phase at the loudspeaker, the speaker is mounted in an infinite baffle and connected to an oscillator through a 100-ohm resistor. With the resistor in series with the voice coil, the current through the voice coil is then in phase with the voltage at the terminals of the oscillator. If the applied frequency of the oscillator is above the resonant frequency of the speaker, the pressure will be in phase with the applied voltage. For an 8-inch speaker having a resonant frequency of 60 Hz, this condition may be attained at frequencies between 100 and 400 Hz.

To ascertain the in-phase terminal of the speaker, a battery is connected across the voice-coil terminals in such a manner that the cone moves *toward* the microphone; the terminal connected to the positive terminal of the battery is the in-phase terminal of the speaker. With the oscilloscope connected as in Fig. 4-124A, microphones are tested by adjusting the oscillator output for a suitable acoustic output of the speaker. The microphone is positioned at a distance of about 2 inches from the speaker, and the orientation of the oscilloscope trace checked. If the trace is in the form of a slanted line or ellipse, with its major axis orientated from lower left to upper right, then the in-phase terminal of the microphone is the terminal connected to the high potential (±) terminal of the amplifier. This relationship should remain over a range of 100 to 400 Hz.

When this procedure is applied to a gradient microphone (velocity), the trace will form a circle, because the out-of-phase relationship between the pressure and velocity is a spreading waveform. This may be corrected by the use of a phase-shift network, consisting of a 50K resistor and a 0.1-uF capacitor, as shown in Fig. 4-124B. Except for this detail the measurement procedure is the same.

The in-phase terminal of a microphone is the number-1 terminal. The in-phase terminal of a loudspeaker and other equipment is generally marked with a plus-minus sign.

4.125 Describe the basic design of an ultrasonic microphone.—Ultrasonic microphones are used in television receiver remote-control systems, opening of garage doors, control of air-conditioning equipment, slide projectors, gas-leak detectors, and for equipment designed for the assistance in directing blind persons. These microphones are sensitive to frequencies only in the range of 25,000 to 40,000 Hz. For the most part, they are manufactured using a two-plate element of lead-zirconium titanate formed into thin, square plates. The size of the plate determines the response to frequency.

The plate is clamped at four nodal points of minimum motion, to ensure a maximum output voltage. The center of the element is masked so that only the corners are driven directly by the ultrasonic sound waves. The spacing between the center mask and the element is such that sound reaching the center of the plate is changed in phase to correspond with the different phase relationships of the center and corners of the plate. The space behind the plate creates a resonate cavity, and the air compliance assists in control of the plate motion.

The output level of an ultrasonic microphone is on the order of minus 65 dB re: 1 V/dyne/cm^2. The resonant frequency is controlled in manufactnre to within 500 Hz by adjusting the size of each individual ceramic element. This is quite necessary since the elements must respond to several different frequencies for control purposes. The remote exciter unit generally consists of a transistor oscillator with a similar transducer generating frequencies between 25,000 and 40,000 Hz.

Ultrasonic microphones may also be designed to use electrostatic elements similar to an electrostatic loudspeaker, as they are broadly nonresonant, and can be operated over a large number of individual frequencies for circuit-control functions.

4.126 Describe an electret capacitor microphone.—This is a relatively new development in capacitor microphones by Sessler and West of the Bell Telephone Laboratories. The device utilizes a foil electret (see Question 25.51) and therefore requires no polarizing voltage. The frequency response is within plus-minus 3 dB, 50 to 15,000 Hz. Sensitivities of 50 μV re: 1 microbar have been achieved. Because of its relatively low impedance, it can be connected directly to a conventional transistor amplifier.

Like any capacitor microphone, the electret capacitor microphone depends for its operation on minute variations of capacitance produced as sound vibrations impinge on one flexible plate of the capacitor head. However, in this instance, the flexible plate is a *foil electret*, constructed of a thinly metalized sheet of fluorocarbon or polycarbonate. The foil contains a permanent static charge. Since its spacing is varied from the fixed element, the electrostatic field is varied, thus producing a varying voltage at the output terminals. Because of the static charge no polarizing voltage is required. The thin film has a thickness of 0.00012 to 0.001 inch, therefore the capacitance of an electret microphone is about three times that of a capacitor microphone of comparable dimensions, with lower impedance.

The foil is polarized by heating it to about 200 degrees Centigrade while it is held between a pair of charged metal plates (spaced 2-mm) which create an electrostatic field of between 10 and 100V/cm. Charges identical in sign to the adjacent plates migrate to the electret, where they remain after cooling.

The sensitivity of the microphone remains essentially constant over very long periods of time. Measurements indicate that the sensitivity will fall 50 percent in about 100 years. Because of its simple, rugged construction and because it is immune to wide temperature changes, it will no doubt find a wide range of uses in the sound industry, as well as in the recording industry.

For sound pressures of 120 to 140 dB (re: 0.0002 dyne/cm^2), the distortion remains about 1 percent, rising to around 5 percent at 150 dB.

4.127 What is the proximity effect in a microphone?—It is the increase in low-frequency response noted in most pressure-gradient microphones, when the distance from the sound source is decreased, and is most noticeable at distances of less than two feet. This effect is not encountered in omnidirectional microphones. The proximity effect for a bidirectional microphone is shown graphically in Fig. 4-57.

Section 5

Attenuators

Attenuator networks have been in use since the inception of the telephone, for controlling sound levels and the matching of impedances. Many of the present day configurations are the work of Otto J. Zobel, W. H. Bode, R. L. Diezold, Sallie Pero Mead, and T. E. Shay, all of the Bell Telephone Laboratories. Tables of constants developed by P. K. McElroy (also of Bell Telephone Laboratories) for various values of expression and substitution in equations that have long been a time-saver for the design engineer and have resulted in greater accuracy are included.

In this section, networks both balanced and unbalanced, fixed and variable, impedance matching, combining, bridging, mixer controls, their design and use are discussed. The combining of the various configurations is explained, with tables of constants to reduce computation to simple mathematics.

5.1 *What does the term attenuation mean?*—The reduction of a sound wave or electrical energy in an electrical circuit.

5.2 *What is an attenuator?*—An arrangement of noninductive resistors in an electrical circuit to reduce the strength of an audio or radio frequency signal without introducing appreciable distortion. Attenuators may be fixed in value or they may be variable. If they are variable, they are generally designed to reduce the signal in a logarithmic manner. The configuration may take one of several forms. Two commercially manufactured fixed attenuators are shown in Fig. 5-2. Similar networks are available in steps of 0.5 dB up to 40 dB for any impedance up to 600 ohms.

5.3 *What is a pad?*—It is another name for an attenuator.

5.4 *What does the term network mean?*—A configuration of circuit ele-

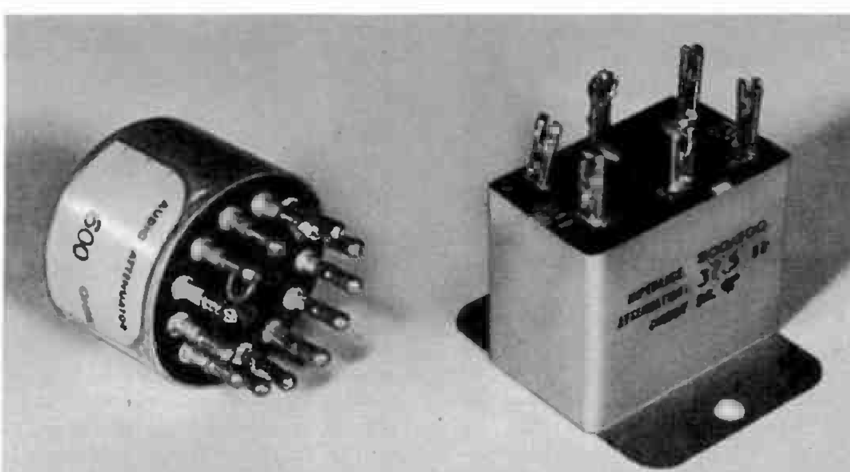

Fig. 5-2. Fixed attenuators. At the left is a "T" -type network that can be varied in steps of 5, 10, and 20 dB, with a total loss of 35 dB. At the right is an "H" network, with a fixed loss of 37.5 dB.

ments such as those used in filters, attenuators, or equalizers.

5.5 ***What does the term configuration mean?***—A circuit or network of circuit elements.

5.6 ***Define the term loss.***—A decrease in the power, voltage, or current at the output of a device compared to the power, voltage, or current at the input of the device. The loss in decibels may be calculated by means of one of the following equations:

$$\text{dB loss} = 10 \operatorname{Log}_{10} \frac{P_1}{P_2} \text{ or,}$$

$$= 20 \operatorname{Log}_{10} \frac{V_1}{V_2} \text{ or,}$$

$$= 20 \operatorname{Log}_{10} \frac{I_1}{I_2}$$

where,

P_1 is the power at the input,
P_2 is the power at the output,
V_1 is the voltage at the input,
V_2 is the voltage at the output,
I_1 is the current at the input,
I_2 is the current at the output.

5.7 ***What is insertion loss?***—The loss created by the insertion of a device in an electrical circuit. The resulting loss is generally expressed in decibels.

5.8 ***What is an impedance-matching network?***—A noninductive, resistive network designed for insertion between two or more circuits of equal or unequal impedance. When properly designed, the network reflects correct impedance to each branch of the circuit.

5.9 ***What is an artificial line?***—A configuration of resistance, capacitance, and inductance representing the electrical characteristics of a transmission line. Attenuators used for reducing the transmission level of a line consist of pure resistance and a uniform frequency characteristic over the whole transmission band. Unless an artificial line is designed as described in Question 25.182, it will not have the electrical characteristics of the line.

5.10 ***What is an attenuation characteristic?***—A graphical presentation of the loss in decibels of a device versus frequency. Attenuators constructed using noninductive resistors offer no discrimination in the normal transmission band. The loss is the same for all frequencies.

5.11 ***What is the difference between the impedance and the dc resistance of an attenuator?***—None, if the resistors are noninductive and correctly terminated. The terms resistance and impedance are used interchangeably with attenuators.

5.12 ***Under what conditions does an attenuator show its correct loss?***—Only when terminated in its characteristic impedance at both the input and output.

5.13 ***What is a line pad and its purpose?***—A line pad is a resistive network placed between the output of a line and the device fed by the line to effect an impedance match. A line pad also supplies a definite termination to the line and to the equipment connected to the line. Line pads are also used to secure a given amount of isolation between the line and the equipment terminating the line. Such a circuit is shown in Fig. 5-13.

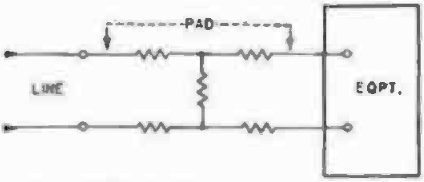

Fig. 5-13. A line-terminating pad.

5.14 ***What does the term "so many decibels of isolation" mean?***—It is a term used to indicate that an attenuator has been connected between the line and a piece of equipment. Isolation, in the form of a pad, is often necessary to supply the correct terminating impedance and to isolate equipment from a line which has been equalized. Isolation pads are also used between filters, equalizers, and amplifiers to isolate them from each other and prevent interaction between them which might upset their frequency characteristics. Pads are also used with impedance-sensitive devices. A typical circuit showing an isolation pad between a low-pass filter and an equalizer is shown in Fig. 5-14.

5.15 ***What is a fader?***—A continuously variable attenuator designed to pass a signal from one signal source to another without interruption, and to provide a smooth transition from one to the other. A typical fader-control circuit is shown in Fig. 5-15.

5.16 ***What is a noninductive resistor?***—A resistor having little or no self-inductance. Such resistors are wound using special winding techniques. A

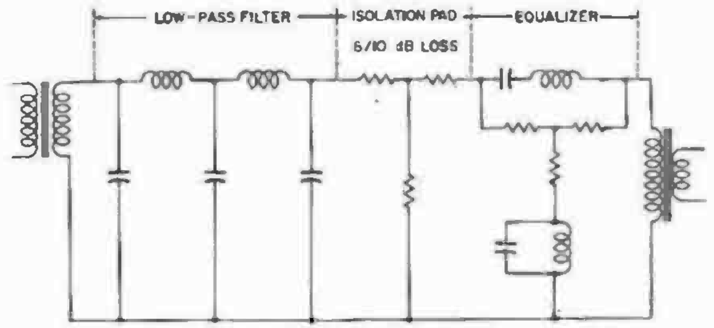

Fig. 5-14. An isolation pad connected between a low-pass filter and an equalizer.

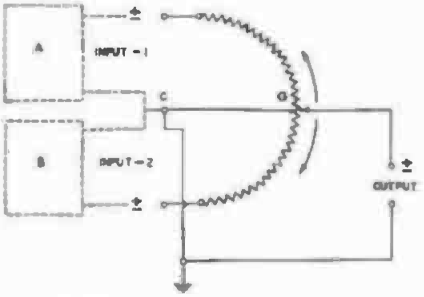

Fig. 5-15. A two-position continuously variable fader. Both signals are at zero when the arm is at the center position.

slotted-form, pi-wound resistor is shown in Fig. 5-16A. In Fig. 5-16B is shown a parallel (bifilar) wirewound resistor. The resistance wire is formed into a loop, then wound with the two wires parallel to each other and in layers. Winding them in this manner cancels the self-inductance, for all practical purposes. Fig. 5-16C shows a group of noninductive wirewound resistors.

5.17 ***May carbon-composition resistors be used for attenuators?***—Yes. They are noninductive at audio frequencies and are convenient to use. (See Question 5.87.) However, some resistors which appear to be carbon are actually wirewound. This may be determined by checking the manufacturer's specifications.

5.18 ***What are the different type windings used for noninductive resistors called?***—Mica-card, Ayrton-Perry, reversed-loop, figure-8, hairpin, fishline, woven-tape, bifilar, bifilar-series, and the slotted-form reversed winding. Slotted-form resistors (shown in Fig. 5-16C) may be used for grid, cathode, plate, and screen resistors in amplifiers, and many other places where noninductive resistors are required.

5.19 ***What tolerance value resistors should be used in attenuators?***—For precision attenuators, one percent; for general test work, five percent.

5.20 ***What effect does an attenuator have on the phase relationships in an electrical circuit?***—None, if the attenuator is constructed of noninductive resistors and the distributed capacity of the circuit is held to a minimum.

5.21 ***What does the term minimum loss mean when applied to an attenuator?***—The minimum loss value for which an attenuator may be designed using a given configuration for a given value of source and load impedance. The minimum loss for attenuators of unequal impedance may be read from the graph of Fig. 5-21.

The graph is entered at the bottom at the desired impedance ratio, then followed vertically until it intersects the diagonal line. The minimum loss is then read at the left margin in decibels. As an example: assume an impedance of 600 ohms is to be matched to an impedance of 150 ohms; this is an impedance

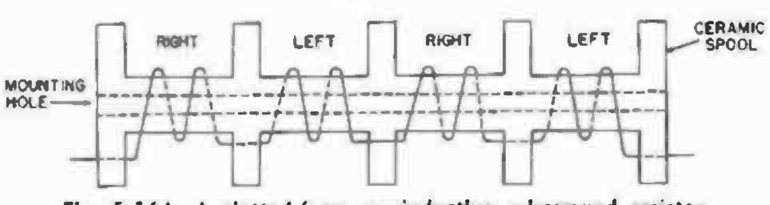

Fig. 5-16A. A slotted-form, noninductive, wirewound resistor.

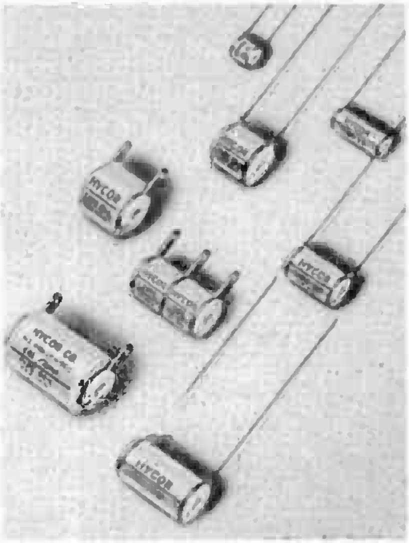

Fig. 5-16C. Noninductive, wirewound resistors that are manufactured by Kelvin Associates.

ratio of four. For this ratio, the graph indicates a minimum loss of 11.5 dB. This is the lowest value for which the attenuator can be designed. In actual practice the network would be designed for a loss of 12 to 15 dB.

5.22 What is the "K" factor used in attenuator equations?—It is the ratio of current, voltage, or power corresponding to a given value of attenuation expressed in decibels. To simplify the calculation of attenuator networks, the values of the most frequently used expressions as tabulated by P. K. McElroy are given in Fig. 5-22. The various values of the expressions are substituted in the equations, thus saving much time and resulting in greater accuracy.

5.23 If attenuators are connected in tandem (series) how is the loss computed?—The internal connections for an

"K" factors—(Continued)

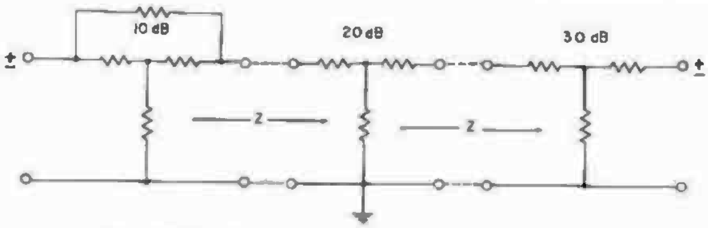

Fig. 5-23A. Three attenuators connected in tandem.

attenuator of the T-type shown in Fig. 5-23A are given in Fig. 5-23B. Contained in the metal housing are *six individual pads* of 1-, 2-, 3-, 4-, 10-, and 20-dB loss. The total loss is 40 dB adjustable in steps of 1 dB, by connecting the appropriate sections in series or tandem. Terminals 1 and 14 are common to all sections and are connected to the low potential side of the circuit in which the attenuator is used. Other types of attenuators have sections with value of 0.5-, 1.5-, 3-, 6-, and 12-dB loss per section. The resistors are noninductively

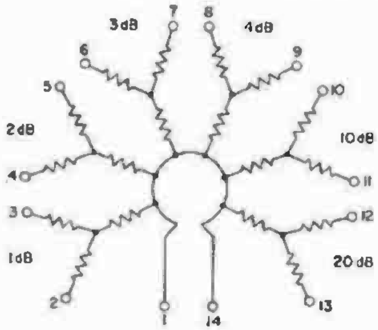

Fig. 5-23B. Internal circuitry for adjustable attenuator having 6 fixed steps of attenuation.

wound, in a metal case that is designed to be mounted with a single screw at the center. They may be obtained for any of the standard impedances.

5.24 ***What is an unbalanced attenuator?***—A configuration with the resistance elements in one side of the line only, as shown in Fig. 5-24.

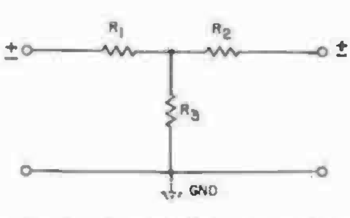

Fig. 5-24. An unbalanced "T" type attenuator.

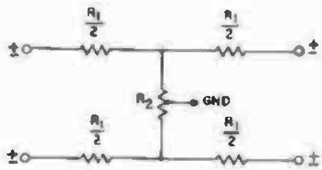

Fig. 5-25. An "H" type or balanced attenuator.

5.25 ***What is a balanced attenuator?***—A configuration with resistance elements in both sides of the line, as shown in Fig. 5-25.

5.26 ***Is it necessary to ground an attenuator?***—If the configuration is unbalanced, the attenuator should be grounded to prevent leakage at the higher frequencies.

5.27 ***Where is a ground connected to an unbalanced pad?***—To the side having no resistance in the line. (See Fig. 5-24.)

5.28 ***Where is a ground connected to a balanced pad?***—To the center of the shunt resistor as shown in Fig. 5-25.

5.29 ***What is the effect if a balanced attenuator is not grounded?***—If the circuits terminating the network are balanced to ground, no difficulty should be encountered. However, if the circuits are unbalanced to ground (unsymmetrical), leakage at the higher frequencies may occur. The amount of leakage may be measured by applying a freqnency of 6000 to 10,000 Hz to the input and observing if the output voltage increases or decreases when the output circuit is reversed. Assuming the transmission characteristics of the circuit are uniform over the above frequency range, no turnover should be noted. Any difference noted with reference to 1000 Hz is caused by leakage. A maximum of 0.25 dB may be tolerated. If possible, a balanced attenuator network should be grounded either by feeding it from, or terminating it by, a balanced to ground circuit, or by connecting a ground directly to the center tap of the shunt resistor.

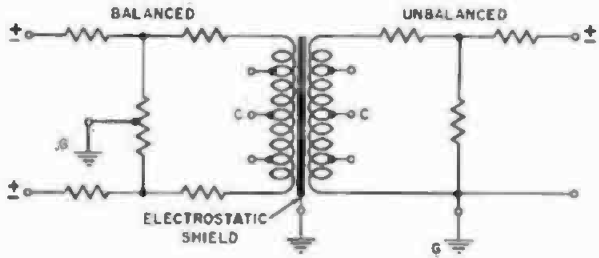

Fig. 5-30A. Connecting balanced and unbalanced networks with a repeat coil.

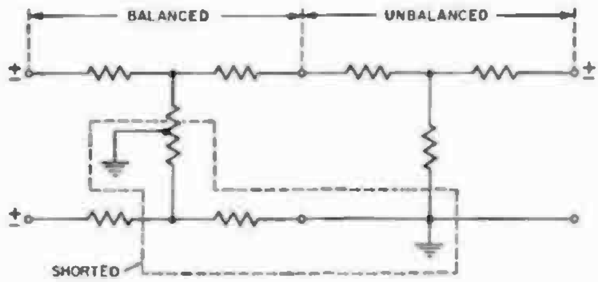

Fig. 5-30B. Two networks connected in tandem.

5.30 ***May a balanced network be directly connected to an unbalanced network?***—Balanced and unbalanced configurations *cannot* be directly connected; however, they may be connected by the use of an *isolation or repeat coil*, Fig. 5-30A. If the networks are not separated electrically, severe instability and leakage at the high frequencies can result. How this occurs is illustrated in Fig. 5-30B. If the networks are connected without the coil, half of the balanced circuit will be shorted to the ground, as indicated by the broken line. The repeat coil will permit the transfer of the audio signal inductively, while separating the grounds of the two networks. Even if the balanced network is not grounded, it should be isolated by a coil. Repeat coils are usually designed for a 1:1 impedance ratio. However, they generally have taps for other impedance ratios.

5.31 ***What is a combining or dividing network?***—A resistive network designed to combine several devices or circuits, each having the same impedance, as shown in Fig. 5-31A. The resistors may be calculated as follows:

$$R_B = \left(\frac{N-1}{N+1}\right) Z$$

where,

R_B is the building-out resistor,
N is the number of circuits fed by the source impedance,
Z is the circuit impedance.

The loss of the network through any two branches is:

$$dB = 20 \operatorname{Log}_{10} (N-1)$$

where,

N is the total number of circuits.

Thus for a three-branch circuit the loss is approximately 6.02 dB.

Unused circuits of a dividing or combining network must be terminated in a resistive load equal to the normal load impedance.

This circuit is often used in the design of sound mixers. This subject is discussed in detail in Section 9. Combining or branching networks may also be designed as a series configuration (Fig. 5-31B). Here are shown three branch circuits combined into one output or input circuit. For equal impedances the equation is:

$$R_t = \left(\frac{N+1}{N-1}\right) Z$$

where,

R_t is the terminating resistor,
N is the number of branch circuits.

The insertion loss may be calculated:

$$dB = 10 \operatorname{Log}_{10} (2N-1)$$

where,

N is the number of branch circuits.

A typical four-circuit combining network, mounted in a metal container, is shown in Fig. 5-31C. The insertion loss of a combining network may be avoided by the use of an *active* combining network, as described in Question 5.99.

5.32 What is a "T" type attenuator?—An attenuator network consisting of three resistors connected in the form

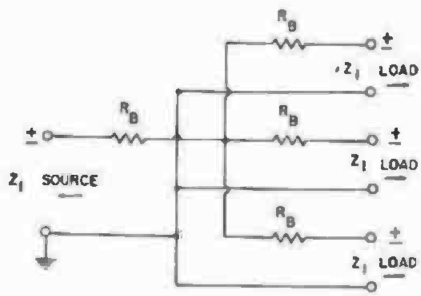

Fig. 5-31A. A combining or dividing network for matching a single circuit to three others.

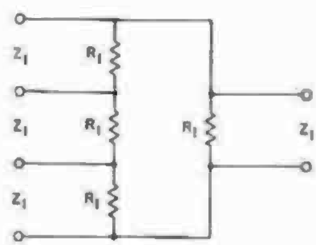

Fig. 5-31B. Series combining network.

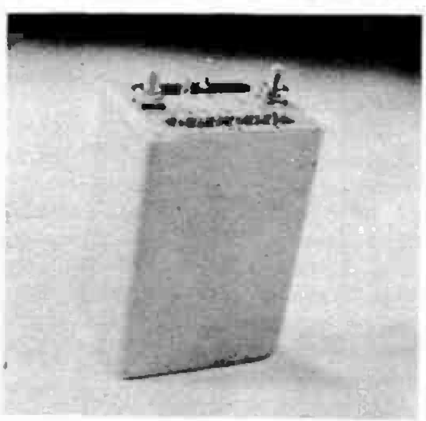

Fig. 5-31C. A four-branch combining network.

of a "T" as shown in Fig. 5-24. The network may be designed to supply an impedance match between circuits of equal or unequal impedance. When designed for use between circuits of unequal impedance, it is often referred to as a taper pad.

5.33 What is the equation used for calculating the element values for a "T" type attenuator, to work between equal impedances?

$$R_1, R_2 = \left(\frac{K-1}{K+1}\right) Z$$

$$R_3 = \left(\frac{K}{K^2-1}\right) 2Z$$

where,

Z is the input and output impedance,
R_1 and R_2 are the series resistors,
R_3 is the shunt arm.

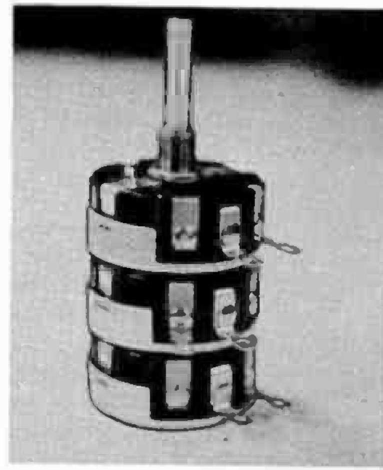

Fig. 5-33. Continuously variable commercial-sound "T" attenuator.

A "T" type attenuator may be designed for any value of loss if designed to operate between equal impedances. The numerical value of the foregoing expressions may be obtained from the table in Fig. 5-22. A commercial-sound, continuously variable attenuator "T" configuration is shown in Fig. 5-33.

5.34 What is a taper pad?—A "T" configuration designed for operation between impedances of unequal value, as shown in Fig. 5-34.

5.35 What is the equation for calculating taper pads?

$$R_1 = Z_1\left(\frac{K^2+1}{K^2-1}\right) - 2\sqrt{Z_1 Z_2}\left(\frac{K}{K^2-1}\right)$$

$$R_2 = Z_2\left(\frac{K^2+1}{K^2-1}\right) - 2\sqrt{Z_1 Z_2}\left(\frac{K}{K^2-1}\right)$$

$$R_3 = 2\sqrt{Z_1 Z_2}\left(\frac{K}{K^2-1}\right)$$

where,

Z_1 is the larger of the two impedances.

The numerical values for these expressions may be taken from the table in Fig. 5-22. Thus, for a network to match 500 ohms to a circuit of 250 ohms with a loss of 20 dB, the resistor values are:

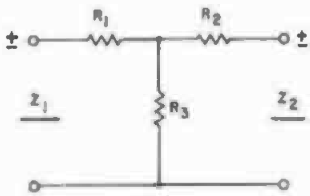

Fig. 5-34. A taper pad used for matching two circuits of unequal impedance.

$$\begin{aligned} R_1 &= 500\,(1.0202) - 2\,(\sqrt{125{,}000})\,(0.10101) \\ &= 510.1 - 2\,(353.55)\,(0.10101) \\ &= 510.1 - 71.42 \\ &= 438.6\Omega \end{aligned}$$

$$\begin{aligned} R_2 &= 250\,(1.0202) - 2\,(\sqrt{125{,}000})\,(0.10101) \\ &= 255.05 - 2\,(353.55)\,(0.10101) \\ &= 255.05 - 71.42 \\ &= 183.63\Omega \end{aligned}$$

$$\begin{aligned} R_3 &= 2\,(\sqrt{125{,}000})\,(0.10101) \\ &= 2\,(353.55)\,(0.10101) \\ &= 71.42\Omega \end{aligned}$$

5.36 ***What is a bridged "T" attenuator?***—An attenuator network containing four resistive elements, as shown in Fig. 5-36. The resistors R_1 are equal in value to the line impedance; therefore, they require no calculation. This network is designed to work between impedances of equal value only, and is the configuration most commonly employed in sound-mixer controls because the configuration requires only two rows of contacts, and two variable resistor groups. The contact arms for resistors R_5 and R_6 are connected mechanically by a common shaft and vary inversely in value with respect to each other.

5.37 ***What is the equation for calculating a bridged-"T" attenuator?***

$$R_1 = Z$$

$$R_5 = (K - 1)Z$$

$$R_6 = \left(\frac{1}{K - 1}\right)Z$$

where,

Z is the line impedance,
R_5 is the bridging resistor,
R_6 is the shunt resistor.

Again the factors may be taken from the tabulations of Fig. 5-22.

5.38 ***What is a balanced bridged-"T" attenuator?***—A configuration similar to the unbalanced bridged-"T" attenuator, except the resistor elements are divided and placed in each side of the line as shown in Fig. 5-38. The principal objection to the use of this configuration, if made variable, is that the shunt resistor R_6 must be divided into two separate arms to provide a ground

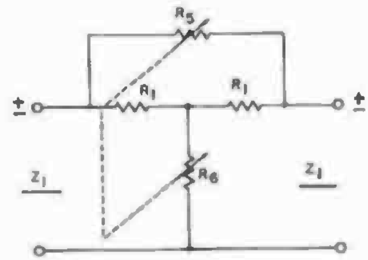

Fig. 5-36. A bridged-"T" attenuator. For variable pads, the arms R_5 and R_6 are made variable.

connection at the exact electrical center. However, if the circuit feeding or terminating the attenuator is balanced to the ground, the ground connection at the attenuator center will not be required.

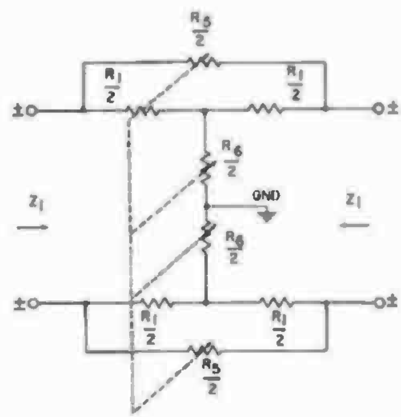

Fig. 5-38. A balanced bridged-"T" attenuator. For a variable configuration four variable arms are required.

5.39 ***What is an "H"-type attenuator?***—A balanced "T" pad. The pad is first calculated as an unbalanced "T" configuration described in Question 5.33. The series resistance elements are then divided and one-half connected in each side of the line as shown in Fig. 5-39. The shunt resistor remains the

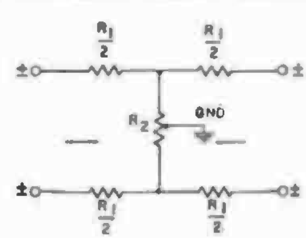

Fig. 5-39. An "H"-type attenuator, also called a balanced "T."

same value as for the unbalanced configuration. A tap is placed at the exact electrical center of the shunt resistor for connection to ground.

5.40 *What is an "L"-type attenuator?*—A configuration consisting of two resistive elements connected in the form of an "L" shown in (a) to (d) of Fig. 5-40. This pad does not reflect the same impedance in both directions. An impedance match is afforded only in the direction of the arrow shown in the figures. If an "L"-type network is employed in a circuit which is sensitive to impedance match, the circuit characteristics may be affected. An "L"-type network should not be used, except where a minimum loss is required and a network of the "T" configuration will not serve because of its minimum loss.

5.41 *What are the equations used for the design of "L"-type attenuators?*—An "L"-type network can only be designed to supply an actual impedance match in a given direction. For unequal impedances, the impedance match may be in the direction of the larger or the smaller impedance but not both.

When an "L"-type network is connected to circuits of equal impedance, the circuits are matched in one direction but not in the other. However, the network may be designed to match either of the terminating impedances.

The arrows in Fig. 5-40 indicate the direction of impedance match. If the network is designed to match the impedance in the direction of the series arm, the mismatch is toward the shunt arm. The mismatch increases with the increase of loss, and at high values of attenuation the value of the shunt resistor may become a fraction of an ohm, which can have a serious effect on the circuit to which it is connected.

The configuration for an "L"-type network operating between impedances of unequal value, Z_1 and Z_2, is shown at (a) in Fig. 5-40. The impedance match is toward the larger of the two impedances Z_1, the values of the resistors are:

$$R_1 = \left(\frac{Z_1}{S}\right)\left(\frac{KS-1}{K}\right)$$

$$R_2 = \left(\frac{Z_1}{S}\right)\left(\frac{1}{K-S}\right)$$

where,

S equals $\sqrt{\frac{Z_1}{Z_2}}$.

For a condition where the impedances are equal, and the impedance match is in the direction of the arrows, as in (b) of Fig. 5-40, the values of the resistors may be calculated by the formula:

$$R_1 = Z\left(\frac{K-1}{K}\right)$$

$$R_2 = Z\left(\frac{1}{K-1}\right).$$

For a condition where the impedances are unequal and the impedance match is toward the smaller of the two impedances, as in (c) of Fig. 5-40, the values of the resistors are determined by the formula:

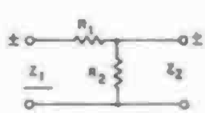
$$R_1 = \left(\frac{Z_1}{S}\right)(K-S)$$

$$R_2 = \left(\frac{Z_1}{S}\right)\left(\frac{K}{KS-1}\right)$$

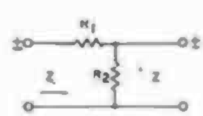
where,

S equals $\sqrt{\frac{Z_1}{Z_2}}$.

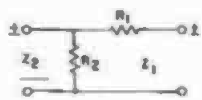
For the conditions shown in (d) of Fig. 5-40, resistors R_1 and R_2 may be calculated by the formula:



(a) Between impedances of unequal value.



(b) Between impedances of equal value.



(c) Impedances unequal, and impedance match is toward the smaller of the two.

(d) Between impedances of equal value, in the direction of the shunt arm.

Fig. 5-40. Configurations that are used for L-type networks.

$$R_1 = Z\,(K-1)$$

$$R_2 = Z\left(\frac{K}{K-1}\right)$$

5.42 What is a pi or delta-type attenuator?—A resistive network resembling the Greek letter pi, or delta, as shown iu Fig. 5-42. Actually there is no difference between the pi or delta configuration, only the manner in which they are drawn. Such networks may be used between impedances of equal or unequal values.

5.43 What are the equations used for designing pi-type attenuators?—For networks operating between impedances of eqnal value:

$$R_1 = Z\left(\frac{K+1}{K-1}\right)$$

$$R_2 = \left(\frac{Z}{2}\right)\left(\frac{K^2-1}{K}\right)$$

where,

R_1 is the input and ontput resistor,
R_2 is the series resistor,
Z is the input and output impedance.

5.44 What are the equations for designing a pi-type attenuator to operate between unequal impedances?

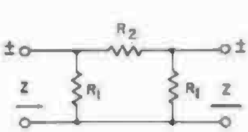
$$R_1 = Z_1\left(\frac{K^2-1}{K^2-2KS+1}\right)$$

$$R_2 = \left(\frac{\sqrt{Z_1 Z_2}}{2}\right)\left(\frac{K^2-1}{K}\right)$$

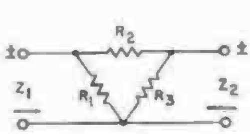
$$R_3 = Z_2\left(\frac{K^2-1}{K^2-2\frac{K}{S}+1}\right)$$

where,

R_1 and R_3 are the shunt resistors,
R_2 is the series resistor,
Z_1 is the input impedance,
Z_2 is the output impedance,
S equals $\sqrt{\frac{Z_1}{Z_2}}$.



(a) Between impedances of equal value.

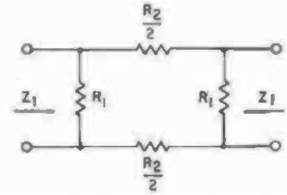


(b) Between impedances of unequal value.

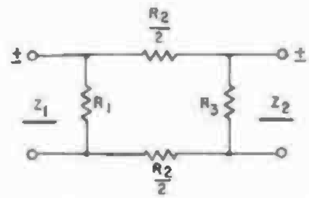
Fig. 5-42. Pi- or delta-type attenuator networks.

To simplify the calculations, the values of the factors may be selected from the table in Fig. 5-22.

5.45 What is an "O"-type attenuator?—A balanced pi-type attenuator configuration. The circuit element values may be obtained by first calculating



(a) Between impedances of equal value.



(b) Between impedances of unequal value.

Fig. 5-45. The "O"-type attenuator.

for a pi-type configuration, described in Question 5.43, then dividing the series resistor and placing half in each side of the line as shown in Fig. 5-45. The shunt resistors remain the same value.

5.46 What is a "U"-type attenuator and where is it used?—"U"-type attenuators may be of a symmetrical or balanced-type configuration, and are quite handy around the laboratory for

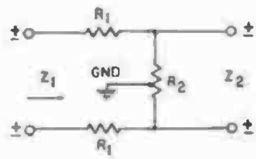


Fig. 5-46. A "U" pad for matching a high impedance circuit to one of very low impedance.

matching a high value of impedance to one of low value. A typical requirement is that of matching the 600-ohm send circuit of a gain set to a microphone preamplifier having a 30-ohm input impedance (Fig. 5-46).

Here the impedance match is of first importance, the loss being secondary. For a symmetrical configuration to work between unequal impedances the resistors may be calculated as follows:

$$R_1 = \left(\frac{Z_1}{2S}\right)\left(\frac{KS-1}{k}\right)$$

$$R_2 = \left(\frac{Z_1}{S}\right)\left(\frac{1}{k-S}\right)$$

where,
- R_1 is the series resistor,
- R_2 is the shunt resistor,
- Z_1 is the larger impedance,
- Z_2 is the smaller impedance,

S equals $\sqrt{\frac{Z_1}{Z_2}}$.

5.47 What is the equation for matching the circuit impedance to the shunt arm of a "U"-type attenuator?—The value of the resistors for the configuration shown in Fig. 5-47 may be calculated as follows:

$$R_1 = \left(\frac{Z_1}{2S}\right)(K-S)$$

$$R_2 = \left(\frac{Z_1}{S}\right)\left(\frac{K}{KS-1}\right)$$

S equals $\sqrt{\frac{Z_1}{Z_2}}$.

The arrow indicates the direction of the impedance match. Any "U" pad may be balanced to ground by connecting a ground to the electrical center of the shunt resistor.

5.48 What is a lattice-type attenuator?—A balanced configuration as shown in Fig. 5-48. Such pads are designed to operate between circuits of equal impedance. They are used in the telephone industry, but are seldom used in normal audio circuits.

5.49 What is the equation for designing a lattice-type attenuator?—The lattice-type attenuator is a truly balanced configuration. Therefore, individual treatment is required for solving the circuit element values. If used in an unbalanced configuration, it degenerates into a pi configuration. The difference between this configuration and the "O" network is that shunt resistors R_2

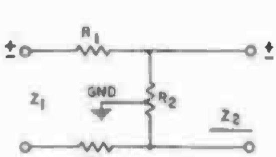

Fig. 5-47. A "U" pad configuration for operation between impedances of unequal value.

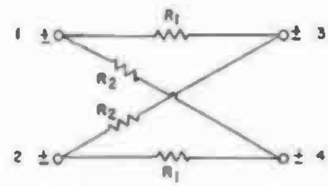
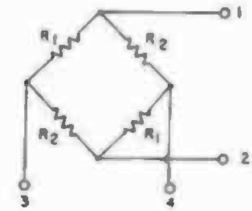


(a) *Lattice configuration.*



(b) *Equivalent circuit (bridge).*

Fig. 5-48. A lattice-type attenuator and equivalent bridge circuit.

are *crossed-over* and connected to both the input and output circuits (Fig. 5-48A). The circuit elements may be calculated:

$$R_1 = \left(\frac{K-1}{K+1}\right)Z$$

$$R_2 = \left(\frac{K+1}{K-1}\right)Z$$

where,
- R_1 is the series resistor,
- R_2 is the shunt resistor.
- Z is the line impedance.

Lattice networks can only be employed in ungrounded circuits of *equal* impedance. If an equivalent circuit is drawn for this pad (Fig. 5-48B), it resembles a balanced-bridge circuit. The principal difference is that resistors R_1 are lower in value than R_2. This difference unbalances the bridge and permits the signal to pass unattenuated in an amount controlled by the ratio of resistors R_1 to R_2.

5.50 Show graphically the loss in level because of impedance mismatch.—If two resistive networks are mismatched, generally the frequency characteristics are not affected; only a loss in level occurs. Attenuators, when properly constructed, consist of pure resistance and are nonreactive; therefore, they present a constant impedance or resistance. If the impedance mismatch ratio is known, the loss in level may be directly read from the graph in Fig. 5-50 (see Question 5.11).

5.51 What is a ladder-type attenuator?—A configuration used for sound

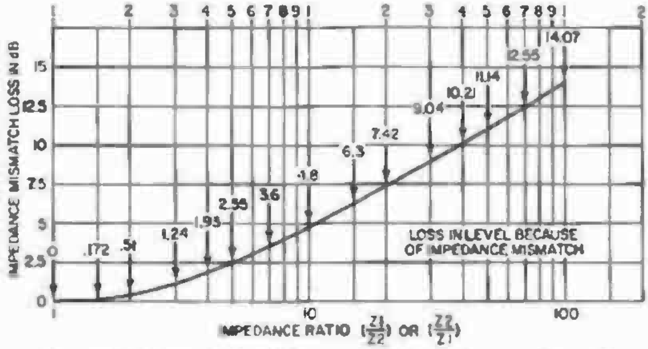


Fig. 5-50. Loss in level because of impedance mismatch.

mixer controls as shown in Fig. 5-51A. Its name is derived from the fact that the configuration is similar to a ladder laid on its side. The configuration of a ladder pot consists of a group of pi-pads connected in tandem. One of the disadvantages of this configuration is the fact that the input and output impedances are not constant throughout its complete range of attenuation. Also, ladder configurations have a fixed insertion loss of 6 dB which is exclusive of the variable setting loss. This loss must be taken into consideration when designing mixer networks.

Ladder pots for mixer-control use, may be obtained in two types of construction—slide-wire and contact types. Ladder pots are designed to operate between circuits of equal impedance.

For motion picture rerecording mixers, the slide-wire type control is generally employed, because it permits a smooth, even attenuation over a wide range. The contact type although not quite as smooth in operation as the slide-wire has only one row of contacts, which reduces the noise and maintenance.

Ladder networks may be designed for balanced operation, also. This is accomplished by connecting two unbal-

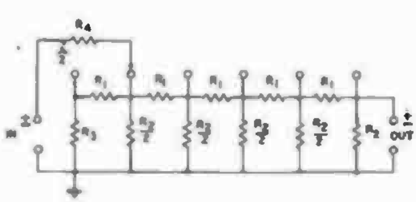

Fig. 5-51A. Configuration for a ladder attenuator for mixer controls. Variable in fixed steps of loss.

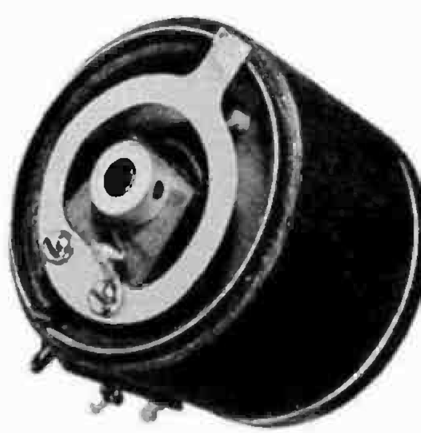

Fig. 5-51C. Unbalanced slide-wire ladder attenuator used in sound mixers.

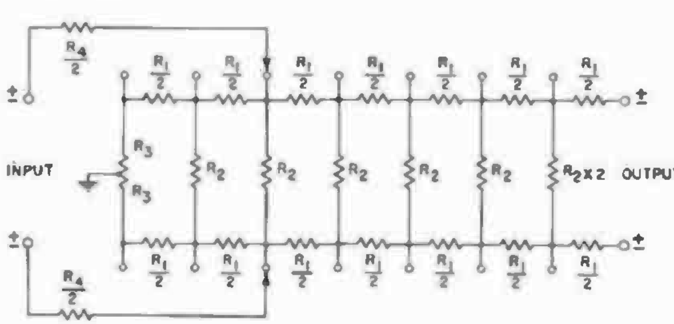

Fig. 5-51B. Balanced ladder network.

anced networks side-by-side (Fig. 5-51B). However, it will be observed, the circuit elements are *not* divided in the same manner as for other type balanced networks. If an unbalanced ladder network is compared with a balanced ladder network, it will be observed that resistors R_1 are divided by *two*, resistors R_1 are also divided by two, and at the output R_4 is now *twice* the value for the unbalanced configuration. Resistor R_3 remains at its *original* value on each side of ground. A typical slide-wire unbalanced ladder attenuator is shown in Fig. 5-51C. The impedance characteristic for a single nnit is given in Fig. 5-83A.

5.52 What is the equation used for calculating a ladder-type attenuator?

$$R_1 = \left(\frac{K^2 - 1}{2K}\right) Z$$

$$R_2 = \left(\frac{K + 1}{K - 1}\right) Z$$

$$R_3 = \frac{R_2 \times Z}{R_3 + Z}$$

$$R_4 = \frac{Z}{2}$$

$$Z_{in} = Z_{out}$$

where,

R_1 is the series resistance,
R_2 is the shunt resistance,
R_3 is the input shunt resistor,
R_4 is the series resistance in the contact arm circuit.

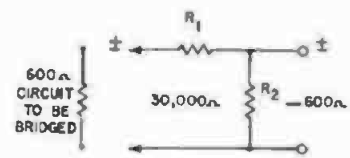
The value of "K" is dependent on the loss per step—not the total loss.

5.53 What is a bridging attenuator? —A pad designed for bridging (paralleling) one circuit while feeding another without disturbing the impedance or frequency characteristics of the circuit being bridged, and absorbing only a small amount of power.

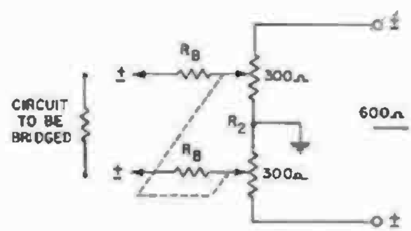
Two such pads are shown in Fig. 5-53, one fixed and the other variable. At (a) is a fixed-loss bridging pad with an input resistance of 30,000 ohms, designed to be terminated in 600 ohms. A pad of this design would have an approximate loss of 40 dB. The resistor R_1 may be changed to any value with a subsequent change of loss. The configuration may be changed to a balanced one by dividing R_1 and placing half in each side of the line.

The pad at (b) may be designed for any bridging resistance by the proper selection of the series resistors R_B, each resistor being one-half the desired bridging resistance. The output resistor R_2 is equal to the impedance of the device across the output terminals of the attenuator. For this illustration, this value is 600 ohms. The two pots in series should total the value of R_2 or, in some instances they can be greater than R_2.

Balanced pads of this design require a ground as shown to prevent leakage at the higher frequencies. The ground to the attenuator is connected to the amplifier ground to prevent the formation of a ground loop.



(a) *Unbalanced (fixed).*



(b) *Balanced (variable).*

Fig. 5-53. Bridging pads.

5.54 What are the resistor values for the more commonly used bridging attenuators?—For the configuration shown at (a) of Fig. 5-53, the following will apply:

R_1	*Loss in dB*	*R_2*
30,000Ω	40.1	600Ω
25,000Ω	38.5	600Ω
20,000Ω	36.6	600Ω
15,000Ω	34.2	600Ω
10,000Ω	30.7	600Ω
7500Ω	28.3	600Ω
5000Ω	24.9	600Ω
3000Ω	20.8	600Ω

The above networks will have the indicated loss only when bridging a circuit of 600 ohms impedance and when terminated in 600 ohms.

The loss for the configuration shown at (a) of Fig. 5-53 may be calculated as follows:

$$dB = 10 \operatorname{Log}_{10} \frac{Z_1}{Z_2} + 20 \operatorname{Log}_{10} \sqrt{\frac{Z_1}{Z_2}} + \sqrt{\frac{Z_1}{Z_2} - 1}$$

where,

Z_1 is the bridging resistance of the pad,

Z_2 is the input impedance of the device to which the pad is connected.

5.55 ***How may a bridging pad be constructed without regard to loss?***—By using the configuration in (a) of Fig. 5-53. Resistor R_1 in the series arm equals the value of the desired bridging input. The shunt resistor R_2 is selected for a value that will properly terminate the input of the device being fed by the pad. The loss may be calculated using the equation given in Question 5.54.

5.56 ***What is the ratio generally employed for bridging pads?***—The bridging impedance should be at least 10 times that of the circuit to be bridged. Standard bridging impedances are: 30,000, 25,000, 10,000, and 7500 ohms.

5.57 ***What is a minimum-loss pad?***—A pad designed to match circuits of unequal impedance with a minimum loss in the matching network. Attenuators designed to work between impedances of unequal value have a minimum loss. This minimum loss is dependent on the ratio of the terminating impedances. As an example: the minimum loss for a pad with an impedance ratio of two is 7.8 dB. Therefore, an attenuator designed to work between 500 and 250 ohms will have a minimum loss of 7.8 dB. The pad may be designed for a greater loss but never less. The minimum loss for various impedance ratios may be determined from the minimum loss chart in Fig. 5-21. Pads designed to work between equal impedances may be designed for any value of loss.

5.58 ***What is the equation used for designing a minimum loss attenuator for matching two impedances of unequal value?***—Using the "L" configuration shown in Fig. 5-58, the resistor values are:

$$R_1 = \sqrt{Z_1 (Z_1 - Z_2)}$$

$$R_2 = \frac{Z_1 Z_2}{R_1}$$

where,

R_1 is the series resistor connected in the side of the larger impedance,

R_2 is the shunt resistor.

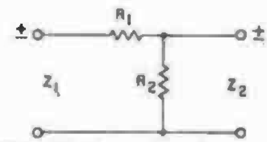


Fig. 5-58. Configuration for a minimum loss attenuator to match two unequal impedances. Match is in the direction of the arrow.

5.59 ***What is the equation used for designing a minimum loss attenuator when only one impedance is to be matched?***—If the larger impedance Z_1 is to be matched, only a series resistor "R" is used as shown in Fig. 5-59. The value of this resistor is:

$$R = Z_1 - Z_2$$

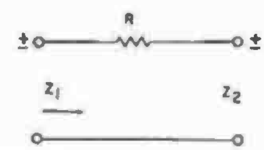

Fig. 5-59. Configuration for a minimum loss attenuator where only the larger impedance (Z) is to be matched. Match is in the direction of the arrow.

5.60 ***What is the equation used for designing a minimum loss attenuator when only the smaller impedance is to be matched?***—In this instance only one resistor is used, connected in shunt with the smaller impedance Z_2, as shown in Fig. 5-60. Its value is:

$$R = \frac{Z_1 Z_2}{Z_1 - Z_2}$$

5.61 ***What are the equations for calculating the loss of a minimum loss attenuator?***—For the "L" type described in Question 5.58:

$$dB = 20 \operatorname{Log}_{10} \sqrt{\frac{Z_1}{Z_2}} + \sqrt{\frac{Z_1}{Z_2} - 1}$$

For Questions 5.59 and 5.60:

$$dB = 20 \operatorname{Log}_{10} \sqrt{\frac{Z_1}{Z_2}}$$

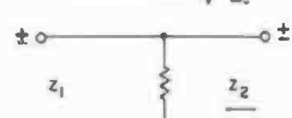

Fig. 5-60. Configuration for a minimum loss attenuator where only the small impedance (Z) is to be matched. Match is in the direction of the arrow.

5.62 What are the resistor element values for the more commonly used minimum loss attenuators?—Values for an "L"-type configuration are as follows:

Z_1/Z_2	R_1	R_2	dB loss
600/500	245	1224	3.8
600/250	458.2	326.8	8.8
600/150	519.6	173.3	11.4
600/30	584.8	30.8	18.9
500/250	253.6	353.6	7.8
500/30	484.8	30.9	18.1
250/30	234.4	32	14.8

This configuration may be converted to a balanced configuration by dividing the series resistor and placing half the value of its resistance in each side of the line.

5.63 What is a grid potentiometer (gain control)? — A potentiometer (pot for short) connected in the control-grid circuit of a vacuum tube for the purpose of controlling the amplification or gain of the stage. The arm of the potentiometer is connected to the control grid of the tube, as shown in Fig. 5-63.

The loss of the pot may be calibrated in decibels by the use of the equation:

$$R_1 = \left(\frac{1}{K}\right) Z$$

$$R = (Z - R_1)$$

where,

- Z is the total resistance of the pot,
- R_1 and R_2 are the upper and lower sections of the resistance, depending on the position of the contact arm.
- K equals a given value of loss in decibels taken from the tables in Fig. 5-22.

The steps may be fixed or continuously variable.

5.64 How may a grid potentiometer be calibrated in voltage?

$$E_2 = E_1 \left(\frac{R_1}{R_1 \times R_2}\right)$$

where,

- E_1 is the input voltage,
- E_2 is the output voltage,
- R_1 and R_2 are the upper and lower sections of the resistance. (See Fig. 5-64.)

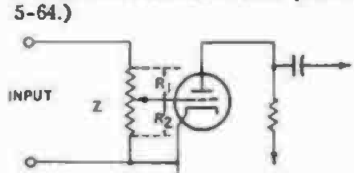

Fig. 5-63. A grid pot.

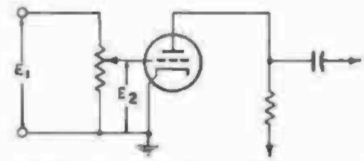

Fig. 5-64. Symbols for calculating the voltage ratio of a grid pot (gain control).

5.65 What is a loudness control?—A ladder-type frequency-compensated gain control consisting of a group of RC circuits. The purpose of this control is to compensate for the human ear characteristic when the sound level is increased or described in a sound reproducing system. The frequency compensation of the control is based on the well-known Fletcher-Munson equal-loudness contours as shown in Fig. 1-76. The configuration of two such controls is shown in Figs. 5-65A and 5-65B. The frequency characteristic of the second control is shown in Fig. 5-65C.

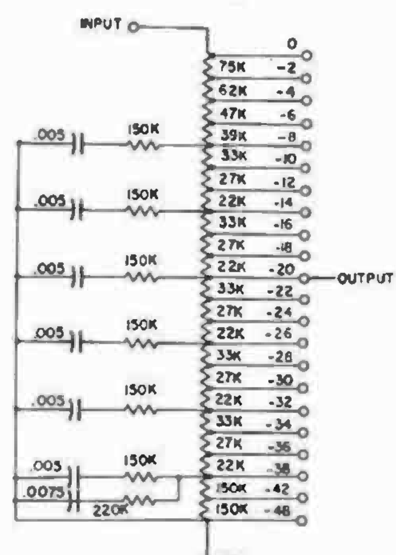

Fig. 5-65A. Configuration for a ladder-type loudness control.

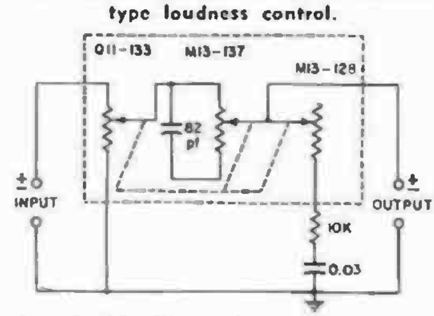

Fig. 5-65B. The IRC loudness control Model LC-1.

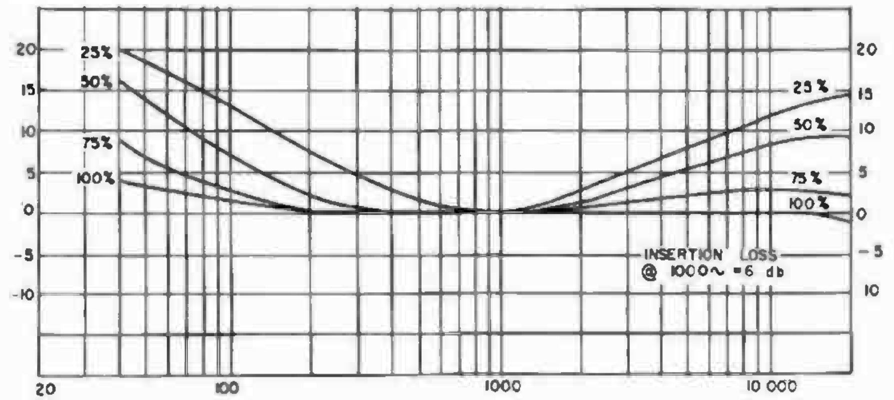

Fig. 5-65C. Frequency characteristics of the IRC loudness control Model LC-1.

5.66 ***Is it practical to construct pads with losses of 60 dB or greater?***—No. It is not good practice to build pads of over 40 dB loss, unless special precautions are taken to reduce the distributed capacity and leakage between the input and output sections. It is more practical to build two or more pads of lower loss and connect them in tandem. The total loss is the sum of the individual losses, assuming that all impedence matches are satisfied between sections.

5.67 ***How may the resistance of an attenuator be measured with an ohmmeter?***—Terminate the output with a resistance equal to the terminating impedance. Measure the input resistance with an ohmmeter. The resistance as measured by the ohmmeter should equal the impedance of the pad. If the attenuator is variable, the dc resistance should be the same for all steps.

5.68 ***If the resistance values of an attenuator are known, how may they be converted to a different impedance?***

$$R_1 = K \times R$$

$$K = \frac{Z_1}{Z}$$

where,
- Z_1 is the new impedance,
- Z is the known impedance,
- K is a multiplying factor,
- R is the known value of resistance,
- R_1 is the new value of resistance.

(See Questions 6.67 and 7.62.)

5.69 ***What is the minimum loss for pads designed to work between equal impedances?***—Pads designed to work between equal impedances may be designed for any value of loss.

5.70 ***What is a compensated L-type attenuator?***—An "L" pad with fixed steps. Each step has a series building-out resistor as shown in Fig. 5-70. The purpose of the resistors in series with the contact arm is to present a constant impedance in both directions. If a constant impedance is required a straight "T" or bridged "T" is recommended.

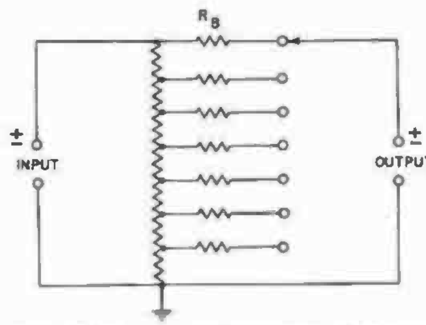

Fig. 5-70. A compensated "L"-type attenuator pad.

5.71 ***How may the impedance of an unknown attenuator be determined?***—By first measuring the resistance looking into one end with the far end open, and then shorted. The impedance is the geometric mean of the two readings:

$$Z = \sqrt{Z_1 \times Z_2}$$

where,
- Z_1 is the resistance measured with the far end open,
- Z_2 is the resistance measured with the far end shorted.

This measurement will hold true only for pads designed to be operated between equal terminations. If the dc resistance of the two ends differs, it may be assumed that the pad is designed to be operated between unequal impedances.

5.72 ***What precautions should be observed when installing attenuators?***—

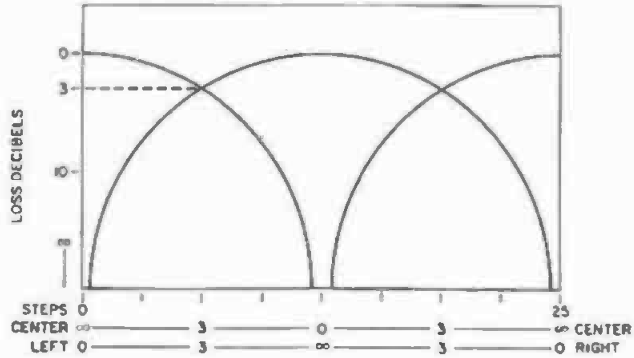

Fig. 5-73B. Characteristics for a three-channel pan-pot.

The input and output circuits must be separated from each other, well shielded, and grounded to prevent leakage at the higher frequencies. As an example: An attenuator of 40 dB loss has a signal voltage reduction of 100:1 between the input and output terminals. Therefore, if coupling between the input and output circuits is permitted, serious leakage can occur at frequencies above 1000 Hz.

5.73 ***Describe a pan-pot (panoramic control).***—Panoramic controls, or pan-pots as they are commonly known, are used in stereophonic rerecording for transferring the *apparent* position of the sound source from one section of a sound field to another. The arrival time of a sound will influence the apparent position of its source, and the intensity offsets the effects of the arrival time. A change of only 3 dB in intensity is enough to displace the apparent source across the sound field. Its effect is controlled by the use of a pan-pot.

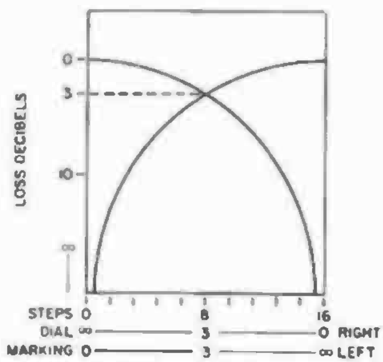

Fig. 5-73A. Characteristics for a two-channel pan-pot.

Either a two- or three-channel pan-pot may be used to pick up a monophonic sound or transfer it to any geometric position desired in the final stereophonic rerecording. Pan-pots designed for stereophonic usage differ from the conventional mixer control in that for a two-channel system, two oppositely wound controls are ganged to-

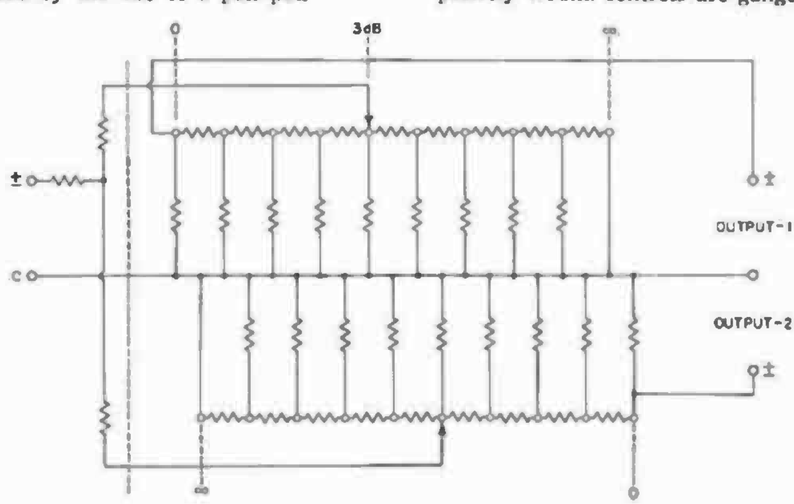

Fig. 5-73C. Two-channel ladder configuration pan-pot for stereophonic recording.

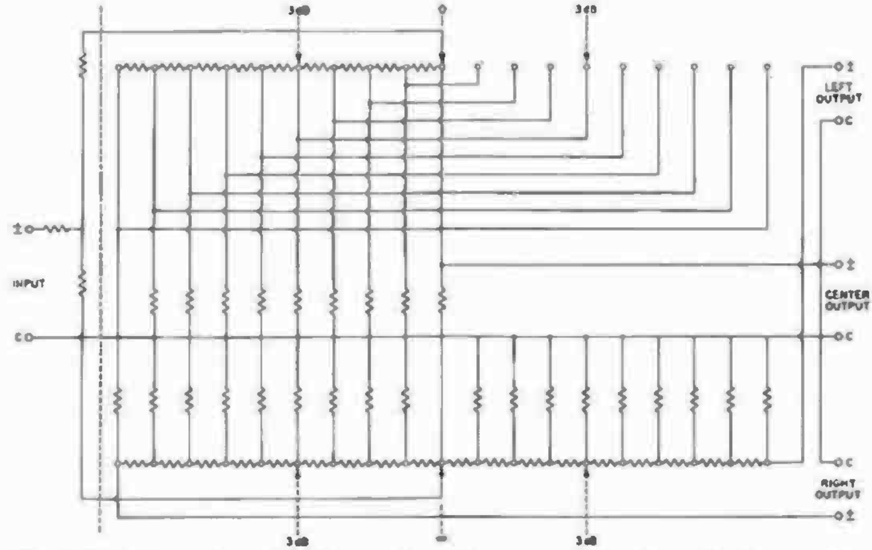

Fig. 5-73D. Three-channel ladder configuration pan-pot for stereophonic recording.

gether in such a manner that the 3-dB down point of each control occurs at zero degrees (Fig. 5-73A). For a three-channel control (Fig. 5-73B), they are so designed that the 3-dB down point occurs at 45 degrees with reference to either side of center. At either of the 90-degree positions, the extreme opposite channel is at infinite attenuation. The usual taper required for such attenuation rate requires at least 16 positions in each control unit to attain the smoothest transition throughout the audible range of control. The attenuation ratio at the extremes is rapid, but slow in the range of overlap from one section to another. The attenuation rate must be precise and conform to the mathematics governing the angular displacement of the sound field with changes of sound level.

Pan-pots lend themselves easily to the ladder configuration, as only two rows of contacts are required for either two- or three-channel control, contrasted to four and six rows for a "T"-type control. The insertion loss is 12 dB for either type. The schematic diagram for a one channel into two is shown at Fig. 5-73C, and a one into three channels in Fig. 5-73D. (See Question 9.22.)

5.74 ***What is a divergence control?*** —A variable network used in stereophonic rerecording for controlling the divergence of the sound field projected by a panometric control over three or more odd-numbered channels. In its narrow position (minimum divergence), a point source of sound is effected. This point lies on the axial position of the sound field under control.

5.75 ***What is a panometric control?*** —A variable network used in stereophonic rerecording to direct a segment of a sound field over a wider field. It is used in conjunction with a divergence control so that the effect may be shaded from a three-speaker width, in a group of five to seven speakers, to a single point sound source. Its effect is similar to a Zoomar optical lens used on motion picture and television cameras.

5.76 ***What is an off-screen fader control?***—A stereophonic control used in rerecording. A single sound source can be made to arrive from a distance at the left off-screen and ride across to the right side of the screen (or vice versa) and then fade away into the distance.

5.77 ***What is a leakage control?***— A control used in stereophonic projection with a built-in leakage to permit a controlled amount of leakage between channels. The leakage is designed for about 10 dB below the normal level on adjacent channels, and 21 dB on second removed channels. This controlled leakage permits the audience in the front rows and side seats of a theater to properly hear the program material.

5.78 ***What is the Hawkins effect?***— J. N. A. Hawkins when exploring the field of stereophonics in 1938 during the development of Fantasound for the Walt

Disney production "Fantasia" observed that if two loudspeakers are energized with the same program material with a level difference of 7 dB, the acoustic level will drop off only 1 dB when the lower-level speaker is cut off.

5.79 *How are mixer controls constructed?*—Mixer controls used for production or rerecording are generally of the ladder or bridged-T configuration. In the bridged-T type, *two* rows of contacts are required, ranging between 20 and 45 per row, in steps of 0.5 dB to 2 dB per step. For ladder configurations only *one* row of contacts is required, and they generally range from 1 dB to 2 dB per step. For the slide-wire ladder control no contacts are used, the loss being continuously variable by the action of the swinger arm on a resistance strip. Straight-T attenuators are rarely used in mixer circuits because three rows of contacts are required to achieve the same amount of attenuation per step. The resistors are generally wound using a bifilar type winding, as discussed in Question 5.16. The important things to look for in a mixer control are internal noise, contact material, ease of operation, and compatibility of the configuration with the design of the mixer network. (See Questions 5.51 and 5.52.)

5.80 *What type mixer controls are recommended for rerecording consoles?*—Mixer controls used for rerecording require a greater number of steps and attenuation to permit a smoother and greater range of control. As a rule, a slide-wire ladder type control will be found the most satisfactory, because of its continuous attenuation without steps (Fig. 5-51C). The next choice is a ladder configuration, using 45 contacts of 1-dB attenuation per step. A third choice is a bridged-T with 45 steps of 0.5-dB attenuation per step. All the above types have rapid cutoff in the last three steps to infinity. It should be remembered the ladder configuration has a *fixed* insertion loss of 6 dB, while the bridged-T has none. If the gain following the mixer network is sufficient, the additional 6-dB loss of the ladder control is of no consequence. This is discussed in detail in Section 9.

There has been over the years a continuing discussion as to the relative merits of the rotary and straight-line attenuators. The selection of a mixer control depends principally on the size of the console and the type rerecording to be done. For small consoles having four to six inputs, the rotary control may be quite satisfactory.

For stereophonic mixer consoles, only straight-line (vertical) controls are used because of space conservation and the necessity of operating several controls simultaneously. It is not uncommon in stereophonic consoles to employ 28 to 34 straight-line controls, plus variable equalizers, filters, and other devices.

Insofar as the electrical characteristics are concerned, the configurations are the same for both the rotary and straight-line controls. Straight-line attenuators lend themselves to simultaneous operation better than the rotary type, although many mixers have mastered the technique of moving two and even three rotary controls with one

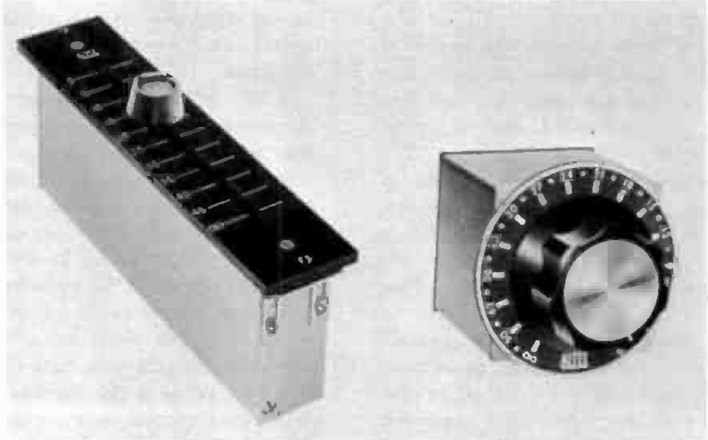

Fig. 5-80. Altec-Lansing straight-line and rotary mixer controls.

Fig. 5-81. Attenuation versus percent rotation for a typical mixer control.

hand. In the straight-line type, three or four can be moved with one hand. For stereophonic rerecording, one straight-line control case may contain up to four individual controls, operated from a single knob at the top. The interior of straight-line multicontrol designs are also shown in Section 9. (See Question 5.79.)

5.81 ***What is the attenuation characteristic used in a typical mixer control?***—The attenuation versus the percent rotation for a typical variable attenuator is shown in Fig. 5-81. It will be noted the attenuation increases quite rapidly after 80 percent of the dial movement is reached. This permits a rapid fade or cutoff.

5.82 ***What are the impedance characteristics of a variable bridged-T attenuator?***—The impedance variations for a typical high quality attenuator

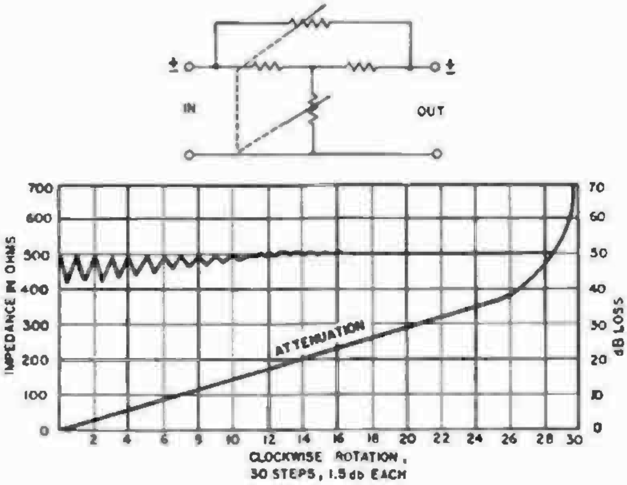

Fig. 5-82. Impedance characteristics for a high-quality 500-ohm variable bridged-"T" mixer control.

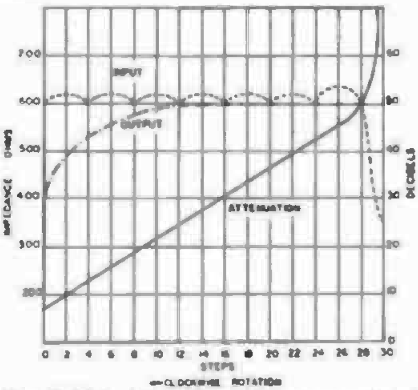

Fig. 5-83A. Impedance characteristics of a 600 ohm ladder-type mixer control.

used in a mixer network are shown in Fig. 5-82. It will be noted the greatest impedance variation occurs as the attenuator arm approaches zero attenuation and amounts to about 80 ohms, reducing the overall impedance to 420 ohms. However, this impedance variation is not too serious, as the mixer-combining network with its building-out resistors isolates this variation to a great extent from associated attenuators. This subject is discussed further in Question 9.24.

5.83 *What are the impedance characteristics for a ladder mixer control?*—This type attenuator will show impedance variations at both the input and output and between steps. However, when used in a combining network with the proper building-out resistors, these variations are of little consequence. A typical impedance curve is shown in Fig. 5-83A.

A plot of the impedance characteristics of a typical four-position mixer network employing four *unbalanced* ladder attenuators is shown in Fig. 5-83B. It will be observed that the principal mismatch occurs at the last three steps, where the attenuation is the least. As a rule, the working range for a typical mixer control is around the 15 to 20-dB loss point. Thus, very little or no mismatch occurs in the operating range.

5.84 *What is a building-out network?*—A resistive combination or combining network used in sound mixers for the purpose of combining the mixer controls in such a manner that the correct impedance match is maintained between the attenuators. Combining networks are also discussed in Question 9.24.

5.85 *What is the cause of noise in a variable attenuator?*—The average noise level for a "T"-type mixer control is on the order of minus 100 dB and is constant; therefore, the signal-to-noise ratio varies with the loss setting. The noise level for a ladder-type attenuator is on the order of minus 120 dB and as the attenuation is increased, the signal-to-noise ratio is *increased*. In high-level mixing circuits, where the mixer control follows a preamplifier, the 6-dB fixed insertion loss of a ladder attenuator increases the signal-to-noise ratio by 6 dB. Also, if the preamplifier employs negative feedback, its internal output impedance will generally be *less* than the impedance of the attenuator. It is not uncommon for a 600-ohm preamplifier to have an internal output impedance of 90 ohms; in this instance building-out resistors should be employed to secure proper impedance

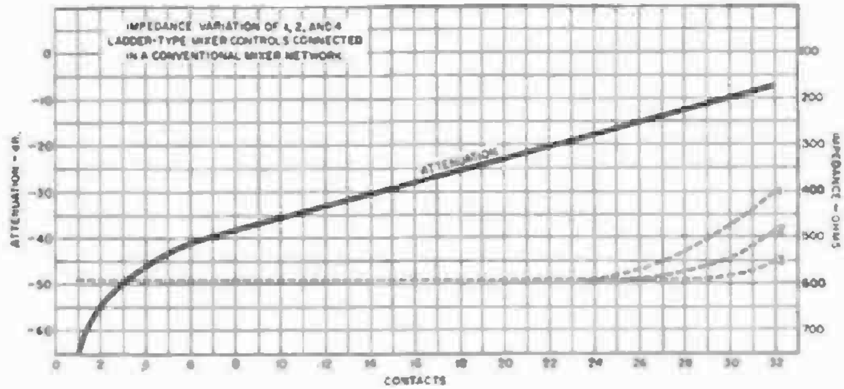

Fig. 5-83B. Impedance variations of 1, 2, and 4 ladder-type mixer controls connected in a conventional mixer network.

match. This subject is discussed in Section 9.

In the case of a slide-wire type attenuator, such as the ladder, the contact noise will be at a minimnm if the material of the contact arm is of the same alloy as the wire. However, noise may be generated when a signal is present if the contact is dirty or corroded because of rectification taking place between the two surfaces. Corrosion will cause a minute current to be generated and this current will be heard every time the arm moves from one wire to the next. As a rule, this type of noise can only be heard when a signal is present. If the contact arm and the wire are of different alloys, minute currents will be generated because of the dissimilar metals and, when amplified, the resulting noise will become quite annoying.

To eliminate the effects of contact noise, manufacturers are now producing variable attenuators with the contacts and arm sealed in *silicone grease*. This design increases the life of the contacts and eliminates noise.

5.86 ***What is an electronic attenuator?***—An amplifier designed to present a loss rather than a gain. Such devices have been constructed with a loss of 75 dB or more.

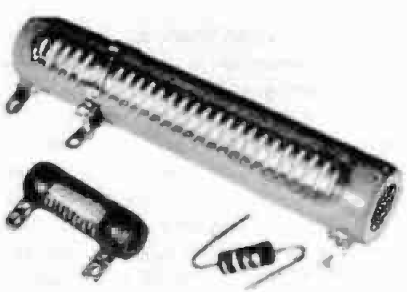

Fig. 5-87. Two variable vitreous resistors and a composition resistor.

5.87 ***What type resistors are used for terminating electronic equipment?***—The type of resistor will depend on the amount of power dissipated in the circuit. For terminating amplifiers and equipment developing a considerable amount of power, wirewound vitreous resistors are used as their self-inductance is quite small. Typical resistors of this type are shown in Fig. 5-87.

For circuits up to one half watt, small composition resistors (shown at the lower right of Fig. 5-87) may be used.

It is the nsual practice to allow a 100 percent safety factor insofar as the wattage rating of the resistor is concerned; that is, if the power dissipated is, say, 5 watts, a 10-watt resistor should be used. (See Question 23.56.)

5.88 ***How are carbon composition resistors constructed?***—By depositing a layer of carbon on a glass or ceramic rod to which wire pigtails are attached. The body of the resistor is completely sealed against moisture. Such resistors are used for all types of circuit elements and, except for certain types of equipment, are quite satisfactory for almost any application.

5.89 ***Describe the type resistance taper curves used in composition control potentiometers.***—Three basic resistance taper curves are shown in Fig. 5-89 for gain controls and other control functions in electronic equipment. Curve 1 is the taper most commonly employed in the manufacture of gain controls (volume controls) for use in amplifiers. The taper is a left-hand logarithmic curve, which provides a small amount of resistance at the beginning of the shaft rotation and a fast increase toward the end. All three curves are plotted for a *clockwise* rotation of the shaft.

The taper of curve 2 is an opposite of curve 1, and is right-hand logarithmic taper. The change in resistance is large for the first half of the shaft rotation and small in the second half. This taper is used for contrast controls in oscilloscopes and bias voltage controls.

The linear taper of curve 3 provides a rate of resistance change that is *proportional* to the shaft rotation. Such tapers are employed for tone control or where a straight-line voltage division is required.

The taper of any control may be measured easily by means of an ohmmeter. First measure the total resistance, then rotate the shaft exactly 50 percent. If the resistance measures 50 percent of its total, it is a curve 3 linear taper; if the measurement is 10 to 20 percent of the total the taper is logarithmic and corresponds to curve 1. But, if the measurement is around 80 percent of the total it is a *reverse logarithmic* taper and corresponds to curve 2.

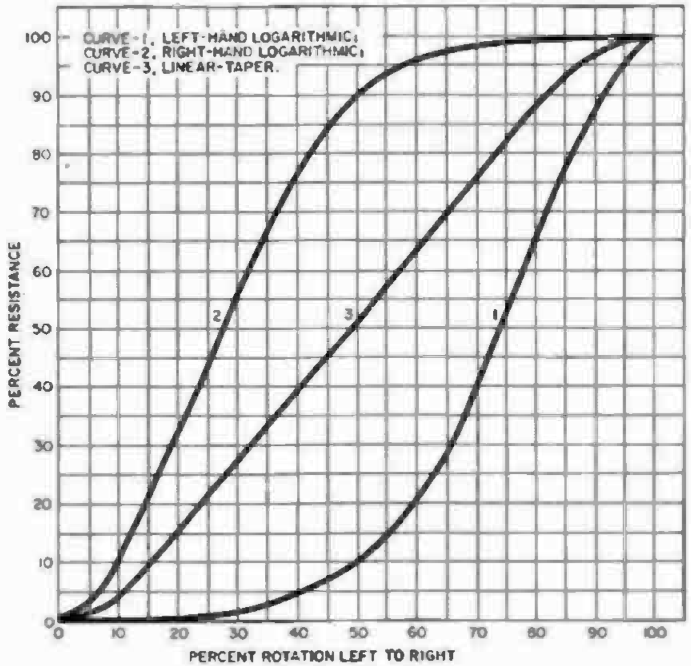

Fig. 5-89. Resistance taper curves for potentiometers. (Courtesy, Mallory Distributor Products, Co.)

5.90 ***What is a dual potentiometer or attenuator?***—Two continuously variable, or step attenuators connected mechanically together by a common shaft. It is used in equipment where the gain must be varied in two circuits simultaneously. Such a control is shown connected at the input of a push-pull amplifier in Fig. 5-90.

5.91 ***What is a compromise network?***—A network used with a hybrid coil for terminating a subscriber's loop (telephone term). The network is not precise but one that will result in the desired isolation between two directions of a hybrid coil. Hybrid coils are discussed in Questions 8.66 and 9.23.

2.92 ***Can a bridged-T attenuator and an L-type attenuator be connected in tandem?***—Yes. Any balanced or unbalanced attenuator may be directly connected to another, provided the impedance match is satisfied and the configurations are of such nature they will not cause an unbalanced condition. At (a) of Fig. 5-92 it is shown how an "L," a bridged-T, and a plain-T pad may be connected in tandem. At (b) is shown the method of connecting balanced attenuator configurations in tandem.

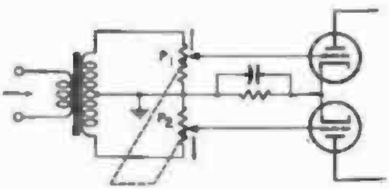

Fig. 5-90. Dual input attenuators that are used for controlling the output of a push-pull amplifier.

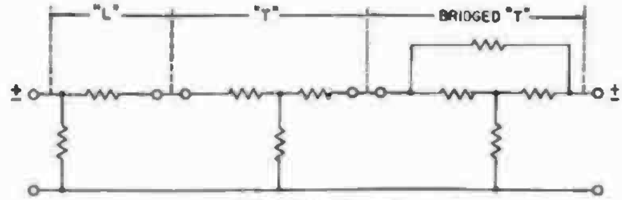
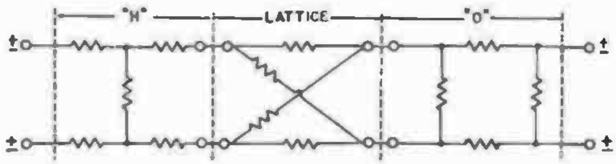
5.93 ***Describe a low- or high-frequency attenuator.***—A low- or high-frequency attenuator is in reality a low- or high-frequency equalizer for attenuating a given range of frequencies. An attenuator is a configuration of *noninductive* elements which in a given design have no effect on the frequency characteristics of the circuit in which it is operating. But, in a low- and high-frequency attenuator, *reactive* elements have been added to make it frequency sensitive for achieving a given frequency characteristic. Equalizers of this type are also termed shelf-equalizers and are used in sound mixer consoles. Such devices are discussed in Section 6 and Section 9.

5.94 ***Describe the construction of a precision potentiometer.***—Precision potentiometers and rheostats have been developed, both mechanically and electrically, to a high degree of accuracy, whereby linear accuracies of 0.015 percent are possible. Although such poten-



(a) *Unbalanced.*



(b) *Balanced.*

Fig. 5-92. Attenuators connected in tandem.

tiometers are not designed specifically for audio work, they find many uses for control circuits in a sound-recording activity. The interior construction of three different precision controls, manufactured by the Amphenol Controls Division, are illustrated in Figs. 5-94A, B, and C.

Referring to Fig. 5-94A, in this control the resistance *strip* consists of a single flat winding, with dual wipers for both the resistance strip and the rotor arm. The shaft is supported on a double shielded ball bearing, and can be rotated 354 degrees. At the rear is a clamp to permit the resistance element to be rotated through a few degrees for phasing with other controls. Up to six units may be ganged together. The resistance strip (depending on the total resistance) may contain 290 to 1457 turns, with linear accuracy of 0.5 percent for a resistance strip length of 2.3 inches. The housing diameter is $1\frac{1}{16}$ inches.

A spiral-type potentiometer that may be rotated 10 turns is illustrated in Fig. 5-94B. In this control, the resistance winding is wound around a large supporting wire (about 14 to 16 gauge enamel), then wound in a *spiral* which permits the wiper-arm to be rotated 3600 degrees or 10 turns. The rotor is of the double-wiper type with zero backlash. The number of turns in the winding around the large wire will vary from 1820 to 11,300, again depending on the total resistance of the winding. The winding covers a total length of 17.64 inches, with linear accuracy of 0.25 percent and a dissipation of 3 watts.

A second type spiral-wound control of 10 turns is shown in Fig. 5-94C, with a winding length of 43.5 inches. The resistance element will range from 2500 to 27,000 turns, depending on the total resistance, with linear accuracy of 0.10 percent, capable of dissipating 5 watts. In the latter two types, the bearings are of the sleeve type. Dials may be attached to the shaft to indicate the number of turns within the accuracy of the potentiometer, in both digital and indexing types. The latter type has an accuracy of 1000:1.

5.95 ***Describe how the linearity of a straight-line potentiometer may be altered.***—Very often in the design of electronic eqnipment, the need for a potentiometer with a special taper or characteristic is required. If a straight-line potentiometer is at hand, its linear characteristics may be altered by the shunting of a *fixed* resistance from one end of the resistance to the swinger-arm. Three methods of shunting a straight-line potentiometer are shown in Fig. 5-95. In the first method, the shunt resistor is connected from the swinger-arm to ground. With the correct value shunt resistance, the potentiometer will have a taper relative to the angular rotation, as shown below the schematic diagram. The second method makes use of a second potentiometer ganged with the straight-line potentiometer. In the third method, two *shunt* resistors connected at each side of the swinger results in a taper resembling a sine wave. A fourth method, not shown, use a shunt resistance connected from the swinger to the top of the potentiometer. For a detailed analysis of the above procedures, the reader is referred to the reference.

5.96 *Describe the construction of a photocell attenuator.*—The photocell attenuator is a radical departure from the conventional mixer control, inasmuch as there is no actual connection to the audio circuits in the mixing console. In the photocell-type attenuator the components consist of a source of dc connected to a *rheostat* in the form of a mixer control, a lamp, and a photocell.

The audio signal is amplified in the usual manner; however the gain of the amplifier is controlled by the *brillance* of the lamp placed in front of the photocell, which is caused to go from a dark condition to full brillance by the posi-

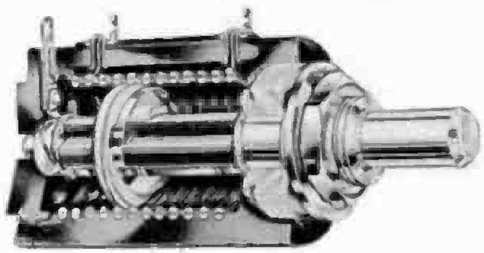


Fig. 5-94A. Amphenol Controls Division, Model 2150 precision potentiometer. Accuracy 0.25 percent.

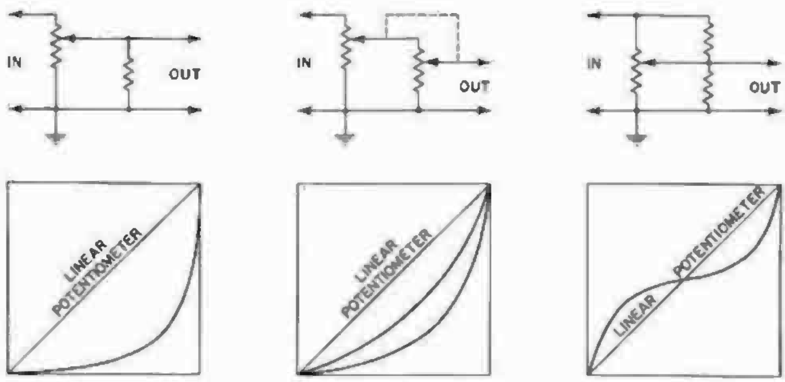

Fig. 5-95. Three methods of applying a shunt resistor to a potentiometer for altering its linear characteristics.

tion of the mixer control (rheostat). In this manner it is claimed that mixer-control contact noise is eliminated. However, there are some drawbacks to this system of mixing.

5.97 ***Describe the construction and operation of an electroluminescence attenuator control.***—Electro-optical attenuators are used in a number of different devices. The one to be discussed is that used in the Teletronix leveling amplifier, described in Question 12.84. Electroluminescence is a method of producing a light source by the passage of current through a thin layer of phosphor. The element, Fig. 5-97, is constructed somewhat similar to a capacitor. The light-producing element consists of a plate of glass or plastic coated with a clear conducting material on one side and a thin layer of phosphor on the

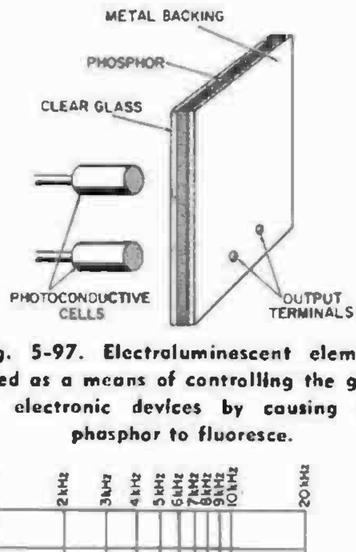

Fig. 5-97. Electroluminescent element used as a means of controlling the gain of electronic devices by causing the phosphor to fluoresce.

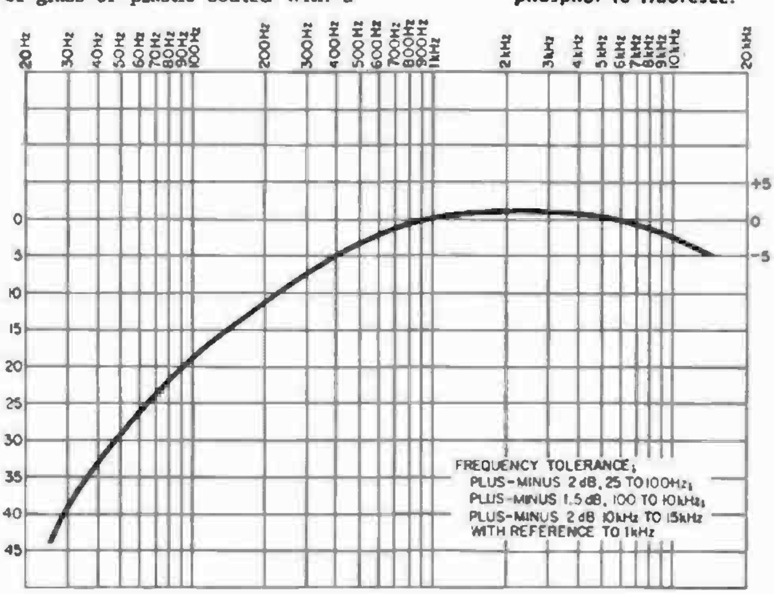

Fig. 5-98A. USASI (ASA) 51.4-1961 Curve "A" weighting network.

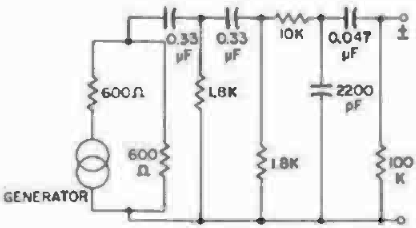

Fig. 5-98B. USASI (ASA) S1.4-1961 curve "A" weighting network for noise measurements, having a frequency characteristic similar to the human ear.

other. The metallic backing contacts the phosphor coating. By applying an alternating current to the conducting plate, the phosphors are excited by the voltage across the dielectric and light is produced. The amount of light emitted depends on the voltage and frequency. The light is picked up by a photoconductive cell whose resistance *decreases* with the impinging light, is amplified, and applied to the control circuitry.

5.98 Describe an RC network for weighted noise measurements.—It is now standard practice for manufactnrers of sound equipment to state the signal-to-noise ratio in terms of a *weighted* curve in accordance with the USASI (ASA) S1-4-1961 Standard Weighted Curve (Fig. 5-98A). This method of measnring signal-to-noise ratios results in a more *realistic* measurement, as the characteristic of the weighting network is similar to the characteristic of the human ear. The network shown in Fig. 5-98B is designed to operate from a 600-ohm circuit, terminated at its output by a vacuum-tube voltmeter or similar device with at least a 1-megohm input impedance, with ballistics and frequency characteristics of a standard volume indicator in accordance with USASI (ASA) Standard C16.5-1961. (See Questions 3.93 and 17.159.)

5.99 Describe an active network and its use.—Active networks are solid-state devices, with or without gain, designed to replace the conventional resistive network used in mixing networks. Fig. 5-99A shows such a network manufactured by Electrodyne having a total of

Fig. 5-99A. Electrodyne Model ACN-1 active combining network.

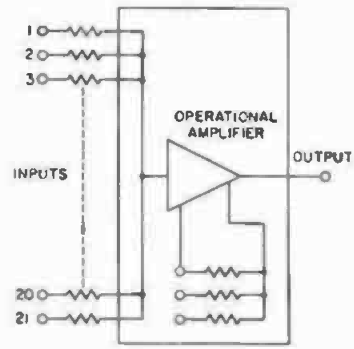

Fig. 5-99B. Block diagram for Electrodyne ACN-1 active combining network.

21 input circuits. Contained within the network is a solid-state integrated circuit (IC) amplifier which may be strapped for a no-gain operating condition, or for a gain of 10 or 20 dB, or varied in steps of 3 dB. Isolation between the input circuits is greater than 70 dB. The use of this device eliminates the need for a booster amplifier to compensate for the insertion loss induced by a resistive type combining network. A block diagram of its internal connections is given in Fig 5-99B.

The frequency response is plus-minus 0.5 dB, 20 to 20,000 Hz, with less than 0.3 total harmonic distortion (THD) for any level up to plus 18 dBm. The input impedance for each input is 10,000 ohms, with an output impedance of 600 ohms. Power requirements are; 24 Vdc at 20 mA. The internal circuitry is protected against accidental reversal.

Section 6

Equalizers

All sound recording and reproducing equipment have one thing in common—the loss of high-frequency response. A greater part of the basic research work was accomplished in the early stages of development of the telephone by Zobel, Shay, Bode and Sallie Pero Mead and others of the Bell Telephone Laboratories. Many of their designs are in current use. In this section, different types of equalization are discussed, using simplified equations and graphs for their design. Numerous practical circuits are given for both recording and reproducing equipment, both solid state and vacuum tube. Of interest to the audio engineer will be the graphs for designing different types of bridged-T equalizers.

6.1 ***What is an equalizer?***—A device consisting of reactive elements which may be connected into an electrical circuit for the purpose of altering the frequency characteristics of that circuit.

6.2 ***What is a compensator?***—It is another name for an equalizer.

6.3 ***What is a duller?***—A form of equalizer used to reduce the high-frequency response of an electrical circuit. It is so named because the high-frequency response appears to be dull and lacking in presence.

6.4 ***What does the term pre-emphasis mean?***—It is the same as pre-equalization. (See Question 6.7.)

6.5 ***What does the term post-emphasis mean?***—It is the same as post-equalization. (See Question 6.8.)

6.6 ***What does the term de-emphasis mean?***—It is the same as post-emphasis.

6.7 ***Define pre-equalization.***—Equalization which is inserted in the recording circuits. (See Question 6.11.)

6.8 ***Define post-equalization.***—Equalization inserted in the reproducing circuits. (See Question 6.11.)

6.9 ***What is the take-off point of an equalizer?***—The frequency where the equalization starts to become effective.

6.10 ***What is a low- or high-frequency attenuator?***—A circuit used in a mixer network to reduce the low- or high-frequency response. It generally consists of a shunt capacitor or reactor in parallel with an input circuit to reduce the high frequencies, or a series capacitor for reducing the low frequencies. This subject is further discussed in Questions 6.80 and 6.81.

6.11 ***What is the purpose of pre- and post-equalization?***—Pre-equalization is connected in the recording circuits and is used to *increase* the amplitude of frequencies above 1000 Hz, and to obtain a greater signal-to-noise ratio during reproduction. Post-equalization is connected in the reproducing circuit and has an *inverse* frequency characteristic to that of the pre-equalization.

The characteristics of both type equalizers is shown in Fig. 6-11. It will be observed that during recording 10,000 Hz is pre-equalized 15 dB with reference to 1000 Hz. When reproduced, 10,000 Hz is post-equalized (attenuated) 15 dB, thereby reducing the surface noise at these frequencies by the same amount. (This curve does not represent present-day pre- and post-equalization; the values shown are for illustration only.)

Pre- and post-equalization may be applied to any type recording system. This subject is further discussed in Section 13 and Section 18.

6.12 ***Describe a variable equalizer.***—It is an equalizer network in which the amount of equalization may be increased or decreased at will. Equalizers of this type are used for rerecording (and other purposes) and are provided

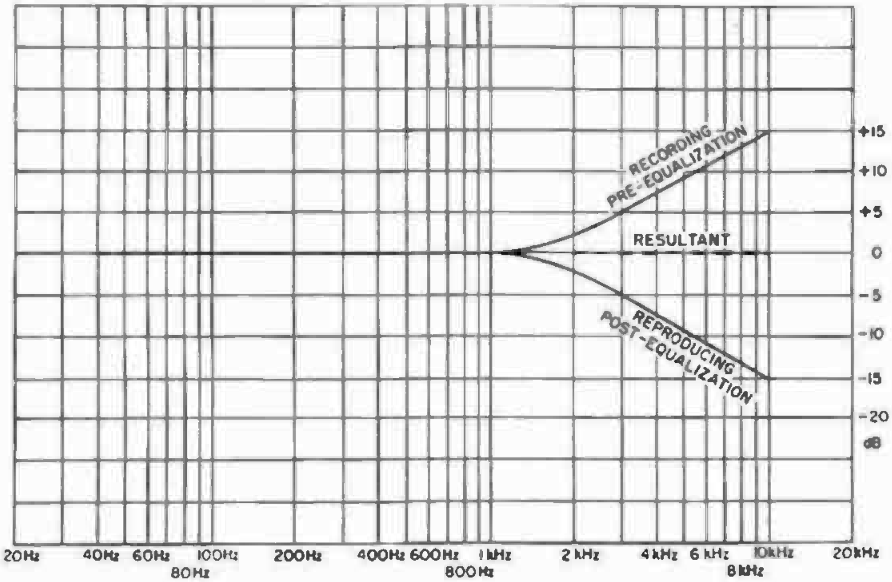

Fig. 6-11. Typical pre- and post-equalization curves.

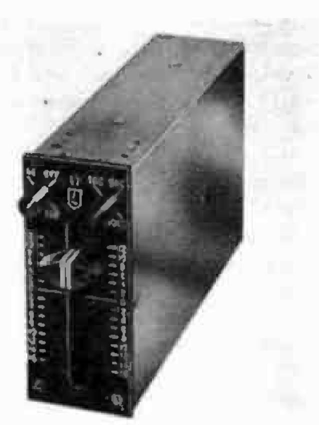

Fig. 6-12A. Program equalizer Model EQ-251A manufactured by Langevin.

with switches for changing the values of the network components. Their design is such they may be changed during actual program operation without affecting the gain or impedance, or introducing noise.

A variable program equalizer manufactured by Langevin is shown in Fig. 6-12A, with its many frequency-response characteristics shown in Fig. 6-12B. Over 1500 different combinations of equalization and attenuation are possible, at frequencies of 40, 100, 3000, 5000, 10,000, and 15,000 Hz. The configuration is a passive constant-B network, employing inductance and capacitance.

Two vertical slide-type switches provide control for a maximum of 12-dB equalization, and a maximum attenua-

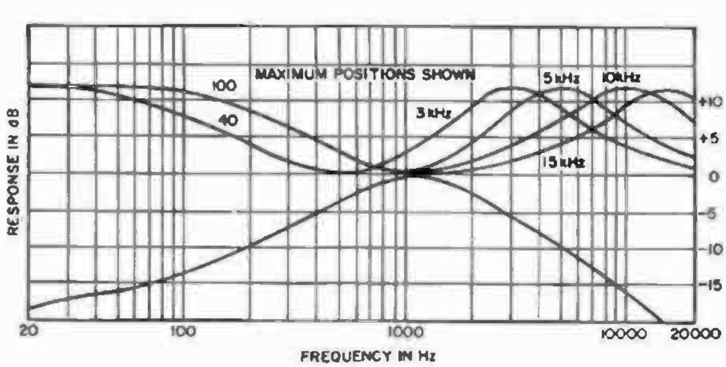

Fig. 6-12B. Frequency-response characteristics of Langevin Model EQ-251A program equalizer.

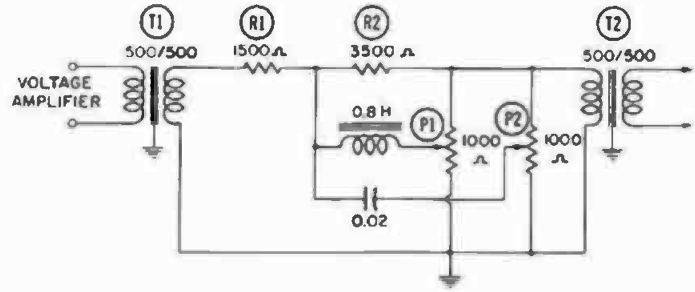

Fig. 6-13A. A simple variable equalizer circuit.

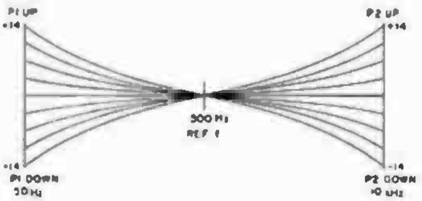

Fig. 6-13B. Frequency characteristics of the variable equalizer circuit given in Fig. 6-13A.

tion of 16 dB. Two rotary switches permit the selection of the peak frequencies. The device presents a *constant impedance* of 600 ohms, with *constant insertion loss* of 14 dB. Because of its physical size, it may be installed above a mixer control The internal wiring consists of printed-circuit boards.

6.13 Show a simple variable equalizer for use in a low-impedance circuit. —A simple variable equalizer consisting of two resistors, an inductance, and a capacitor is shown in Fig. 6-13A. Near the center setting of the variable pots P1 and P2, the frequency response is flat. Moving P1 upward increases the low-frequency response and moving it downward decreases the low-frequency response. When P2 is moved upward the high-frequency response is increased and the reverse takes place when it is moved downward. The total equalization is 28 dB, or 14 dB plus or minus the reference frequency. This equalizer has two disadvantages: (1) the insertion loss is not constant and varies with the amount of equalization and (2) the impedance is not constant. Therefore, the device must be operated from and into circuits presenting a solid termination. The approximate equalization obtained for different settings of P1 and P2 is shown in Fig. 6-13B.

6.14 What effect does an equalizer have on the gain of a circuit?—It presents a loss at a given reference frequency. The amount of loss will depend on the circuit design. If the insertion loss is appreciable, additional amplification will be required to compensate for the insertion loss.

6.15 What is a constant-loss equalizer?—An equalizer having a constant insertion loss regardless of the amount of equalization. Variable equalizers, unless specially designed, have a variable amount of equalization. To overcome this difficulty, equalizers have been designed that will present a constant loss for any setting of their equalization. Such equalizers employ two attenuator pots connected mechanically in such a manner that, as the loss of one pot is increased, the other is reduced in a like amount. Thus, the loss in the circuit remains constant—only the amount of equalization is changed. This equalizer is often erroneously referred to as a constant-gain equalizer. A diagram of a constant-loss equalizer is shown in Fig. 6-15. It will be noted that the loss of the two pots P1 and P2 always remains the same—for this example, 12 dB. Therefore, the insertion loss is 12 dB. (See Question 6.107.)

6.16 What effect does an equalizer have on the impedance relations of a circuit?—If the equalizer is not of constant resistance or impedance, the impedance of the circuit will be disturbed and the expected equalization may not be obtained. Whenever possible, constant-resistance equalizers should be used.

6.17 What is a constant-resistance equalizer?—A configuration using a constant resistance or impedance pad in conjunction with reactive elements. The reactive elements in the shunt and series arms have an inverse relationship; therefore, the impedance at either the input or output is essentially constant.

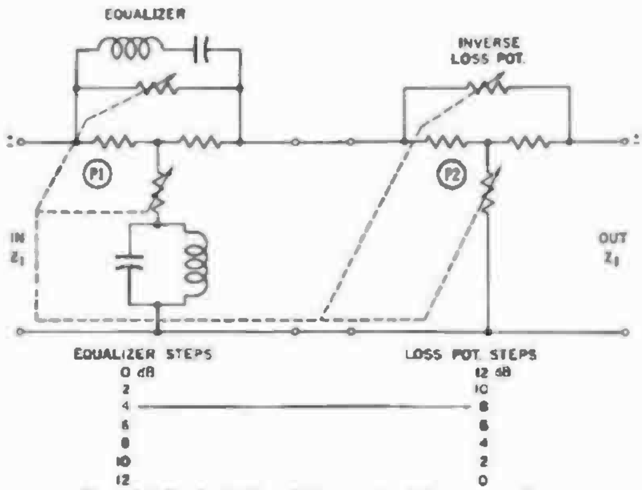

Fig. 6-15. A bridged-T constant-loss equalizer.

6.18 What is the configuration for a constant-resistance equalizer?—Generally, a plain-T pad, as shown in Fig. 6-18. If the equalizer is to be variable, a T pad, variable in steps of 1 dB, is substituted for the fixed pad. As a rule, variable T-type equalizers employ bridged-T attenuators as described in Question 6.48.

6.19 What is the maximum equalization that can be obtained with a constant-resistance equalizer?—About 20 dB is the practical limit. If a greater amount of equalization is required, two or more equalizers may be connected in tandem. The amount of equalization at the lower frequencies is limited by the reactive elements, particularly the inductances. Only coils of the highest Q should be employed in conjunction with high-grade paper or mica capacitors. The coils should have their maximum Q at the resonant frequency.

6.20 What is an L-type equalizer?—One employing a single coil and capacitor as shown in Fig. 6-20. The chief disadvantage of this equalizer is that it does not present a constant resistance to the operating circuits. (See Question 6.95.)

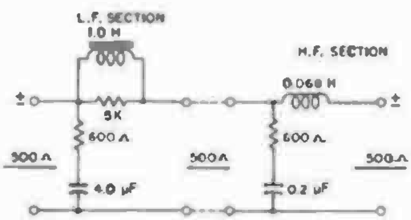

Fig. 6-20. L-type equalizers connected in tandem. Values shown are suitable for the reproduction of 16" transcriptions using the NAB characteristic.

6.21 What does the term "shelving" mean when applied to an equalizer?—It means that the frequency response has a shelflike characteristic at the upper and lower ends of the spectrum as shown in Fig. 6-21.

6.22 What is the phase shift for a bridged-T equalizer?—About 40 degrees.

6.23 What is an attenuator equalizer?—An equalizer using an attenuator

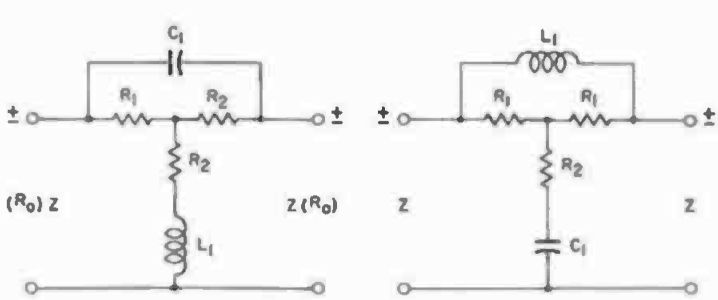

Fig. 6-18. Constant-resistance or impedance equalizers.

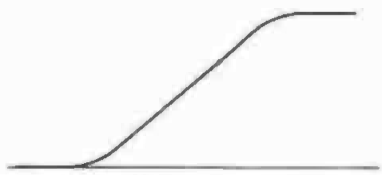

Fig. 6-21. Shelving characteristic of an equalizer.

network for controlling the amount of equalization. They are also known as constant-resistance or constant-impedance equalizers. The equalizers described in Question 6.48 are attenuator equalizers.

6.24 ***Describe an equalizer amplifier.***—Equalizer amplifiers were used in the early days of radio for reproducing 16-inch electrical transcriptions. The required equalization consisted of RC equalizer sections interposed between the first and second stages. The advantage of this design was that the equalizer and preamplifier were one unit. Equalizer amplifiers are now obsolete.

6.25 ***What is a degenerative amplifier equalizer?***—An equalizer employing reactive components in the cathode and plate circuits of a vacuum tube (Fig. 6-25). The amount of equalization is controlled by the two potentiometers, which control the degeneration in the cathode circuit. Many different combinations of both the low and high frequencies are possible.

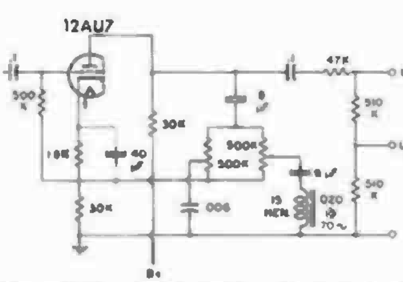

Fig. 6-25. Configuration of a cathode equalization circuit.

This amplifier is often used in public address systems. Because the amount of equalization affects the gain of the amplifier stage, the main gain control of the amplifier system must be changed to compensate for every change in the amount of equalization. The potentiometers are especially designed for this equalizer circuit.

6.26 ***What are the characteristics of a resonant circuit containing capacitance and inductance?***—Referring to the graph in Fig. 6-26, it will be seen that as the frequency is increased from the lowest value to a high value, the capacitive reactance (X_C) decreases, while the inductive reactance (X_L) increases. At the resonant frequency, the circuit behaves as a resistance. Below the resonant frequency it behaves as a capacitor, while above the resonant frequency, the circuit behaves as an inductance. Below the resonant frequency, the current leads the voltage, while above the resonant frequency, it lags the voltage.

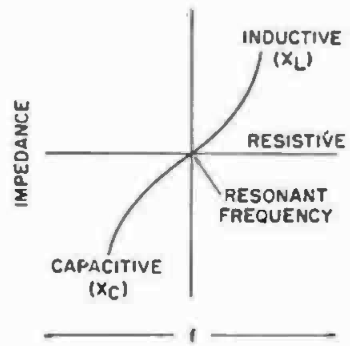

Fig. 6-26. Characteristics of a resonant circuit consisting of inductance and capacitance.

6.27 ***What is a diameter equalizer?***—In disc recording, as the smaller diameters are approached, the groove velocity is lowered, with an accompanying loss in high frequencies, particularly above 3000 Hz. (See Question 13.49.) To overcome this deficiency, diameter equalization is automatically introduced in the recording circuits at diameters previously determined by a family of frequency-response measurements, at a rate of 1 dB per step. The resonant frequency of the equalizer is about 10,000 to 12,000 Hz. Diameter equalization should not be confused with pre-equalization, for it is a form of equalization used *in addition* to regular pre-equalization.

The principal objections to the use of diameter equalization are that it increases the intermodulation distortion at the smaller diameters and adds to the difficulty of tracking the pickup during reprodnction. Also, the power handling capabilities of the recording amplifier must be increased to overcome the additional insertion loss of the diameter equalizer. As a rule, for installations using the standard RIAA pre-equalization and 6 dB of diameter equalization, a recording amplifier of 100 to 120 watts output is required. Since the adoption of the hot-stylus technique for recording disc records, diameter equalization is not used to any great extent. Hot stylus recording techniques are discussed in Questions 15.58 to 15.71.

6.28 ***What type equalizer is used for diameter equalization?***—A bridged-T, constant-loss type. (See Question 13.111.)

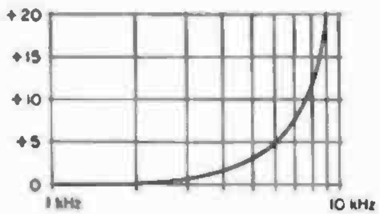

Fig. 6-29A. Transmission characteristics of a high-frequency equalizer.

6.29 ***How are equalizer characteristics plotted?***—Equalizer characteristics may be plotted in two ways, using either the transmission loss or the insertion loss versus frequency. As a rule equalizer plots are made showing their transmission characteristics as it is easier to picture their operation in a recording circuit. An insertion-loss plot is used when designing such devices.

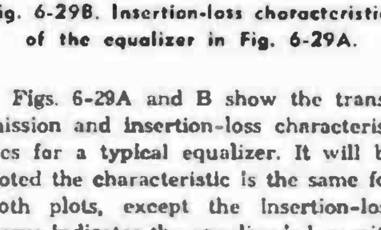

Fig. 6-29B. Insertion-loss characteristics of the equalizer in Fig. 6-29A.

Figs. 6-29A and B show the transmission and insertion-loss characteristics for a typical equalizer. It will be noted the characteristic is the same for both plots, except the insertion-loss curve indicates the equalizer's loss with respect to frequency and the transmission curve the gain of the circuit with respect to frequency.

6.30 ***Can equalization be obtained with simple circuits containing only capacitance and inductance?***—Yes, except that such circuits are not constant-impedance and a given frequency response is difficult to obtain.

6.31 ***If a capacitor is connected in series with a circuit, how is the frequency response affected?***—If the capacitor is small, the low frequencies will be attenuated as shown in Fig. 6.31. The smaller the capacity, the greater will be the attenuation.

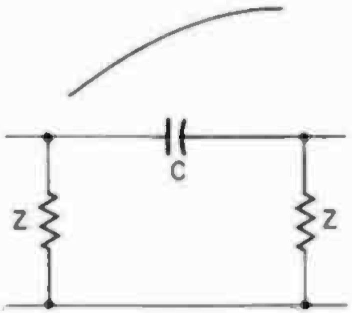

Fig. 6-31. A simple equalizer using one capacitor in series with a circuit.

Although this circuit could be used to increase the high-frequency response or decrease the low-frequency response, it is not entirely satisfactory because the rate of cutoff, frequency response, and impedance match cannot be controlled to any great extent. The circuit functions by virtue of the capacitive reactance. At the low frequencies the reactance is quite high and at the high frequencies it is quite low, permitting the higher frequencies to pass with little attenuation. The capacitor might be looked upon as a variable resistance in series with the circuit controlled by the applied frequencies. Therefore, the impedance varies with frequency.

6.32 ***If a capacitor is connected in parallel with a circuit, how is the frequency response affected?***—The higher frequencies are attenuated. The larger the capacity the greater will be the attenuation, and the reverse of Fig. 6-31. As the higher frequencies are approached, the capacitive reactance decreases, shunting the high frequencies to the low potential side of the circuit. It might be said that the capacitor acts like a *variable short circuit*, controlled by the applied frequencies. The reactance of the capacitor for any frequency may be computed:

$$X_C = \frac{10^6}{2\pi fC}$$

where,

X_C is the capacitive reactance in ohms,
f is the frequency in Hz,
C is the capacitance in microfarads.

At a frequency where the capacitive reactance equals the circuit impedance, the response is down 3 dB.

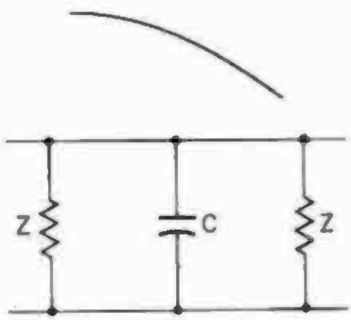

Fig. 6-32. A simple equalizer using one capacitor in parallel with a circuit.

When the capacitive reactance is one-tenth of its original value, and the impedance of the circuit is ten-times the reactance of the capacitor, the change with frequency becomes negligible. To evaluate the change with frequency, it is necessary to refer to a reference frequency, generally 1000 Hz.

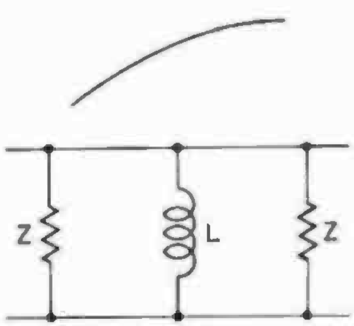

Fig. 6-33. A simple equalizer using one inductor in parallel with a circuit.

6.33 If an inductance is connected in parallel with a circuit, how is the frequency response affected?—If a constant voltage is applied to the input and the frequency varied, the voltage at the output will *increase* with frequency, because of the increase in the inductive reactance of the coil. This is similar to the series capacitor in Fig. 6-31. The

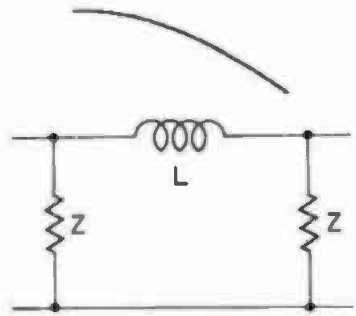

Fig. 6-34. A simple equalizer using one inductor in series with a circuit.

circuit impedance will vary with frequency.

6.34 If an inductance is connected in series with a circuit, how is the frequency response affected?—As the frequency is increased the inductive reactance *increases*, attenuating the higher frequencies, and the response becomes similar to that in Fig. 6-32. The inductive reactance for any frequency may be computed:

$$X_L = 2\pi fL$$

where,

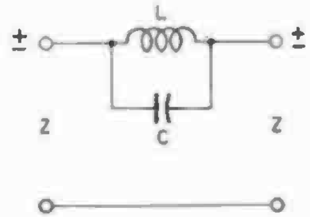
X_L is the inductive reactance in ohms,
f is the frequency in Hz,
L is the inductance in henries.

The inductive reactance of the coil may be looked upon as a series resistance which varies with frequency; thus the circuit impedance changes with frequency.

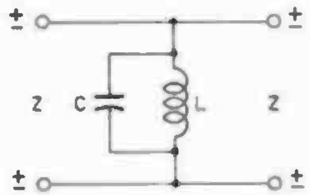
6.35 What is a parallel-resonant equalizer?—A configuration with the circuit elements connected in parallel. The completed network is then connected either in series or parallel with the circuit to be equalized. (See Fig. 6-35.)

6.36 What is a series-resonant equalizer?—A configuration with the circuit elements connected in series. The completed network is then connected either in series or parallel with the circuit to be equalized. (See Fig. 6-36.)

6.37 Why is it necessary to equalize a telephone line?—For ordinary telephone lines, it is not necessary unless they are to be used over long distances. Telephone lines used for radio transmission are equalized to secure a uniform frequency response within limits, depending on the classification of the line. A telephone line may be considered as a low-pass filter, the circuit



(a) Connected in series with a line.



(b) Connected in parallel with a line.

Fig. 6-35. Parallel-resonant equalizer circuits.

elements being series inductance, shunt capacitance, and the dc resistance of the conductors.

To correct for these deficiencies, equalizers, phase-correction networks, and amplifiers are connected in the line at given intervals called repeater stations. The amplifiers compensate for line losses and the insertion loss of the corrective networks. The phase-correction network reduces distortion due to phase shift. (See Questions 7.23 and 7.24.)

6.38 ***Show a simple telephone-line equalizer.***—Fig. 6-38 shows a parallel-resonant equalizer connected in parallel with a line through a variable resistor. The capacitor and coil in parallel resonate at the desired frequency. The resistor R controls the amount of equalization.

The resonant frequency of the equalizer is made slightly higher than the highest frequency to be transmitted by the line. High quality lines are equalized to within plus or minus 1 dB from a reference frequency of 1000 Hz. A typical line-equalizer characteristic is shown in Fig. 6-39.

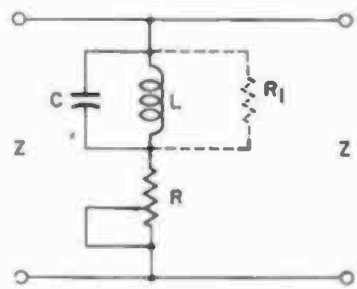


Fig. 6-38. A simple telephone-line equalizer network.

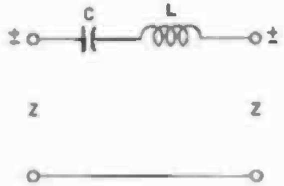
6.39 ***Show the frequency characteristics of a line before and after equalization.***—The plot of a typical telephone line consisting of a No. 19 nonloaded cable pair, 10.8 miles in length is shown in Fig. 6-39. Curve A shows the frequency response of the line before equalization, and C after equalization. Curve B is the equalizer characteristic alone. Although the line characteristic at C is plotted to 10,000 Hz, it is the practice to equalize lines for broadcast use to within 1 dB at 8000 Hz only. For fm use, the frequency response is extended beyond 15,000 Hz.

It will be noted the equalizer reduced the line level from a minus 14 dBm to a minus 30 dBm, after equalization. This loss is caused by the insertion loss of the equalizer.

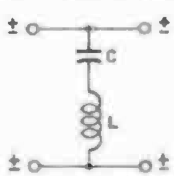
The Western Electric 23A equalizer which is similar to that shown in Fig. 6-38 may be used on longer lines with the following results:

Line Length (Miles)	*Cable Pair Size*	*Equal. at 10 kHz*
10.0	19	1 dB
11.5	19	2 dB
21.5	16	1 dB
25.0	16	2 dB

This is for a nonloaded pair. Cable loading is discussed in Question 25.186.



(a) Connected in series with a line.



(b) Connected in parallel with a line.

Fig. 6-36. Series-resonant equalizer circuits.

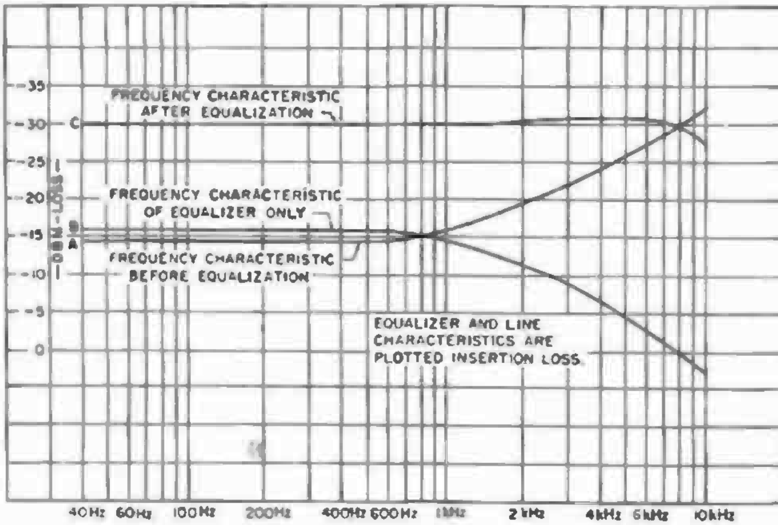


Fig. 6-39. Frequency characteristics of No. 19 nonloaded cable before and after equalization using Western Electric 23A equalizer.

6.40 How is the amount of equalization estimated for a given line?—The amount of equalization may be calculated from the known characteristics of the line. Open pairs require less equalization than cable pairs, because of the greater distributed capacity and series inductance of the cable pairs. The loss in dB per mile for standard telephone cable may be obtained from the cable manufacturer, and the equalizer designed accordingly.

6.41 Explain how the equalizer in Fig. 6-38 functions.—An equalizer may be looked upon as a variable-loss device, controlled by the applied frequencies, which varies the gain of the circuit (at a given frequency) in which it is connected. Frequencies attenuated by a line or device cannot be replaced; however, the predominating frequencies can be reduced to the level of the attenuated frequencies. Thus, a uniform level or response is obtained.

Referring to the equalizer in Fig. 6-38, below the resonant frequency, a parallel-resonant circuit functions as an inductance and offers a low reactance at the low frequencies and a high reactance at the high frequencies. As the frequency is increased, the reactance increases and builds up the voltage across the line, with the greatest voltage occurring at the resonant frequency. This action is opposite to that of the transmission-line characteristic which attenuated the high frequencies.

An equalizer of the type shown in Fig. 6-38 may, therefore, be viewed as a variable short circuit in parallel with the line and controlled by the applied frequencies. At the lower frequencies the reactance is low and at the high frequencies it is high. Thus, at the high frequencies, the shunt effect of the equalizer is reduced to a small amount.

The value of the series resistance R is determined by the length of the transmission line. As the distributed capacity of the line increases, the high-frequency loss increases. Hence, less series resistance is required for a long line than for a short one.

6.42 Where should a telephone equalizer be connected?—At the receiving end of the line. This will result in a maximum signal-to-noise ratio.

6.43 Describe the procedure for designing a telephone-line equalizer.—The first step in the design is to measure the frequency characteristics of the line to be equalized, as described in Question 23.96. After the response has been plotted, the resonant frequency of the equalizer may be determined.

Assume an equalizer is to be designed for a transmission line having a frequency characteristic of that shown in Fig. 6-39. It will be observed that at the reference frequency of 800 Hz, the line has a loss of 15 dB, compared to 8000 Hz. A rising frequency characteristic is required; therefore, a parallel-resonant circuit is employed and connected in shunt with the line (Fig. 6-44). Since the highest frequency to be eqnalized is 8000 Hz, a resonant frequency of 9000 Hz will be used. The line will be terminated in 600 ohms. To obtain an equalization of 15 dB, a *toroidal-wound* coil is required, with a "Q" of at least 50 or 60 at 9000 Hz. The value of the inductance may be found with the assistance of the reactance chart in Fig. 25-201. As this is to be a high-frequency equalizer, a ratio of capacitance to inductance is selected that will result in a low inductive reactance at 100 Hz.

Selecting a value of 100 ohms at 100 Hz, the reactance chart is entered at 100 Hz at the bottom of the chart and followed upward to where an inductive reactance of 100 ohms is encountered on the left-hand margin. At this point, a diagonal line representing a value of 160 millihenries crosses the 100-Hz line. The 160-millihenry line is followed to where it intersects the 9000-Hz line. At this juncture, another diagonal line is encountered. Following this downward to the right-hand margin, the value of capacitance is found to be 0.00195 μF. This value of capacitance in parallel with a 160-millihenry coil will resonate at 9000 Hz. The reactance of the network may now be read at the left-hand margin, where it crosses the 9000-Hz line; for this example this is 9000 ohms.

In a parallel-resonant circuit, the voltage falls off on either side of the resonant peak, attenuating the frequencies on both sides. Below the resonant frequency, the circuit functions as an inductance; hence, it offers a *low* reactance to the low frequencies and a *high* reactance to the high frequencies. As the frequency increases, the inductive reactance increases and the voltage across the line is built-up, the greatest voltage occurring at the resonant frequency. This action is *diametrically opposite* to that of the transmission line, whose attenuation *increases* with frequency.

Thus, the equalizer may be viewed as a variable short circuit in parallel with the line, with the amount of short-circuiting a function of frequency. At 100 Hz the network used for this illustration presents an impedance of 100 ohms in parallel with the line impedance, thereby attenuating the low frequencies. At 9000 Hz the network impedance rises to 9000 ohms; thus, the voltage across the line at 9000 Hz is increased.

6.44 *How is a line equalizer adjusted?*—By sending a series of constant-amplitude frequencies from the sending end of the line to the receiving end where the equalizer is connected. (See Fig. 6-44.) The resistive networks at the send and receive ends supply a solid resistive termination, while isolating the line from the measuring instruments. The series resistance R is adjusted for a uniform frequency response within a given set of limits. This subject is further discussed in Question 23.96.

6.45 *If more equalization is required than can be obtained with one equalizer, how is the equalization increased?*—By connecting two equalizers in tandem. The total equalization is the sum of the two, if they have the same frequency characteristics. If the characteristics are not the same, it will be the algebraic sum of the two.

6.46 *What is a series-resonant equalizer and how is it designed?*—Series-resonant equalizers are designed in a manner similar to the parallel-resonant equalizer, using the reactance chart in Section 25. Series-resonant equalizers are connected in parallel, with a line to remove peaks as shown in Fig. 6-46A. The action of this con-

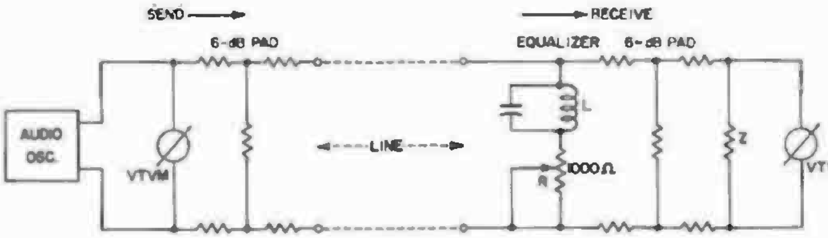

Fig. 6-44. Test setup for measuring the frequency characteristic of a telephone line with equalization.

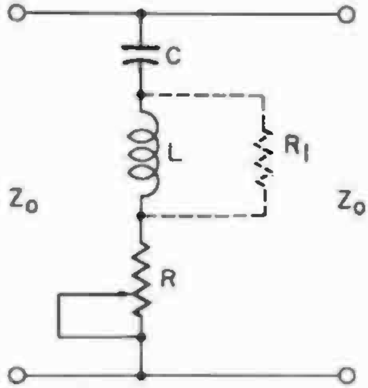

Fig. 6-46A. A simple series-resonant equalizer network.

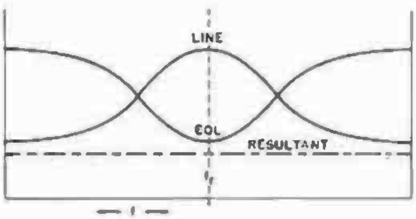

Fig. 6-46B. The effect of connecting a series-resonant equalizer in parallel with a transmission line and the resulting frequency response.

figuration is the reverse of the parallel-resonant type. In Fig. 6-46B is shown a peak removed from a circuit by the use of a series-resonant equalizer connected as shown in Fig. 6-46A. The resistance shown in dotted lines may be connected in parallel with the coil to lower the Q of the circuit, thus, flattening out the response. However, the use of this resistance will also reduce the amount of equalization normally obtained without it.

6.47 ***How are the exact values of capacitance obtained for equalizer construction?***—By connecting capacitors in parallel, in series, or in series-parallel.

6.48 ***Describe the four basic bridged-T equalizers most commonly used in audio work.***—The four basic bridged-T equalizers are shown in Figs. 6-49A and B and 6-50A and B, with their frequency characteristics depicted with their configurations. The configuration in Fig. 6-49A is a low-frequency shelf-type suppressor equalizer employing only two reactive elements, a capacitor and an inductance. The positions of the reactive elements have been reversed in Fig. 6-49B. A high-frequency shelf-type suppressor equalizer is the result, with an inverse characteristic of that in Fig. 6-49A. The configurations shown in Figs. 6-50A and B are similar in nature but employ series and parallel resonant circuits to achieve their characteristics. Although the configurations shown are designed for bridged-T pads, straight-T pads may be substituted, if desired. For variable equalization, a 20-dB bridged-T pad, variable in steps of 1 dB, is used. As these equalizers are of constant impedance or resistance, they must be operated from, and in to, a solid termination. The pads may be designed from the data given in Questions 5.33 and 5.37.

6.49 ***How do the reactive elements in a bridged-T equalizer function?***—They control the pad loss as a function of frequency. In the design of a bridged-T pad, as described in Question 5.37, the two resistors R_1 are equal in value to the circuit impedance. Resistors R_5 and R_6 are varied in their values, inversely to each other, to obtain different values of loss. For a condition of zero loss, R_5 has zero resistance and R_6 infinite resistance. Now, if reactive elements are connected in parallel and in

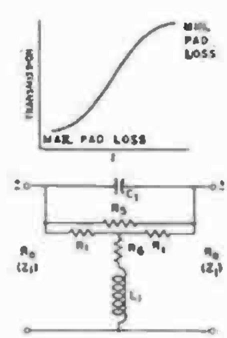

Fig. 6-49A. High-frequency shelf-type suppressor equalizer.

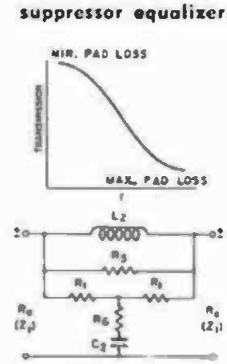

Fig. 6-49B. Low-frequency shelf-type suppressor equalizer.

series with resistors R_5 and R_6, and R_5 and R_6 are selected for a given pad loss, the reactive elements may be employed to control the pad loss as a function of the applied frequencies.

The configuration shown in Fig. 6-49A is a high-frequency equalizer similar to that used in recording circuits for pre-equalization. Capacitor C_5 is connected in parallel with R_5 and the inductance L_6 in series with R_6. At the lower frequencies C_5 has a high reactance and the inductance L_6, a low reactance. Under these conditions, the pad loss is approximately normal.

As the frequency is increased, the reactance of C_5 starts to decrease and the reactance of L_6 starts to increase. When the maximum frequency is reached, C_5 shunts out R_5 and L_6 has, for all intents and purposes, opened up R_6 (because of the high reactance of L_6). Thus, the pad loss is theoretically zero.

Removing the pad loss from the circuit increases the gain at the higher frequencies. When complex waveforms are applied to the equalizer, the pad loss will appear to be different for each frequency component in the waveform. Therefore, the pad loss is controlled by the applied frequencies. The frequency response shown with the configuration is the transmission characteristic plotted for frequencies of constant amplitude applied to the input of the network. Equalizers of this type may be used to increase the frequency response of a circuit at either end of the spectrum. It will be noted that the response at the extreme upper and lower ends is shelved.

Twenty dB of equalization is about all that can be obtained with a single equalizer of this configuration. If a greater amount of equalization is required than can be obtained with a single unit, two or more equalizers may be connected in tandem. The total equalization will be the algebraic sum of the two equalizers. The coils should be of toroidal design with a Q at the lower frequencies of at least 25.

6.50 What is the purpose of using resonant circuits with bridged-T equalizers?—To resonate the equalizer at a predetermined frequency. Equalizers using this type configuration may be designed to attenuate or accentuate certain frequency bands. These designs may also be used to equalize the extreme ends of the spectrum, by selecting the proper circuit elements and using the left or right side of the resonant response curve shown above the configurations in Figs. 6-50A and B.

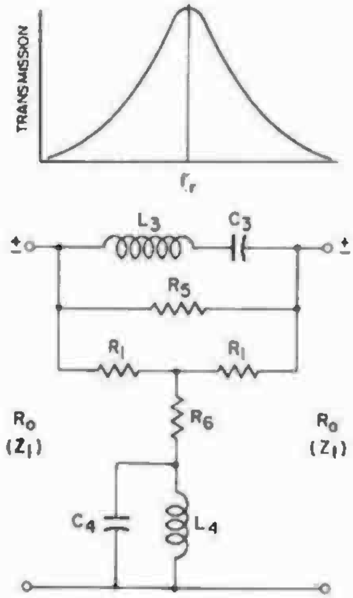

Fig. 6-50A. A resonant circuit peak-type equalizer.

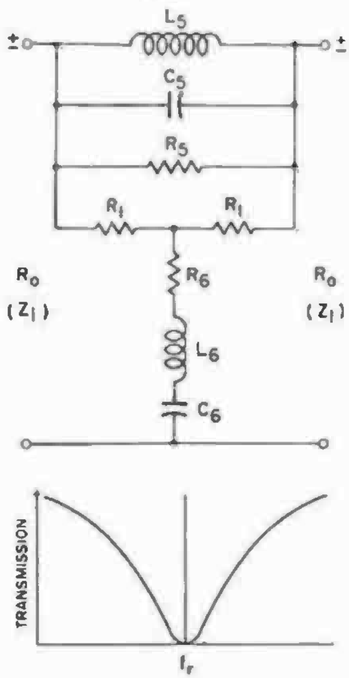

Fig. 6-50B. A resonant circuit dip-type equalizer.

When using the configuration in Fig. 6-50A to increase the high-frequency response, the left side of the response curve is used to provide the lift. For low-frequency equalization, the right side of the curve provides the lift.

The configuration in Fig. 6-50B may be used to attenuate either the high or low frequencies. The right side of the response curve is used for attenuating the lower frequencies and the left side the high frequencies.

The action of the reactive circuits is similar to that described for the configurations in Figs. 6-49A and B. As the frequency of resonance is approached, the impedance of L_3 and C_3 in Fig. 6-50A decreases, shunting out R_3. While this is happening, the reverse is taking place at L_4 and C_4. Thus, the pad loss is removed from the circuit. It will be noted the positions of the resonant circuits are reversed in Fig. 6-50B. Therefore, the actions of the resonant circuits are also reversed and, thus, an inverse frequency characteristic to that in Fig. 6-50A is obtained.

It should be remembered that in a parallel-resonant circuit the impedance increases with an increase in frequency. The reverse is true for a series-resonant circuit. The configurations shown may be designed to induce a peak or dip anywhere in the frequency spectrum, by the selection of the proper configuration and circuit-element values. These equalizers may also be made variable in steps of 1 dB by the use of a 20-dB variable attenuator. The maximum equalization is about 15 dB, although more may be obtained if toroidal coils with the maximum Q occurring at the resonant frequency are used.

6.51 ***How is the equalizer shown in Fig. 6-49A designed?***—For this design, the configuration in Fig. 6-49A will be used. The transmission characteristics for the configurations of Fig. 6-49A and B are given in Fig. 6-51A. The curves are plotted for a 10-dB loss pad. The figure 1.0, at a point where the curves cross is termed the *crossover* frequency and represents the frequency where *one half* the pad loss occurs. For this example, curve 1 will be used, with point 1.0 representing 1500 Hz. The frequency response may now be plotted as in Fig. 6-51B, by first indicating a loss of 5 dB at 1500 Hz. Again referring to Fig. 6-51A, at 3000 Hz (2.0) the loss is 1.25 dB; and at 4500 Hz (3.0), the loss is negligible; at a frequency of 750 Hz (0.5), the loss is 8.75 dB; and at 500 Hz (0.3), it is 10 dB.

To make the curve fit a particular requirement, the frequency at the crossover point (1.0) is shifted up or down on the curve, as required. Three different plots, using *one-half pad loss* frequencies of 100, 1000, and 3000 Hz

are shown in Fig. 6-51C. It may be observed that all the curves have the same shape, and only the frequency of the one half pad loss has been shifted. The affected portion of the frequency spectrum extends from about one third of the half-loss point to three times the half-loss point.

After the frequency response has been plotted and if it is satisfactory, the values of C_1 and L_1 are selected from the table in Fig. 6-51D. Under the 1.5 kHz column, L_1 equals 0.053 henry, and C_1 is 0.147 μF. After having determined the circuit element values and the frequency characteristics, the configuration may be *converted* to an impedance other than 600 ohms and for a pad loss greater than 10 dB by the use of the simple *conversion factors* given in Questions 6.56 and 6.57.

6.52 *How is the equalizer configuration shown in Fig. 6-49B designed?*—It is designed in a manner similar to the example given in Question 6.51, except that *curve-2* of Fig. 6-51A is used. Assume that a low-frequency, shelf-type equalizer with a half-pad loss occurring

for 500-ohm equalizer shown in Fig. 6-50A.

increase the high-frequency response. The right side is used for increasing the low-frequency response. The complete curve is used when designing a resonant or peaked equalizer. To illustrate how the chart functions, assume an equalizer is required for increasing the high-frequency response at 10,000 Hz 10 dB, for a circuit impedance of 500 ohms.

Referring to the chart in Fig. 6-53A, three sets of transmission curves are given. Because this is to be a high-frequency equalizer, a curve is selected from the left-hand group that will approximate the desired response, with the point (1.0) representing the resonant frequency of 10,000 Hz. The ratio of other frequencies to the resonant frequency may now be plotted.

Assuming the desired frequency response approximates curve 2 at the left, 1000 Hz (0.1) will be up 0.4 dB; 2000 Hz (0.20), up 1 dB; 5000 Hz (0.5); 5 dB, 7000 Hz (0.07), 8 dB; and 10,000 Hz, 10 dB.

While it is true the curves in Fig. 6-53A will not satisfy all requirements, they will be sufficiently close for all practical purposes.

After plotting the frequency response, the circuit element values are selected from the table in Fig. 6-53B under the resonant frequency of 10,000 Hz. For the above example, these values are: L_a 5.9 mH, L_1 10.7 mH, C_3 0.043 μF, and C_1 0.024 μF. The pad loss is 10 dB.

After the unit had been completed and transmission measurements made, the values of the capacitors may be shifted to bring the curve closer to requirements. However, unless extreme accuracy is desired, the indicated values will be close enough.

6.54 How is a low-frequency equalizer similar to the one shown in Fig. 6-50A designed?—By using the same procedure as described for the high-frequency equalizer, with one exception. The right-hand group of curves in Fig. 6-53A is used. The circuit elements are selected from the table in Fig. 6-53B.

6.55 How is the equalizer shown in Fig. 6-50B designed?—By the use of the chart in Fig. 6-55A and using the procedure described in Question 6.53. However, as this equalizer has characteristics reversed from those in Fig. 6-50, the frequency response is plotted as a loss, as the curves approach resonance. The circuit elements are selected from the table in Fig. 6-55B. The left-hand group of curves is used for high-frequency attenuation, and the right-hand group for low-frequency

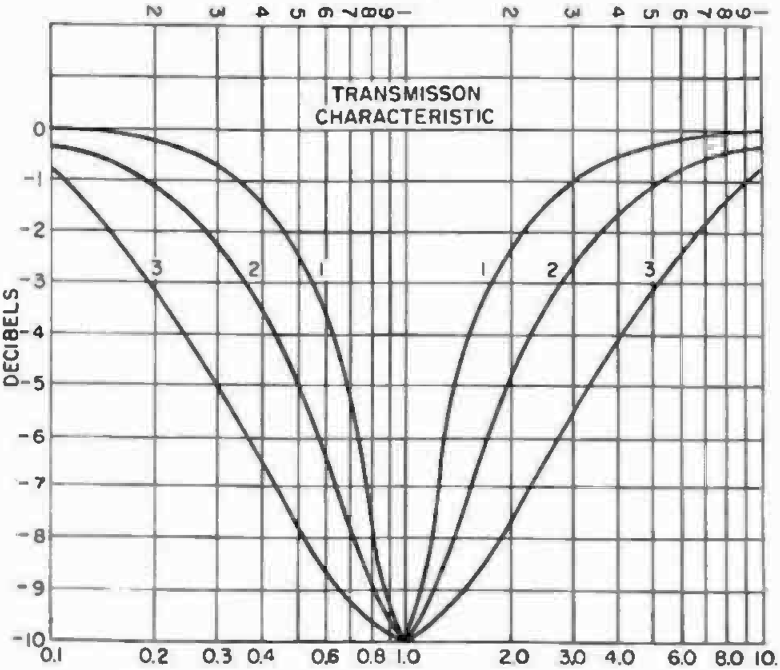

Fig. 6-55A. Equalizer design chart for equalizer shown in Fig. 6-50B.

attenuation. For a dip-type equalizer, the complete curve is used.

6.56 ***How are the foregoing equalizers converted to impedances other than 500 or 600 ohms?***—All of the foregoing design data have been based on either a 500- or 600-ohm circuit impedance. If the equalizer is to be used in a circuit impedance other than that given, *new* circuit component values are required. In this situation the equalizer network is designed for the impedance given,

used. For situations less than maximum, the curves will approximate the same general shape. Higher values of attenuation will cause the curve to become steeper, with the break at the no-loss point remaining around the same point. This will move the design point of the half-pad loss closer to the break from the no-loss portion at the higher values of attenuation, and vice versa. (See Questions 6.61, 6.67, and 6.124.)

6.57 ***How are the foregoing equalizers converted to other pad losses?***—When pad losses other than 10 dB are required, a change in the circuit element values is necessary. The new values are obtained by multiplying or dividing the values given for the 10 dB, 500-ohm equalizer by the factors given in Fig. 6-57.

6.58 ***What is a balanced equalizer?***—One in which the circuit elements are connected in each side of the line in a manner similar to a balanced attenuator. Four such configurations are shown in Figs. 6-58A, B, C, and D. The configurations of Figs. 6-58A and B are derived from those shown in Figs. 6-49A and B, while those in Figs. 6-58C and D are derived from the configurations of Figs. 6-50A and B. The terminating circuits must be balanced or be symmetrical to ground.

6.59 ***Is it permissible to connect a balanced and an unbalanced equalizer***

dB Loss	K	dB Loss	K	dB Loss	K
3	0.30	9	0.89	15	1.62

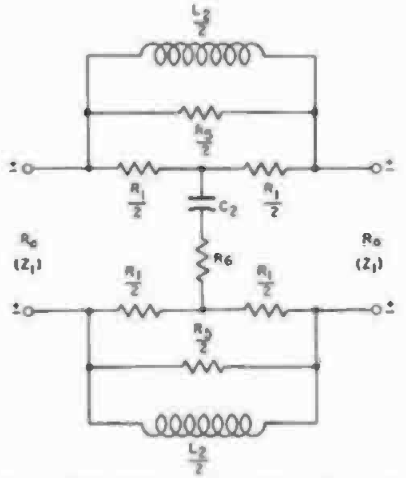

Fig. 6-58B. Balanced configuration, derived from Fig. 6-49B, showing the division of circuit elements.

in tandem?—No. They cannot be directly connected, but must be isolated from each other by a repeat coil as described for attenuators in Question 5.30. Otherwise, serious leakage will occur at freqnencies above 2000 Hz.

6.60 ***What is the designed procedure for a balanced equalizer?***—Balanced equalizers are first designed as an unbalanced configuration and then converted to a balanced configuration, as shown in Figs. 6-58A, B, C, and D.

6.61 ***How is the attenuator loss selected for a variable equalizer?***—The

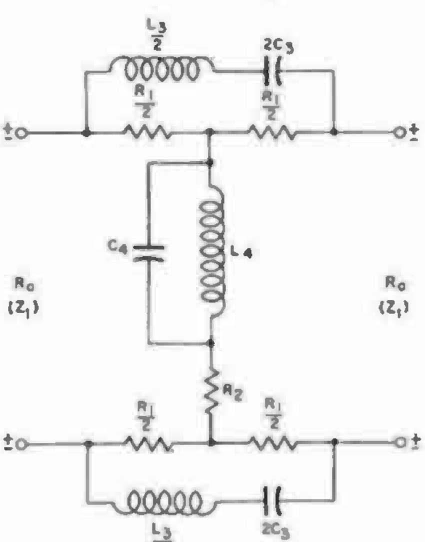

Fig. 6-58C. Balanced configuration, derived from Fig. 6-50A, showing the division of circuit elements.

attenuator loss is selected for the desired maximum value. The transmission curves of the equalizer will remain essentially the same for all loss settings of the attenuator up to 10 dB. For greater values of loss, the curves will become steeper.

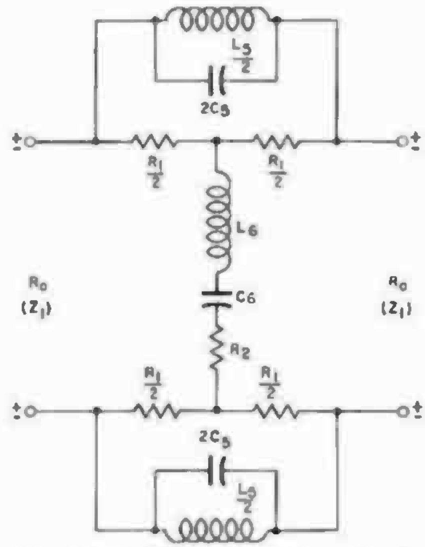

Fig. 6-58D. Balanced configuration derived from Fig. 6-50B, showing the division of circuit elements.

Variable attenuators for use with constant-resistance type equalizers as a rule employ the hridged-T attenuator. However, the plain-T may also be used, except that more noise may be encountered when changing the attenuation becanse of the additional contacts and also because of its configuration. The bridged-T attenuator is less noisy when moved, because of the loading effect of the fixed resistors R_1 in the upper side of the configuration. Generally, the attenuator is so designed that it will increase the loss in steps of 1 dB.

6.62 ***Is a ground connection required with an unbalanced equalizer?***—Yes. If the equalizer is not grounded, leakage will occur at the higher frequencies.

6.63 ***Where is the ground connected to an unbalanced equalizer?***—To the side which has no circuit elements, similar to an unbalanced attenuator.

6.64 ***Is it necessary to ground a balanced equalizer?***—No. If the source and terminating impedances are balanced with respect to ground no equalizer ground is necessary.

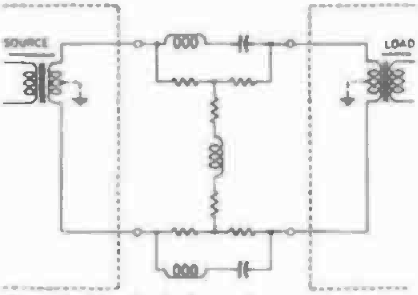

Fig. 6-65. A balanced equalizer connected in a balanced-to-ground source or load circuit. The circuit may be grounded at both the input and output or at one end only.

6.65 Where is a ground connected to a balanced equalizer?—If the circuit is not balanced to ground, the ground is connected to the exact electrical center of the configuration. Because this may be impractical in some configurations, the source and/or terminating circuits are balanced to ground as shown in Fig. 6-65.

6.66 If two equalizers are connected in tandem, what is the overall frequency characteristic?—It is the algebraic sum of the two characteristics as shown in Fig. 6-66. Curves 1 and 2 are the characteristics of the individual equalizers. Curve 3 is the overall characteristic.

6.67 If the frequency characteristics and component values of an equalizer are known, can it be converted to a different frequency?—Yes, by changing the reactive component values inversely with respect to frequency. As an example, an equalizer with a resonant frequency of 1000 Hz may be changed to a resonant frequency of 100 Hz by multiplying the reactive elements by a factor of 10. If this same equalizer were to be converted to 5000 Hz, the circuit elements would be divided by a factor of five. The impedance would remain the same as it was for the original design.

6.68 What type coils are recommended for equalizer construction?—Coils of high Q, such as toroidal-wound coils. The efficiency of a toroidal coil is extremely high compared to other designs. Also, they are not affected by external magnetic fields and may be mounted alongside each other without fear of coupling.

6.69 At what frequency is the maximum Q specified for equalizer coils?—At the resonant frequency. (See Question 8.72.)

6.70 How are toroidal coils constructed?—They are wound on a circular core composed of molybdenum permalloy dust mixed with a plastic binder. The core is compressed into the shape of a doughnut under a pressure of 200 tons per square inch. A typical toroidal coil is shown in Fig. 6-70. By the use of this type winding, coils with a Q of several hundred are possible.

6.71 What is the turnover frequency of a toroid coil?—It is the frequency at which the Q stops rising with frequency and starts downward, as shown by the curves in Fig. 6-71.

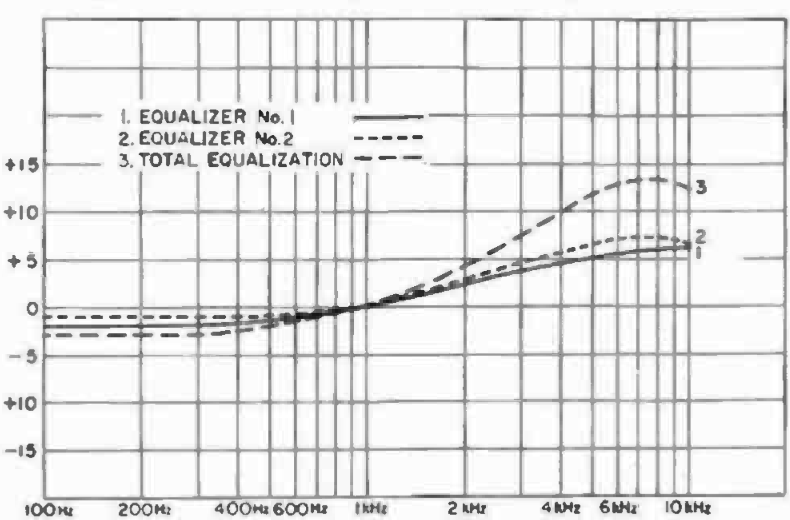

Fig. 6-66. Frequency characteristic of two equalizers connected in tandem.

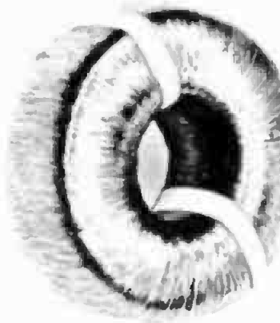

Fig. 6-70. A toroidal-wound coil without the insulating cover.

6.72 ***What is a honeycomb-wound coil?***—An air-core coil wound in such a manner the turns cross over each other and appear as a honeycomb. This design results in low distributed capacity but a low Q.

6.73 ***What is a negative-feedback loop equalizer?***—An equalizer network composed of reactive elements connected in the feedback loop of a negative-feedback amplifier. The equalization may be fixed or variable. However, variable equalization in a feedback loop is not desirable because each time the equalization is changed, the feedback benefits are changed, as is the gain of the amplifier. Typical negative-feedback loop-equalizer circuits are shown in Fig. 6-73. The subject of negative feedback is discussed in Questions 12.136 through 12.168.

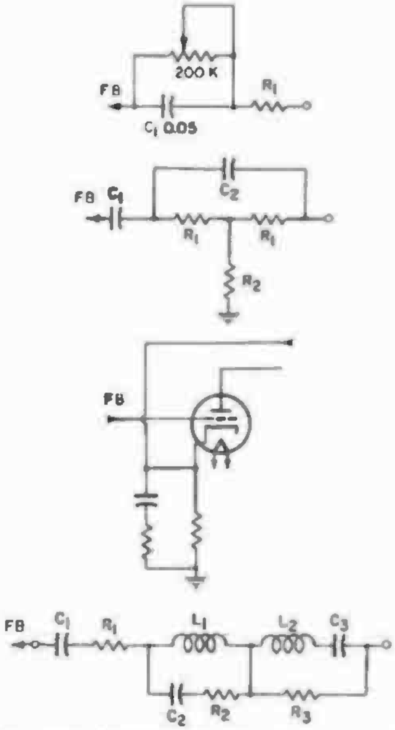

Fig. 6-73. Negative-feedback loop equalizers.

6.74 ***What is a plate-circuit equalizer?***—Reactive elements connected in the plate circuit of an amplifier to produce a given frequency characteristic. A typical circuit is shown in Fig. 6-74. This circuit may be used for securing a low-frequency boost by the change of

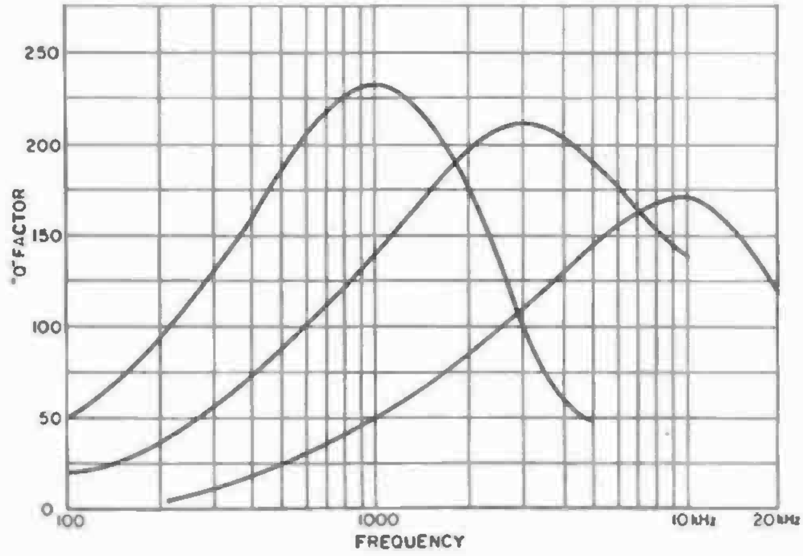

Fig. 6-71. Toroidal coil "Q" versus frequency curves.

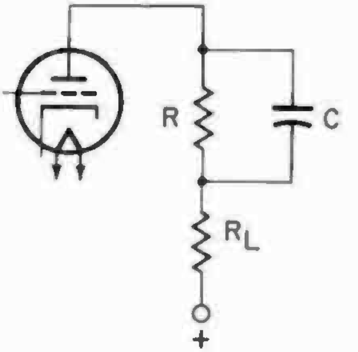

Fig. 6-74. Low frequency plate-circuit equalizer.

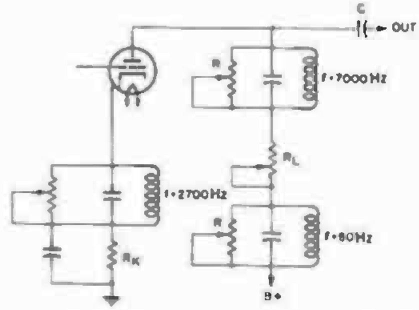

Fig. 6-76. Cathode- and plate-circuit equalizers.

reactance of the capacitor C connected across the load resistor R. The capacitor is selected for a value that will attenuate the high frequencies, beginning at a predetermined frequency. As the frequency is decreased, the reactance of the capacitor increases permitting resistor R to become effective in the circuit. In this way, the gain of the stage is increased at the lower frequencies.

6.75 ***When is a circuit said to be at resonance?***—When the inductive reactance equals the capacitive reactance.

6.76 ***What is a resonant plate-circuit equalizer?***—A vacuum-tube amplifier, with resonant circuits in the plate and cathode, used for equalizing in fixed-frequency bands. A typical circuit is shown in Fig. 6-76. The circuits are designed for a high Q at the resonant frequency. Variable resistors (R) are shunted across the coils to control the amount of equalization. The plate load resistor R_L will vary depending on the type tube used. When the shunt resistors in parallel with the resonant circuits are varied, it will be necessary to change the load resistance R_L to compensate for the loss induced by the networks. As a rule, this type of equalization is only used with triode vacuum tubes.

6.77 ***What tolerance should be specified for equalizer coils?***—Plus or minus two percent.

6.78 ***What tolerance values should be specified for capacitors used in equalizer design?***—Plus or minus three percent. However, if greater accuracy is required, they may be adjusted to the exact value by paralleling. In practice, the equalizer is first completed and measured. The capacitors are then tailored to obtain the desired response.

6.79 ***What tolerance should be specified for resistors used in equalizer design?***—Plus or minus five percent. However, if wirewound resistors are used, they are generally specified plus or minus one percent.

6.80 ***How is low-frequency attenuation achieved in a mixer circuit?***—By connecting a capacitor in series with the hot side of the mixer-input circuit as shown in Fig. 6-80A. This method of obtaining low-frequency attenuation is simple and effective and is often used

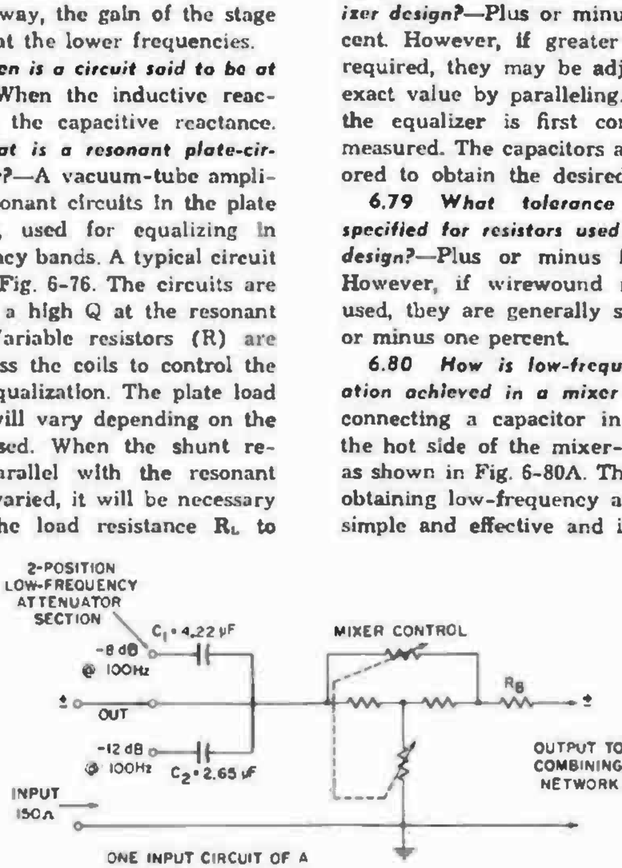

Fig. 6-80A. Low-frequency attenuation in a mixer network achieved by means of series capacitors.

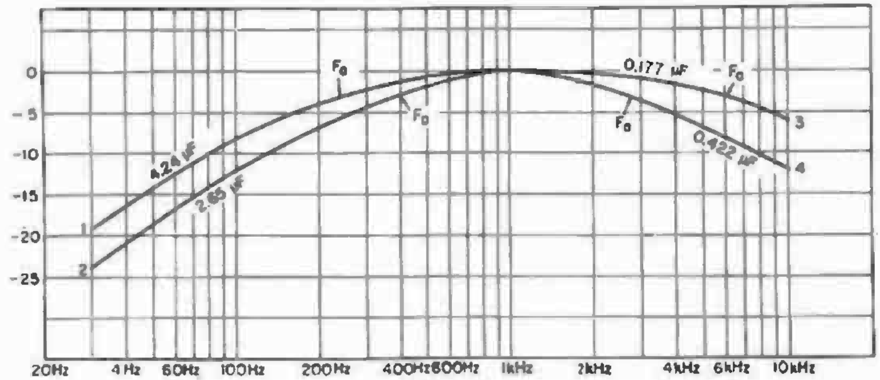

Fig. 6-80B. Typical low- and high-frequency attenuation curves.

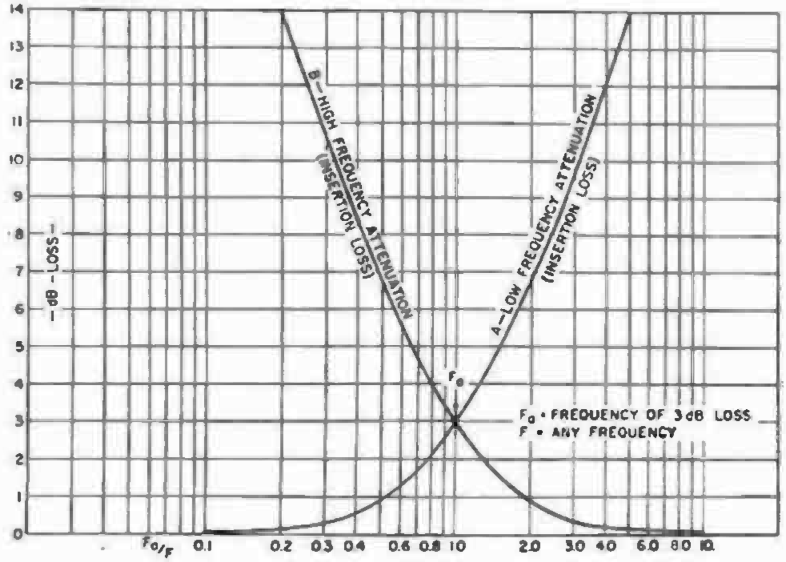

Fig. 6-80C. Design graph for attenuation and L-type equalizers.

in dialogue recording mixers. Generally, two positions of low-frequency attenuation are provided, either one of which may be cut in or out of the circuit by means of a key switch.

The value of the capacitor for a given frequency characteristic is dependent on two factors—the frequency of F_a (the frequency of 3-dB attenuation), and the impedance of the mixer-input circuit. The value of the capacitor may be calculated:

$$C = \frac{10^6}{2\pi F_a R_a}$$

where,

F_a is the frequency of 3-dB attenuation,
R_a is the circuit impedance.
C is the capacitance in microfarads.

To illustrate the design procedure, Fig. 6-80B shows typical low-frequency attenuation curves used in the motion picture industry. Assume a frequency response similar to that of curve 1 is desired. For this characteristic, 100 Hz is to be down 8 dB with respect to 1000 Hz; therefore, a frequency of 250 Hz is selected for F_a. The circuit impedance is 150 ohms. The capacitor is equal to:

$$\frac{10^6}{6.28 \times 250 \times 150} = \frac{10^6}{235{,}500} = 4.24\ \mu F$$

After calculating the value of C, its insertion loss is plotted with respect to frequency, with the aid of the right-hand curve (A) in Fig. 6-80C. Assuming F_a is 250 Hz and is represented by 1.0 on the graph, 250 Hz will have a loss of 3 dB. The response at other frequencies is calculated by dividing F_a by F for each frequency and tabulated as shown in Fig. 6-80D as F_a/F. The

F	$\frac{F_o}{f}$	dB loss
1000 Hz	0.10	− 0.10
500 Hz	0.50	− 0.90
400 Hz	0.62	− 1.40
300 Hz	0.83	− 2.20
250 Hz	1.00	− 3.00
150 Hz	1.66	− 5.70
100 Hz	2.50	− 8.24
80 Hz	3.13	− 10.00
60 Hz	4.16	− 12.40
50 Hz	5.00	− 14.00

Fig. 6-80D. Insertion-loss plot of curve 1, Fig. 6-80B.

loss for each frequency is obtained by entering the graph along the bottom for different values of F_o/F and then reading the loss where F_o/F intersects the right-hand curve (A). The overall frequency response is plotted as shown in Fig. 6-80B.

If the frequency response does not fit a particular response curve, the frequency F_o is shifted to bring the response to the desired shape. It should be kept in mind that such circuits are used only for a slow roll-off type attenuation. If a faster and steeper response is desired, a more elaborate type circuit will be necessary.

Equalizers employing series capacitors in the input circuit are shown in Fig. 6-80A. Although not of constant impedance design they are a simple and economical method of reducing the low frequency response for dialogue recording. However, they should only be employed when the preamplifier offers a solid termination, such as one nsing building-out resistors, or negative feedback, or a combination of both. Because of the solid termination of the preamplifier and the resistive uetwork of the

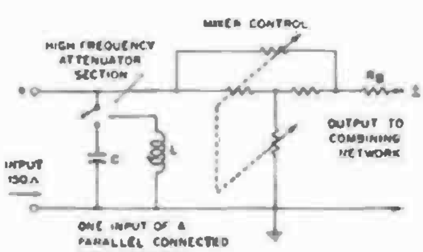

Fig. 6-81. A high-frequency attenuator circuit for a mixer network. Either an inductance or capacitor may be used.

mixer, this method of equalization will operate quite satisfactorily in circuit impedances of 150, 250 and 600 ohms. (See Questions 6.131 and 9.24.)

6.81 ***How is high-frequency attenuation achieved in a mixer circuit?***—By connecting either a capacitor or inductance in parallel with the mixer input circuit, as shown in Fig. 6-81.

In Fig. 6-80B, two high-frequency rolloffs are shown. If a capacitor is to be used, its value is calculated as described in Question 6.80. The frequency response is plotted using the left-hand curve (B) of Fig. 6-80C. If an inductance is used, its value may be calculated:

$$L = \frac{R_o}{2\pi F_o}$$

where,

F_o is the frequency of 3-dB loss,
R_o is the circuit impedance.

The procedure for plotting the insertion loss is the same as described for a capacitor.

6.82 ***Can low-frequency attenuation be obtained using an inductance?***—Yes. After calculating the inductance, the insertion loss is plotted as for a capacitor. Assume a frequency response is desired similar to curve 2 of Fig. 6-80B. The value of the inductance may be calculated:

$$\frac{150}{6.28 \times 400} = \frac{150}{2512} = 0.0597 \text{ henry}$$

where,

F_o equals 400 Hz,
R_o equals 150 ohms.

6.83 ***How is a high-frequency attenuator designed using an inductance?***—The inductance is calculated as described in Question 6.82. The insertion loss is plotted using the left-hand curve (B) of Fig. 6-80C.

6.84 ***How may the frequency response be shifted to meet a given requirement?***—By changing the frequency of F_o, the frequency of 3-dB attenuation.

6.85 ***What is a compensated volume control (loudness control)?***—A volume control used in amplifiers to compensate for the human ear characteristic when the volume level is increased or decreased. The characteristic of the control is based on the well-known Fletcher-Munson or equal-loudness contours. This subject is further discussed in Questiou 5.65.

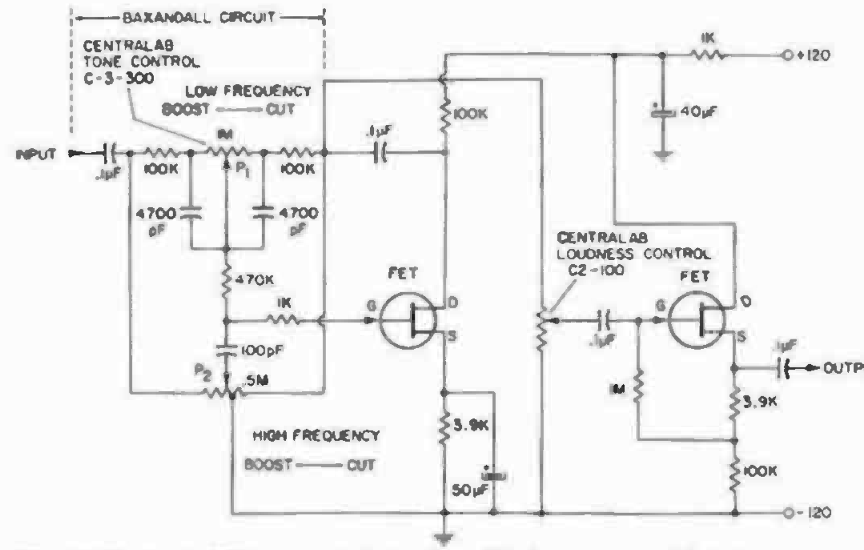

Fig. 6-86A. Baxandall tone-control circuit modified to operate with field effect transistors. (Courtesy, Wireless World)

6.86 *Describe the Baxandall equalizer circuit (tone control)*—The circuit shown in Fig. 6-86A was first described by P. J. Baxandall in 1952 in Wireless World (English publication), and is the basis for many tone controls used in high fidelity sound reproducing equipment. The basic circuit consists of two linear potentiometers, three resistors, and three capacitors. The circuit is generally connected between the plate and grid in vacuum-tube amplifiers, and in transistor circuits, between the emitter and base of the following transistor.

In Fig. 6-86A the circuit is connected between the source and gate elements of two field-effect transistors (FET's). With potentiometers P_1 and P_2 set to their center positions, the circuit has a flat frequency response. Moving the upper control to the *left* increases the low-frequency response, while moving it to the *right* decreases the low-frequency response.

It will be observed, the potentiometers of Fig. 6-86B are of higher value than ordinarily used in transistor circuits (suitable for vacuum tubes also). The equalization at 20 Hz is about plus or minus 18 dB, and for the high frequency control plus and minus 16 dB with reference to 1000 Hz. When the low-frequency control is set for a 10 dB boost or cut, 125 Hz is plus or minus

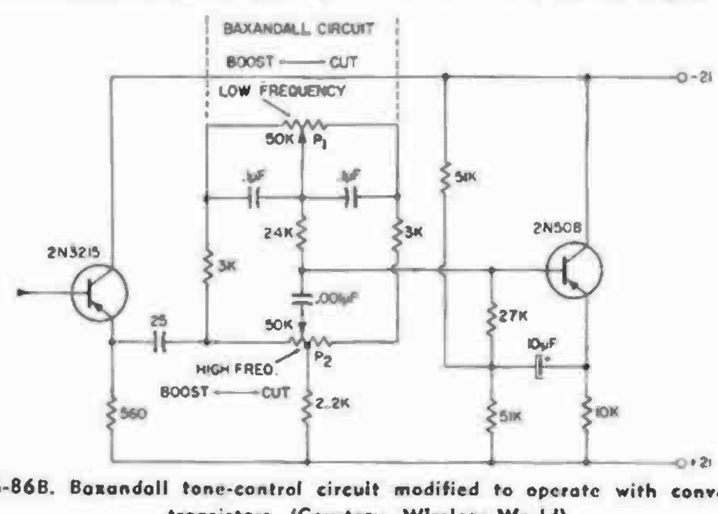

Fig. 6-86B. Baxandall tone-control circuit modified to operate with conventional transistors. (Courtesy, Wireless World)

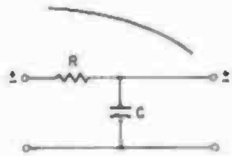

Fig. 6-88. A simple low-pass filter RC equalizer.

3 dB. With the high-frequency control set to a maximum, the boost or cut at 3500 Hz is also 3 dB.

6.87 ***What does the term resonant frequency mean?***—It is the frequency at which the inductive and capacitive reactances in a tuned circuit are equal.

6.88 ***How is a simple low-pass filter characteristic obtained with an RC equalizer?***—As shown in Fig. 6-88. The frequency response is rather broad for a single network; however, the response may be made steeper by cascading two or more sections. When a frequency is reached where the capacitive reactance is one-tenth its original value, little change with frequency is noted. The insertion loss of an RC circuit is rather high; therefore, it must be used with an amplifier. The resistor must be non-inductive.

6.89 ***Show an RC circuit for boosting the low-frequency response.***—Such a circuit is shown in Fig. 6-89. The input signal is applied to terminals 1 and 2, and the output is taken across terminals 3 and 4. With the proper selection of resistance and capacity, the impedance of the capacitor will increase with a decrease of frequency. Thus, the capacitor has less shunting effect across the resistauce R2 and, thereby, the gain at the lower frequencies is increased.

6.90 ***How is a simple high-pass filter characteristic obtained with an RC equalizer?***—As shown in Fig. 6-90.

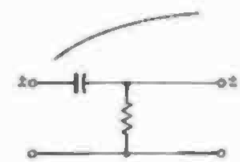

Fig. 6-90. A simple high-pass filter RC equalizer.

6.91 ***Show a simple grid-circuit equalizer, similar to that used in preamplifiers.***—The circuit shown in Fig. 6-91A is rather common in phototube amplifiers. It will be noted the equalizer circuit, C1 and R1, is connected in the grid circuit after the regular grid coupling capacitor C. Generally, the capacitor C1 is of the order of 25 to 150 picofarads. The resistor R1 will range be-

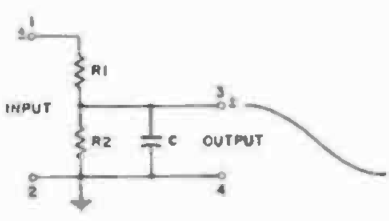

Fig. 6-89. An RC low-frequency boost circuit.

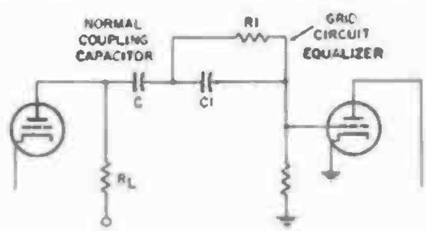

Fig. 6-91A. An RC grid-circuit equalizer.

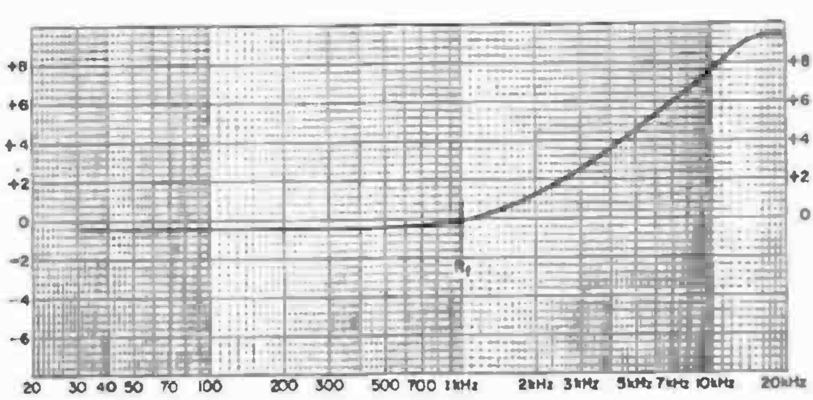

Fig. 6-91B. Frequency response of the grid-circuit equalizer in Fig. 6-91A.

tween 250,000 ohms and 1 megohm in value. The take-off point will depend on the value of C1. The amount of equalization and shape of the curve are controlled by the value of R1.

Because of the insertion loss of the equalizer, the overall gain of the amplifier is reduced at the reference frequency; therefore, the amplifier should be designed with sufficient gain to compensate for the equalizer loss and sufficient output level to prevent overloading at the maximum frequency of equalization, 15,000 Hz. The frequency response for a grid-circuit equalizer using a 65-pF capacitor and 1.25-megohm resistor is shown in Fig. 6-91B.

6.92 ***What frequency is used for the reference in equalizer design?***—Generally, 1000 Hz; however, 400 Hz is also used.

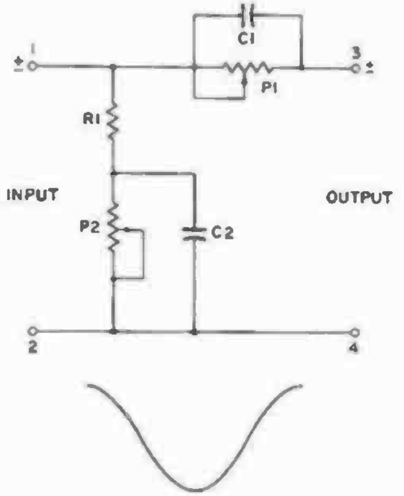

Fig. 6-93. An RC high- and low-frequency equalizer.

6.93 ***Show an RC configuration that may be used for both high- and low-frequency correction.***—Such a circuit is shown in Fig. 6-93, with its frequency characteristic given at the right. The amount of frequency correction is obtained by the position of the two variable pots, P1 and P2. In the mid-frequency range, the circuit is practically resistive, consisting principally of the two variable pots, and resistor R1. The capacitor C1 is practically an open circuit because of its high reactance, while the low reactance of C2 at these frequencies causes it to act as a short circuit across P2. Thus, only P1 and R1 are effectively in the circuit.

As the frequency increases, the reactance of C1 decreases until, finally, at some frequency, its reactance becomes so small as to effectively short circuit P1. Conversely, as the frequency becomes lower, the reactance of C1 increases until only the resistance which is constant for all frequencies remains in the circuit. However, the shunt reactance of C2 increases with the decrease in frequency, leaving only resistance, which results in a higher voltage across the output terminals 3 and 4. Therefore, the equalization depends on the setting of P1 and P2.

6.94 ***Show an amplifier with RC equalizers for increasing or decreasing the high- and low-frequency response.***—Fig. 6-94 shows a two-stage RC coupled amplifier, with variable RC equalizers for increasing or decreasing the high- and low-frequency response. To compensate for the insertion loss of the RC circuits, two pentode amplifier stages are necessary. The variable controls P1 and P2 are standard, center-tapped, audio-taper controls. This amplifier is designed to be inserted between the output and input of two triode amplifier stages. The frequency response is uniform when the pots P1 and P2 are in their midpositions. The overall gain of the amplifier will change with changes of equalization; therefore, the gain control P3 will require resetting to maintain the same gain through the amplifier. About 14 dB of equalization is available at either end of the spectrum. This, together with 14 dB of attenuation at either end, makes a total of approximately 28 dB of equalization or attenuation available.

6.95 ***What is the procedure for designing an L-type equalizer?***—L-type equalizers consist, basically, of two configurations as shown in Figs. 6-95A and B. Although the L-type equalizer presents a constant impedance only in one direction (terminals 1 and 2), it is used in many applications where the circuit is not impedance sensitive. The impedance at terminals 3 and 4 is subject to wide variation, similar to the L-type attenuators described in Questions 5.40 and 5.41.

The design of an L-type equalizer is started by first selecting a design point called F_r which is the frequency of 3 dB insertion loss. F_r is the frequency where both the reactive elements L and

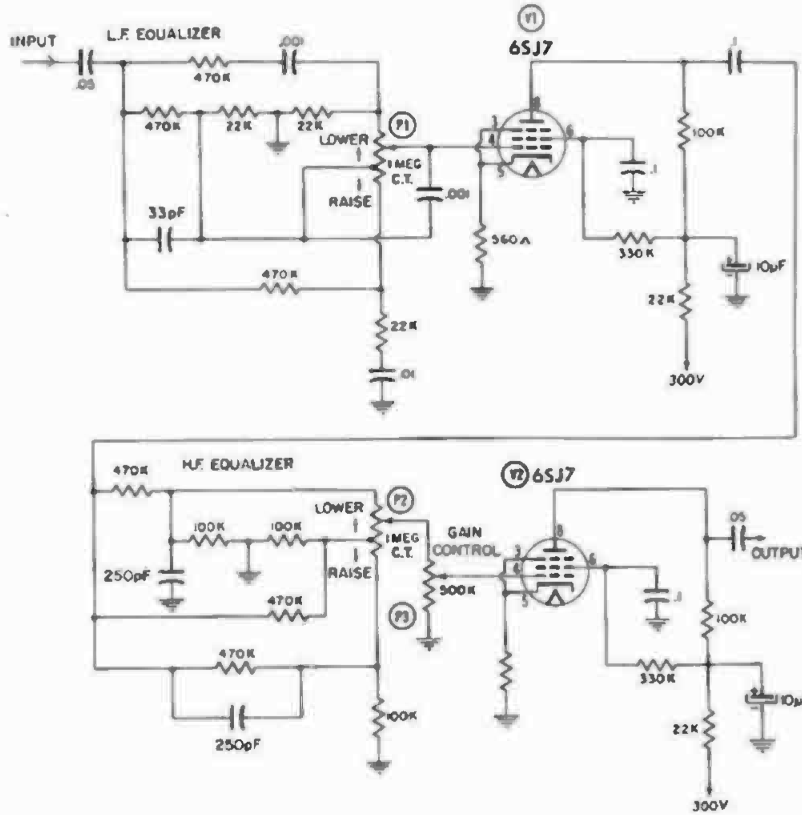

Fig. 6-94. An amplifier with high- and low-frequency variable equalization.

C have the same reactance and equal the line impedance R_o. Knowing the 3 dB insertion-loss frequency, the frequency response for a given value of F_c may be plotted by the aid of the graphs in Fig. 6-80C.

Assume, for a given frequency response, that F_c is equal to 2000 Hz. Referring to curve A of Fig. 6-80C, frequency F_c is represented by the figure 1.0 at the bottom of the graph. This point represents the 3 dB insertion loss point. Therefore, 2000 Hz will be down 3 dB. The figure 2.0 on the chart will then represent 4000 Hz and 4.0, 8000 Hz. Figure 0.5 represents 1000 Hz and 0.25, 500 Hz. The response at any other frequency may be calculated by dividing F_c by F, F being any frequency. The loss for each frequency of interest is obtained by entering the graph at the bottom and following the frequency line to where it intersects the curved line, then reading the loss from the right- or left-hand side of the graph. Several plots appear in Figs. 6-95C and D, illustrating how the insertion loss is plotted for a given value of F_c. After

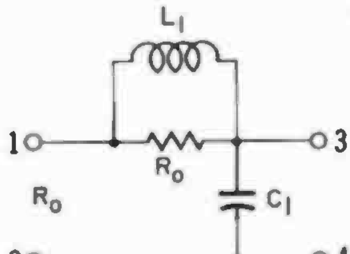

Fig. 6-95A. A low-frequency boost, high-frequency attenuated inverted L-type equalizer.

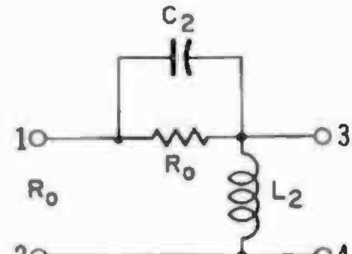

Fig. 6-95B. A high-frequency boost, low-frequency attenuator, inverted L-type equalizer.

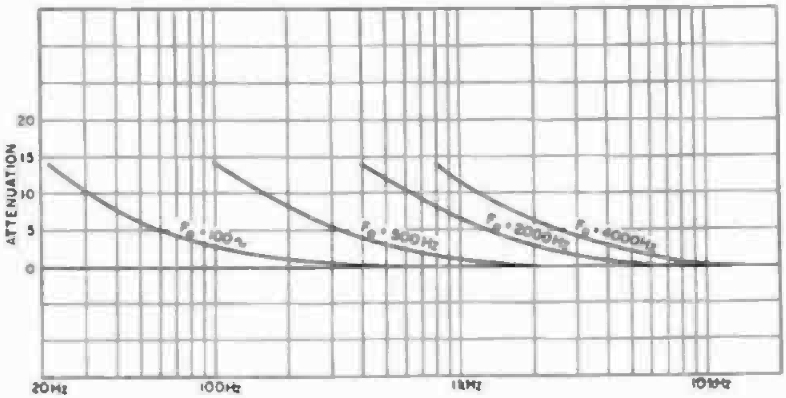

Fig. 6-95C. Typical response curves for different values of F_o for inverted L-type equalizer shown in Fig. 6-95A.

the response has been plotted, the values of inductance and capacity are calculated:

$$L_1 \text{ or } L_2 = \frac{R_o}{2\pi F_o}$$

$$C_1 \text{ or } C_2 = \frac{1}{2\pi F_o R_o}$$

where,

R_o is the circuit impedance,
F_o is the frequency of 3 dB insertion loss.

The insertion loss for any frequency may be calculated:

$$10 \operatorname{Log}_{10}\left[1 + \left(\frac{F}{F_o}\right)^2\right]$$

or

$$10 \operatorname{Log}_{10}\left[1 + \left(\frac{F_o}{F}\right)^2\right]$$

where,

F_o is the frequency of 3 dB insertion loss,
F is the frequency.

The first equation is used with curve A of Fig. 6-80C and the second equation is used with curve B. Curve A is used when designing an equalizer for increasing the low-frequency response or attenuating the high frequencies. Curve B is used when designing an equalizer for increasing the high-frequency re-

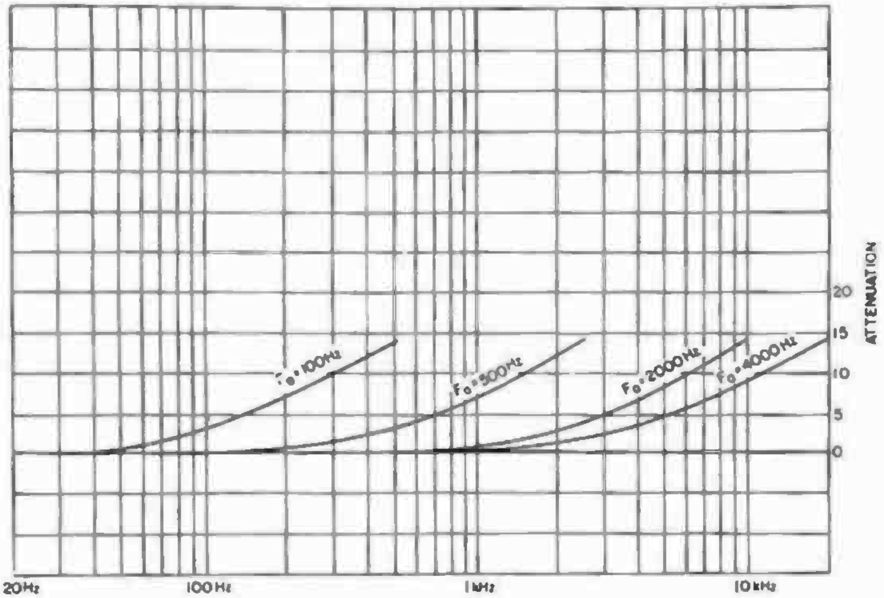

Fig. 6-95D. Typical response curves for different values of F_o for inverted L-type equalizers shown in Fig. 6-95B.

sponse and attenuating the low frequencies.

6.96 ***Show a typical amplifier circuit with the points in the circuit where the frequency characteristics may be changed.***—A schematic of a two-stage amplifier with various points where equalization may be inserted to alter the frequency characteristics is given in Fig. 6-96. Neither the circuit nor the values of the components in Fig. 6-96 are intended to represent any particular amplifier or produce a given response. It presents only a composite picture of the methods used to secure frequency compensation.

Beginning at point 1, Fig. 6-96, T1 is the conventional input transformer with a terminating resistor R1 across the primary to present a solid termination to the source impedance.

At point 2 is a capacitor C1 and re-

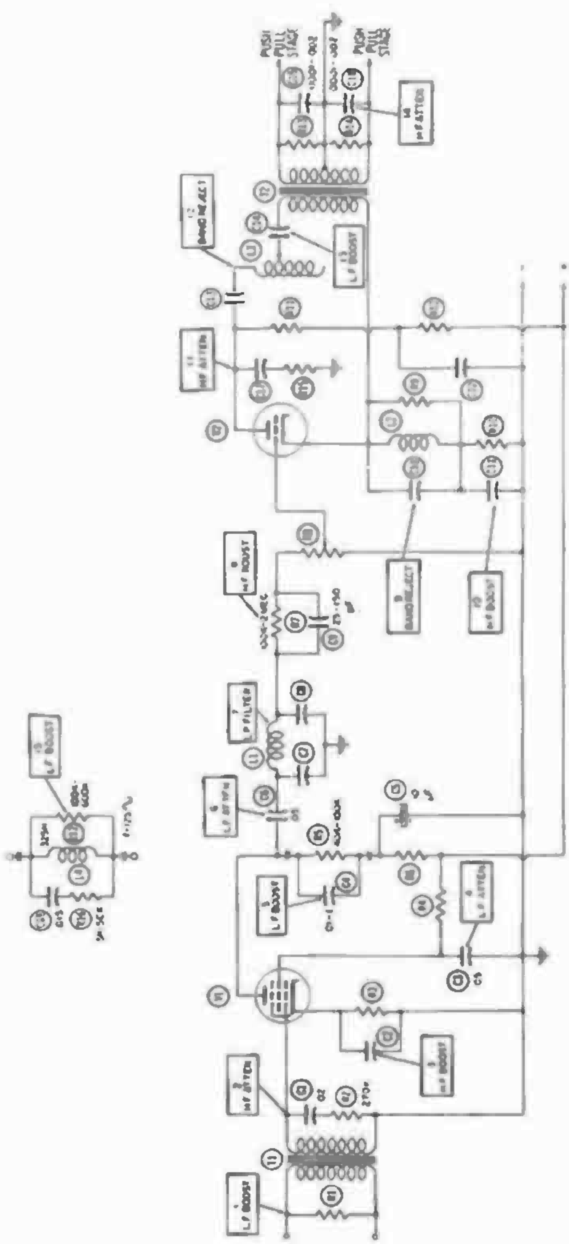

Fig. 6-96. A two-stage amplifier showing different points where equalization may be inserted. The values are for illustration only.

sistor R2 which may be used to secure a slow rolloff at the higher frequencies. The capacitor value selected determines the frequency at which the rolloff begins, while the series resistor controls the amount of attenuation.

At point 3, tube V1, varying the size of the cathode-bypass capacitor C2 will control the high-frequency boost. The smaller the value of this capacitor the greater will be the high-frequency response, because of degeneration in the cathode circuit. For high-frequency boost, the capacitor will vary from 0.10 to 0.02 μF. If the cathode circuit is not used for frequency correction, it is bypassed with a 40 μF or greater capacitor.

Low-frequency attenuation may be obtained by reducing the size of the screen-grid bypass capacitor C3, at point 4. Normally, the capacitor would be 10 μF. By reducing the size to 1 μF or less, the low-frequency response may be reduced accordingly.

Low-frequency boost may be obtained at point 5 by the use of capacitor C4 in the plate circuit of V1 which bypasses a portion of the plate-load resistor R5. Capacitor C4 is selected for a value that will attenuate the high frequencies, beginning at a predetermined frequency; thus, a low-frequency boost is obtained. Capacitor C5 and resistor R6 comprise the usual decoupling circuits common to high-gain amplifiers.

Decreasing the size of the grid-coupling capacitor C6 at point 6, results in a decrease of the low-frequency response. However, it is better to secure low-frequency attenuation in some other part of the circuit and not reduce the coupling capacitor below 0.05 μF.

Should a low-pass filter be required, it may be inserted in the plate circuit of V1 at point 7. The resistor R7 and capacitor C9 shown at point 8 are used for high-frequency equalization and form the familiar grid-circuit equalizer so frequently found in many general-purpose amplifiers. The value of C9 is, as a rule, on the order of 25 to 150 pF. The value of R7 will vary from a few hundred ohms to several megohms.

A dip filter consisting of inductance L2, capacitor C10, and resistor R9 is included in the cathode circuit of V2 at point 9. This circuit is used to remove specific bands of frequencies between 150 and 350 Hz. It is this range of frequencies which causes tubby reproduction in large auditoriums. The inductance L2 is resonated by C10. Resistor R9 is used to broaden the resonance curve. Capacitor C11 across the cathode of V2 at point 10 may also be used for high-frequency boost and is similar in action to that of C2 at point 3.

The series resistor R15 and capacitor C17 at point 11 may be connected from the plate of V2 to ground for the reduction of the higher frequencies. Its action is similar to that of the familiar tone control. Band rejection may also be secured by means of capacitor C13 and coil L3 connected in series with the primary winding of the push-pull interstage transformer T2.

At point 13 the primary of the push-pull transformer is parallel-coupled through capacitor C14 to the plate of V2. If a value of C14 is selected to resonate the primary of T2 at some frequency, a low-frequency boost is obtained. However, it is not good practice to nse this method, as distortion may be induced.

High-frequency attenuation may also be secured by shunting capacitors C15 and C16 across the secondary of the interstage transformer T2, indicated at point 14. Resistive terminations R13 and R14 across the secondary may also be used. Resistor R12 and capacitor C12 are connected in the plate circuit of V2 for decoupling purposes.

In the upper portion of the diagram at point 15 is shown a low-frequency booster circuit which may be used in place of C4 and R5 (point 5) in the plate circuit of V1. The circuit consists of a large inductance, L4, of approximately 325 henries resonated by capacitor C18 in series with R16. The parallel resistor, R17, controls the amplitude, and resistor R16 controls the width of the resonance curve.

Numerous other methods will suggest themselves for securing frequency correction; however, it should be remembered that circuits such as those illustrated, while effective, must be very carefully applied to prevent overload and distortion, since these latter conditions rise rapidly when circuits as described are employed. It is good engineering practice to divide the equalization between stages whenever possible. Many of the circuits shown in Fig. 6-96 are used in projection amplifiers in motion picture theaters to obtain characteristics to suit individual installations.

6.97 ***Show a three-channel equalizer amplifier.***—Fig. 6-97A depicts a three-channel equalizer amplifier which will permit control of high, low, and intermediate frequencies independently of each other. This device consists of three separate amplifier stages, each designed to cover a limited frequency range. The three interstage amplifiers are fed from a single input stage, while the outputs are combined and fed into one output amplifier stage. At the input of each amplifier is an RC network for limiting the amplifier response. The network consists of elements C1, C2, R1, and P1. The gain of each stage may be controlled by means of the individual gain controls P1, P2, and P3. The frequency response of a single stage is given in Fig. 6-97B.

6.98 ***How can the frequency response of an amplifier using negative feedback be altered?***—Frequency correction may be connected in any stage outside of the feedback loop. Frequency correction may also be obtained by changing the values of the elements in

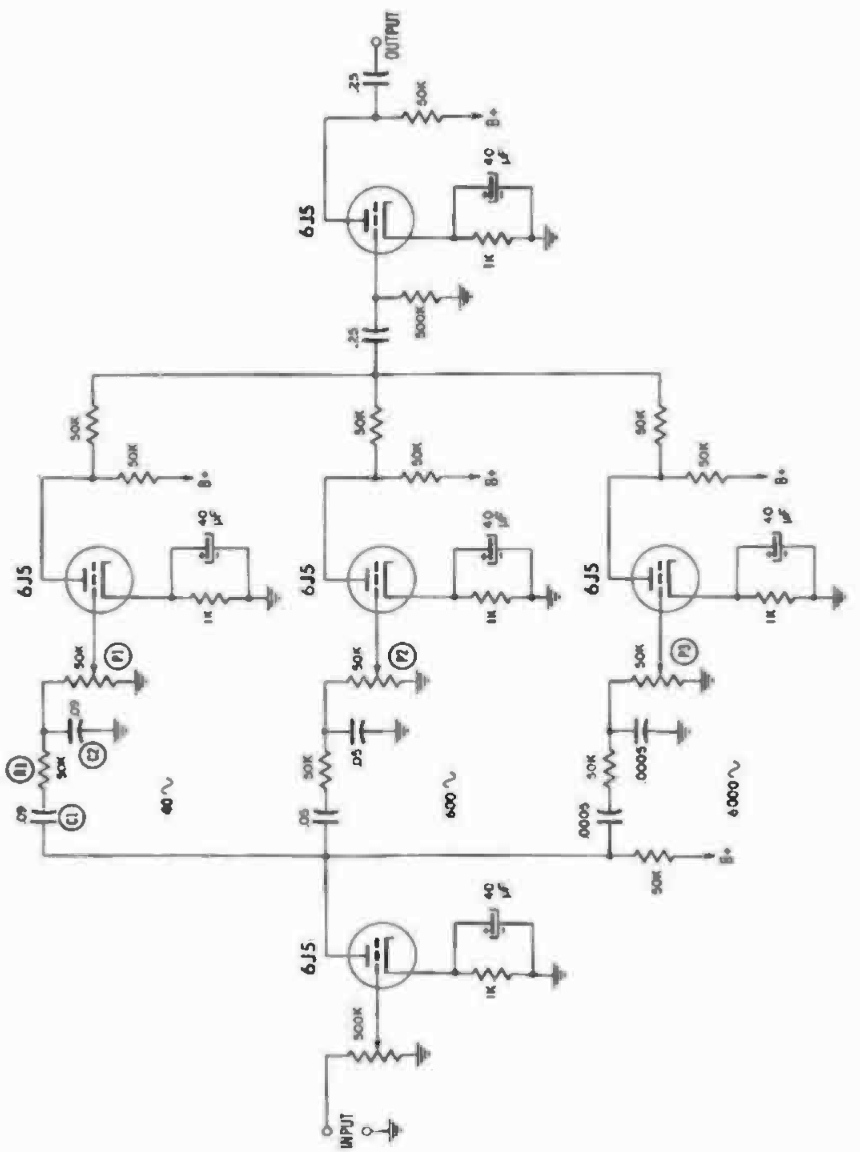

Fig. 6-97A. A three-channel equalizer amplifier.

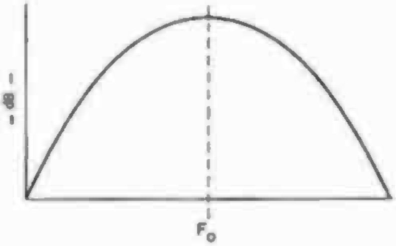

Fig. 6-97B. Frequency response of a single stage of the amplifier shown in Fig. 6-97A.

the feedback loop. Negative-feedback amplifiers are discussed in Questions 12.136 through 12.168.

6.99 *What is a tone control?*—A simple, high-frequency attenuating network used in radio sets to reduce the high-frequency response. A typical circuit is shown in Fig. 6-99.

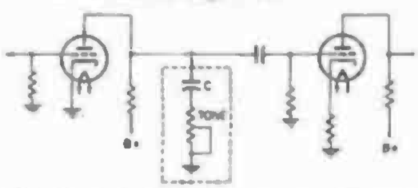

Fig. 6-99. A typical tone-control circuit used in radio receivers.

6.100 *Describe a microphone equalizer.*—Microphone equalizers are used ahead of the mixer control and are installed in the mixer panel as a part of the mixer network. They permit the recording engineer to select a given microphone which provides an optimum response and polar pattern, and match the response of the other microphones

Fig. 6-100A. Altec-Lansing microphone equalizer Model 9060A.

to the master microphone. Such equalizers are designed for correcting the variations in response, changes in the *apparent* response caused by variation in the microphone to source distance, and the acoustical characteristics of the recording stage. They may also be used to a good advantage for matching indoor and outdoor scenes or live and dead rooms, as well as for dialogue equalization as discussed in Question 6.80.

An equalizer of this design is shown in Fig. 6-100A. The device consists of a *passive* network employing inductance, capacitance, and resistance in a bridged-T configuration. Two slide-type switches provide a maximum equalization of plus 12 dB at 100 Hz and 7000 Hz, and a minimum attenuation of minus 16 dB at 100 Hz and 10,000 Hz. The insertion loss is 14 dB, and has a

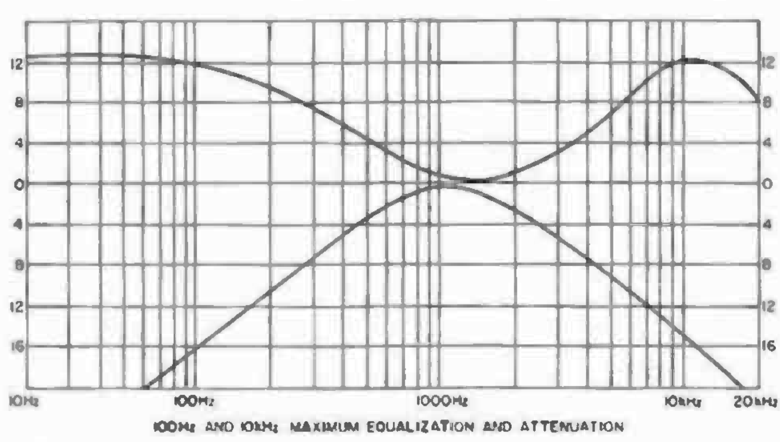

Fig. 6-100B. Frequency characteristics of Altec-Lansing microphone equalizer Model 9060A.

constant input and output impedance of 600 ohms. The maximum and minimum limits of equalization and attenuation are shown in Fig. 6-100B. The basic design is the *constant-B* equalizer discussed in Question 6.124. The internal wiring consists of printed-circuit boards.

6.101 ***Give the component values for an RC equalizer suitable for reproducing the RIAA disc record characteristic.***—A circuit, with its component values, designed to be connected between the plate and grid circuits of two vacuum tubes is shown in Fig. 6-101.

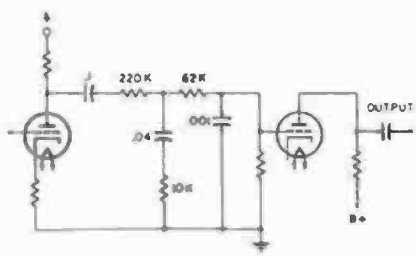

Fig. 6-101. RC equalizer network suitable for reproducing using the RIAA standard reproducing characteristic.

6.102 ***What are the component values for a 600-ohm high-frequency bridged-T equalizer suitable for reproducing the RIAA characteristic?***—Such a circuit appears in Fig. 6-102.

6.103 ***What are the component values for a 600-ohm low-frequency bridged-T equalizer suitable for reproducing the RIAA characteristic?***—Such a circuit is shown in Fig. 6-103.

6.104 ***What are the component values for a 600-ohm high-frequency bridged-T recording equalizer suitable for recording the RIAA characteristic?***—The circuit and component values are given in Fig. 6-104.

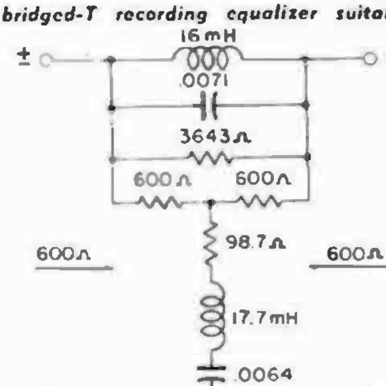

Fig. 6-102. A high-frequency, bridged-T, post-equalizer for reproducing recordings using the RIAA characteristic.

Equalizers of this design and characteristic were used in disc recording circuits before the adoption of the RIAA Standard Reproducing Characteristic. (See Question 13.95.)

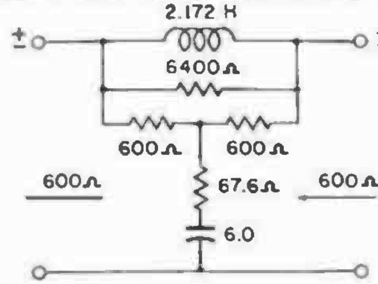

Fig. 6-103. A low-frequency, bridged-T, post-equalizer for reproducing the RIAA characteristic.

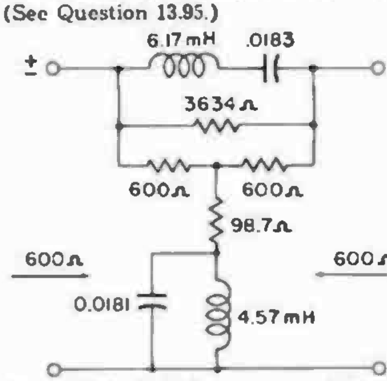

Fig. 6-104. A high-frequency, bridge-T, pre-equalizer for recording using the RIAA recording characteristic.

6.105 ***What are the RIAA recording and reproducing characteristics?***—The recording and playback characteristics as standardized by the RIAA are plotted in Fig. 13-95. These standards are employed by the majority of the recording companies in the United States and also by some foreign recording companies. It will be noted the reproducing characteristic is an inverse curve to the recording characteristic. The curves shown are used for recording 16-inch transcriptions, 78 rpm, and microgroove records. A different recording and reproducing characteristic is used for vertical recording and reproduction. This characteristic is shown in Fig. 13-94.

6.106 ***What are the component values for a bridged-T variable equalizer***

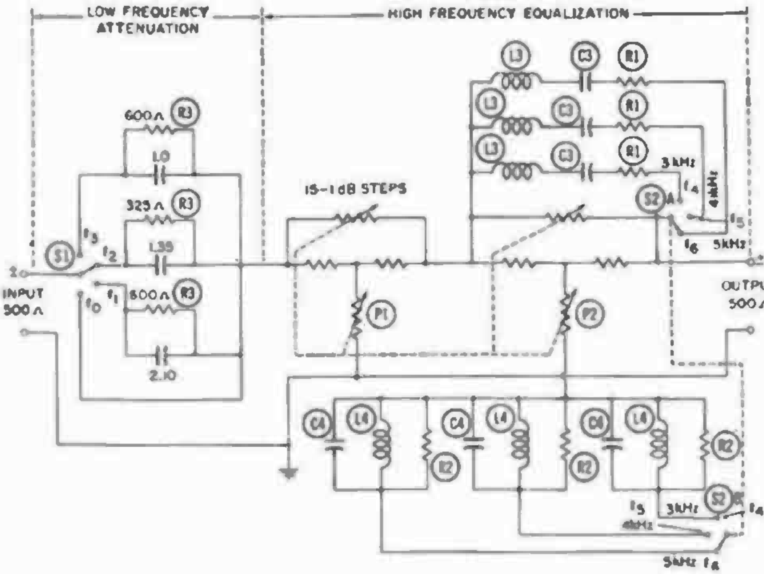

Fig. 6-106A. A constant-loss variable equalizer suitable for motion picture rerecording.

suitable for rerecording purposes?—Fig. 6-106A depicts a constant-loss bridged-T equalizer with three high-frequency characteristics (Fig. 6-106B). In addition to the above, three low-frequency attenuation positions are provided. Resistors R1 and R2 are connected in series and in shunt with the inductances to permit broadening the resonance curves, if desired. Resistors R3 are connected in shunt with the capacitors in the low-frequency attenuation circuits to provide a shelving characteristic at the extreme low-frequency end. Circuit element values may be calculated from the information contained in Question 6.53.

6.107 *Show a schematic diagram for a variable dialogue equalizer suitable for motion picture rerecording.*—Fig. 6-107A is the schematic diagram of a six-position, variable dialogue equalizer with suitable characteristics for use during rerecording operations. Basically, the device consists of three high-frequency equalizers, Sections 1, 3, and 5, resonated at 1.5, 3, and 6 kHz; and three dip equalizers resonated at the same frequencies. Each of the six equalizer circuits may be varied individually in steps of 1 dB, for a total of 12 dB. The six networks are connected in tandem and may be varied during recording, if necessary.

Sections 1, 3, and 5 are of constant-loss design as described in Question 6.51. Sections 2, 4, and 6, the dip equalizers, require only one attenuator because the network is designed to induce a loss at the resonant frequency. If these sections were to be made constant-loss, no effect would be noted when the attenuator was rotated.

Two amplifiers are used, one ahead of the networks and the other following. Their purpose is to compensate for the insertion loss of the attenuator networks and permit the device to be operated in a recording channel as a no-loss, no-gain device. The required

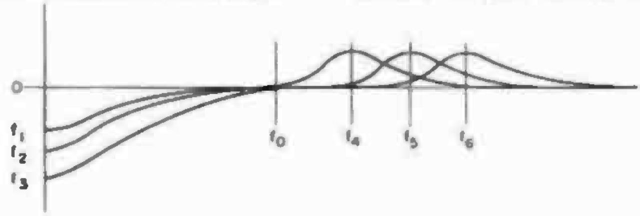

Fig. 6-106B. Frequency characteristics of the variable equalizer shown in Fig. 6-106A.

gain is divided between the two amplifiers. The gain is so set that, when a given signal level is applied to the input (zero equalization), the same signal level is obtained at the output. Operating in this manner permits the complete equalizer to be keyed into and out of the circuit without disturbing the gain of the recording channel.

The coils for the equalizer and dip sections are toroidal wound and encapsulated in plastic. (See Fig. 8-94.) Because these coils are toroidal wound, they may be mounted one above another without fear of intercoupling. The Q of the coils ranges from 60 to 125 at the resonant frequency, which is necessary if they are to meet the frequency response shown in Fig. 6-107B. Although the attenuators are shown having a 12-dB loss, the circuit elements have been computed using a maximum

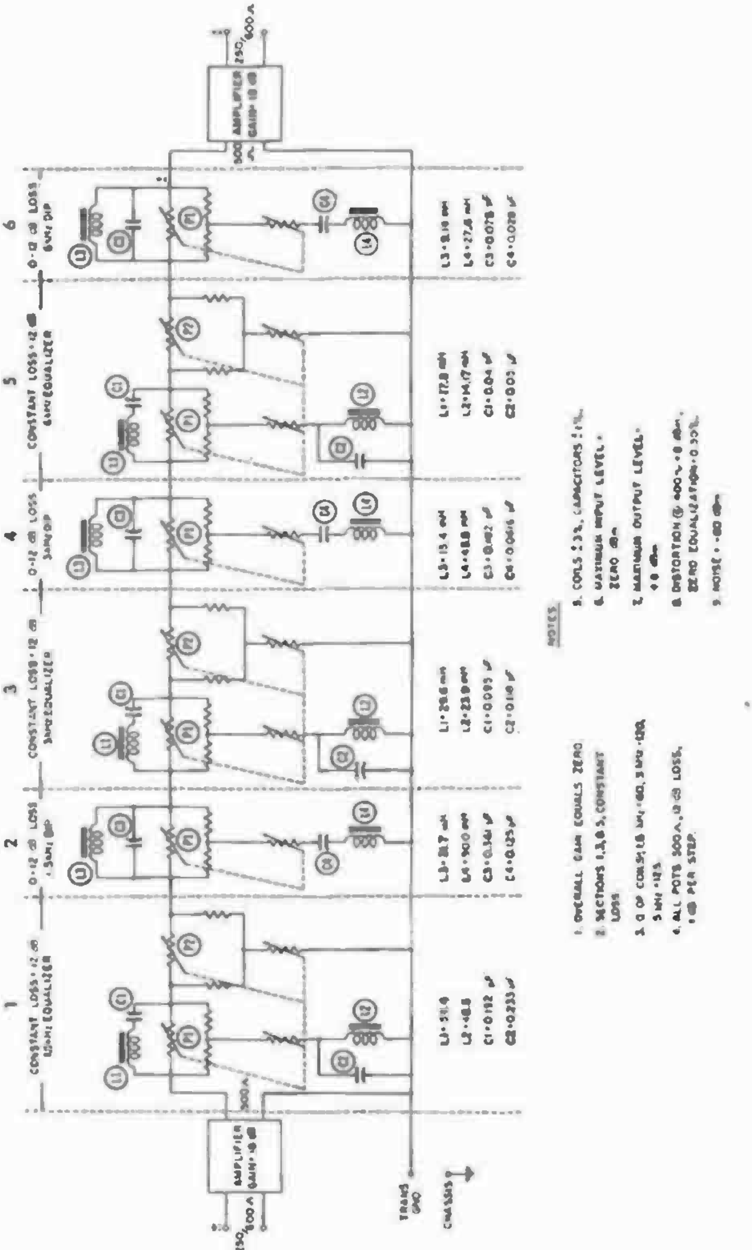

Fig. 6-107A. Schematic diagram for three-frequency variable dialogue and sound effects equalizer.

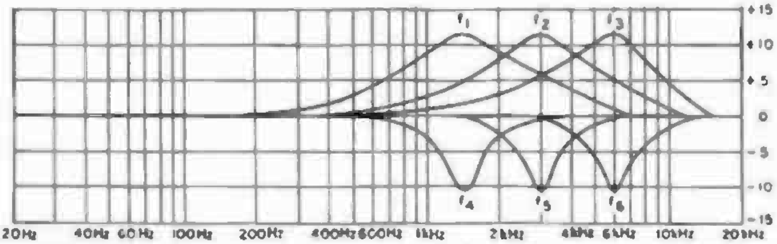

Fig. 6-107B. Frequency response of equalizer shown in Fig. 6-107A.

loss of 7 dB. This was done to obtain a broader response curve for the first 7 steps of the attenuator. After the 7th step, the curves become somewhat steeper.

6.108 Describe a graphic equalizer? —It is a variable equalizer used for the rerecording of motion pictures and is similar to that shown in Fig. 6-108A. The equalizer consists of two units: an amplifier and a group of resonant circuits; and a control panel containing a group of attenuator controls, with straightline characteristics, operating in conjunction with a panel designed to show the equalization graphically by the position of the equalizer controls. Each control permits a portion of the audio frequency spectrum to be increased or decreased 8 dB in steps of 1 dB. Frequencies of 63, 160, 400, 1000, 2500, and 6300 Hz have been selected to provide a balanced energy response in the intermediate frequencies. Because of the control panel design the mixer sees the amount of equalization graphically at all times; hence its name. As a rule, the device is operated as a no-gain, no-loss device as explained in Question 6.107.

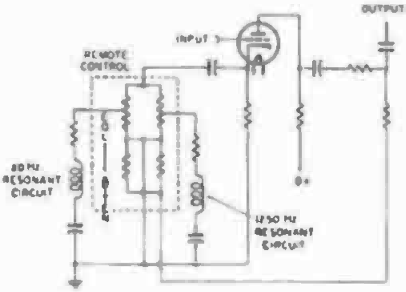

Fig. 6-108B. Simplified diagram of graphic equalizer showing the circuitry of the first amplifier stage.

A simplified diagram of one of the three first amplifier stages is shown in Fig. 6-108B. The same principle of operation and design is employed in the second and third stages.

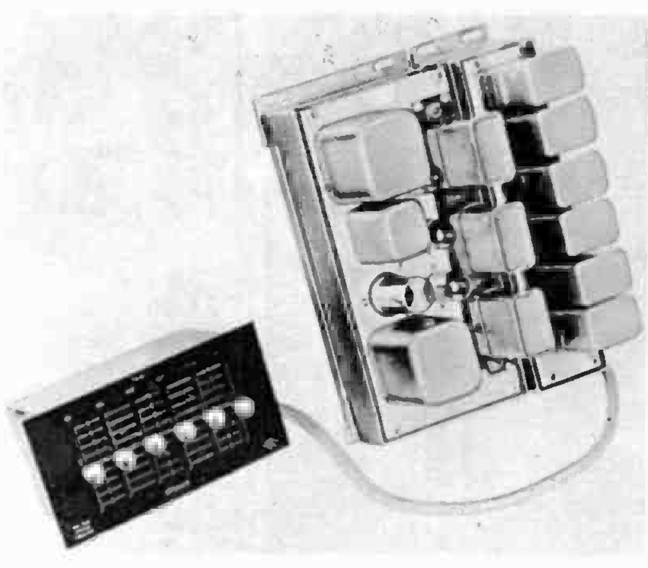

Fig. 6-108A. Cinema Engineering Co., type 7080, graphic equalizer amplifier.

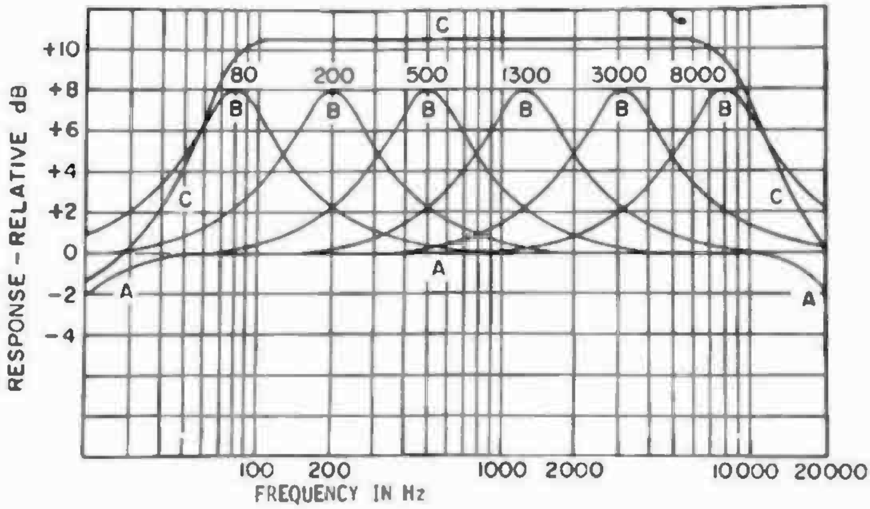

Fig. 6-108C. Frequency characteristics of a typical graphic equalizer using 80, 200, 500, 1300, 3000, and 8000 Hz.

The control potentiometers between the top and the midpoint (which connects to ground) connect the tuned circuits across the cathode resistor, providing a rise of 8 dB in 1 dB steps, at two different frequencies.

The lower portion of the control pots connect the tuned circuits in series with a network in the plate circuit, thus providing attenuation of the frequency bands covered by the tuned circuits.

The "Q" of the tuned circuits is such that when the controls are set in line mechanically the circuit is electrically flat with respect to frequency.

In Fig. 6-108C are shown the frequency characteristics of the device with all the controls set to zero (curve A), the *individual* frequency response of each control at plus 8 dB *equalize* (curve B), and the frequency response with *all* controls set to plus 8 dB equalize (curve C).

In the attenuate positions the frequency characteristics of the individual controls are inverse to that of when the controls are set to the equalize (rise) positions. For certain types of recording it might be desirable to use frequencies of 82, 205, 500, 1250, 3200, and 8000 Hz.

The schematic diagram of a typical graphic equalizer is shown in Fig. 6-108D with only *two* of the controls and their tuned circuits shown to simplify the diagram. The total resistance of the control is approximately 10,000 ohms, and is calibrated in steps of 1 dB, 8 dB, plus, and 8 dB minus from center.

Graphic equalizers may also be designed using *passive* networks requiring no amplifiers. The gain of the system is adjusted to compensate for the *fixed* insertion loss of the equalizer network (about 14 to 16 dB). Such devices are discussed in Question 6.126.

6.109 Show the configuration for a high-frequency post-equalizer for reproducing vertical cut records.—A high frequency post-equalizer suitable for reproducing vertical cut records is shown in Fig. 6-109. The low-frequency post-equalizer shown in Fig. 6-103 is connected in tandem with the high frequency equalizer to compensate for the constant-amplitude characteristics of the recording system.

6.110 Give a schematic diagram for an equalizer suitable for transferring 35-mm photographic sound track to 16-mm photographic sound track.—A bridged-T equalizer and low-pass filter, suitable for transferring 35-mm optical sound tracks to 16-mm optical film is shown in Fig. 6-110A.

The equalizer consists of three sections: a low-frequency attenuator, a low-pass filter to provide a sharp cutoff at the higher frequencies, and a high-frequency adjustable equalizer to compensate for film losses. The bridged-T equalizer employs a 10-dB pot adjustable in steps of 1 dB. In addition to the equalizer shown, an 80-Hz high-pass filter should be patched into the channel to limit the low-frequency response. The frequency characteristic of the equalizer and low-pass filter are shown in Fig. 6-110B.

This equalizer combination will be found useful also when transferring 35-mm magnetic sound track to 16-mm photographic sound-track negative; in fact, it is quite useful in many operations involving 16-mm photographic sound track.

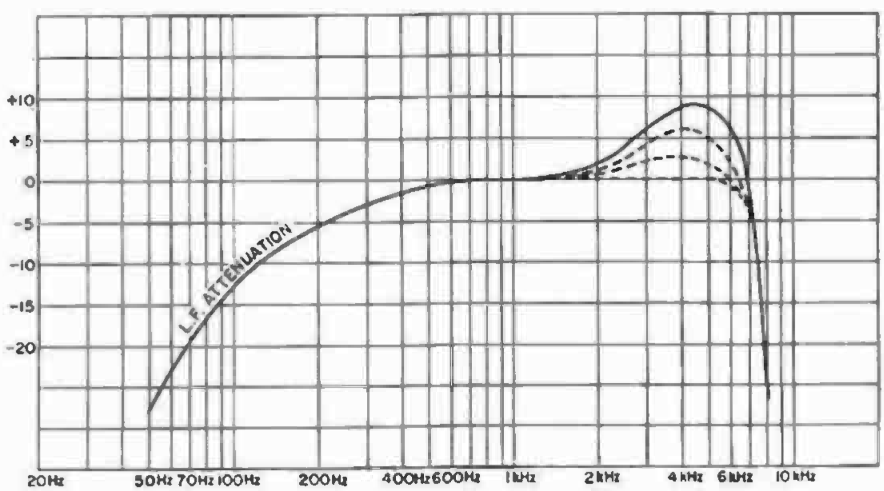

Fig. 6-110B. Frequency characteristics of 16-mm film recording equalizer shown in Fig. 6-110A.

6.111 What are the pre-emphasis and post-emphasis characteristics used in fm radio transmitters and receivers? —Because most of the energy of human speech is in the low and middle frequencies, it is necessary to increase the signal-to-noise ratio of radio-transmitted speech by pre-emphasizing the higher frequencies as illustrated in Fig. 6-111A. The FCC specifies that pre-emphasis shall be employed in accordance with the impedance-frequency characteristic of a series inductance-resistance circuit having a time constant of 75 microseconds.

To return the frequeucy response to one of uniform characteristics in the radio receiver, a post-emphasis or de-emphasis circuit must be connected at the output of the discriminator in the

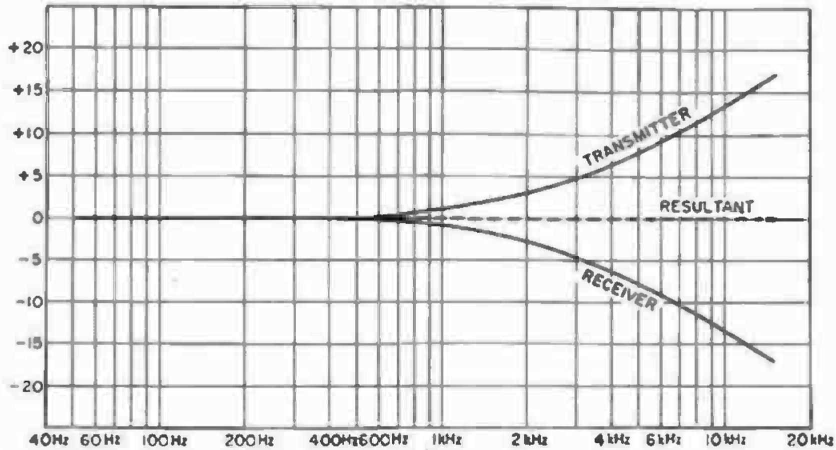

Fig. 6-111A. Pre-emphasis frequency characteristics used in fm and television transmitters and de-emphasis characteristic used in fm and television receivers.

radio receiver. The above circuit may consist of a simple RC network as shown in Fig. 6-111B. The time constant may be calculated:

$$T = R \times C$$

where,

R is the resistance in ohms,
C is the capacitance in microfarads.

Although the circuit values shown in Fig. 6-111B are 100,000 ohms with a capacitance of 0.00075 μF, any values of resistance and capacitance may be used if the time constant is 75 microseconds.

If the high-frequency response is lacking because of the sharpness of the intermediate amplifier in the rf section of the receiver, the high-frequency response may be increased by reducing the time constant to 40 or 50 microseconds. This is often done in the less expensive fm receivers to increase the high-frequency response.

6.112 How is pre-emphasis obtained in an fm radio transmitter?—By connecting an inductance in the plate circuit of a pentode amplifier stage in the speech amplifier, as shown in Fig. 6-112A. At the lower frequencies the reactance of the inductance is negligible; therefore, a plate-load resistor R_L must be connected in the plate circuit. As the frequency rises, the reactance of the coil will also rise, increasing the amplitude of the high frequencies and resulting in a frequency characteristic as shown in Fig. 6-111A.

To obtain a 75-microsecond rise, the ratio of the inductance to the plate resistance of the tube must be in the order of 13.3 ohms of resistance to one millihenry of inductance. A 75-microsecond rise time may also be obtained

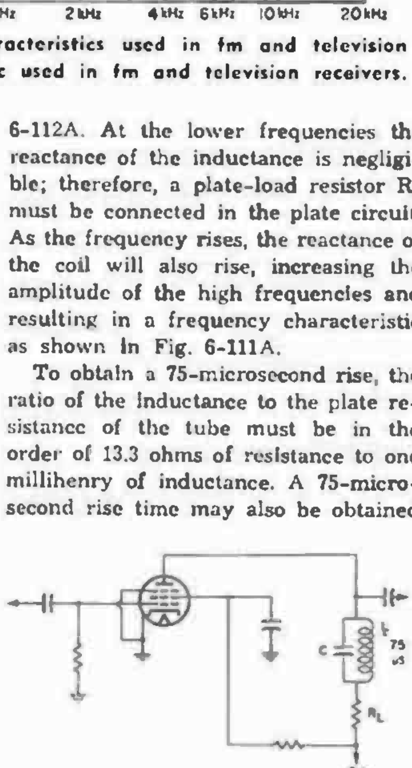

Fig. 6-112A. A 75-microsecond pre-emphasis circuit, connected in the plate circuit of a pentode, in the speech amplifier of an fm radio transmitter.

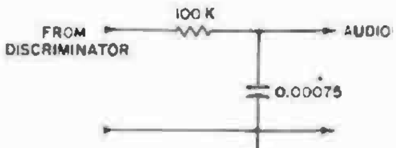

Fig. 6-111B. De-emphasis circuit for fm receiver. This network is connected between the output of the discriminator and the input of the audio stages.

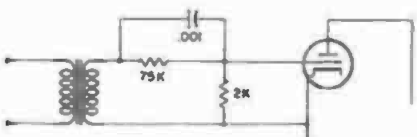

Fig. 6-112B. A 75-microsecond, RC pre-emphasis circuit connected in a low-level stage of the speech amplifier in an fm transmitter.

by the use of an RC circuit as shown in Fig. 6-112B. This circuit is also installed in one of the low-level stages of the speech amplifier. The attenuation characteristics of a de-emphasis circuit expressed in microseconds may be calculated:

$$dB = 10 \log_{10} (1 + w^2T^2)$$

where,

w equals $2\pi f$,
T is the time constant in seconds ($R \times C$).

For a 75-microsecond de-emphasis circuit, this may be written:

$$dB = 10 \log_{10} (1 + 0.222f^2)$$

where,

f is the frequency in hertz,
0.222 is a constant.

6.113 What is split-termination equalization?—Equalization obtained by altering the frequency characteristics of an input transformer by the use of terminating resistors across the primary and secondary as shown in Fig. 6-113.

Assume an input transformer of uniform frequency characteristics with an impedance ratio of 500 to 100,000 ohms is to be used in a microphone preamplifier and that a rising characteristic at the higher frequencies is desired. Further, assume the transformer is normally designed to operate with a 100,000-ohm resistive termination across the secondary. Now, if the secondary is terminated with a 200,000-ohm resistor and the primary terminated with a 1000-ohm resistor, the high-frequency response above 1000 Hz will be increased. By increasing the secondary termination to double that normally used, the reflected primary impedance is also doubled and becomes 1000 ohms, rather than 500 ohms. Connecting a 1000-ohm resistor across the primary returns the impedance, looking into the primary, to 500 ohms again, by

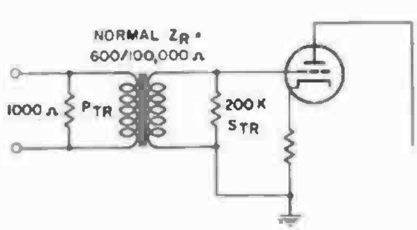

Fig. 6-113. A transformer with split termination to obtain a rising frequency response at the high frequencies.

virtue of the primary impedance being in parallel with the terminating resistor. This combination causes the secondary impedance to look like 66,000 ohms when the primary winding is operating from a 500-ohm source.

The rise in the high-frequency response may be attributed to the mutual capacity existing between the windings of the primary and secondary. The rise at the high frequencies will continue to increase (within limits) as the secondary termination is increased. Double-terminating a transformer increases its insertion loss; however, as a rule, this is not important in an input transformer and may be disregarded.

Split terminations are often used in preamplifiers designed for use with both microphones and photocells. However, they are not recommended for microphone preamplifiers because of the loss of voltage at the secondary. This subject is also discussed in Questions 8.43 to 8.48.

6.114 What is the approximate length of transmission line that may be used without equalization?—The maximum lengths are given:

No. 16 wire	5 miles
No. 19 wire	2.5 miles
No. 22 wire	1.5 miles

6.115 What does the term LC ratio mean?—It is the ratio of inductance to capacitance in a resonant circuit. The frequency of resonance may be calculated for either a series or parallel circuit by the formula:

$$F_r = \frac{159}{\sqrt{LC}}$$

where,

F_r is the frequency of resonance,
L is the inductance in henries,
C is the capacitance in microfarads,
159 is a constant.

As it will be seen, only one value of L times C will resonate to a given frequency. The intended use of the circuit will determine the LC ratio. For a series resonant circuit, the LC ratio is made high. Reducing the LC ratio reduces the steepness of the resonant curve, and the selectivity.

The LC ratio affects a parallel resonant circuit in a manner opposite to the series resonant circuit. As the LC ratio is increased, the selectivity of a parallel resonant circuit is decreased.

6.116 *What is the impedance characteristic of a parallel resonant circuit?*—In a parallel resonant circuit, the impedance reaches a maximum at the resonant frequency. The impedance of a parallel resonant circuit is determined by the formula:

$$Z = Q \times L$$

where,

Z is the impedance,
Q equals X_L/R,
L is the inductance,
R is the dc resistance of the coil.
(See Question 8.72.)

6.117 *What is the impedance characteristic of a series resonant circuit?*—The impedance is at a minimum at the resonant frequency.

$$Z = R$$

where,

Z is the impedance,
R is the ac resistance of the coil.

6.118 *Does the Q of a coil affect the bandwidth?*—Yes. The bandwidth may be expressed as:

$$F_2 - F_1 = \frac{F_r}{Q}$$

where,

F_1 and F_2 are the freqnencies at the edge of the bandwidth, at 0.707 times the current at resonance,
F_r is the frequency of resonance,
Q equals $X_L R$.

6.119 *Where is the bandwidth taken for a series resonant circuit?*—It is designated as a point on the resonance curve that is 0.707 times the current at resonance. Bandwidth is expressed as $F_2 - F_1$. These frequencies are the highest and lowest frequencies at the edges of the bandwidth.

6.120 *What are the essential differences between a series and a parallel resonant circuit?*—The series resonant circuit passes a given band of freqnencies and excludes all others. A parallel resonant circuit excludes a given band of frequencies and passes all others.

6.121 *How may the Q of a circuit be lowered?*—By connecting a resistor in series or parallel with the resonant circuit.

6.122 *What factors influence the equalization characteristics of a dialogue recording channel?*—Several characteristics must be considered. Among them are:

(a) Probable accentuation of the dialogue low frequencies due to the reverberation of the set and recording stage.
(b) The accentuation of the low frequencies because the reproducing level in a theater is generally 6 dB higher than the recording level.
(c) Low-frequency accentuation due to the lowering of the voice approximately 5 dB while recording.

The foregoing factors are plotted as shown in Fig. 6-122 and evaluated as follows: Curve A is the reverberation characteristics of a typical recording stage and set; Curve B is the accentuation of low frequencies, because the recording level is approximately 6 dB lower than the reproduction level in an average theater; Curve C is the accent-

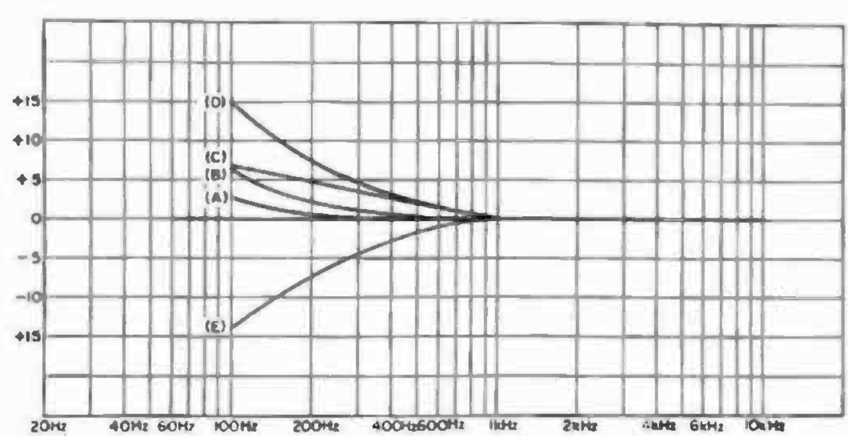

Fig. 6-122. Factors affecting the choice of equalization for dialogue recording.

uation of the low frequencies when the voice is lowered 5 dB during recording. Curve D is the algebraic sum of Curves A, B, and C. Curve E is the inverse of Curve D minus the low-frequency dialogue equalization required for naturalness and intelligibility when reproducing the human voice.

The resulting characteristic is that shown by Curve E, indicating the dialogue should be rolled-off at the lower frequencies, starting at 800 Hz and continuing downward until 100 Hz is attenuated approximately 14 dB with respect to 1000 Hz, when using a microphone of uniform frequency characteristics below 1000 Hz.

In actual practice, 100 Hz is attenuated either 8 or 12 dB with reference to 1000 Hz. This subject is further discussed in Question 18.81 and in Questions 4.114, and 4.27.

6.123 ***What is a delay equalizer?***—A network which adds a time delay in a given frequency band to correct phase-shift distortion. It is used in long line transmissions. The configuration is generally balanced and of the lattice type.

6.124 ***What is a constant-B type equalizer?***—A special type bridged-T equalizer which incorporates two additional resistance arms, R5A and R6A (Fig. 6-124A). It will be noted that one arm is in series with the series-reactive element X_1 and the other is in shunt with the shunt-reactive element X_2.

The conventional bridged-T equalizer requires that the values of the reactive elements be changed to maintain a constant slope for different values of attenuation.

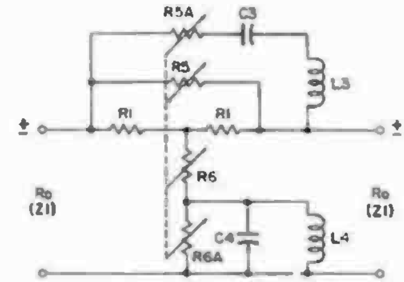

Fig. 6-124A. Constant-B equalizer configuration. The four arms of the attenuator must be varied simultaneously.

The constant-B equalizer controls the slope of equalization without changing the values of the reactive elements. The values of the reactive elements are changed only when changing the resonant frequency. The name constant-B is acquired from the fact that the design frequency for this type equalizer is at one-half the equalizer loss and is designated F_b.

The mechanical construction of a constant-B attenuator is more complicated than the conventional bridged-T attenuator, inasmuch as it requires *four* variable arms that must be operated simultaneously. In the conventional bridged-T equalizer, the shape of the equalization envelope changes with each change of attenuation or equalization, and if plotted for several steps,

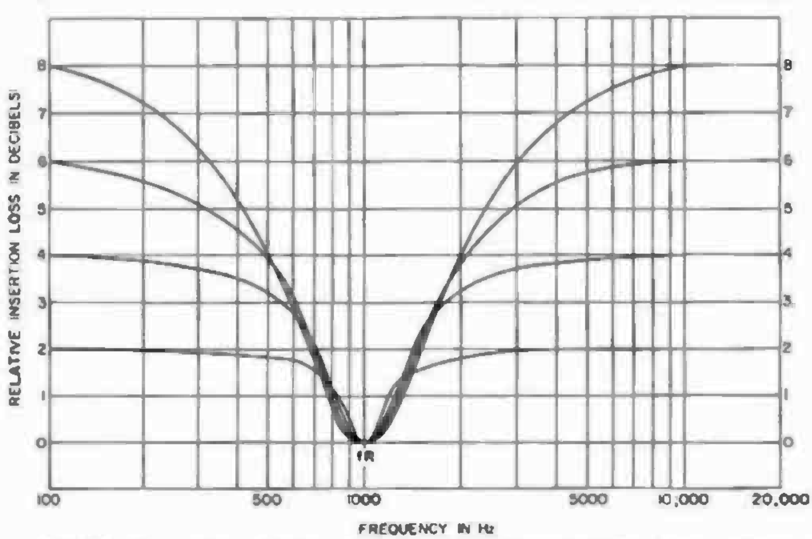

Fig. 6-124B. Conventional bridged-T equalizer characteristics (after Miller and Kimball).

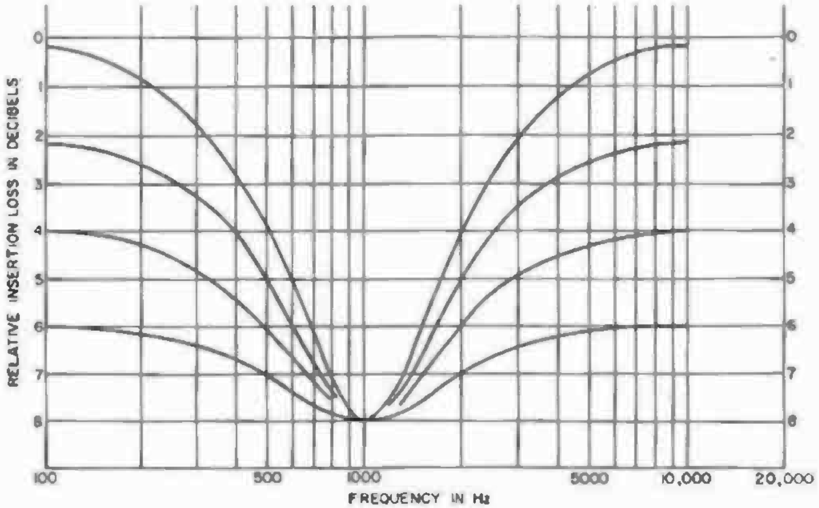

Fig. 6-124C. Constant-B equalizer characteristics (after Miller and Kimball).

will appear as shown in Fig. 6-124B. It will be observed that for an attenuator loss of 2 dB, the half-loss (1 dB) frequency equals 850 Hz, and for 4-dB loss it is 700 Hz and for an 8-dB loss it is 500 Hz. To maintain the half-power frequency at its original point would require that the values of the reactive components be altered each time the attenuation was changed. This can be confirmed by referring to the tables in Questions 6.51 to 6.55. To overcome the characteristics of the bridged-T equalizer, the constant-B equalizer was devised. While it should be understood that the conventional bridged-T equalizer is quite satisfactory for the majority of work (as evidenced by its extensive use in the industry), for equalizers such as described in Questions 6.12, 6.100 and 6.126, constant-B design is a necessity to obtain the proper operating characteristics.

Referring to Fig. 6-124C, the frequency characteristics for a constant-B equalizer, it will be noted as the equalization is increased the half-loss frequency remains the same for any setting between 1-dB and 8-dB attenuation. The frequency of the half-power point is held constant by the additional arms, R5A and R6A. The addition of

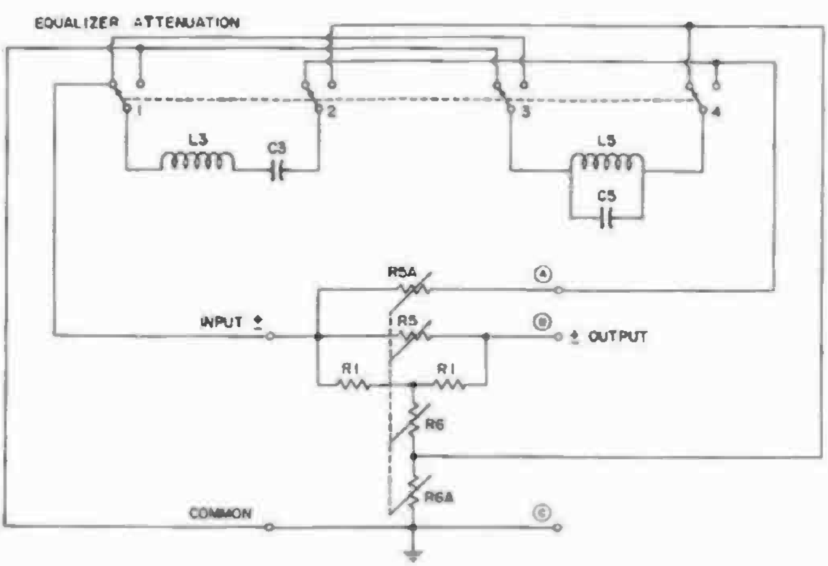

Fig. 6-124D. Constant-B equalizer designed for equalization or attenuation.

these arms modifies the characteristic curve by controlling the amount of maximum and minimum insertion loss while maintaining the difference between the two constants. At a frequency where the reactance X_1 is infinite and X_2 is zero, the configuration becomes the well-known bridged-T pad. When the conditions are reversed and X_1 is zero and X_2 infinite, the circuit becomes an attenuator in which R5 and R5A are in parallel, and R6 and R6A are in series, and is a condition of minimum loss.

To design a constant-B equalizer, the first step is to select the curve of maximum equalization, which means R5A is infinite and R6A is zero, reducing the circuit to a conventional bridged-T equalizer. The circuit is designed as discussed in Question 6.51, and the values of X_1 and X_2 determined. The condition where F_0 will remain constant for all steps of equalization may be approximated:

$$\left[\begin{array}{l}\text{Maximum dB loss}\\ \text{any step}\end{array}\right]^2 = \left[\begin{array}{l}\text{Equalization on}\\ \text{same step}\end{array}\right] \times \left[\begin{array}{l}\text{Equalization on}\\ \text{top step}\end{array}\right]$$

where, equalization is defined as the difference between the *maximum* and *minimum* values of insertion loss, or equalization is equal to the *maximum loss minus the minimum loss*. The top loss is zero but this is not true for the other steps.

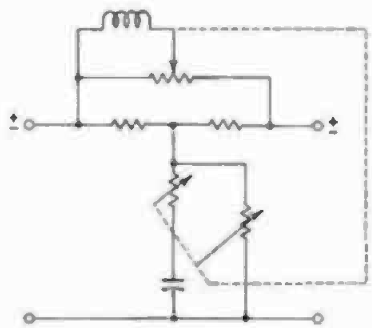
Since the values on the right of the equation are known, only the left side of the equation is to be calculated. A bridged-T attenuator with this loss is now designed to obtain the values of R5 and R6, using the design data given in Question 5.37. To calculate the values for R5A and R6A:

$$\text{Equalization} = \text{Maximum loss} - \text{Minimum loss}$$

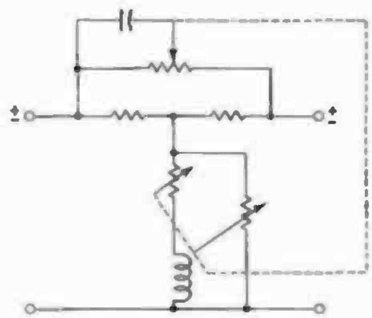
A bridged-T pad is now designed having the loss as determined by the above equation. Resistors R5 and R5A now in parallel form the bridging arm, and as the value of R5 is known, R5A may be calculated. Resistors R6 and R6A form the shunt-arm, and in series must equal the shunt-arm value; R6A may be calculated since R6 is known. In this manner, each step of the network configuration is determined.

Another advantage of the constant-B equalizer network is that it may be used to attenuate or equalize the same band of frequencies by *reversing* the reactive elements (Fig. 6-124D). Symmetrical equalizer and attenuate characteristics will be attained when the maximum loss of the constant-B attenuator is 8.36 dB.

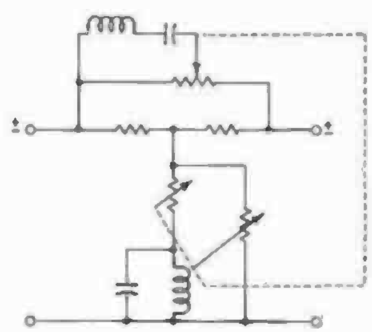
6.125 Describe a constant-S type equalizer.—It has been stated for the bridged-T equalizer that the insertion loss for the unequalized frequencies is changed from step-to-step, and the maximum equalization held constant. In the constant-B equalizer, the slope



(a) *Low frequency.*



(b) *High frequency.*



(c) *Midfrequency.*

Fig. 6-125. Basic configurations for constant-S type equalizer networks (after Solomon and Broneer).

Fig. 6-126A. Graph equalizer Model 9062A manufactured by Altec-Lansing.

of the equalization envelope is controlled without having to change the values of the reactive elements. In the constant-S type equalizer, the insertion loss for the unequalized frequencies is held constant and the point of maximum equalization is changed from step to step. The term "S" is the symbol for the insertion loss.

The constant-S configuration is used in small compact equalizer networks, since the number of contact arms may be reduced to three. Also, the insertion loss is less than for other configurations for a given value of equalization. Three possible configurations are given in Fig. 6-125. The reader is referred to the reference.

6.126 Describe a graphic equalizer of the passive network type.—Graphic equalizers may be designed in two different manners, the *active* type, using a degenerative amplifier as discussed in Question 6.108, or one using a *passive* network requiring no amplification. The statement that a passive network requires no amplification means that it has no internal amplifiers and requires no source of power for its operation. However, because it is a resistive network, it does have an insertion loss; therefore, the system gain following the equalizer must be increased to compensate for the network insertion loss.

The basic design for the equalizer to be described is the constant-B attenuator network, discussed in Question 6.124. Because of its design, the insertion loss is constant for any given frequency, with the equalization variable over its complete operating range, without changing the shape of the equalization characteristic. The constant-B network for this particular equalizer is designed around the half-loss point, for a total loss of 16 dB, resulting in a capability of plus 8-dB equalization and minus 8-dB attenuation, resulting in a total operating range of 16 dB. A front panel view of such an equalizer is shown in Fig. 6-126A.

Two groups of operating frequencies

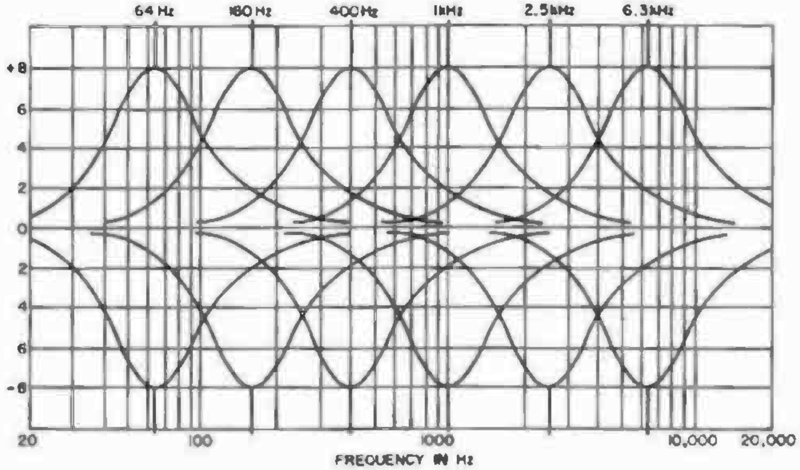


Fig. 6-126B. Frequency response curve for Altec-Lansing Model 9073A motion picture rerecording and dialogue.

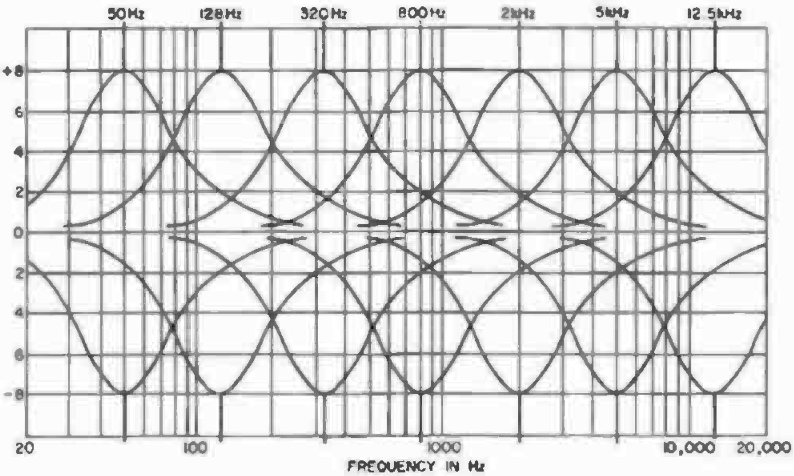

Fig. 6-126C. Frequency-response curve of graphic equalizer for music recording.

are available. The one is for motion picture rerecording, using 64, 160, 400, 1000, 2500, and 6300 Hz. The second group is for wide-range music recording, using frequencies of 50, 128, 320, 800, 2000, 5000, and 12,000 Hz. In the center or zero position the frequency is flat, within plus or minus 0.5 dB. The frequency response for the two type equalizers is given in Figs. 6-126B and 6-126C. The internal circuitry consists of printed-circuit boards. The physical dimensions are 3½-inches high, 10-inches wide and 5¼-inches deep. The usual method of connection is to insert the equalizer between the output of a microphone preamplifier, or reproducing machine, and the input to the mixer console, as in Fig. 6-126D.

6.127 ***Describe a film-loss equalizer and its purpose.***—Film-loss equalizers are used to compensate for the inherent high-frequency losses of photographic film, recorder optics, laboratory processing, and the linear speed of the film. Film loss is measured as set forth in Question 18.170.

After the loss has been plotted, the equalizer is connected in the recording circuit and adjusted for a flat response from the film, within plus or minus 1 dB,

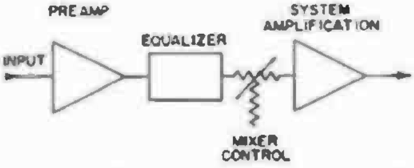

Fig. 6-126D. Connections for a graphic equalizer and mixer network.

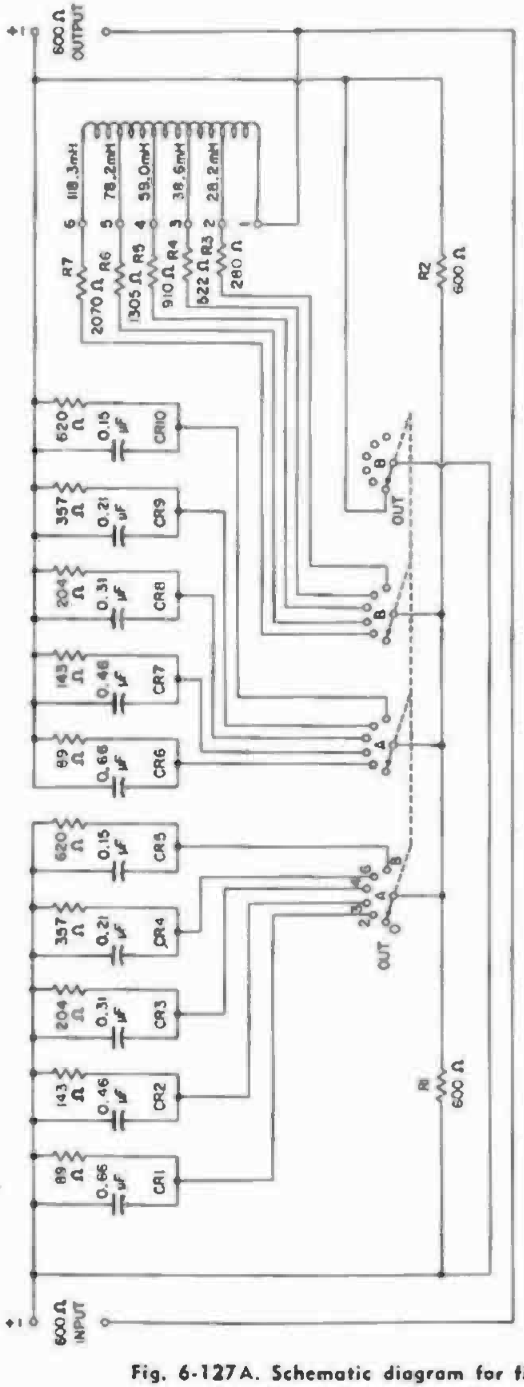
by making further measurements. In some instances, the equalization is increased 1 or 2 dB over that required to compensate for high-frequency losses due to variation in recording stock and processing. These are determined from day to day, when the cross-modulation or intermodulation tests are read. Once adjusted the equalizer will require no further attention, unless a radical change is made in the recording stock or laboratory processing.

The schematic diagram for a film-loss equalizer is shown in Fig. 6-127A, with a family of response curves in Fig. 6-127B. The equalizer shown is suitable for either 6000 Hz used for 16-mm film recording, or 9000 Hz used with 35-mm film. The equalization is obtained by means of capacitors and resistors in parallel, with capacitors and building-out resistors in series with the coil taps. The purpose of the resistors in parallel with the capacitors is to shape the curve. If a different slope is required, they may be altered to suit the situation. However, the resistors must be matched in pairs. Since the configuration is unbalanced, the low potential side must be grounded to prevent leakage at the high frequencies. The position of the equalizer in a recording channel is discussed in Questions 18.330 and 18.331.

6.128 ***What is a loudspeaker low-frequency boost equalizer?***—It is a shelf-type equalizer, which is shown in Fig. 6-49B, for increasing the low-frequency response of small loudspeaker systems. It is installed between the output of the driving amplifier and the input to the loudspeaker. Basically the device is designed for 16 ohms, but it may be used with either 8-ohm or 16-ohm systems. However, if used in an 8-ohm circuit the increase in the low-frequency response is less, as indicated by the frequency-response curve of Fig. 6-128. Because the equalizer induces a 4 to 6-dB loss at 100 Hz, the amplifier must be capable of developing sufficient power to compensate for the insertion loss. At least 40 watts of power should be available; if not, severe overloads may be noticed on the heavy low-frequency passages.



RESISTORS ± 1%
CAPACITORS ± 2%
COIL ± 3%

POS	dB EQUALIZATION AT 6000 HERTZ	dB EQUALIZATION AT 9000 HERTZ	dB INSERTION LOSS AT 400 HERTZ
1	OUT	OUT	0
2	1.8	2.0	1.9
3	2.6	2.9	3.1
4	3.4	3.8	4.1
5	4.8	5.5	6.4
6	7.2	8.3	9.2

Fig. 6-127A. Schematic diagram for film-loss equalizer.

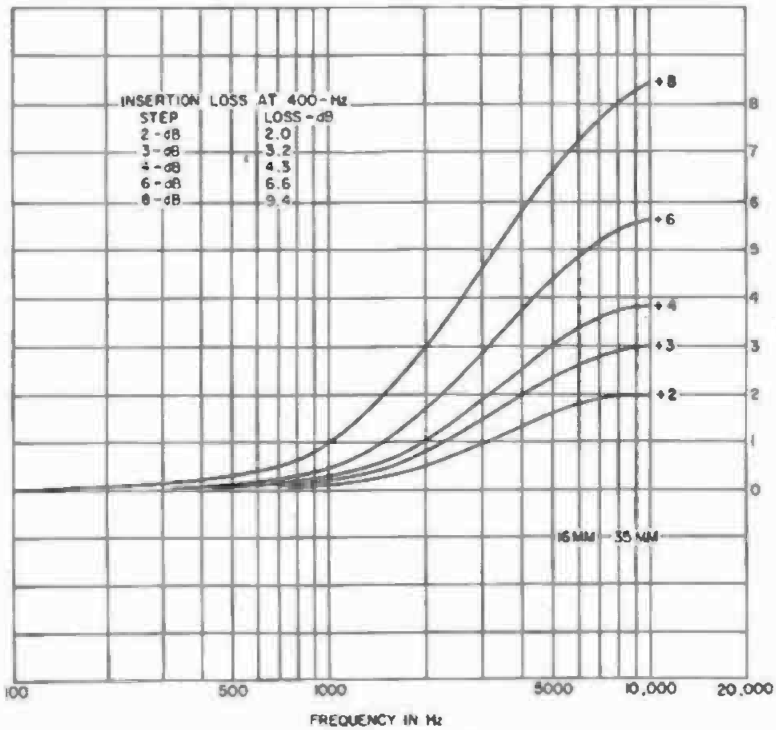


Fig. 6-127B. Film loss equalizer frequency response.

It should be remembered, inducing only a 3-dB loss at 100 Hz lowers the power output from the amplifier to the loudspeaker by 50 percent. Therefore, for a given loudness from the loudspeaker, the amplifier must be driven harder, which in some instances may drive the amplifier into overload. The circuit elements may be designed as discussed in Question 6.49.

6.129 ***Describe a stereophonic pickup equalizer suitable for low-impedance lines.***—A dual equalizer developed by Shure Bros. Inc., for use with stereophonic pickup cartridges is shown in Fig. 6-129A. Although the circuitry (Fig. 6-129B) was developed for use with the manufacturer's pickup, it may be used equally well with pickups of other manufacture. Three different frequency-response characteristics are available: flat response for the repro-

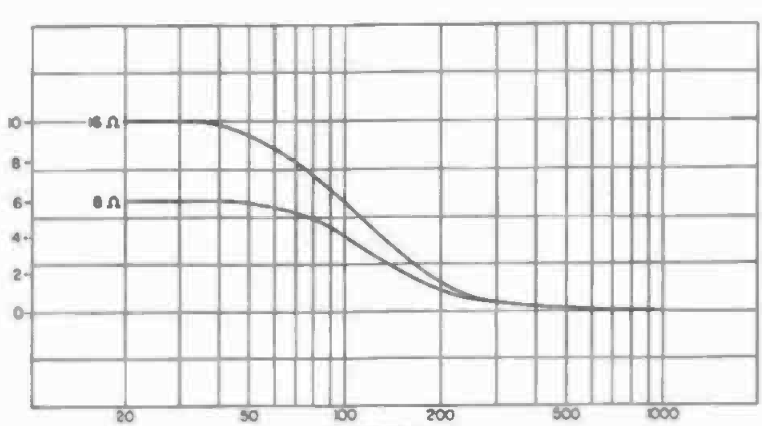

Fig. 6-128. Frequency response of a loudspeaker low-frequency equalizer.

duction of recordings without high-frequency pre-emphasis, standard RIAA response, and a high frequency rolloff for reducing surface noise (Fig.

Fig. 6-129A. Shure Bros. Inc. Model M66 broadcast stereophonic equalizer.

6-129C). For use with high-impedance cartridges having an inductance of 365 to 500 millihenries, the response is plus or minus 1 dB from 30 to 20,000 Hz. For low-impedance cartridges having an inductance of 175 millihenries, the response is within plus or minus 2 dB from 50 to 20,000 Hz. For monophonic reproduction, the inputs of the two sides are connected in parallel. The channel separation is better than 30 dB over the complete spectrum, and may be used with line impedances of 150 to 600 ohms.

6.130 *What is a universal equalizer?*—It is an equalizer having multiple frequency characteristics. The universal equalizer to be discussed has incorporated in its design many features that make it ideal for both large and small studios, where many different types of equalization or filtering are a

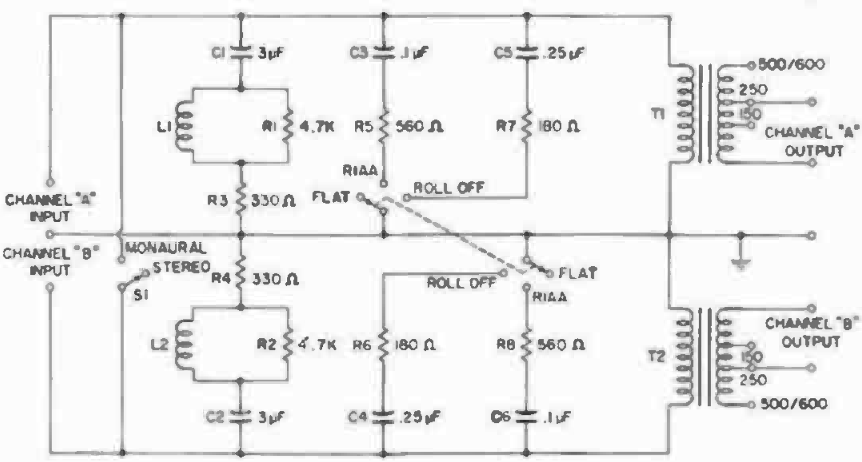

Fig. 6-129B. Schematic diagram for Shure Bros. Inc. Model M66 broadcast stereophonic equalizer.

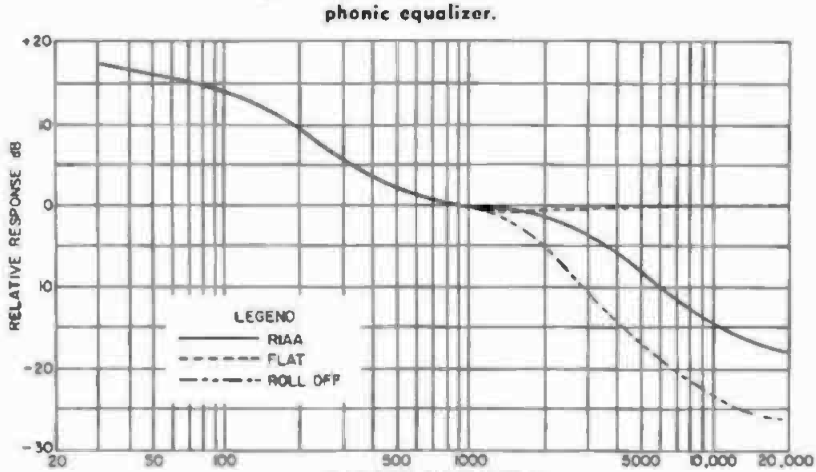

Fig. 6-129C. Frequency response for Shure Bros. Inc. Model M66 broadcast stereophonic equalizer.

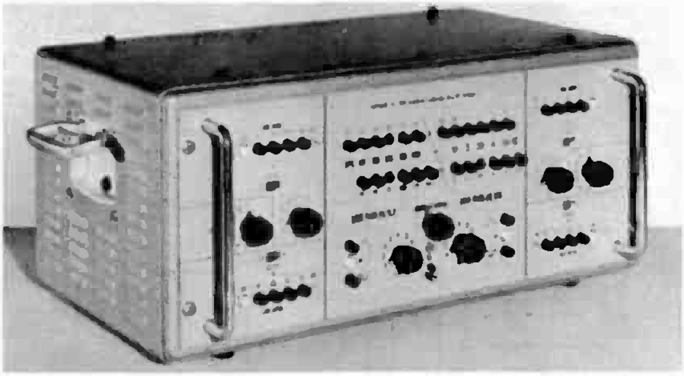

Fig. 6-130. Gotham Audio Corp. Model EQ 1000 universal equalizer.

part of the daily routine. A front view of a universal equalizer, Model EQ 1000, Gotham Audio Corp., and manufactured by Klein-Hummel of West Germany, is pictured in Fig. 6-130.

At the left are several push-buttons for selecting low-frequency equalization or attenuation at a rate of 6, 12, or 24 dB per octave. In the center is a second group of push-buttons for selection of high-pass, low-pass or band-rejection filters. At the right are several push-button controls for high-frequency equalization or attenuation, at rates of 6, 12, and 24 dB per octave.

The circuitry of this instrument consists of only resistance and capacitance; no inductance is used in any of the equalizer or filter circuits to achieve its characteristics. The elimination of inductance helps to reduce harmonics and intermodulation distortion, eliminate pickup from stray magnetic fields, and permit a good square-wave response, with smooth transition from one set of conditions to another. Each set of push-buttons has in modular form its own set of amplifiers, resistors, and capacitors, divided into seven subassemblies. The device is designed to be connected directly into a microphone line, or used as a bridging input. It can also be used to reproduce a given frequency response, compensate for unwanted response, or be adjusted by listening for the desired characteristic. In stereophonic reproduction its design permits operation in either one or both channels simultaneously, without a phase shift. Due to its design, previous settings may be duplicated accurately.

The frequency response in its linear condition is plus or minus 0.25 dB, from 20 to 20,000 Hz. The input impedance is 5000 ohms balanced; output is 600 ohms. The total rms distortion from 50 to 10,000 Hz is less than 0.4 percent. Maximum output is plus 22 dBm. Intermodulation distortion is less than 1 percent, using 50 and 7000 Hz, mixed in a ratio of 4:1, at plus 18 dBm out. Noise level unweighted is minus 78 dBm, or using the CCIR weighted curve, minus 93 dBm. It may be operated as a zero-gain device, or with a gain of 5 dB. It requires 14 vacuum tubes for its operation.

6.131 Describe a constant-impedance low-frequency attenuator equalizer. —As was pointed out in Question 6.80, capacitor equalizers used to achieve low-frequency attenuation for dialogue recording are not constant impedance. In mixer networks, where a constant impedance is essential, the equalizer circuit in Figs 6-131A and B is employed. This particular design uses a 600-ohm T-type attenuator network; however, the usual shunt-resistor connected in series with the inductance is omitted to achieve the proper frequency characteristic. A key switch is employed to change the value of inductance and capacitance for 6-dB or 8-dB rolloff. The actual configuration for the two key positions is shown in Fig. 6-131B. It will be noted the greatest amount of low-frequency attenuation is attained with the smallest value of capacitance. This may appear to be confusing; however, it should be remembered that the *smaller* the value of a capacitance, the *greater its reactance* at a given frequency. Therefore, the greatest rolloff is attained with the smallest value of capacitance and vice versa. The coil has a total inductance of 0.412 henry, with a tap at 0.25 henry. To prevent pickup

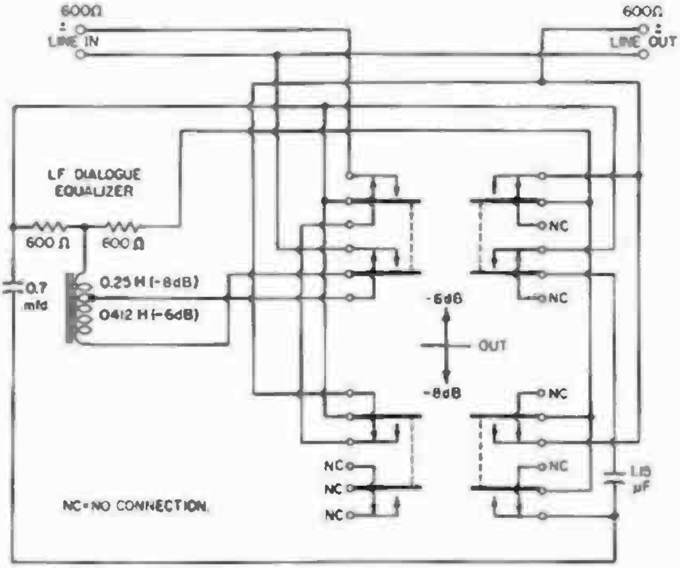

Fig. 6-131A. Low frequency attenuator-type equalizer and its switching circuit.

from stray magnetic fields, a toroidal coil housed in a Mumetal case is necessary.

6.132 *Describe an integrated circuit equalizer-amplifier module.*—It has become common practice in the designing of mixing consoles to provide plug-in units whenever possible to facilitate construction and maintenance. This includes amplifiers, mixer controls, transformers, equalizers, and other devices. An integrated circuit equalizer-amplifier unit Model 709-L manufactured by Electrodyne, is pictured in Fig. 6-132. In this unit a microphone and line amplifier is provided, with both low- and high-frequency equalization. Each equalizer has six positions of equalization and six positions of attenuation, thus providing a total range of 24 dB for each equalizer. Frequencies of equalization are 40 and 100 Hz, 1.5, 3, 5, and 10 kHz, in steps of 2 dB each. In addition, a cuing, echo send, and a level input key to adjust the gain for different type microphones are provided.

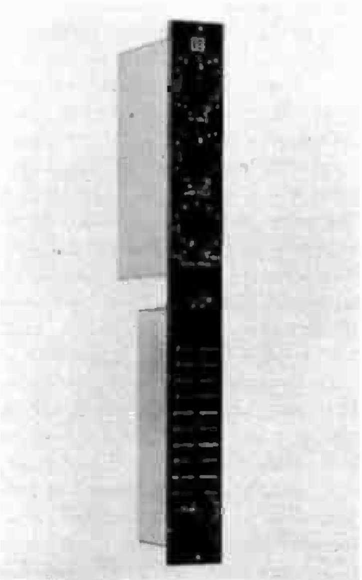

Fig. 6-132. Electrodyne Model 709-L integrated circuit equalizer-amplifier module for mixing consoles.

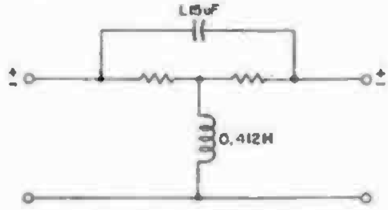
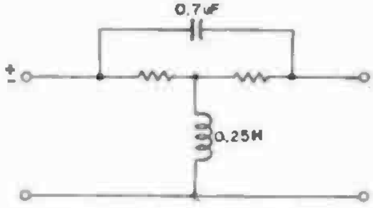


(*a*) *—6 dB attenuation.*



(*b*) *—8 dB attenuation.*

Fig. 6-131B. Configurations for the two switch positions in Fig. 6-131A.

The microphone and line amplifier are of the differential type. Both inputs of the microphone amplifier are utilized and are driven by a special push-pull input transformer. One input of the line amplifier is used for the signal input and the second is used for equalization. The input impedance is designed for operation with a 50-, 200-, or 600-ohm source impedance. The frequency response is plus or minus 1 dB from 20 to 20,000 Hz, with a THD of 0.5 percent at plus 18-dBm output. The unweighted noise level is equivalent to minus 127 dBm, 20 to 20,000 Hz. Isolation between the cue and program output is greater than 77 dB. The mixer control may be either straight-line or rotary design.

6.133 What type equalizers are used for auditorium tuning?—In reality, these equalizers are tuned filters, consisting of a coil and capacitor connected in parallel, then inserted in a transformer-coupled line, between the voltage and power amplifier of a sound system. The coils must be of fairly high "Q" to permit connection of a resistance in parallel with the coil to broaden the response curve. This subject is discussed in Question 2.117.

Section 7

Wave Filters

A wave filter is an electrical network of reactive elements designed to transmit or suppress a given band of frequencies. Wave filters are used extensively for recording and reproducing sound. Much of the present day knowledge of these devices came from the research of W. H. Bode, T. E. Shay, and Otto J. Zobel, all of the Bell Telephone Laboratories.

This Section will deal with the design of constant-k, m-, mm′-, mm″-derived high-pass, low-pass, bandpass, band-elimination, and composite filters. Also included are loudspeaker crossover networks, recording and reproducing filters, pink-noise filters, phase-shift filters, parallel-T filters, Wien-bridge filters, noise-measurement filters, and dip filters. The combining of various types of wave filter sections is explained using ladder configurations. Simplified equations, graphs, and tables of constants with many practical circuits are given.

7.1 ***What is a wave filter?***—An electrical network composed of reactive elements used for attenuating or removing a given band of either audio or radio frequencies.

7.2 ***What is an ideal filter?***—A perfect filter designed without regard to losses, physical size, cost, and other factors.

7.3 ***What is a practical filter?***—A physical filter designed from the ideal filter, in which the losses, physical size, cost, and shielding efficiency have been taken into consideration.

7.4 ***What is a passive network?***—One not acting itself, but being acted upon by an external source.

7.5 ***What is an active network?***—One which supplies power. It may be composed of batteries, a generator, or an amplifier.

7.6 ***What is a high-pass filter?***—A network of reactive elements which attenuate all frequencies below a predetermined frequency selected by the designer. Frequencies above cutoff are passed without discrimination, as shown in Fig. 7-6.

7.7 ***What is a low-pass filter?***—A network of reactive elements which attenuate all frequencies above a predetermined frequency selected by the designer. Frequencies below cutoff are passed without discrimination. (See Fig. 7-7.)

7.8 ***What is a bandpass filter?***—One in which only a predetermined band of frequencies is passed. (See Fig. 7-46.)

7.9 ***What is a band-rejection filter?***—One which rejects or removes a predetermined band of frequencies. (See Fig. 7-47.)

7.10 ***What is a band-elimination filter?***—Another name for a band-rejection filter.

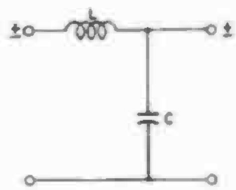
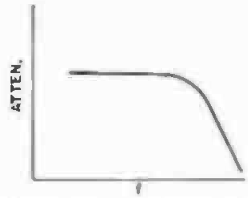
(b) Transmission characteristics.

Fig. 7-6. A high-pass filter.



(a) Configuration.



(b) Transmission characteristics.

Fig. 7-7. A low-pass filter.

7.11 What is an all-pass filter?—A filter which will pass all frequencies without attenuation from zero hertz to infinity. Such devices are used for phase-shifting and time-delay networks. (See Questions 7.23 and 7.24.)

7.12 Describe a notch or dip filter.—It is a filter for removing a given frequency or a very narrow band of frequencies. The device generally consists of an RC network using a parallel-T configuration. (See Question 7.72.) Notch filters are also called dip filters and may use LC or LCR configurations. A dual notch filter manufactured by Altec-Lansing is shown in Fig. 7-12A, with notch frequencies at 150 and 820 Hz. The configuration and frequency response for a similar filter, using 150 and 520 Hz, is shown in Fig. 7-12B.

Fig. 7-12A. Model 64A double-notch or dip filter using 150 and 820-Hz, manufactured by Altec-Lansing.

Such filters can be used for tuning an enclosure, using the Boner system as described in Question 2.117.

7.13 What is a brute-force filter?—One in which the reactive elements are so large that the filtering is forced to take place. This term is generally applied to low-pass filters used in power supplies.

7.14 What is a composite filter?—One which employs two or more filter sections. They may be of constant-k or m-derived design.

7.15 What is the transmission band of a filter?—The portion of its frequency characteristic which passes a band of frequencies without attenuation. (See Fig. 7-15.)

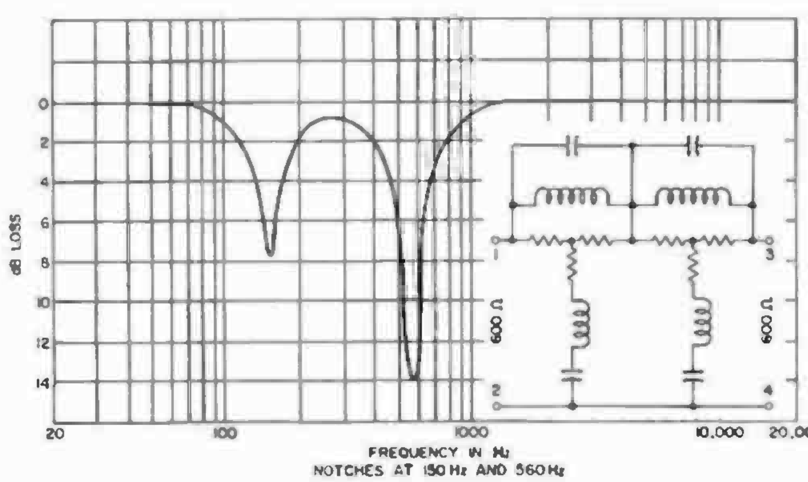


Fig. 7-12B. Frequency response of double-notch filter using 150 and 520-Hz.

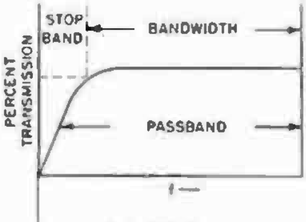
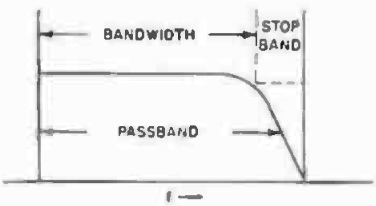


(a) *High-pass.*



(b) *Low-pass.*

Fig. 7-15. Transmission characteristics of a high- and low-pass filter.

7.16 What is the passband of a filter?—It is another name for the transmission band. (See Question 7.15.)

7.17 What is the bandwidth of a filter?—The number of hertz expressing the difference between the lower and upper limiting frequencies. It is also called the passband. (See Fig. 1-15.)

7.18 What is a stop band?—The frequency of a band-rejection or band-elimination filter.

7.19 What is the cutoff frequency of a filter?—The frequency above or below which a filter fails to respond. The terminology used for expressing the characteristics of filters is discussed in Question 7.102.

7.20 What is a two-terminal network?—A configuration such as shown in Fig. 7-20.

7.21 What is a three-terminal network?—An unbalanced configuration with one terminal common to both the input and output. (See Fig. 7-21.)

7.22 What is a four-terminal network?—A balanced configuration as shown in Fig. 7-22.

7.23 What is a phase-shift or phase-correction network?—An electrical network composed of reactive elements as shown in Fig. 7-23. The purpose of such networks is to induce a time delay in a given frequency band to correct for phase distortion in long-line telephone transmission. They are also used in recording circuits to compensate for phase shift of certain type equalizers.

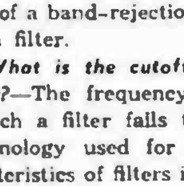


Fig. 7-20. A two-terminal network.

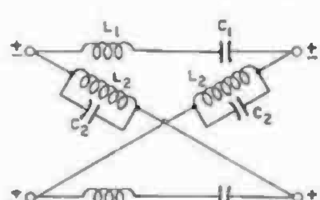
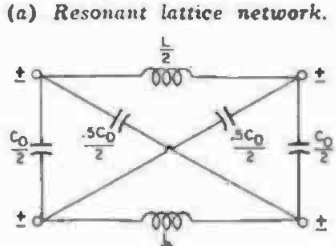
Fig. 7-22. Four-terminal networks.



(a) *Resonant lattice network.*



(b) *Single nonresonant lattice network.*

Fig. 7-23. Configurations of balanced phase-correction networks.

A lattice (balanced) configuration phase-correction network employing both series and parallel resonant circuits is shown at (a) of Fig. 7-23. Each complementary pair is resonated to a selected frequency band to induce a given time-delay. The circuit shown at (b) of Fig. 7-23 is a similar type network using nonresonant circuits for high-frequency phase correction. (See Question 7.112.)

7.24 ***How are wave filters classified?***—Wave filters are classified according to their function and the procedure used for determining their circuit element values. The four design procedures are: the constant-k (prototype); the m-derived; the mm' (double-m, prime derived); and the mm" (double-m, double-prime derived). The latter two are used only in advanced filter design where the characteristics must be closely controlled. For audio work, usually a constant-k or an m-derived type is used, or a combination of both types. Such a filter is termed a composite filter.

7.25 ***What is the characteristic impedance of a wave filter?***—Its design impedance, as designated by the symbol R_o. A typical impedance curve for a constant-k type filter is shown in Fig. 7-25. The actual impedance, Z_1, presented by the filter to the line is equal to the line impedance R_o only at one frequency and is one of the characteristics of a constant-k filter.

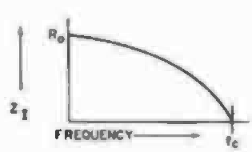


Fig. 7-25. Impedance characteristic of a constant-k filter.

7.26 ***What is surge impedance?***—The terminating impedance required at the end of a transmission line to prevent reflection losses.

7.27 ***What is the terminal impedance of a filter?***—The impedance seen when looking into the input or output terminals when measured with an impedance bridge.

7.28 ***What does the term constant impedance mean?***—Any device which maintains a fixed terminal impedance under normal operating conditions.

7.29 ***What is a pi-type filter?***—A filter which has a configuration resembling the Greek letter pi. (See Fig. 7-39.)

7.30 ***What is a constant-k filter?***—A wave filter in which a constant termed k is used. This term is sometimes misconstrued as meaning that the impedance of the filter is constant; however, this is not the case. The impedance of a constant-k filter is equal to the line impedance at only one frequency and presents a mismatch at all other frequencies, as described in Question 7.25.

7.31 ***What is an m-derived filter?***—A wave filter in which the impedance and attenuation characteristics may be controlled by the designer. The term m is a constant lying between zero and one. An m-derived filter can be designed to match approximately 85 percent of the frequency band covered by the filter. For audio frequencies, the constant m is generally made to equal 0.60. An m-derived filter may also be combined with a constant-k section to secure a given frequency characteristic. When a constant-k and an m-derived filter section are combined, the filter is called a composite filter.

7.32 ***What is the insertion loss of a filter?***—It is the loss in level measured at a given frequency in the passband, with the filter in and out of the circuit. The insertion loss of a filter (in decibels) may be found by determining the amount of the current reduction at the load side of the network. As a general practice, the insertion loss of any network is measured at a frequency within the *flat* portion of the passband; the exact frequency depends on the individual characteristics of the network. The expression for calculating the insertion loss is:

$$IL = 20 \mathrm{Log}_{10}\left(\frac{E_1}{E_2}\right) - 20 \mathrm{Log}_{10}\left(\frac{R_{in} + R_{out}}{R_{out}}\right)$$

where,

E_1 and E_2 are the voltages at the inpnt and output terminals,
R_{in} and R_{out} are the impedances of the network at its terminals.

This formula takes into consideration the *mismatch* of impedances at either end of the network and the effect of *series and shunt reactances* in the network.

7.33 What causes insertion loss?—The dc resistance of the coils and the series and shunt reactance of the circuit elements.

7.34 How can the impedance of an unknown filter be measured?—By measuring the geometric mean of the filter impedance in the passband at a given frequency. The impedance is first measured with the far end shorted, then open. The characteristic impedance R_o is then equal to:

$$R_o = \sqrt{Z_1 \times Z_2}$$

where,

Z_1 is the first measurement,
Z_2 is the second measurement.

7.35 What is the transmission characteristic of a wave filter?—It is the frequency characteristic of the filter plotted as frequency versus attenuation and is the characteristic seen by the circuit in which it operates (Fig. 7-15).

7.36 What are the attenuation characteristics of a wave filter?—The loss of a filter plotted as frequency versus insertion loss in decibels.

7.37 Define the term, "image impedance."—The image impedance of a wave filter is presented by a group of curves, each curve having a different impedance characteristic, depending on the character of the configuration. (See Fig. 7-48A.) The image impedance consists of two impedances, not necessarily alike, that will simultaneously terminate the network at its two ends, thereby avoiding internal reflection losses. This occurs when the image impedance is equal to the impedance looking into the filter network. When the image impedances are equal in value (input and output), the filter is symmetrical and is equal to Z_1, the characteristic impedance of the network.

The term impedance can best be explained by means of Fig. 7-37A. The image impedances are equal to Z_1 and Z_2 if the termination impedances are of such value that, with Z_1 disconnected, the impedance looking into the input of the filter equals Z_1; with Z_1 connected and Z_2 disconnected, the impedance

Fig. 7-37A. Filter network terminated in its image impedances.

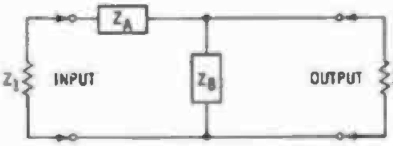

Fig. 7-37B. Elementary filter network terminated in its image impedances.

looking into the output terminals equals Z_1. Thus, the term image impedance may be explained as follows; looking into the input terminals Z_1 sees its image, and looking back into the network Z_2 sees its image. This is the condition when a filter network is said to be terminated in its image impedance. Mathematically the image impedance, with Z_1 disconnected and Z_2 connected is:

$$Z_{in} = Z_A + \frac{(Z_B Z_2)}{(Z_B + Z_2)}$$

Disconnecting Z_2 and connecting Z_1, the image impedance is:

$$Z_{out} = \frac{(Z_A + Z_1)\, Z_B}{(Z_A + Z_1 + Z_B)}$$

Therefore,

$$Z_1 = \sqrt{(Z_A + Z_B)\, Z_A}$$

$$Z_2 = Z_B \sqrt{\frac{Z_A}{(Z_A + Z_B)}}$$

where,

Z_1, Z_2, Z_A and Z_B are as shown in Fig. 7-37B.

Mathematically, the foregoing gives the image impedance for any given set of circuit constants. However, in design of practical filters, the image impedance is known in advance, and the circuit constants are then computed to result in the desired image impedance. The image or characteristic impedance of an existing filter may be measured as given in Question 7.34.

7.38 What is meant when it is said two impedances are conjugates of each other?—When their resistive components and their reactive components are equal in magnitude but opposite in sign.

7.39 What are the basic configurations and equations for constant-k low pass filters?—The basic designs for constant-k low-pass filter sections are shown in Fig. 7-39. It will be noted that a T-type network has an inductance (L_1) in series with the line and a capacitance (C_2) in shunt with the line. Operation of the network may be visu-

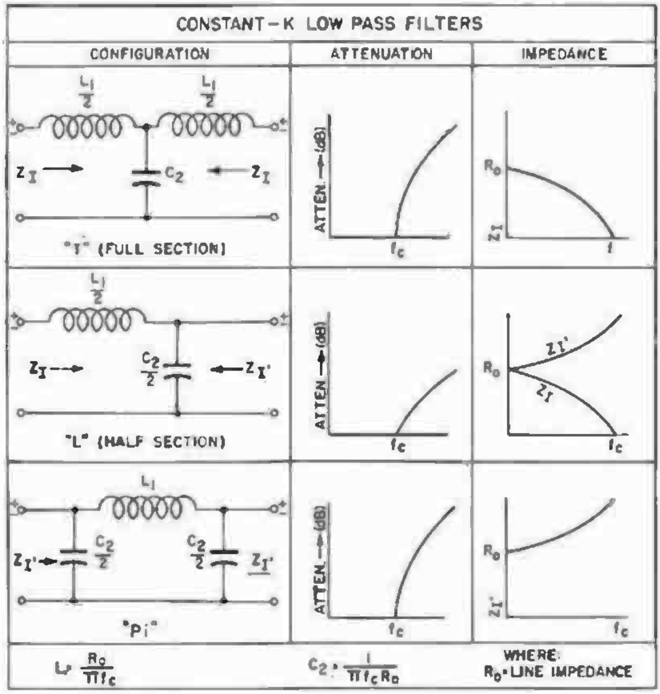

Fig. 7-39. Configuration and frequency characteristics of a constant-k low-pass filter.

alized by consideration of the properties of inductive and capacitive reactance.

Inductive reactance varies directly with frequency. Since an inductive reactance is connected in series with the line, it offers an increasing opposition to transmission as the frequency is increased. The capacity in shunt with the line presents a capacitive reactance which decreases with frequency. As the frequency is increased, this capacitive reactance becomes more effective in shunting the audio currents, thereby reducing the transmission through the filter. The combination of the inductive and capacitive reactance produces a net attenuation characteristic beginning at the cutoff frequency and continuing beyond the cutoff frequency. The impedance presented by a T network to the transmission line is designated Z_I. This impedance is equal to the line impedance at zero frequency only and decreases progressively through the passband. This may be seen by referring to the impedance curve for a T section (Fig. 7-39).

An L-type network may be thought of as one-half of a T section or one-half of a pi section. An L section is also called a half-section and has an attenuation characteristic which is half as much as the attenuation of a full section (T or pi) at the same frequency. The impedance of an L filter is designated Z_I and Z_I'. These two designations are used because the impedance of the filter at one set of terminals differs from the impedance at the other. It will be seen that at one end the impedance is the same as for the T network and, at the other, the impedance characteristic is the same as that of the pi network.

The attenuation characteristics of a pi section can be made identical to those of a T section, as indicated by the attenuation curves. The attenuation of either a pi or a T section is twice as much as for the L or half-section network. The impedance of the pi section is designated Z_I' for both ends. A constant-k pi section presents an impedance to the line which equals the line impedance at zero frequency and increases as the frequency increases within the passband.

7.40 How are the different filter sections selected?—By their attenuation and impedance characteristics. The attenuation of a constant-k full section is approximately 23 dB, one octave removed from the cutoff frequency. This is not considered to be a sharp rate of cutoff. If the attenuation is not sufficient, combinations of filter sections may be connected in tandem.

7.41 How are different type filter sections combined?—To better understand how filter sections are combined, in Fig. 7-41A is shown the familiar ladder-type network with its series reactive element Z_1 and shunt reactive element Z_2. These reactive elements (impedance) may be either capacitive or inductive. If two lines, A and B (Fig. 7-41B) are drawn through the midpoint of the two series elements, the familiar T-section is developed. In this configuration the series arms are denoted $Z_1/2$, since they are a half of Z_1 in Fig. 7-41A, and they are referred to as *midshunt* terminals. Referring again to Fig. 7-41B, drawing a line at C, the structure between B and C becomes an L-type configuration. In this instance the series arm is also $Z_1/2$, while the shunt arm is $2Z_2$, and the terminals are termed midshunt. Cutting the network with a line D, the configuration between C and D becomes a pi-type configuration. The series element is Z_1, while the shunt element is $2Z_2$. For the element (Z_2) to equal Z_2 in Fig. 7-41A, its value must be *doubled*. In practice, when two elements appear in series or parallel, they are combined into one element.

The input terminals of the L-type configuration, Fig. 7-41B are termed *midseries*, while the output terminals are called midshunt. An L section is also referred to as a *half-section*, since two L sections connected in tandem form a T type or *pi section*, depending on whether they are joined at their midshunt or midseries terminals. The method used for combining the elements of two T-type configurations is shown in Fig. 7-41C. Combining two pi sections is shown in Fig. 7-41D.

Any number of filter sections may be combined in tandem to secure the desired attenuation. A filter of this design is referred to as a composite filter. For

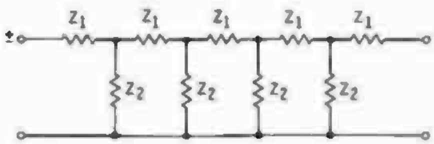

Fig. 7-41A. Ladder network used in basic design.

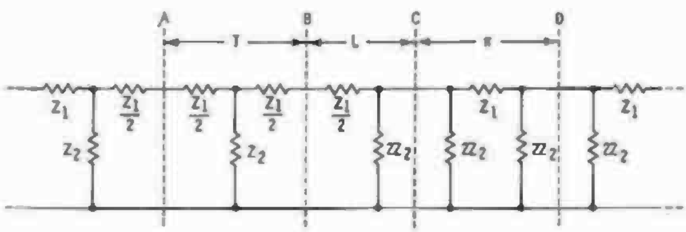

Fig. 7-41B. Ladder network broken down into filter configurations.

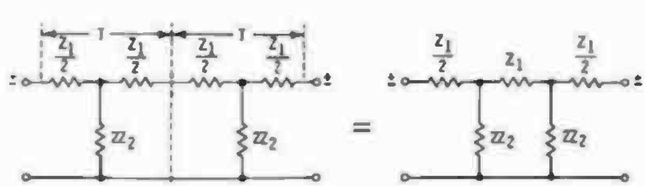

Fig. 7-41C. Combining two T filters.

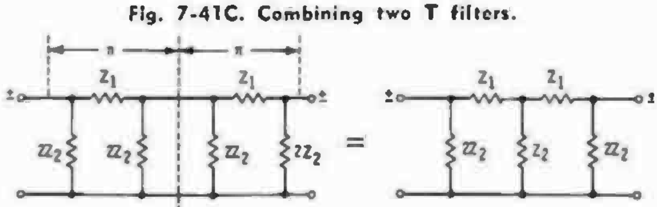

Fig. 7-41D. Combining two pi filters.

audio frequency work, generally, two sections are sufficient. In assembling a composite filter, sections with similar impedance characteristics are connected in tandem. This is important in order that one section may properly terminate the other. It is apparent that none of the sections present a constant impedance; however, if two sections whose impedances vary in exactly the same manner are connected in tandem, then each will properly match the other at all frequencies. Thus, within a composite filter there are no mismatches of impedance and, therefore, no reflection losses. This is accomplished by observing the terminology Z_1 to Z_1, Z_1' to Z_1', etc.

From the characteristics given in Fig. 7-39 it is evident that a T section cannot be connected to a pi section. However, an L section may be connected between them to match the impedances in both directions. Although an internal impedance match can be obtained in a composite filter, none of the configurations matches the line impedance through the passband. This is the disadvantage of the constant-k filter.

7.42 How are the circuit elements combined in a composite filter?—A T section and an L section, connected in tandem, are shown in Fig. 7-42. In the actual physical filter, the right-hand inductance of the T section and the inductance of the L section are combined into one inductance. Whenever two capacitors appear in parallel adjacent to one another, they are also lumped into one unit.

7.43 What are the basic considerations when designing a filter?—To design a constant-k filter, the following information is required:

Line impedance,

Filter type (low-pass, high-pass, etc.),

Tolerable mismatch for R_o.

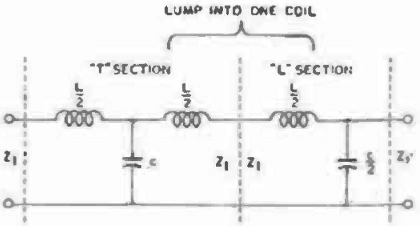

Fig. 7-42. Method of combining two filter sections.

The line impedance (R_o) is the impedance of the circuit in which the filter is to operate. It will be noted that, if the value of the inductance has been calculated for a pi section, the value is divided by two when used in the L or T sections. However, in the pi section, the value of the inductance remains unchanged. It will also be noted that the calculated value of the capacity for a T section is divided by two for the L and pi sections.

7.44 Show the design procedure for a 500-ohm constant-k 10,000 Hz low-pass filter which is required to have at least 40 dB of attenuation at 20,000 Hz.—Two full sections will have approximately 46 dB of attenuation, at twice the cutoff frequency; therefore, two such sections using the T configuration will be used. The first step is to calculate the values of L and C:

$$L = \frac{R_o}{\pi f_c}$$

$$= \frac{500}{3.141 \times 10{,}000}$$

$$= 0.0159 \text{ henries}$$

$$C = \frac{1}{\pi f_c R_o}$$

$$= \frac{1}{3.141 \times 10{,}000 \times 500}$$

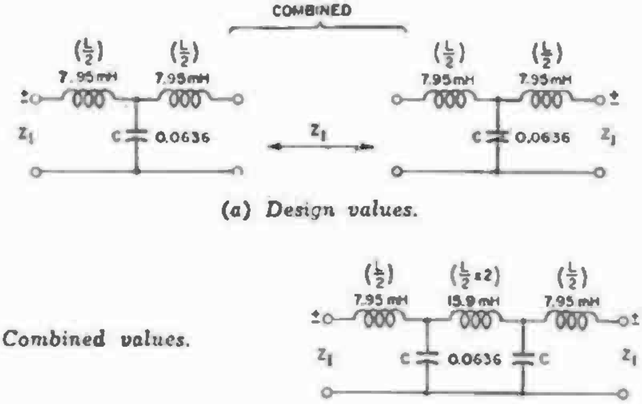
$$= 0.0636\ \mu F$$

where,

R_o is the line impedance,
f_c is the cutoff frequency.

The two sections of the filter are shown at (a) in Fig. 7-44. At (b) in Fig. 7-44 the circuit element values have been combined and one coil is used in place of the two nsed at the output and the input of the separate filters shown at (a).

7.45 What are the basic configurations and equations for constant-k high-pass filters?—The basic designs for constant-k high-pass filter sections are shown in Fig. 7-45. It will be noted the positions of the inductance and capacity are inverse to those of the low-pass filter. The design equations appear at the bottom of the configurations. A full section will provide approximately 23 dB of attenuation one octave removed from the cutoff frequency. A half section or L configuration will provide one half the attenuation of a full section at any frequency. The various sections may be connected in tandem to



(a) *Design values.*

(b) *Combined values.*

Fig. 7-44. Method of combining filter element values.

form a composite filter. As for the low-pass filter, the impedance match must be made so that each section is properly terminated. This is accomplished by observing the impedance characteristics for each type section. The procedure for designing and combining high-pass, constant-k filters is the same as that described for the low-pass filter in Questions 7.39 and 7.40.

7.46 What are the configuration and equations for designing a constant-k bandpass filter?—The configuration for a bandpass filter and its equations are shown in Fig. 7-46. It will be observed that these filters utilize resonant circuit arms, both in series and in shunt with the line. The frequencies f_1 and f_2 in the equations are frequencies at the edges of the passband. The frequency f_m is the frequency in the center of the passband. The frequencies of $f_1\infty$ and $f_2\infty$ are the frequencies at the edge of the widest part of the passband.

7.47 What are the configuration and equations for designing a constant-k band-rejection filter?—The configuration for a band-rejection or band-elim-

$$C_2 = \frac{1}{\pi(f_2-f_1)R_0}$$

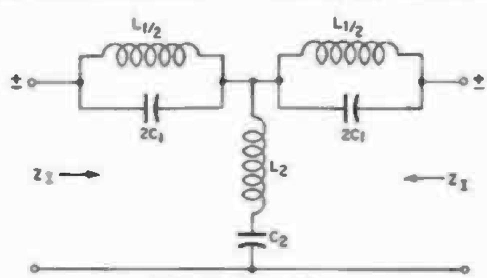
(c) Equations.

Fig. 7-46. Constant-k bandpass filter.

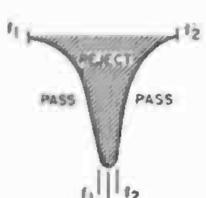
ination filter is shown in Fig. 7-47. It will be noted that the configuration is reversed from that of the bandpass filter. For this filter, the frequencies $f_1\infty$ and $f_2\infty$ are frequencies at the edge of the reject band. Frequencies f_1 and f_2 are at the edge of the widest part of the reject band, and f_m is the center frequency of the reject band.

7.48 What are the basic principles of an m-derived filter?—An m-derived filter is so designed that either the impedance or the attenuation characteristic, but not both, may be controlled by the designer. This overcomes some of the objection to the constant-k type filter. An m-derived filter is designed by first calculating the values of capacitance and inductance for the constant-k type filter and then modifying these values by an algebraic expression containing the term m. The term m is a positive number lying between one and zero. The value of m governs the characteristic of the m-derived filter.

In certain type sections m governs the impedance. By the proper selection of m it is possible to match the line impedance over approximately 85 percent of the transmission band, which is



(a) Configuration.



(b) Transmission characteristics.

$$L_1 = \frac{(f_2-f_1)R_0}{\pi f_1 f_2} \qquad L_2 = \frac{R_0}{4\pi(f_2-f_1)}$$

$$C_1 = \frac{1}{4\pi(f_2-f_1)R_0} \qquad C_2 = \frac{(f_2-f_1)}{\pi f_1 f_2 R_0}$$

$$f_m = \sqrt{f_1 f_2} \qquad R_0 = \sqrt{\frac{L_1}{C_2}} = \sqrt{\frac{L_2}{C_1}}$$

(c) Equations.

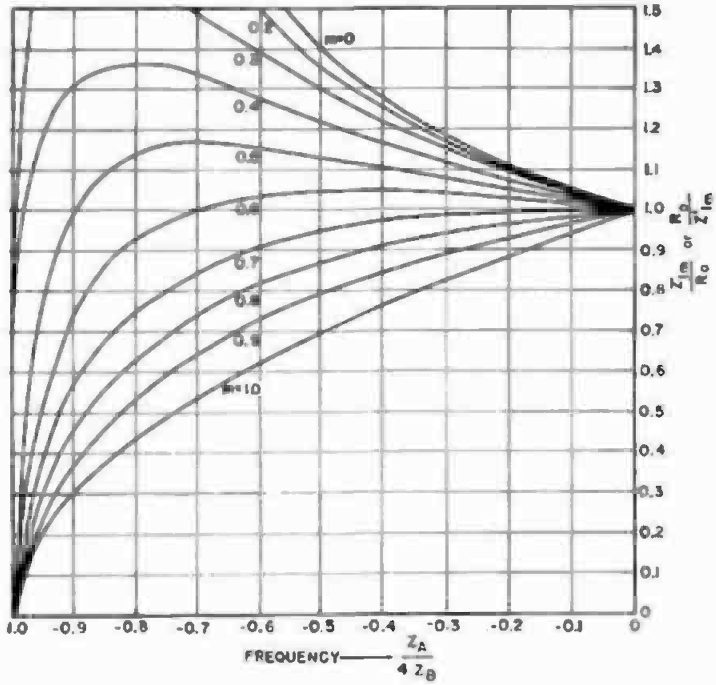

Fig. 7-48A. Impedance characteristics of m-derived filters, for different values of m.

considerably better than the constant-k type filter. An m-derived filter employs resonant circuits in the series and shunt arms. Theoretically, the filter presents an infinite attenuation termed f∞ (infinity).

In the design of an m-derived filter two frequencies are involved, the cutoff frequency and the frequency of infinite attenuation. The term m may be used to control the spacing between the frequency of cutoff and that of attenuation. Fig. 7-48A shows the effect on the impedance for different values of m between zero and one. It will be noted that the best impedance match is obtained when m equals 0.60. This is the value generally used for audio-frequency filters. It should be understood these data are for an ideal filter and

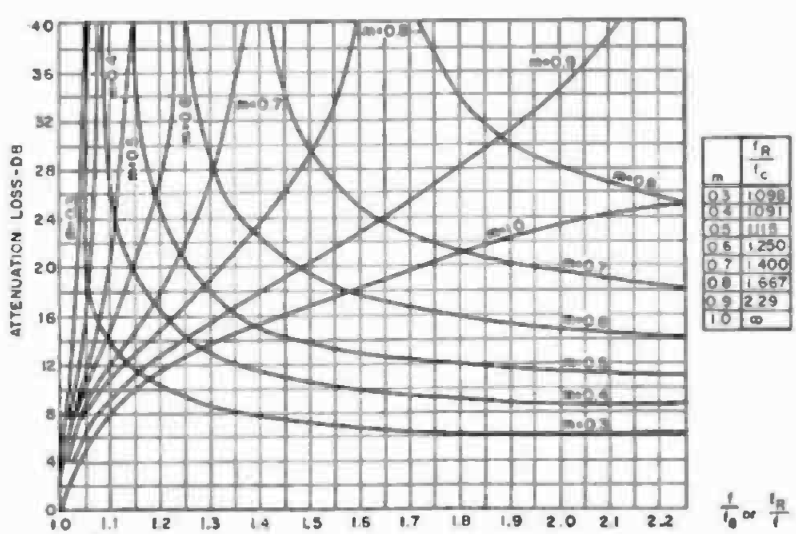

Fig. 7-48B. Attenuation characteristics of m- derived filter sections.

will vary in the practical filter due to the components, particularly the inductances. Attenuation characteristics for different values of m are shown in Fig. 7-48B. It will be noted from this family of curves that the attenuation rises to a maximum and then decreases. This is due to the resonant circuit incorporated in the m-derived filter. The graph in Fig. 7-48B is plotted to show the attenuation losses. This ratio may be inverted, if necessary, to make the number greater than one. The graph may be used for either low- or high-pass filters.

7.49 ***What are the advantages of combining a constant-k filter with an m-derived filter?***—The attenuation of a constant-k network rises progressively as the frequency departs from cutoff. The attenuation of an m-derived type rises to a maximum and then falls off. In a composite filter, the m-derived section governs the initial rate of attenuation and the constant-k section maintains attenuation at frequencies where the m-derived section becomes less effective.

It may be desirable to incorporate a full or half section at each end of the filter having an impedance characteristic controlled by m and for which m is 0.60. This will provide a match to the line at either end of the filter. The block diagram of a composite filter of this type is shown in Fig. 7-49. This filter has four sections. The attenuation characteristic for each section is shown below the block. The total attenuation is the sum of the individual attenuation of each section. Because the end sections have been designed using a value of 0.60 for m, they present to the line a very nearly constant impedance, R_o, over most of the passband. Configurations which match each other have been chosen so that at every junction of the sections an impedance match exists.

7.50 ***What is the effect of an m-derived filter if m equals one?***—The filter degenerates into a constant-k type. Therefore, it may be said that a constant-k filter is a special case of the m-derived filter with m equal to one.

7.51 ***What sections of an m-derived filter have the same impedance characteristics as a constant-k section?***—The T section, series m-derived. The series m-derived family consists of the T, L, and the pi sections.

7.52 ***Show the configurations and equations for a series m-derived low-pass filter.***—The configurations and equations appear in Fig. 7-52A. It will be noted the configurations are similar to those of the constant-k type filter, except series resonant circuits are used in the shunt arms. The terms $L_{1(K)}$ and $C_{2(K)}$ in the equations below the configurations are the values obtained for a constant-k filter. These values are then used with the m-derived equations given for L_1, L_2, and C_2 to calculate their values. A table of the most commonly used factors employed in the design of m-derived filters is given in Fig. 7-52B.

7.53 ***How is the constant "m" determined?***—As previously stated, m is a number between zero and one and controls the point of maximum attenuation with reference to the cutoff frequency of a filter. By the proper selection of m, the rate of attenuation for a given section can be determined; that is, it can be designed to attenuate gradually beyond the cutoff point or it can be designed to cut off sharply. To determine the value of m, the cutoff frequency and frequency of infinite at-

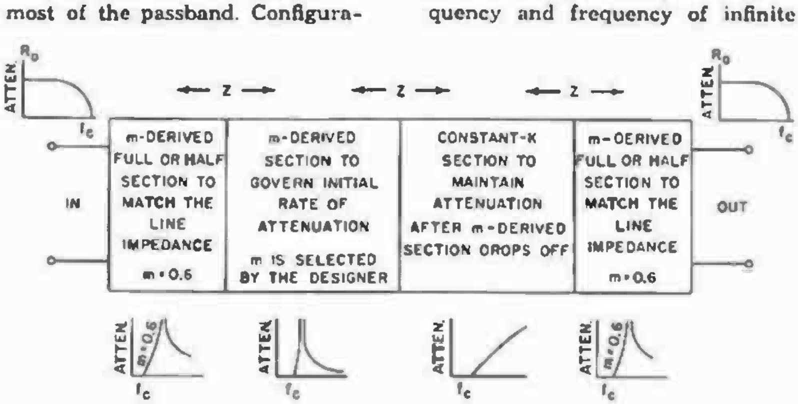

Fig. 7-49. A composite filter consisting of constant-k and m-derived sections.

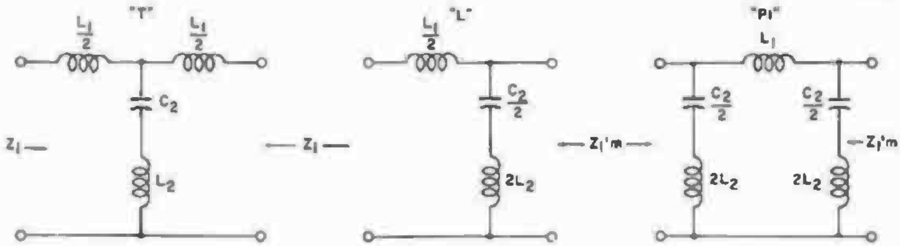

$$L_{1(K)} = \frac{R_0}{2\pi f_c} \qquad C_{2(K)} = \frac{1}{\pi f_c R_0}$$

$$L_1 = mL_{1(K)} \qquad L_2 = \frac{1-m^2}{4m} L_{1(K)} \qquad C_2 = mC_{2(K)}$$

Fig. 7-52A. Configurations and design equations for series *m*-derived low-pass filters.

tenuation (maximum) must be known. The values may then be substituted in the equation:

$$m = \sqrt{1 - \left(\frac{f_c}{f\infty}\right)^2}$$

$$m = \sqrt{1 - \left(\frac{f\infty}{f_c}\right)^2}$$

where,

f_c is the cutoff frequency in hertz,
$f\infty$ is the frequency of maximum attenuation.

The first equation is for low-pass filters and the second is for high-pass filters. The constant m is always less than one.

7.54 What are the configurations and equations for series m-derived high-pass filters?—The configurations with their equations are given in Fig. 7-54.

7.55 What are the configurations and equations for shunt m-derived low-pass filters?—The configurations with their equations are given in Fig. 7-55.

7.56 What are the configurations and equations for shunt m-derived high-pass filters?—The configurations with their equations are given in Fig. 7-56.

7.57 What are the advantages of the shunt-type m-derived filter over the series m-derived type?—Electrically there are none. However, the two types of design permit a wide selection of circuits. In building a filter, it is more economical to use the series-derived

type because of the cost of an inductance compared to a capacitor. In certain phases of telephone work, it is desirable that the filter have a capacitor input rather than an inductive input. The two designs will permit either type input to be used, with the same frequency characteristics.

7.58 Show a typical design problem for a 600-ohm, 1400 Hz shunt m-derived low-pass filter.—Basically, the filter will consist of a constant-k pi section with two shunt m-derived end sections as shown in Fig. 7-58A. The calculations have been tabulated to demonstrate the design procedure in Fig. 7-58B. The derived values are given in Fig. 7-58C and the final values used are given in Fig. 7-58D.

7.59 What is a balanced filter?—Filters, like attenuators and equalizers, may be designed for balanced and unbalanced operation. In Fig. 7-59 the filter of Fig. 7-44(b) is shown converted to a balanced configuration. It will be noted the values of the inductances have been divided by two, and one half placed in each side of the line. The capacitor values remain unchanged.

7.60 How is an unbalanced high-pass filter converted to a balanced configuration?—To illustrate the procedure, Fig. 7-60 shows a 45-Hz high-pass filter both as an unbalanced and a balanced

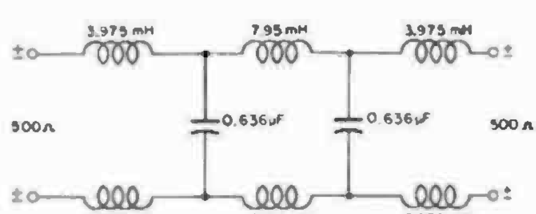

Fig. 7-59. The low-pass filter shown in Fig. 7-44(b) converted to a balanced configuration.

configuration. In the balanced configuration it will be noted that the inductances remain unchanged in value but the capacitor values have been doubled. The reason for this is that the capacitors of the balanced configuration may be considered to be in series in each side of the line. Therefore, to maintain the same impedance, the capacitance must be doubled because capacitors in series divide themselves.

Filters, like equalizers, are designed to present a given impedance to certain frequency bands and to accomplish this a definite value of capacity and inductance is required. If the circuit element values are maintained regardless of the type configuration employed, the impedance presented to the circuit is the same; therefore, the frequency characteristic will be the same.

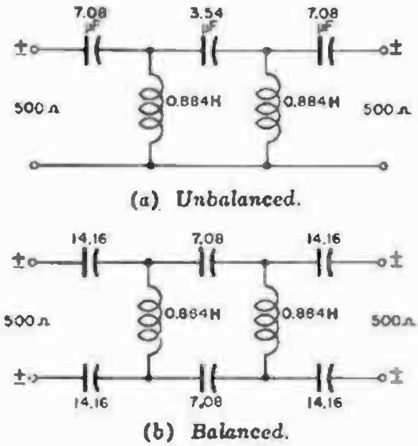

Fig. 7-60. A 45-Hz unbalanced high-pass filter converted to a balanced configuration.

7.61 How are the frequency characteristics of a filter measured?—This subject is discussed in detail in Question 23.61.

7.62 How may a filter of known characteristics be converted to an impedance other than the one for which it was originally designed?—By the use of the following equations, if the circuit constants are known.

$$L_x = \frac{Z_1}{R_o} \times L$$

$$C_x = \frac{C}{\frac{Z_1}{R_o}}$$

where,

L_x is the new value of inductance,
L is the original value of inductance,
R_o is the characteristic impedance,
Z_1 is the new impedance,
C_x is the new value of capacitance,
C is the original value of capacitance.

7.63 How may a filter of known frequency characteristics and components be converted to another frequency?—By changing the values of the inductance and capacitance inversely with frequency. For example, if a 1000-Hz low-pass filter is to be converted to 100 Hz, the new values may be calculated:

$$C_x = C \times 10$$

$$L_x = L \times 10$$

where,

C_x is the new value of capacity,
C is the original value of capacity,
L_x is the new value of inductance,
L is the original value of inductance.

Although the frequency is changed, the impedance remains the same.

7.64 What type coils are recommended for filter construction?—Toroidal coils because of their high Q and the fact that they are not affected by extraneous magnetic fields. However, conventional coils may be used, if properly shielded. (See Questions 6.68 to 6.71 and Questions 8.72 and 8.73.)

7.65 What tolerance should be specified for coils and capacitors used in filters?—For coils, plus or minus two percent; for capacitors, plus or minus three percent.

7.66 How are the coils for filters specified for manufacture?—By the value of the inductance, the signal level at which the coil is to operate, the frequency of maximum Q, the filter configuration, the impedance of the circuit, and the effective shielding of the coils in decibels.

7.67 If a low-pass and a high-pass filter are connected in tandem, what is the overall frequency characteristic?—A bandpass characteristic.

7.68 What is the overall frequency response of two low-pass filters connected in tandem?—The frequency response is the algebraic sum of the individual frequency characteristics. This is explained in more detail in Question 6.66.

7.69 What is the center frequency of the passband and how is it determined?—The center frequency of the passband of any type filter, or combination of filters, is the geometric mean of

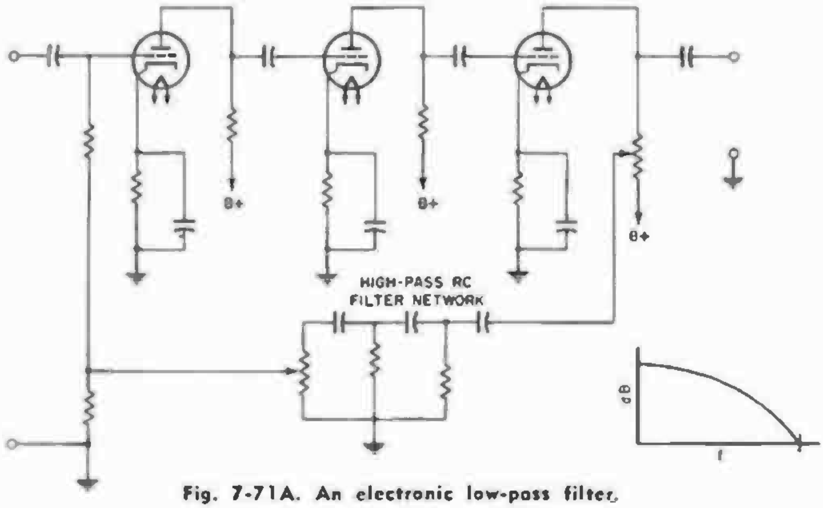

Fig. 7-71A. An electronic low-pass filter.

the lowest and highest frequency of the passband. A typical example would be a recording channel employing a 40-Hz high-pass filter and a 10,000-Hz low-pass filter. The geometric mean, or center frequency, is:

$$f_m = \sqrt{f_1 \times f_2}$$
$$= \sqrt{40 \times 10{,}000}$$
$$= 632.4 \text{ Hz}$$

where,

f_1 is the cutoff frequency of the high-pass filter,
f_2 is the cutoff frequency of the low-pass filter.

The cutoff frequency of a filter is taken at the frequency of 10 dB attenuation. Filter nomenclature is discussed in Question 7.102.

7.70 What is a crystal filter?—A filter composed of quartz crystals. They are used in wave analyzers to obtain an extremely sharp passband characteristic. (See Question 22.65.) Crystal filters are also used in communication-type radio receivers for reducing noise in the reception. Such filters are also referred to as mechanical filters.

7.71 What is an electronic filter?—An amplifier especially designed to have a selective transmission characteristic. Such filters make use of a negative-feedback amplifier with a frequency-selective network such as the parallel T which may be controlled from the panel of the instrument.

Electronic filters are also used for removing unwanted noises in sound

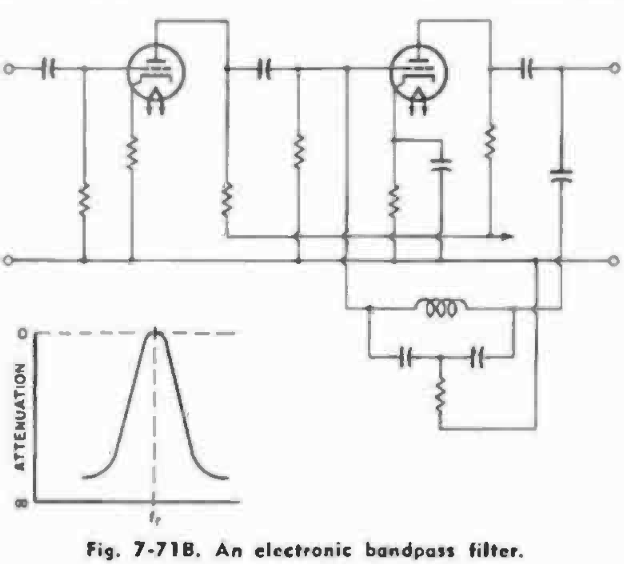

Fig. 7-71B. An electronic bandpass filter.

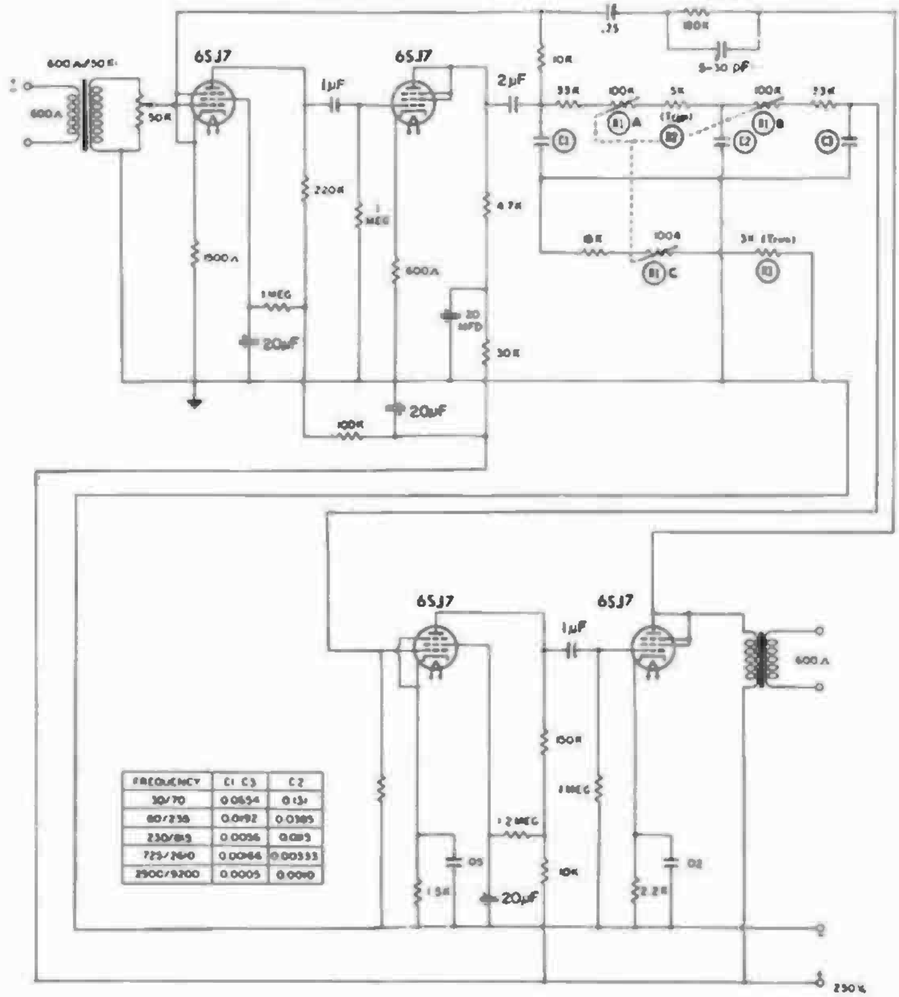
tracks during the rerecording of motion pictures. Typical low-pass and band-pass filters of the electronic type are shown in Figs. 7-71A and B.

7.72 Show a schematic diagram for a variable dip-filter for rerecording use.—Variable dip filters are used in rerecording to remove unwanted frequencies such as radar, beacon signals, ac hum, arc-light whistles, and many other sounds picked up acoustically or electrically. Fig. 7-72A shows the schematic



FREQUENCY	C1 C3	C2
30/70	0.0654	0.131
80/235	0.0192	0.0385

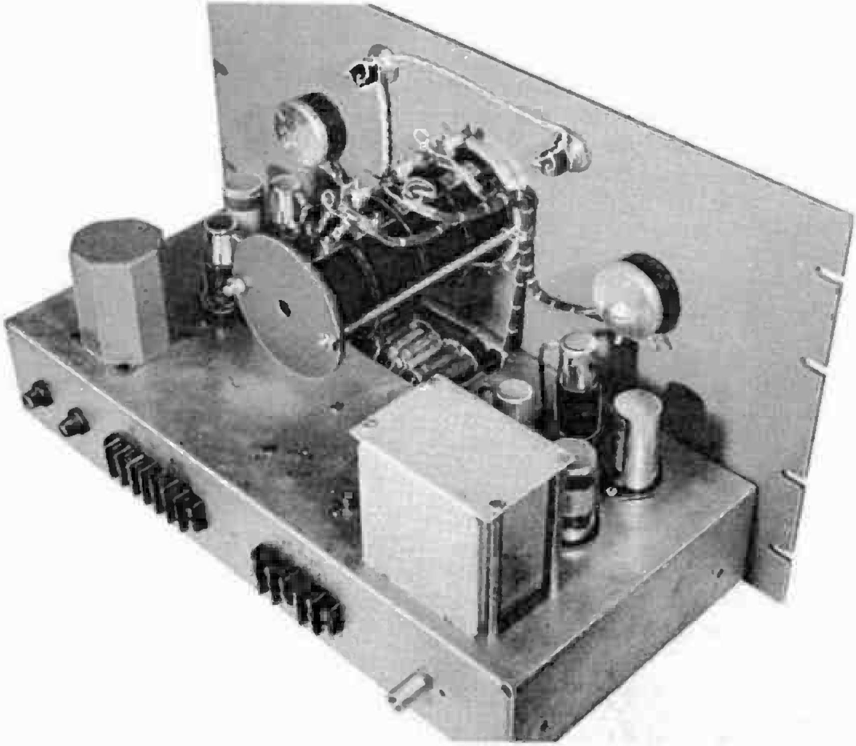

Fig. 7-72C. Rear view of variable parallel-T dip filter.

diagram for a dip filter which has a frequency range of 30 to 9000 Hz, with a band rejection, at the peak frequency, of 50 dB or better. Basically the device is a variable parallel-T network, consisting of capacitors C1, C2, and C3, and three wirewound potentiometers R1A, R1B, and R1C, ganged together. Two additional potentiometers R2 and R3 are used as trimmers to obtain a sharp null point. By the use of a large amount of negative feedback (26 dB) around the parallel-T network, the rejection characteristic is considerably sharpened, as

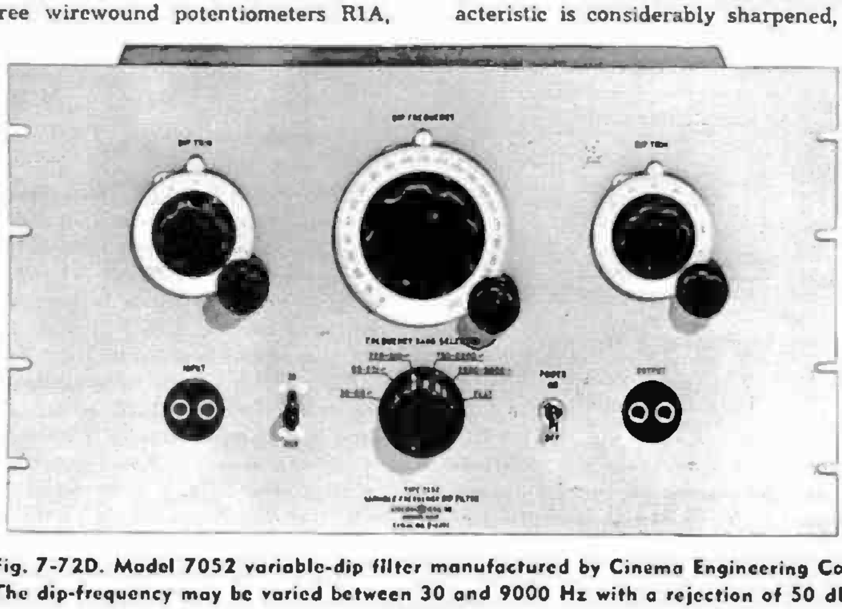

Fig. 7-72D. Model 7052 variable-dip filter manufactured by Cinema Engineering Co. The dip-frequency may be varied between 30 and 9000 Hz with a rejection of 50 dB or better.

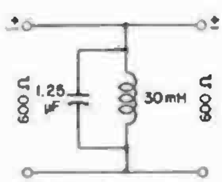
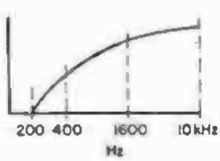
shown in Fig. 7-72B. A rear view of such an instrument built by the author is shown in Fig. 7-72C. For convenience of operation a switch is provided to cut the instrument in and out of the circuit. Therefore, the gain is generally adjusted for a no-gain condition.

After the frequency of an unwanted frequency has been determined, the filter is switched in and adjusted for a *null* at the unwanted frequency, and a test recording made and played back. If the original sound track contained several harmonics besides the fundamental frequency, the rerecorded sound track is played back and the remaining frequencies are dipped out. This procedure may be followed to a third generation provided the signal-to-noise ratio is not too seriously affected. After the final transfer is made it can then be re-equalized. If carefully done, the dip filter may be used in dialogue without it affecting the final result, because of the narrow bandwidth. A dip filter having similar characteristics to that discussed is shown in Fig. 7-72D.

7.73 Show the configuration for a 500-ohm telephone sound-effects filter. —The configuration and component values for such a filter are shown at (a) in Fig. 7-73 and the frequency characteristic is shown at (b).



(a) *Configuration.*



(b) *Frequency response.*

Fig. 7-73. A telephone sound-effects filter for a 500-ohm circuit.

7.74 What are the circuit constants for the more commonly used 500-ohm, constant-k, low- and high-pass filters?— Using the constant-k configurations of Figs. 7-39 and 7-45, filters may be constructed using the following values for a circuit impedance of 500 ohms. If an impedance other than 500 ohms is required, the filter may be converted to any other impedance by the use of the equations given in Question 7-62. For frequencies not appearing in the tabulation, the values may be converted to

7.78 ***What are the circuit values for the more commonly used shunt m-derived high-pass filters?***—The values given in Fig. 7-78 are to be used with the configurations shown in Fig. 7-56. The value of m is equal to 0.6.

7.79 ***What are the configuration and circuit constants for a variable high-pass filter suitable for rerecording purposes?***—The configuration and circuit constants for a 600-ohm unbalanced variable high-pass filter designed for the express purpose of removing the low frequency end of dialogue are shown in Fig. 7-79A. The frequency range covered is from 80 to 150 Hz. For dialogue recording, it is generally set for 80 Hz cutoff, which is standard in the motion-picture industry. At times it may be desirable to use a higher cutoff frequency to remove low-frequency noise falling between 150 and 80 Hz. However, male dialogue becomes thin if the cutoff is raised above 100 Hz.

Fig. 7-78. Values for Question 7.78.

The coils should be of toroidal design with the maximum Q at the cutoff frequency. Because this filter operates in a frequency band near frequencies which can produce hum and noise, the wiring should be well shielded and the whole unit enclosed in a metal case. The use of toroidal coils will reduce hum pickup to a minimum. The configuration should be grounded to prevent leakage. The frequency characteristic of this filter is shown in Fig. 7-79B.

7.80 ***What is a crossover network?***—In modern high-fidelity sound reproducing systems, the loudspeaker is designed to cover a wide range of frequencies, generally 30 to 15,000 Hz or more. To obtain satisfactory operation over this wide range requires the use of two or more loudspeakers, each operating in a given frequency range, as it is not practical to attempt to obtain this wide range with a single loudspeaker.

When two or more loudspeakers are used in combination, the frequency spectrum is divided into bands and controlled by a crossover or frequency-dividing network composed of two or more filters. As a rule, they are a high-

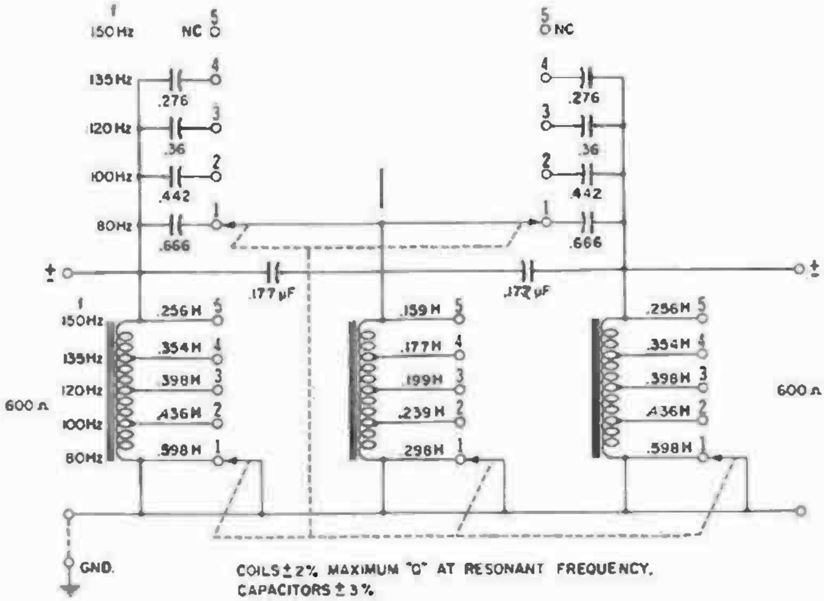

Fig. 7-79A. A variable high-pass filter for rerecording.

pass and a low-pass filter. The low-pass filter limits the high-frequency response of the low-frequency speakers and the high-pass filter limits the low-frequency response of the high-frequency speakers.

A three-way network consists of a low-pass, bandpass, and high-pass filter section. The low- and high-frequency sections function as for a two-way system. The bandpass section limits the frequency response for the midrange speaker unit, permitting it to extend only into a portion of the low- and high-frequency ranges. The result is a smooth transition over the complete range of the three speaker units.

The sole purpose of a crossover network is to limit the operating range of a given speaker unit. The network cannot be used to correct for deficiencies in the amplifier system, speaker units, or enclosure. One of the most important conditions imposed on the network is that it must not induce an appreciable amount of loss (insertion loss) between the amplifier and the speaker units; this could result in a considerable

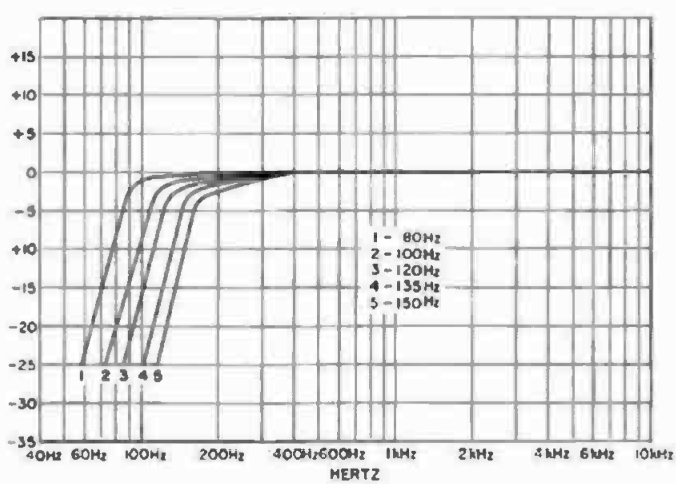

Fig. 7-79B. Frequency characteristics of the variable high-pass filter shown in Fig. 7-79A.

Fig. 7-80. A 400-Hz speaker-crossover network.

loss of power particularly with amplifiers of 50-watts power or more. (See Question 7.84.)

7.81 What is the frequency response of a typical crossover network?—A typical frequency response for a crossover network comprised of a low-pass and a high-pass filter is shown in Fig. 7-81. The curves are ideal curves for three different rates of cutoff. The point where the curves cross over is called the crossover frequency.

The characteristics above and below the crossover frequency drop off approximately 6, 12, or 18 dB per octave, depending on the design of the network. In practice, because of the dissipative losses in the circuit elements, the first octave for the 12 dB per octave filter falls off about 10 dB and 12 dB thereafter. The 6 and 18 dB per octave filters fall off correspondingly.

7.82 What are the advantages of a parallel crossover network over a series type?—The selection of the configuration for a crossover network is not critical; either the series or parallel network may be used. However, the parallel configuration does offer slightly better characteristics in the transmission and attenuation bands. Series configurations are used only with two-way speaker systems. Most commercial units employ the parallel configurations because the component values are the same for each filter; thus, manufacturing costs are reduced. Theoretically the constant-k, constant-resistance network reflects a constant resistance back to the amplifier output. Since a speaker

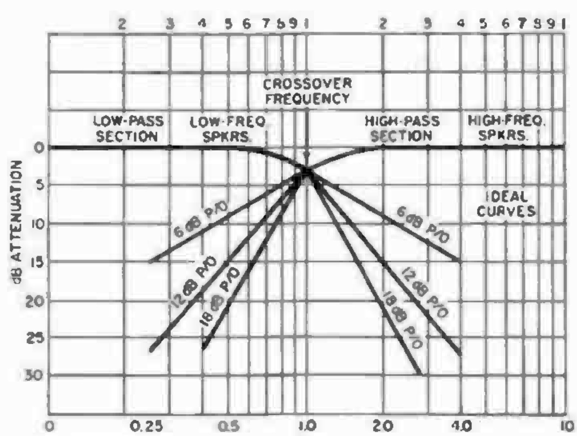

Fig. 7-81. Typical frequency characteristic for ideal 6, 12, and 18 dB per octave crossover networks.

unit does not reflect a constant resistive load, the amplifier does not see a constant resistance. This disadvantage is somewhat compensated for by the use of negative feedback in the amplifier circuitry. The only time an amplifier sees a purely resistive load is when the network is terminated, on the speaker side, in the *pure* resistance. In a two-section constant-resistance network, the frequency response is complementary, and the sum of the power delivered to the output section is constant for a constant input voltage at the input of the network. When the output sections are terminated in a resistive load, the input impedance presented to the amplifier is constant throughout the entire frequency range. The frequency response of the filter sections in the passband is uniform, with constant phase-difference at the output of the high and low-frequency sections. (See Fig. 7-82.)

7.83 ***Are equalizers ever included in a crossover network?***—Yes, some manufacturers include a simple high-frequency equalizer in the network to increase the response of the midrange and high-frequency units. This equalizer, though included with the network, is an *added* feature and is not a part of the network proper. The equalizer generally consists of a resistor in series with the midrange or high-frequency speaker unit, and a group of capacitors which may be cut in or out of the circuit by a switch. The capacitors are connected in parallel with the resistor. The switch permits the user to select a capacitor that will increase the high-frequency response to suit his local acoustic conditions.

7.84 ***What causes insertion loss and what is the average loss for a crossover network?***—The insertion loss of any network is caused by the dc resistance of the coils, and the shunt and series reactance of the circuit elements. As a rule, the insertion loss of a crossover network due to circuit elements is approximately 0.5 dB and is exclusive of the crossover-frequency loss which is 3 dB.

Insertion losses up to 1 dB are not too important if the amplifier power output is not greater than 20 watts. However, if the amplifier system is greater than 20 watts, the insertion loss becomes important, especially in commercial installations where 100 watts or more may be used. As an example, for an insertion loss of 0.5 dB at 50 watts, the power dissipated by the network is approximately 6 watts, and for a 100-watt system the loss is more than 10 watts (measured by using a steady

Fig. 7-82. Constant-k constant-resistance, crossover networks and design equations.

input voltage in the passband). To obtain a low insertion loss, the coils must have a low dc resistance, and the capacitors must have a *low power factor*. Special nonpolarized electrolytic and paper capacitors are available for crossover network construction. Conventional nonpolarized electrolytic capacitors should not be used because of their power factor and leakage. The characteristics for capacitors manufactured especially for crossover-network use are given in Figs. 7-84A and B with standard ratings given in Fig. 7-84C. Capacity tolerances are plus or minus 20 percent of the rated value. The peak signal voltage must *never* exceed the dc working voltage ratings.

7.85 What factors dictate the crossover frequency of a network?—The choice of crossover frequency is dictated by the frequency response of the speaker units. Typical crossover frequencies for low-frequency sections are 400, 450, and 600 Hz, with 3000 and 5000 Hz for the high-frequency sections. Ideal crossover characteristics are shown in Fig. 7-85 for both two-way and three-way systems. The crossover frequency must become effective before the response of a given speaker unit falls off, and the movement of the diaphragm becomes nonlinear. Low-frequency speakers designed for multiple speaker systems seldom have much response above 1500 to 2000 Hz. The frequency response of the midfrequency speakers must be restricted to those frequencies where the wavelengths are such that the excursion of the dia-

phragm will not exceed the *diaphragm displacement* recommended by the manufacturer.

Networks employing a 6 dB per octave cutoff do not as a rule provide a rapid enough cutoff. The network rolloff should be at a frequency high or low enough to protect the midrange and high-frequency units from damage. The low-frequency unit must be capable of handling at least *one octave above* the crossover frequency, and the high-frequency unit *one octave below* the crossover frequency, at the full power of the driving amplifier. The use of a 12 dB per octave cutoff rate will greatly assist in overcoming this difficulty, and offers greater protection to the midrange and high-frequency units. For a two-way system, a crossover frequency above 600 Hz should be avoided, as most of the peak power is concentrated below 500 Hz. The use of a 350- to 400-Hz crossover results in equal division of

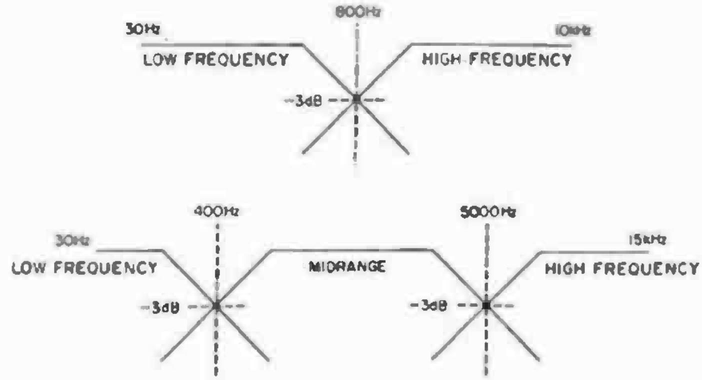

Fig. 7-85. Frequency response for two-way and three-way crossover filter networks.

the total peak power between the low- and high-frequency speaker units. For a three-way system 400 to 500 Hz for the low-frequency crossover and 5000 Hz for the high-frequency end seems a good compromise.

7.86 What is the power loss at the crossover frequency?—In a well-designed network, 3 dB, exclusive of the insertion loss. At the crossover frequency the power applied to the high- and low-frequency speakers is divided equally. Limiting the low-frequency response of the high-frequency speakers prevents damage to the diaphragm.

Above the frequency of the crossover point, the movement of the high-frequency speaker diaphragm is only a few thousandths of an inch, while the low-frequency speaker diaphragm may be moving up to ⅜ of an inch.

Although a 3-dB loss occurs at the crossover frequency, this is not particularly noticeable to the ear and is generally within the overall frequency limits of the speaker system.

7.78 What is a constant-resistance network?—A network that will reflect a constant resistance to the output circuit of the driving amplifier when terminated in a resistive load. Loudspeakers do not reflect a constant impedance; therefore, the amplifier does not see a constant resistance. This disadvantage may be somewhat compensated for by the use of negative feedback in the amplifier.

In a constant-resistance type network, the frequency response of the two filter sections is complementary. The sum of the power delivered to the output circuits of the filters is constant for a constant input voltage. When terminated in a pure resistive load, the input impedance of the filter is constant throughout the whole frequency range. The frequency response of the filters in the passband is uniform, with a constant phase difference at the outputs. Constant-resistance filters may be designed for either series or parallel operation.

7.88 Is there any advantage in increasing the cutoff-frequency rate beyond 18 dB per octave?—No, 18 dB is the maximum rate used in practice, as the improvement does not offset the additional power losses. Most crossover networks employ a 12 dB per octave cutoff rate.

7.89 What is the advantage of an m-derived crossover network compared to a constant-k type?—Constant-k networks are limited to a maximum cutoff rate of 12 dB per octave, while the m-derived network cau provide a 12 dB greater rate of cutoff. An additional advantage of the m-derived filter is that the impedance or attenuation characteristics can be closely controlled by the designer. For most audio filter work, m equals 0.6; the same holds true for crossover networks. Configurations for both 12 and 18 dB per octave, series and parallel types are given in Fig. 7-89.

7.90 What type coil is used in crossover networks?—Air-core coils are used. Because the coils used in crossover networks are of only a few millihenries inductance, they may be wound with number 10 and number 18 gauge wire on an air core. The winding may be on a wooden core and scrambled-wound.

7.91 What type capacitor is used in crossover networks?—Paper dielectric or special nonpolarized electrolytic capacitors, as discussed in Question 7.84.

Fig. 7-89. Conventional m-derived crossover networks and design equations.

7.92 ***Are iron-core coils used in crossover networks?***—No. Iron-core inductances induce distortion because of saturation. Also, their cost is considerably higher than air-core types.

7.93 ***Can a crossover network be designed to operate with speakers of unequal impedance?***—Yes, by the use of the circuit in Fig. 7-93 and by using the design data given in the following equations:

$$L_1 = \frac{\sqrt{2}\,R_L}{w_c}$$

$$L_2 = \frac{\sqrt{2}\,R_H}{w_c}$$

$$C_1 = \frac{1}{\sqrt{2}\,R_L w_c}$$

$$C_2 = \frac{1}{\sqrt{2R}\,R_H w_c}$$

where,

R_L is the impedance of the low-frequency speaker,

R_H is the impedance of the high-frequency speaker,

w_c is 2π times the frequency of cutoff.

The circuit elements are connected in the output of a normal output transformer having an 8-ohm and a 16-ohm winding. If the output transformer in a particular amplifier has only one winding, a matching transformer may be used to supply the desired impedances.

7.94 ***Show the different methods of connecting loudspeakers to the output of crossover networks.***—In Fig. 7-94 part (a), an 8-ohm network is shown connected to two 16-ohm low-frequency speakers in parallel. The two 16-ohm speakers *reflect* an 8-ohm load impedance to the network. The high-frequency speaker unit has an impedance

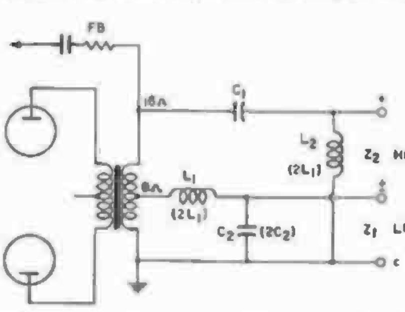

Fig. 7-93. Crossover network for loudspeakers of unequal impedance.

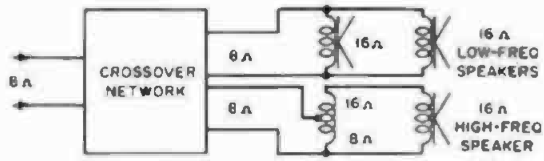
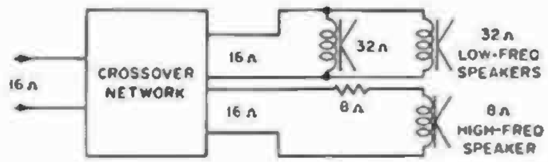
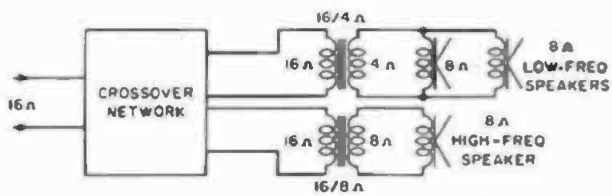


(a) *Two 16-ohm low-frequency speakers matched to 8-ohm network and one 16-ohm high-frequency speaker matched to 8-ohm network.*



(b) *Two 32-ohm low-frequency speakers matched to 16-ohm network and one 8-ohm high-frequency speaker matched to 16-ohm network.*



(c) *Two 8-ohm low-frequency speakers matched to 16-ohm network and one 8-ohm high-frequency speaker matched to 16-ohm network.*

Fig. 7-94. Various methods that are used for matching the speaker impedance to the network impedance.

of 16 ohms and is connected to the output of the network by means of an autotransformer to match the 8-ohm output to the 16-ohm speaker.

Two 32-ohm low-frequency speakers connected in parallel to the output of a 16-ohm network, appear in Fig. 7-49 part (b). The high-frequency unit has an impedance of 8 ohms, therefore an 8-ohm resistor is connected in series with the speaker unit to increase the load impedance to 16 ohms. It should be pointed out that the use of a resistor is *not* recommended unless the high-frequency unit has high sensitivity, since half of the power is dissipated in the resistor. Because of the loss incurred with a resistor and the higher power required to drive low-frequency speaker units, *resistors should not be used with low-frequency units.*

A third method of impedance matching is shown in Fig. 7-94 part (c). Here, two 8-ohm low-frequency units are matched to a 16-ohm network by means of a transformer having an impedance ratio of 4:16. The 8-ohm high-frequency unit is matched to the network with an 8:16-ohm transformer. Whenever possible, the network should be designed for a given impedance, and the speaker units selected for that impedance. Transformers are quite expensive and induce a *power loss*, particularly for good frequency response below 50 Hz.

7.95 ***Why is an autotransformer recommended for matching the voice-coil impedance to a crossover network?*** —Because it has less insertion loss and is less expensive.

7.96 ***What are the circuit-constants for crossover networks?***—The circuit constants for constant-k and m-derived crossover networks, both series and parallel configuration, are given in Figs. 7-96A and B. The constants for the desired network and frequency are selected from the tables, and then converted *from an impedance of 10 ohms to the required impedance.* No further calculations are required. (See Question 7.62.)

7.97 ***How are the network constants shown in Fig. 7-96A and B converted to other impedances and frequencies?***—The impedance may be changed by use of the equations given in Question 7.62,

while the frequency may be changed by use of those given in Question 7.63.

7.98 ***Show the configurations for three- and five-way crossover networks.*** —The three-way crossover network differs from the two-way network, only in the addition of the midrange (bandpass filter) circuit elements. The configuration for the design of a three-way constant-k network, using 6 dB per octave rolloff is given in Fig. 7-98A, and is basically the same as Fig. 7-82C, except for the addition of C_{1A} and L_{1A}. The circuit element values are calculated by using the equations below the diagram. Analyzing the frequency-response curve above the filter sections reveals that

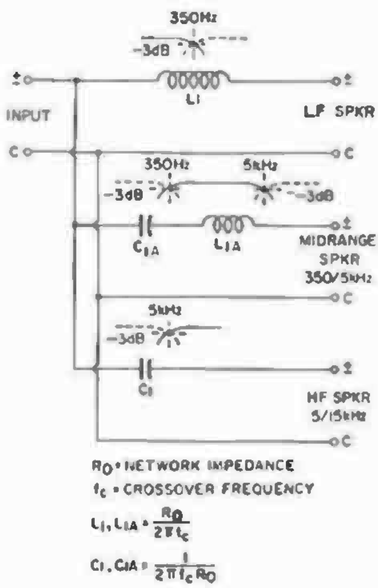

Fig. 7-98A. A constant-k, three-way 6 dB per octave crossover network.

two crossover frequencies are established at a point 3 dB down from the flat portion of the characteristic. A three-way constant-k, 16-ohm, 12 dB per octave network is shown in Fig. 7-98B, with its frequency response shown in Fig. 7-98C. Components C_{3A} and L_{3A} constitute a *low-pass* filter with a cutoff frequency of 450 Hz.

The midrange section is a *bandpass* filter, consisting of a simple 450 Hz high-pass section, and a 5000-Hz low-pass filter. Circuit element C_{3A} and L_{3A} form a high-pass filter, and L_{3B} and C_{3B} form a low-pass filter. These two sections together form a bandpass section. Comparing the low-pass section and the high-pass section of the bandpass filter, it will be observed that both curves are down 3 dB from the flat portion of their response curve, and the crossover frequency is 450 Hz. The output portion of the midrange filter L_{3C} and C_{3C} at the lower portion of the configuration form a 5000-Hz high-pass filter. Comparing the frequency response of the two sections, a crossover frequency of 5000 Hz has been established.

The design procedure is to *first* calculate the value of the low-pass section L_3 and C_3. Circuit elements L_{3A} and C_{3A} must also cross over at 450 Hz, but in an *inverse* manner; therefore, their values are equal to L_3 and C_3. The output portion of the midrange forms a low-pass filter with a cutoff of 5000 Hz; these values are calculated for that frequency. Circuit elements C_{3C} and L_{3C} form a high-pass filter (5000 Hz) with the same values as C_{3B} and L_{3B}, but inversely connected. When the frequency

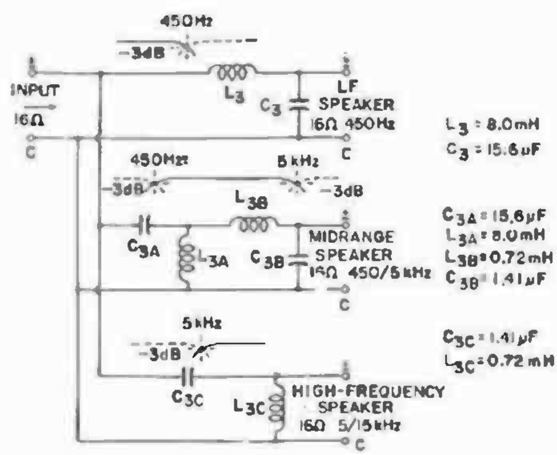

Fig. 7-98B. Three-way, 12 dB per octave, 16-ohm crossover network.

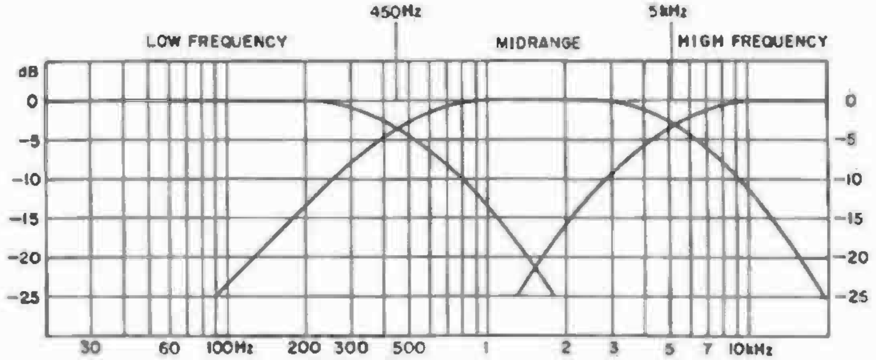

Fig. 7-98C. Frequency response for network of Fig. 7-98B.

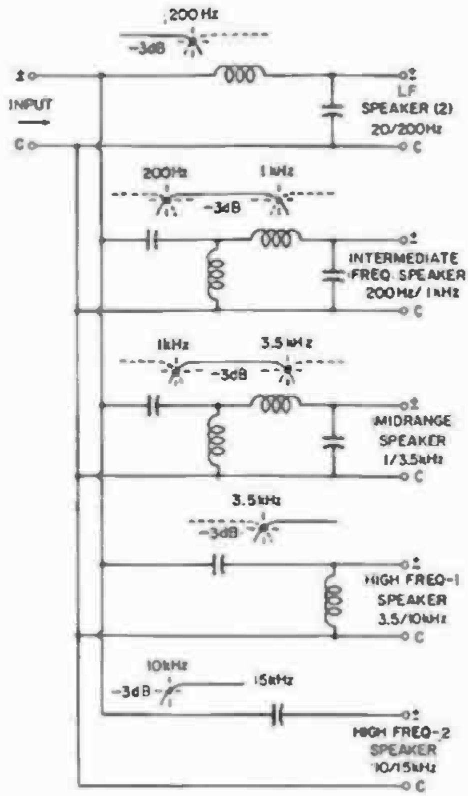

Fig. 7-98D. Five-way, constant-k crossover network.

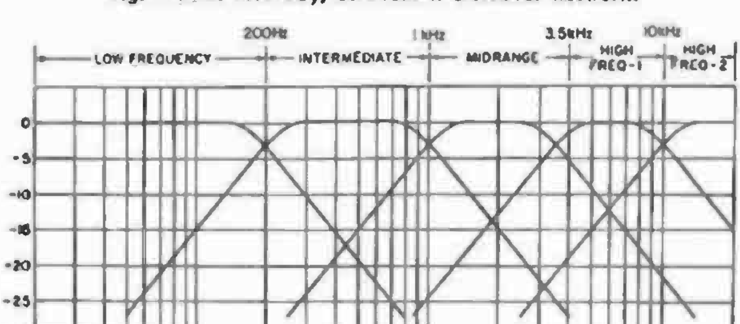

Fig. 7-98E. Frequency response for network of Fig. 7-98D.

response of the two are compared, a crossover of 5000 Hz is created. The circuit element values of Fig. 7-98B may be converted to an m-derived network by the use of the equations:

$$L_a, L_{an} = (1+m)\left(\frac{R_o}{\omega_c}\right) \text{ henry}$$

$$L_{aA}, L_{ac} = \left(\frac{R_o}{\omega_c}\right) \text{ henry}$$

$$C_{3A}, C_{3C} = \left(\frac{1}{1+m}\right)\left(\frac{1}{\omega_c R_o}\right) \text{ farad}$$

$$C_{3B} = \left(\frac{1}{\omega_c R_o}\right) \text{ farad}$$

where,
- m equals 0.6,
- ω equals 2π fc;
- R_o is the circuit impedance.

Actually there is little difference in the design of four- or five-way networks, except for the *crossover* frequencies. A typical five-way network is given in Fig. 7-98D, with its frequency response shown in Fig. 7-98E. The circuit element values are calculated as for the three-way network (Fig. 7-98B) with additional high-pass sections. It will be observed the fifth section (10,000 Hz) consists of a single capacitor connected in series with the second high speaker unit. As this latter unit is confined to frequencies of slightly less than 10,000 Hz and above, a more elaborate network is not required. The frequency response for each section of the network is plotted above each configuration. The values of the series capacitor may be calculated:

$$C = \frac{79{,}600}{f \times R_o}$$

where,
- 79,600 is a constant,
- f is the cutoff frequency,
- R_o is the speaker impedance.

7.99 Can a crossover network be designed for 250- or 600-ohms impedance?—Yes, many theater installations use 250- or 600-ohm crossover networks because of the long transmission line between the amplifier system and the stage speakers. Autotransformers are used at the speaker end to convert the high impedance down to the voice-coil impedance.

By using a high-impedance transmission line, the voltage is high and the current low; thus, the power losses that would be encountered using a low impedance line are avoided. The configuration for a 250-ohm crossover network used in motion picture theater installations is given in Fig. 7-99.

7.100 What is a rumble filter?—A filter used in a record-reproducing sound system for removing rumble created by the turntable mechanism. Generally, these filters, because of their very low frequency characteristics, are composed of only capacitance and resistance, and are connected in the preamplifier stages of the amplifier system.

7.101 What is a line-noise suppression filter?—A filter used in the power line at the primary of a power transformer to prevent radio and line noises from entering the power snpply circuits and causing noise in amplifier systems. A typical circuit for such a filter is shown in Fig. 7-101.

Filters of this natnre may be used in either ac or dc lines. The coils are air core and wound with quite large wire capable of carrying the full current load of the equipment. The capacitors are either paper or oil insulated. (See Question 24.71.)

7.102 What method is used by the motion picture industry to identify the

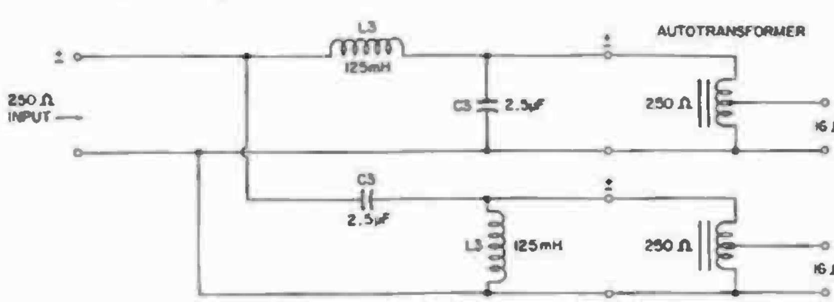

Fig. 7-99. Configuration for 12 dB per octave crossover network used in motion picture theater sound installations. Autotransformers are used at the speaker end to match the low impedance of the speaker voice coils. The network is mounted at the speakers on the stage.

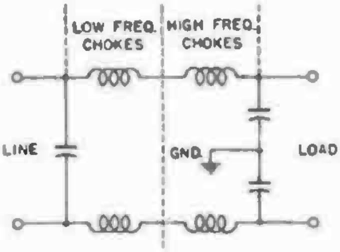

Fig. 7-101. Configuration for a line-noise suppression filter.

frequency characteristics of wave filters? —The method recommended by the Motion Picture Research Council for marking the nameplate of filters is as follows: Two frequencies which are down 3 and 10 dB with reference to 1000 Hz are stated. As an example: A high-pass filter designated 50-HI-42 would indicate that the frequency response at 50 Hz is down 3 dB and at 42 Hz 10 dB. A second example: An 80 Hz, high-pass filter is designated 90-HI-78. This would indicate that 90 Hz is down 3 dB and 78 dB is down 10 dB. The configuration and impedance are also stated.

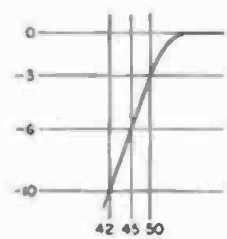

Fig. 7-102. The frequency characteristics of a 45-Hz high-pass filter designated 50-HI-42.

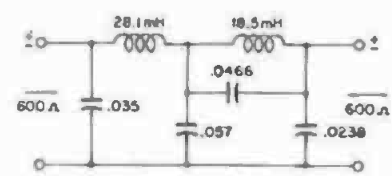
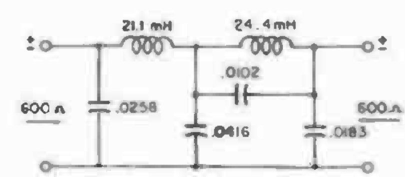
7.103 What are the impedance and phase-shift characteristics for constant-k and m-derived crossover networks?—In general, the impedance characteristics of a corresponding series or parallel networks are *inverse* to each other, and vary from one to the other. If a network is terminated at the output in R. ohms, the impedance at the input is the same. However, since the voice coil does not present a constant load impedance, this does not hold true. This effect is somewhat offset by the isolating effect of the intervening filter sections, particularly for the networks in Figs. 7-89A and C. For the m-derived networks in Figs. 7-89B and D, a slight improvement of the input impedance characteristic can be obtained by using the value of 0.45 for m. The improvement being small, little is gained by making this change.

As a rule, the designer of a crossover network finds little interest in the phase-shift characteristics; however, the following information is approximately correct. For the m-derived networks of Figs. 7-89A and C, the phase shift at the crossover is approximately 321°. For the networks of Figs. 7-89B and C approximately 221°. The phase shift at crossover for constant-k networks in Figs. 7-82A and C is approximately 90°, and for Figs. 7-82B and D it is approximately 180°.

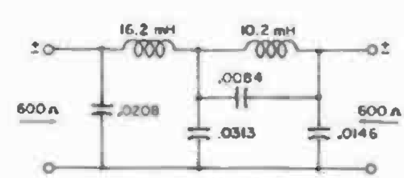
7.104 What are the circuit element constants for a 6-kHz, 8-kHz, and 10-kHz, 600-ohm low-pass filter having sharp cutoff characteristics? — Three low-pass filters that may be used for recording purposes are given in Fig. 7-104.



(*a*) *6000 Hz.*



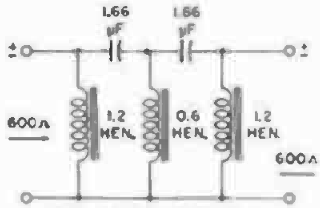
(*b*) *8000 Hz.*



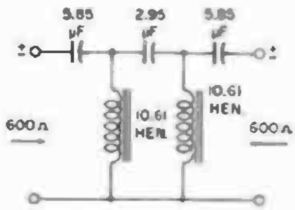
(c) *10,000 Hz.*

Fig. 7-104. Three 600-ohm low-pass filters suitable for recording purposes.

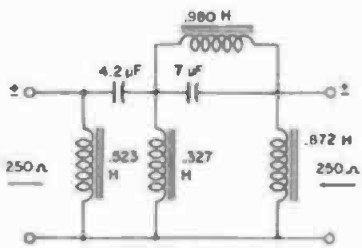
7.105 What are the circuit element constants for a 45 Hz and 80 Hz, 600-ohm high-pass filter?—Three high-pass filters suitable for recording purposes are shown in Fig. 7-105. The configuration shown at (c) has the sharpest cutoff characteristics.



(a) *80 Hz-600 ohm.*



(b) *45 Hz-600 ohm.*



(c) *80 Hz-250 ohm.*

Fig. 7-105. High-pass filters that are suitable for recording.

7.106 What is a wratten filter?—An optical filter used for filtering a given band of light. They are used in film recorder optical systems when recording directly on color film (direct positive) and are also extensively used in photography.

An optical filter may be likened to an electrical filter. A red optical filter appears red to the eye because it absorbs green and blue light rays, but passes red light freely. Such filters are made of glass and gelatin.

7.107 Give a schematic diagram for a 20,000-Hz low-pass filter for eliminating the high-frequency bias current in the output when making frequency-response measurements on a magnetic recorder.—When making frequency-response measurements on a magnetic recorder using the playback circuit, the bias current will often affect the frequency-response measurement. To eliminate this effect, a 20,000 Hz low-pass filter is connected in the output of the playback circuit which eliminates the effect of the bias current. Such a filter is shown in Fig. 7-107A, with its frequency-response curve shown in Fig. 7-107B. The filter configuration is designed for 550 ohms which will permit it to be operated in either a 500- or 600-ohm circuit. If a vacuum-tube voltmeter is used at the

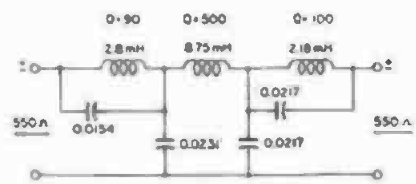


Fig. 7-107A. A 20-kHz low-pass filter for removing the high-frequency bias current in the output of a magnetic tape recorder when making frequency-response measurements.

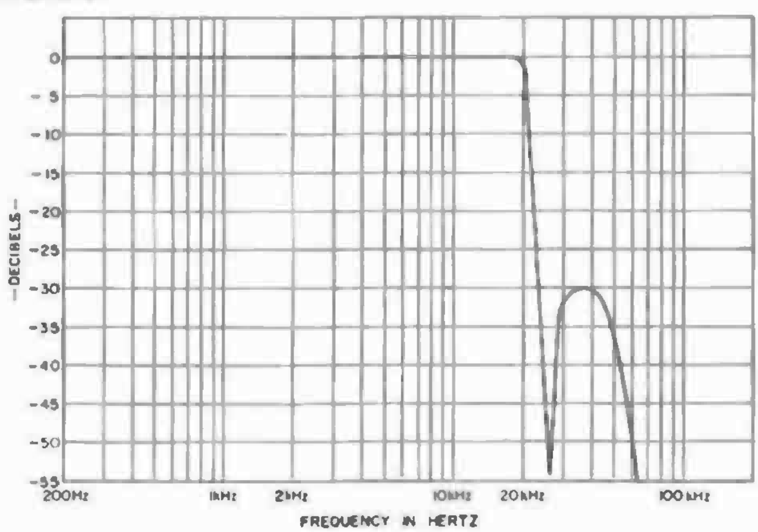

Fig. 7-107B. Frequency response of 20-kHz low-pass filter shown in Fig. 7-107A.

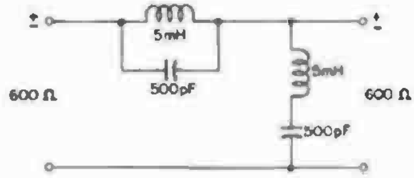

Fig. 7-107C. Low-pass filter for eliminating the effects of bias current when making measurements on magnetic recorders.

output of the filter, the filter must be terminated in either 500 or 600 ohms. If not, the filter frequency characteristics may be altered and the frequency response of the recorder under test may be affected. A second filter configuration, having similar characteristics to that in Fig. 7-107A, is shown in Fig. 7-107C.

7.108 What is an electronic crossover network?—An amplifier with variable RC circuits which are used to control the frequency of crossover, in a multiple loudspeaker system. Electronic crossover networks are connected after the preamplifier stage and feed two power amplifiers, one for the high-frequency speakers and one for the low-frequency speakers.

Electronic crossover networks are discussed in Section 20.

7.109 Describe the construction of a variable filter panel.—Variable filter panels are quite handy in making measurements on almost any type of electronic equipment, and they are used extensively in the laboratory and in sound recording systems. A variable filter panel, incorporating a high-pass and low-pass section, is shown in Fig. 7-109A. The two filter sections are completely isolated from each other, but may be connected in tandem by strapping the binding posts on the front of the panel. An octave bandswitch associated with each filter section, permits the cutoff frequency to be changed in octave steps, in conjunction with a multiplier dial for tuning the cutoff frequency over a range of one octave. The multiplication factor read on the dial multiplied by the octave band setting indicates the frequency, and when used with the tables at the upper portion of the front panel requires no calculations. As an example, setting of the octave bandswitch to 300 Hz and the multiplier to 1.8, results in a cutoff frequency of 540 Hz. The cutoff frequency is defined as the frequency attenuated 3 dB down from the maximum insertion loss.

By connecting the high-pass and low-pass sections in tandem, the device becomes a bandpass filter, without increasing the insertion loss which is so common to most bandpass filters with a bandwidth of ⅓ octave. Setting the high- and low-frequency sections to the same frequencies narrows the bandwidth to ¼ octave. Using an external 10-dB pad connected to the binding posts between the high- and low-frequency cutoffs will reduce the passband to approximately ⅙ octave.

Fig. 7-109A. Model 2AR variable LC filter panel manufactured by the Allison Laboratories, Inc.

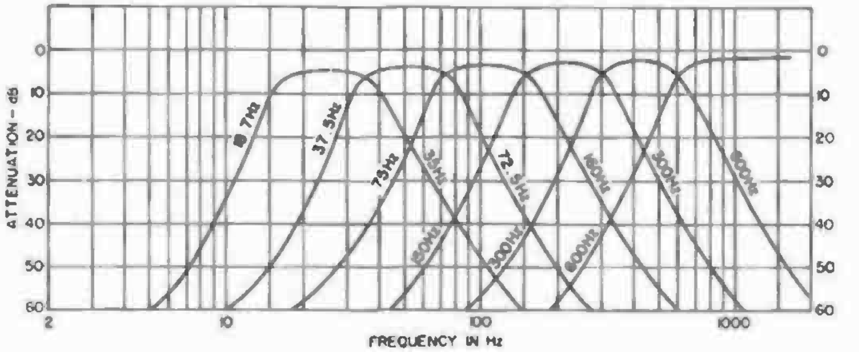

Fig. 7-109B. Frequency response for Allison Laboratories Model 2AR variable filter panel.

The normal rate of cutoff for both sections is 30 dB per octave, when properly terminated with an input and output impedance of 600 ohms. Measurements down to minus 120 dB below 1 volt are possible, without interference. The frequency response for bandpass operation below 1000 Hz is shown in Fig. 7-109B.

Variable filters are used extensively in rerecording sound tracks for the removal of unwanted sounds above and below the dialogue range. They are also used for creating narrow band response to simulate a telephone, dictating machine, radio, or an intercommunicating system. A variable sound-effects filter panel of this type is shown in Fig. 7-109C, with its many frequency characteristics shown in Fig. 7-109D. Two switches are provided for cutting the filter panel in and out of the circuit and for operating as a high-pass, low-pass or bandpass filter. The insertion loss is less than 0.25 dB. The coils are toroidal wound to eliminate stray magnetic fields. The filter configurations are of the constant-k type. For sound effects, the cutoff rate is generally not less than 12 dB per octave, and not more than 18 dB per octave.

7.110 Describe the basic configurations for double-m and double-m prime filter sections.—Although an m-derived filter section can be designed to provide an impedance match over about 85 percent of the passband, such a match may not be sufficient for certain filter applications. With further modification of the m-derived equations, it is possible to develop other m-derived sections from existing m-derived sections, or from their prototype, the constant-k section. Such sections are termed mm′ and mm″ filters, and can be designed to have a more constant impedance in the passband than that which can be obtained with the conventional m-derived section. Double m-derived sections provide an impedance match within 2 percent over 96 percent of the passband. However, their attenuation characteristics remain the same as for the m-derived section of a similar design.

Typical examples of the double-m or mm′ filters are shown in Fig. 7-110. The design procedure is somewhat similar to that of the m-derived. First the filter is designed as a constant-k section, then the circuit elements are modified, using the factors given in the diagram. The filter sections shown are termed termi-

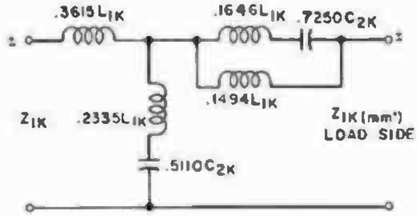
nal sections and are used as end sections. These sections may be used with other m-derived and constant-k sections, provided the image impedance match is satisfied between the sections. The mm'-derived filters have been included to show only the basic conception of design. The reader is referred to the references.

7.111 What are the design characteristics for filters to be operated in parallel or series?—Wave filters to be operated in either series or parallel require special treatment, because the impedances are joined to a common source impedance. Since filter impedances vary with frequency in the stop band, both the parallel impedance and the insertion loss are affected. The loudspeaker crossover networks of Fig. 7-111 are typical examples of parallel and series filter combinations.

For parallel operation, the low- and high-pass sections must employ T-type intermediate sections with an L-type input half-section, designed for m equal to 0.6. With equal load impedances at the output terminals of each filter, a normal impedance match is achieved by omitting the shunt impedance (Z_4 and Z_3) at the input of each filter section. For series operation the filter sections are designed using pi intermediate sections, with pi input half-sections. Again using a value of m equals 0.6, and using equal termination impedances at the output, a normal impedance match is obtained by omitting the series impedance at the input of each filter section.

When low- and high-pass sections are connected in parallel, the circuit elements of the high-pass filter replace the shunt inductance and capacitance of the low-pass filter of the passband.



$L_{1K} = \frac{R_0}{\pi f_0}$

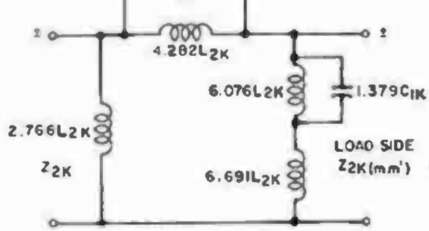
$L_{2K} = \frac{R_0}{4\pi f_1}$

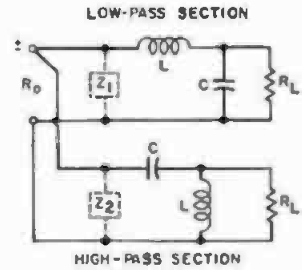
(c) *Series-derived, high-pass terminal section.*



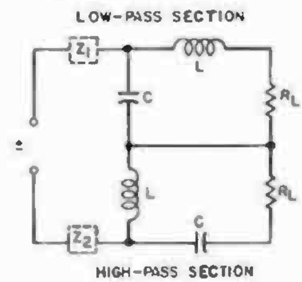
$C_{1K} = \frac{1}{4\pi f_1 R_0}$

(d) *Shunt-derived, high-pass terminal section.*

Fig. 7-110. Double m- or mm'-derived filter sections.



(a) *Parallel-connected.*



(b) *Series-connected.*

Fig. 7-111. Filters connected in parallel and series.

The circuit elements of the low-pass filter replace the inductance and capacitance of the high-pass filter of the passband. When connected in parallel, the two filters will exhibit about the same amount of attenuation and impedance characteristics as if the input elements Z_1 and Z_2 had not been removed. When connected in parallel, about 12 dB attenuation per octave may be expected.

In the series circuit, the procedure used in the parallel network is not necessary, as filters connected in series are inverse to each other. The foregoing design procedures are applicable in all instances where filters are complementary: that is, where frequencies that lie in the stop band of one filter are in the passband of the other.

7.112 Describe the basic principles of a phase-shift or phase-correction network.—An ideal transmission line would be one in which the received signal currents represent a faithful copy of the transmitted signal—in other words, a distortionless transmission system. For relatively short distances, the effect of phase distortion is not appreciable; however, this is not true for long-distance transmissions. Here the phase distortion can become serious enough to impair the commercial efficiency of the line. The correction of frequency dis-

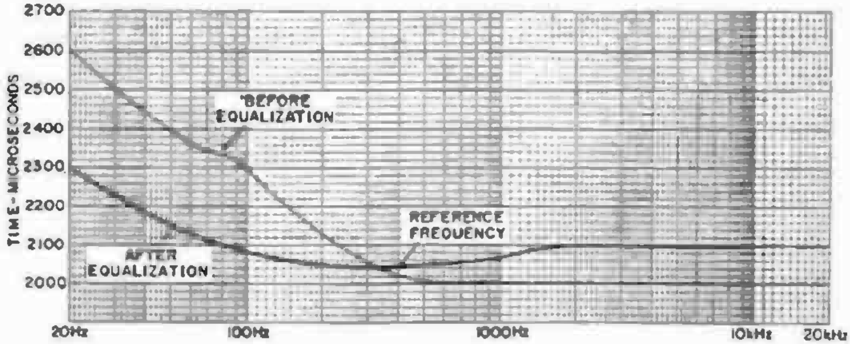


Fig. 7-112A. Time-delay characteristics of a transmission line equalized ±1 dB, 10 to 20,000 Hz.

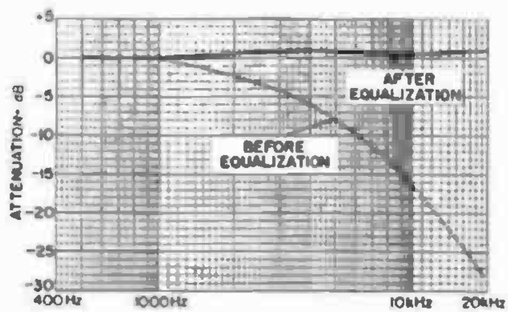

Fig. 7-112B. Frequency characteristics of the transmission line in Fig. 7-112A.

tortion by the use of equalizers is not enough because as the equalizatiou is increased, the phase distortion is likewise increased. For high-quality traus-missions, the phase distortion must be reduced to a negligible amount.

Distortion due to frequency variations and phase differences between the signal at the sending and receiving ends of the line gives rise to what is termed transient effects. The signal after arriving at the far end of the line requires an appreciable time, which varies with frequency, to build up, and may at times never build up to anything resembling the transmitted signal. To correct for these deficiencies, filter networks, termed phase-correction or all-pass filters, are used. Such networks have zero attenuation for all frequencies within their design range. They are used as phase-correction equalizers to induce a time delay for a given group of frequencies.

By applying a complex waveform consisting of many frequencies to a long transmission line, each frequency will be delayed in its transmission a different length of time, the delay time increasing with the length of the line and

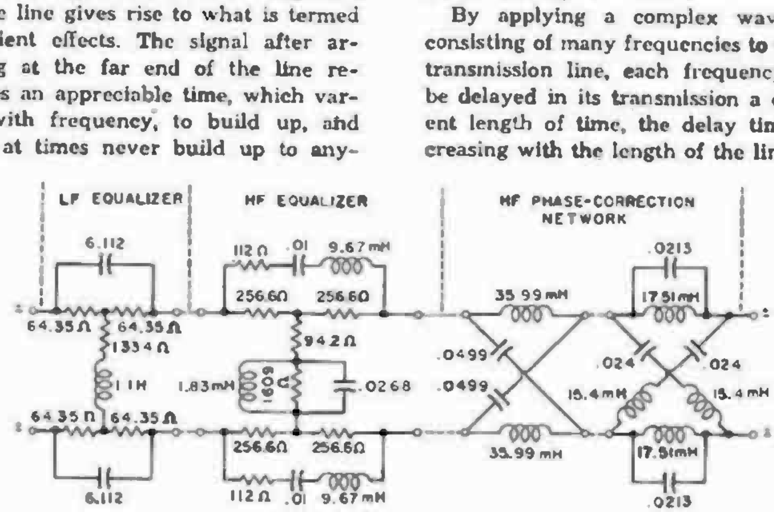

Fig. 7-112C. Low- and high-frequency equalizers and a phase-correction network.

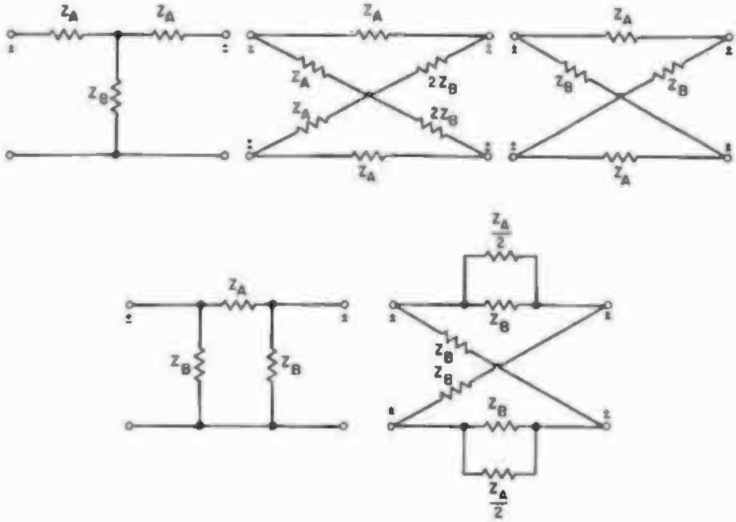

Fig. 7-112D. Converting T and pi networks to lattice networks.

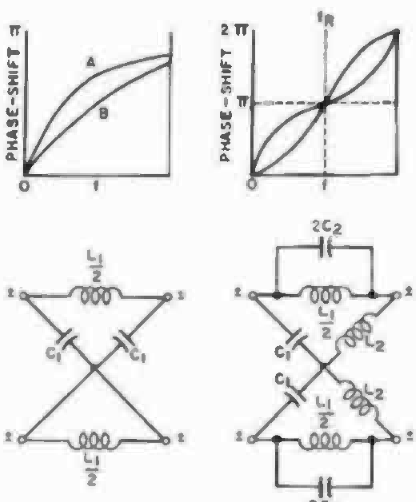
the frequency. The actual time delay is not important, but the relative time delay between the frequencies is important. The difference in phase between the signal at the sending and at the receiving end of line can be expressed in terms of time through the line:

Phase-shift $= \gamma\omega + n\pi$ radians

where,

γ is the time delay of the network,
ω is equal to $2\pi f$,
and n is an integer.

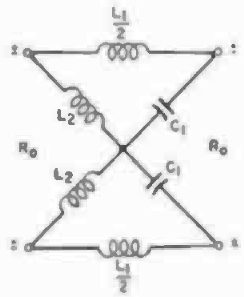


(a) *Simple network.* (b) *Complex network.*

Fig. 7-112E. Phase-shift characteristics for two different types of networks.

For a network to have zero phase shift γ must remain constant for all frequencies, or the curve of the phase shift, as a function of frequency, must be a straight line. When a complex waveform is applied to a system which has a linear phase shift, the transmitted signal is received at the far end of the line after a definite time delay, but all frequencies in the waveform will be received at the same instant in the same relationship as they were at the sending end of the line. A time delay at the high frequencies is more noticeable than at the low frequencies because the human ear depends on the higher frequencies for definition. In the range between 5000 and 8000 Hz, it has been determined that the time-delay should not exceed the 1000-Hz delay time by more than 10 milliseconds. The delay at 50 Hz may be up to 75 milliseconds more than that at 1000 Hz, without noticeable effects. The low frequencies are delayed by the presence of series capacitance and shunt inductance, the delay increasing with the value of the circuit constants. High frequencies are delayed by the presence of series inductance and shunt capacitance, the delay increasing with the increase of these values.

The effect of phase distortion for a transmission line 285 miles in length and terminated in 600 ohms at each end, is shown in Fig. 7-112A. This line, an experimental one, was designed to have a frequency response of plus or minus 1 dB, from 10 to 20,000 Hz. This required



$$f_C = \frac{1}{\pi\sqrt{L_K C_K}}$$

$$R_o = \sqrt{L_K C_K}$$

$$L_K = \frac{R_o}{\pi f_C}$$

$$L_1 = \frac{m}{2} L_K$$

$$L_2 = \frac{1}{2m} L_K$$

$$C_K = \frac{1}{\pi f_C R_o}$$

$$C_R = \frac{m}{2} C_K$$

$$\text{time} = \frac{2m}{\sqrt{1-(f/f_C)^2}\left[1-(1-m^2)(f/f_C^2)\right]}$$

Fig. 7-112F. Configuration for an all-pass network and its design equations.

that 20,000 Hz be equalized 28 dB, with reference to 500 Hz. After the line was equalized (Fig. 7-112B) it was discovered the high-frequency equalizer induced phase distortion, more than twice as great as that of the line itself. To correct for this deficiency, a phase-correction network of the design of Fig. 7-112C was connected in tandem with the equalizer networks. Time-delay networks can not be developed using the conventional ladder-type networks; instead, symmetrical m-derived networks of the T- or pi-type are used. Conversion of a T section and a pi section to a lattice network is shown in Fig. 7-112D. All-pass networks are developed by the use of lattice networks, in which the reactances Z_A and Z_B are reciprocal with respect to image impedances R_o. This results in a passband in which the attenuation is zero, and the image impedance is a constant resistance (R_o) for all frequencies.

The phase-shift characteristics for two different types of networks are given in Fig. 7-112E. Fig. 7-112E part (a) indicates the phase-shift characteristic when the L/C ratio is large, and part (b) indicates when the L/C ratio is small. Phase-correction networks have been used with success in disc recording systems employing diameter equalization, and pre- and post-equalization. Fig. 7-112F gives the equations used in the design of all-pass networks.

7.113 Describe a low-frequency, high-pass filter for use with microphones.—A rather simple 100-Hz filter for use with a microphone to reduce the effects of wind noise is shown in Fig. 7-113, part (a). The device consists of a pi section, high-pass filter connected between two impedance-matching transformers. This filter is generally made and packaged in a metal box with standard microphone connectors at each end, for connecting directly into the microphone cable. The taps on the transformers permit the filter to be used with different impedances. The coils are toroidal wound, high-Q, and are encased in a mu-metal box to eliminate the effect of stray magnetic fields. The frequency response is shown in Fig. 7-113 part (b).

7.114 Describe the characteristics and use of a pink-noise filter.—A pink-noise filter (Fig. 7-114A) converts the output signal of a random-noise generator to a constant energy per octave generator which facilitates measurements to constant-percentage bandwidth analyzers. The circuit in Fig. 7-114B is an RC low-pass network with a slope of 3 dB per octave from 20 to 20,000 Hz, and a slope of 16 dB per octave at the higher frequencies shown in Fig. 1-114C.

If the output of the random-noise generator is connected to a constant-percentage bandwidth analyzer, the output-voltage characteristic appears as white noise (Fig. 7-114D). Connecting the pink-noise filter in the output produces an output signal as shown in Fig. 7-114E, termed pink noise. The white- and pink-noise spectrums shown were made with a one-third octave bandwidth analyzer and recorded using a graphic level recorder.

It is interesting to note that certain noises occurring in nature are closer in spectral characteristics to pink noise

than to white noise. This is also characteristic of low-frequency noise found in semiconductor devices and in certain acoustical background noises.

7.115 Describe an RC filter for making noise measurements.—When making conducting-noise measurements, particularly on magnetic tape or film equipment, the noise is measured while erasing the high-frequency bias current signal. To properly measure the noise, a filter (Fig. 7-115A) with the frequency characteristic shown in Fig. 7-115B is required to attenuate noises outside the audio spectrum. The filter shown is designed to operate in a 600-ohm circuit. Noise measurements are discussed in Section 23.

7.116 What are Butterworth, Chebyshev and elliptic filters?—Such filters are used for rf and crystal bandpass design. The equations used replace the

conventional equations used for the design of constant-k and m-derived filters.

Conventional filters are designed section by section, matching the impedance of each section to the other. Butterworth, Chebyshev and elliptic filters are designed as a whole which simplifies the matching of the sections, permitting the response to be optimized, and are expressed using transfer equations. As a rule, the configuration is either a ladder or lattice network.

Bessel filters, because of their excellent phase-shift linearity characteristics, are often referred to as linear phase- shift filters. Filters of this design are generally fabricated using solid-state techniques in the form of an operational amplifier. For mathematical treatment of such devices the reader is referred to the references.

Section 8

Transformers and Coils

Transformers and coils play an essential part in the field of Audio Engineering. Types such as input, output, intermediate, repeat, power and modulation, to mention but a few, often serve as a key component in audio circuitry. Such devices are used for matching impedances, isolation, bridging low-impedance circuits, and in power supplies.

Work by men such as Clark, Lenz, Maxwell, and Steinmetz has added greatly to our understanding and usage of transformers and coils. The various segments, construction detail, and design characteristics of these devices, are discussed in this section, with charts and graphs for determining their characteristics, when used under conditions other than for which they were designed. Constant-voltage transformer, their design and use, are also covered.

8.1 What is a transformer?—An electrical device consisting of one or more coils wound on a magnetic material core. Electrical energy may be transmitted between one or several of the windings. Transformers designed for audio frequency use must be capable of transmitting currents over a wide frequency range, in contrast to a power transformer which transmits currents over a narrow frequency band. Transformers for either service may be designed to step-up or step-down the current. Typical schematics for an audio and a power transformer are shown in Figs. 8-1A and B, respectively.

8.2 Why are laminated cores used in transformers?—To reduce eddy-current loss in the core material, thereby improving the transformer characteristics. Hysteresis losses in the core are caused by molecular friction and are reduced by the use of alloy steel, such as silicon, hypersil, and hypernic. The latter two metals are manufactured by Westinghouse.

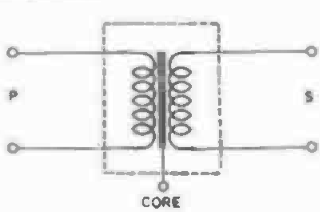

Fig. 8-1A. A typical audio transformer.

8.3 What takes place in a transformer when the core material is saturated?—When the core becomes saturated in a power transformer, it is no longer able to produce additional lines of force. Hysteresis losses occur, the coils become overheated, and damage to the winding may take place under these circumstances.

In an audio-frequency transformer, if the core cannot produce the required lines of force the inductance drops and, because of the core saturation, the core losses increase, and the frequency response is affected, particularly at frequencies below 100 Hz.

8.4 What is copper loss?—A power loss caused in a power transformer by the dc resistance of the coils. The loss varies as the square of the current.

8.5 What is iron or core loss in a transformer?—The loss of energy due to

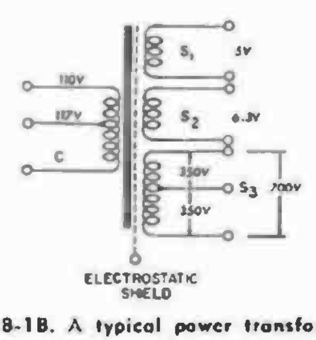

Fig. 8-1B. A typical power transformer.

eddy currents in the core material. In practical transformers, the core loss remains almost constant from no load to full load, under normal conditions. (See Question 23.158.)

8.6 ***What are eddy currents?***—Circulating currents induced in a conducting material as the result of the rapid reversal of the magnetic field. (See Question 8.2.)

8.7 ***What causes current flow in the primary of a power transformer operating with an unloaded secondary?***—The primary impedance has both an ac reactance and a dc resistance, which will cause a current flow. In well-designed transformers this current is small and is referred to as the mag-I current, or magnetizing current.

8.8 ***What is an autotransformer?***—It is a transformer with a single winding as shown in Fig. 8-8A. Such transformers may be designed for stepping the voltage up or down, and may be used with any type equipment. Autotransformers are also constructed to be continuously variable over their entire range. The interior construction of a variable autotransformer manufactured by General Radio Co. and sold under the trade name of *Variac* is pictured in Fig. 8-8B.

The autotransformer used in this device consists of a single layer winding on a toroidal core. As the shaft is rotated, a brush contact traverses the winding turn-by-turn; thus, the voltage may be varied from zero to full voltage. A tap on the winding permits the input voltage (line) to be changed, resulting in an overvoltage connection (zero to 140 volts for a line voltage of 117 volts). Autotransformers are sometimes used in audio amplifiers for interstage coupling and for impedance matching in loudspeaker systems.

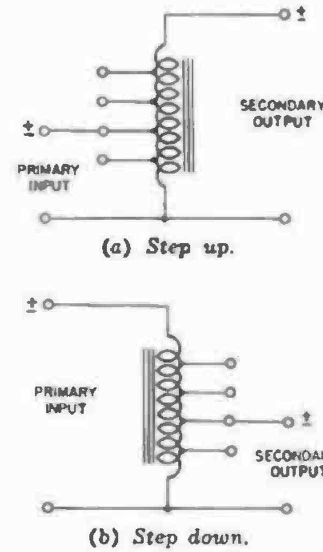

Fig. 8-8A. Two types of autotransformers.

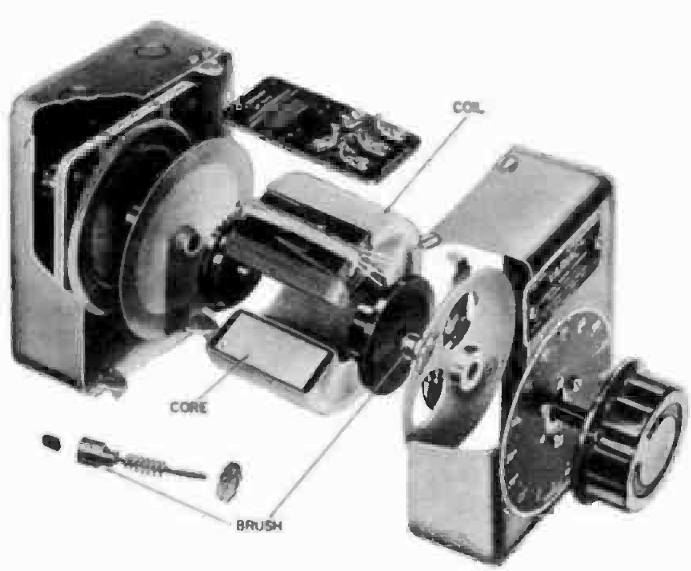

Fig. 8-8B. Interior construction of a General Radio Company Variac, showing the autotransformer winding.

8.9 What is a bifilar winding?—A coil is said to be bifilar wound when, to achieve a balance between windings, two conductors are wound side by side. (See Fig. 5-16B.)

8.10 What is a pie winding?—A thin sectional winding used in transformers and coils to reduce the effect of distributed capacity between the windings.

8.11 How is the wattage rating of a transformer determined if rated in volt-amperes?—The power rating of a transformer depends on the amount of heat the windings can stand. The power rating in watts is the product of the volt-ampere rating times the power factor. Small transformers employed in electronic equipment generally have efficiencies of 95 to 98 percent; therefore, efficiency as a rule is ignored. Assume a power transformer is rated 117 volts, 60 Hz, 100 volt-amperes, with a secondary of 6.3 volts. The rating of 100 volt-amperes means the product of voltage times the current ($E \times I$). Since the secondary can never exceed 100, and if it has a load of 12 amperes, the wattage will be 75.5 watts, ignoring the power factor. If the power factor is to be taken into consideration, the rating of 100 volt-amperes is multiplied by the power factor. For a power factor of 0.9, the maximum wattage at the secondary is $100 \times 0.9 = 90$ watts.

To convert the volt-ampere rating into kilovolt-amperes, divide the volt-ampere rating by 1000. The transformer would then be rated 0.100 kilovolt-amperes. *If the transformer has more than one secondary winding, the total load wattage cannot exceed the 100 volt-ampere rating.* Power factor is discussed in Questions 3.14, 3.58, and 3.62. Other formulas used with power transformers are shown in Fig. 8-11. For 3-phase circuits I and E are per phase.

8.12 Define an electrostatic shield and its purpose in a power transformer.—An electrostatic shield consists of a single turn of copper or brass covering the entire length of the primary winding. The ends of the shield are insulated from each other to prevent the shield from acting as a shorted turn. A connection to the shield is brought out to a separate terminal for grounding. The purpose of the shield is to prevent the passage of line noises and radio-frequency signals from the transformer into the power supply, and thence to other parts of the equipment. Electrostatic shields are also used in audio transformers. (See Question 8.42.)

8.13 What is the effect of connecting a power transformer designed for 60-Hz operation to a 25-Hz line?—The inductive reactance of the primary is considerably lower when connected to the 25-Hz voltage source. This causes the primary current to be more than double its normal value. The increased current through the primary winding will cause serious overheating and, eventually, will cause the primary to burn out.

To Find	Knowing	1-phase	3-phase
Amperes	E, hp, PF, Eff.	$\frac{hp \times 746}{E \times Eff. \times PF}$	$\frac{hp \times 746}{1.73 \times E \times Eff. \times PF}$

kVA	I, E.	$\frac{E \times I}{1000}$	$\frac{E \times I\ 1.73 \times PF}{1000}$

where,
E is voltage,
I is current,
Eff is efficiency,
PF is power factor,
hp is horsepower,
kW is 1000 watts.

Fig. 8-11. Formulas used with power transformers.

Transformers designed for 25-Hz operation have about 50 percent more core material than do transformers designed for 50- to 60-Hz operation.

8.14 Can a transformer designed for 60 Hz be operated on 400 Hz?—If the core material is of a good quality, a transformer which has been designed for 60 Hz may be operated on 400 Hz. However, a transformer which is designed for 400 Hz operation cannot be operated on 60 Hz, as the core is smaller for a given power rating.

8.15 What is a filament transformer?—A transformer used for supplying a source of voltage to the filament or heater circuit of a vacuum tube.

8.16 What is the electrical center of a coil?—The point of equal impedance. In audio transformers this may not always indicate equal dc resistance from the center to the ends of the winding. The reason for this is the center tap is made on the basis of *impedance* rather than dc resistance. However, in high-quality audio transformers, the dc resistance is the same for both sides of the coils because the windings are split into several separate coils and then connected in series. The center tap is taken at the junction of the coils. The internal connections for a 1:1 repeat coil, Fig. 8-16, shows how the coils are connected in series, and the taps taken for the different impedances.

8.17 What are the essential differences between an audio and a power transformer?—Power transformers are designed to operate at one frequency or over a small range of frequencies. Audio transformers must operate over a frequency range of 20 to 20,000 Hz. Many audio transformers are designed to operate over a frequency range of 10 to 200,000 Hz. Such wide frequency characteristics require careful design as to the method of winding the coils, their connection, material for impregnating the windings, core types and material, and the method used for stacking the laminations.

8.18 Define ampere turns.—The equations for determining ampere turns are given below:

$$\text{ampere turns} = \frac{V}{R} \times T$$

$$\text{ampere} = \frac{AT}{T}$$

$$\text{resistance} = \frac{V}{R} \times T$$

$$\text{effective turns} = \frac{\text{total resistance}}{\text{resistance of coil}} \times \text{turns of coil}$$

where,

A is the current in amperes,
R is the dc resistance,
T is the number of turns in the coil,
V is the voltage applied to the coil.

The latter takes into consideration any resistance external to the coil. One ampere turn equals 1.257 gilberts.

8.19 What is a current transformer?—A special transformer designed to work with a current-indicating instrument. The primary of the transformer is connected in series with the load, and the indicating instrument is connected to the secondary, as shown in Fig. 8-19. In this manner, the transformer carries the load while the instrument is com-

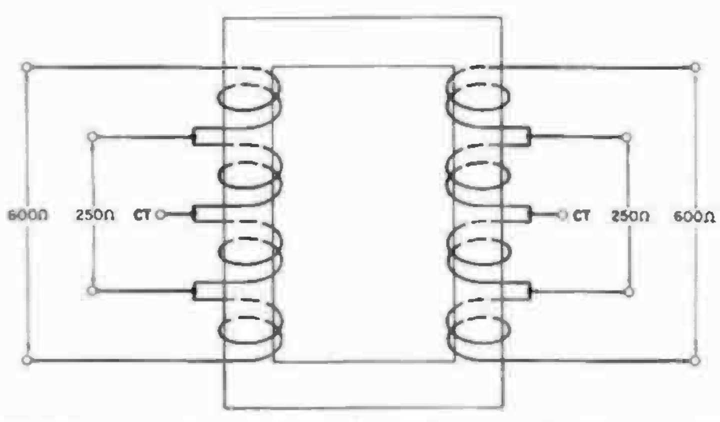

Fig. 8-16. Coil construction and winding for a 1:1 repeat coil with taps at 250 ohms and center.

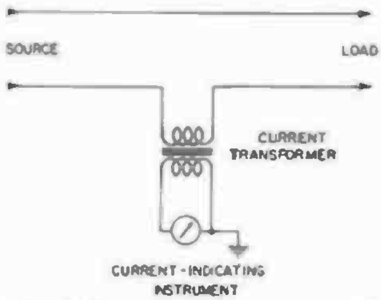

Fig. 8-19. Current transformer connected to indicate load current.

pletely isolated. The indicating instrument is actually a voltmeter, although calibrated in amperes.

8.20 How is the turns ratio calculated for a current transformer?

$$\frac{I_p}{I_s} = \frac{N_s}{N_p}$$

where,

I_p is the current in the primary,
I_s is the current in the secondary,
N_p is the number of primary turns,
N_s is the number of secondary turns.

8.21 How is the voltage regulation of a transformer calculated?—The voltage is first measured in a no-load condition, and then with a full load applied. This information is then substituted in the following equation:

$$\%\ \text{Regulation} = \frac{V_1 - V_2}{V_2} \times 100$$

where,

V_1 is the no-load voltage,
V_2 is the full-load voltage.

8.22 How are three-phase power transformers connected for utility service?—Several methods used for connecting 3-phase power transformers for commercial services are shown in Figs. 8-22A to F. Fig. 8-22A shows an open-delta connection and is the simplest of all 3-phase transformer connections as each winding consists of only two coils. In Fig. 8-22B is shown a six-winding transformer connected in delta. Figs. 8-22C and D illustrate two transformers connected in a star or wye configuration using a 3-wire and a 4-wire feed system. The 4-wire connection will permit the taking of 115 volts from any one winding to a neutral wire connected at the center of the three secondaries.

Fig. 8-22E shows a star-delta, or delta-wye, connection. Here, one side of the transformer winding is delta connected and the other side is star connected. In Fig. 8-22F is shown a 4-phase or quarter-phase connection. The various voltage combinations are shown relative to the common center tap and to the outside ends of the coils. (See Question 3.32.)

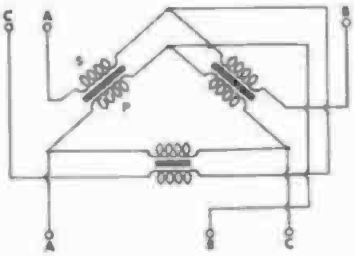

Fig. 8-22E. A three-phase transformer with windings connected in delta and wye.

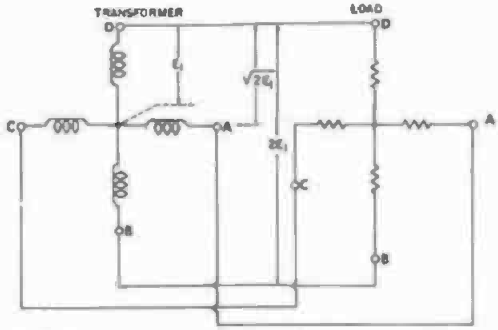

Fig. 8-22F. A four-phase or quarter-phase connected transformer.

8.23 What is a teaser transformer?—A power-transmission transformer used with 3-phase power-distribution systems, as shown in Fig. 8-23.

Assume a 1000-volt, 3-phase power source is to be stepped down to 100 volts. The primary of a 1:1 teaser transformer, T2, is connected in the center leg of the main power transformer as shown. The secondary of the teaser is connected to a center tap on the secondary of T1. The voltages developed by the system are given in the diagram. It will be noted the teaser transformer develops only 86.6 volts across both its primary and secondary windings.

The advantage of such a system is that moderate amounts of power may be transformed with only two transformers. About 58 percent of the system rating may be used with a teaser transformer, compared to one using a transformer in each phase. Because of dissymmetry, the system can easily become unbalanced. The phasing of the transformer windings must be carefully carried out to prevent damage.

8.24 Describe a repeat or isolation coil.—An audio transformer consisting of two windings with a one-to-one impedance ratio. However, repeat coils are generally designed with taps at various points on the coils to provide impedance matching between circuits of unequal impedance. A typical schematic of a repeat coil is shown in Fig. 8-24. It will be noted that although the coil is designed for an impedance of 600 ohms, ranging downward to 250 ohms, the center tap is balanced with respect to the center of the coil. High quality repeat coils used for transmission measurement work, as described in Question 23.14, employ an electrostatic shield between the two windings to prevent the transfer of noise by means of the capacitance existing between the two windings.

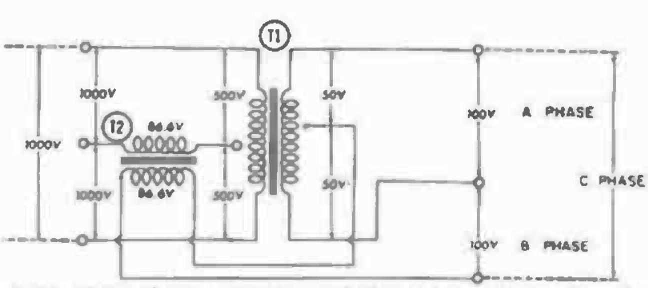

Fig. 8-23. Three-phase power transmission using a teaser transformer.

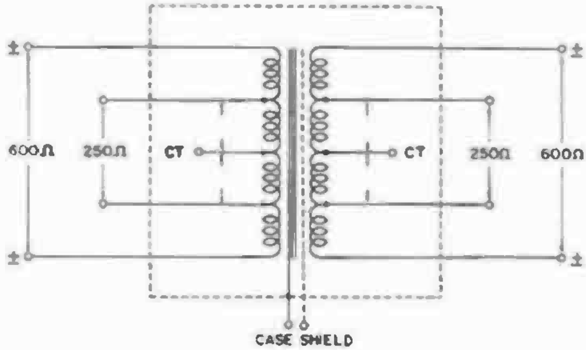

Fig. 8-24. Typical 600:600-ohm repeat or isolation coil. In-between impedances are indicated for ready reference.

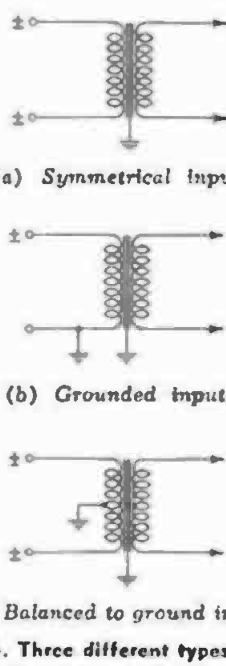
Thus, a signal is transferred from one coil to the other coil inductively only.

The windings consist of several separate coils, each with the same number of turns and connected in series in such a manner that the capacitance between coils is reduced to a minimum. This method of construction permits the various impedance taps to be taken at the exact electrical center, resulting in a well balanced design. The insertion loss of the average repeat coil is about 0.10 to 0.5 dB.

Repeat coils are often referred to as isolation coils, when they are employed to separate an unbalanced circuit from a balanced one. This is demonstrated by the extensive use of such coils in mixer consoles.



(a) *Symmetrical input.*

(b) *Grounded input.*

(c) *Balanced to ground input.*

Fig. 8-25. Three different types of transformer-input circuits.

8.25 Define the terminology used with input transformers.—Terminology used with input transformers is often misused, especially when referring to grounded-input circuits. Fig. 8-25 illustrates three methods most commonly employed. At part (a) is shown an ungrounded symmetrical input, often erroneously referred to as a balanced input. A true balanced circuit is one using an input transformer with a center tap to ground, as shown in part (c). For the circuit of part (a) to be truly balanced (although no ground is used) the transformer windings must be wound so that the distributed capacitance to ground is the same for each coil. Also, each coil must have identical inductance and dc resistance, and be physically interleaved to reduce the effects of leakage inductance. If all these conditions are met, the coil may be said to be balanced. However, in the average coil these conditions do not always prevail, therefore this circuit is said to be symmetrical.

The circuit in part (b) is an unbalanced input with one side of the input winding connected to ground. This input is often used with circuits such as a high-impedance microphone employing a single conductor and shield. The shield is connected to the ground side of the transformer.

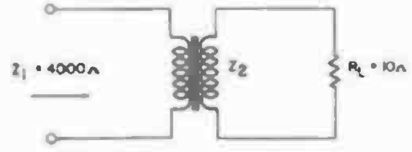
8.26 What is an impedance-matching coil?—A coil similar to a repeat coil, except it has more taps and a wider range of impedances. A typical impedance-matching coil may have a 600-ohm winding with taps at 500, 250, and 150 ohms; the other coil may be a 5000-ohm winding with taps at 1000, 500, 250, 150, 50, or 30 ohms. Such coils are not always balanced in their design and should be carefully checked for unbalance when connected in a circuit subject to leakage.

8.27 What causes the insertion loss in a transformer?—It is the loss caused by the shunt reactance, distributed capacitance, dc resistance of the coils, core material, and other losses due to the geometry of the coils. In the average audio transformer, this loss is not too important unless the power in the transformer is large, such as in an output transformer.

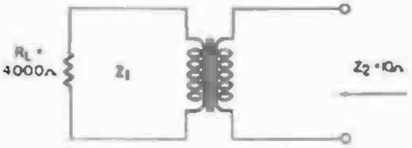
8.28 What are the basic principles of impedance matching?—The formula for impedance matching states: The impedance ratio of a transformer is directly proportional to the square of the turns. Frequency does not enter into this formula.

8.29 What is meant by the term impedance ratio?—Transformers are generally used to step up or step down a voltage or to transfer power from one circuit to an her. Because circuits differ in their in edance, if the maximum transfer of power is to take place, the turns ratio of the transformer must be such that an impedance match is effected between the two circuits, the source and the load. As an example, assume the plate circuit of an amplifier is to be connected to a loudspeaker.

As the plate resistance of a tube may run into several thousand ohms and the loudspeaker only a few ohms, the transformer will have to be of such a turns ratio that the impedance reflected back by the loudspeaker will cause the



(a) Step-up transformer.



(b) Step-down transformer.

Fig. 8-30. Reflected impedance by termination of a transformer winding.

primary of the transformer to present the correct load impedance to the plate of the tube. If the tube requires a load impedance of 5000 ohms and the speaker 16 ohms, the impedance ratio is 5000/16 or 312.

For a transformer of this design, if a 16-ohm resistance is connected across the output winding, the reflected impedance seen by the tube plate circuit will be 5000 ohms. The turns ratio of the coils is 17.66 or the square root of 312. Thus, it may be said:

$$\frac{Z_s}{Z_p} = \left(\frac{N_s}{N_p}\right)^2 \quad \text{or} \quad \frac{N_s}{N_p} = \sqrt{\frac{Z_s}{Z_p}}$$

where,

Z_s is the impedance of the secondary,
Z_p is the impedance of the primary,
N_s is the number of turns in the secondary winding,
N_p is the number of turns in the primary winding.

The foregoing relationship is generally stated: The impedance ratio is equal to the turns ratio squared, or the turns ratio is equal to the square root of the impedance ratio. The voltage ratio is equal to the turns ratio.

In a well-designed transformer the impedance ratio will remain the same throughout the normal frequency band. If a pure capacitance or indnctance is connected across the transformer rather than a resistance, the impedance seen by the primary will appear as a capacitance or inductance. Very often advantage is taken of this fact to transform small capacitors to a larger value for starting capacitor-start motors. (See Question 8.34, and Question 3.9.)

Because of the practical limits of a transformer, a given transformer cannot be used over a wide range of impedances. Attempting to use a transformer to obtain a given impedance ratio, but with the impedance diverging considerably from the original design, will result in frequency discrimination and a loss of power transfer.

8.30 What is reflected impedance?—The impedance seen when looking into a given winding of a transformer with one or more of the other windings terminated in a given load resistance.

To illustrate how the reflected impedance of a transformer winding is calculated, assume an ideal transformer (one with no losses) is available with a turns ratio of 20:1. The secondary winding (the smaller of the two) is terminated with a resistive load of 10 ohms as shown in part (a) of Fig. 8-30. The reflected impedance to the primary winding may be calculated:

$$Z_1 = N^2R_L \text{ or } Z_1 = N^2Z_2$$

where,

N is the turns ratio,
R_L the load resistance in ohms across the secondary,
Z_1 the primary impedance,
Z_2 the secondary impedance.

The impedance seen by the generator is the turns ratio (20) squared, or 400 times the impedance (10 ohms) of the secondary. The 4000 ohms seen at the primary winding is the "reflected impedance" caused by the 10-ohm secondary terminating resistance. The 4000 ohms will only be seen when the secondary is terminated in 10 ohms. If the primary impedance is measured with the secondary unterminated, only the actual inductive reactance of the primary coil will be measured. The reflected impedance of a step-up transformer of known turns ratio is calculated using the foregoing equation. For a step-down transformer, Fig. 8-30 part (b), the equation is:

$$Z_2 = \frac{Z_1}{N^2}$$

where,

Z_2 is the smaller impedance of the two windings,
Z_1 is the larger impedance of the two windings,
N^2 is the impedance ratio (turns ratio squared).

It should be understood that a transformer does not supply an impedance, but is designed to effect an impedance match between two circuits by supplying the correct turns ratio between the source and load impedances. Transformers will only present the correct impedance match when they are properly terminated. Transformers may be supplied with a solid termination on either winding to deflect a given impedance to the other winding. This method of operation is used with amplifiers employing beam-power tubes in the output stage. The plate resistance of such tubes is generally of the order of 25,000 to 90,000 ohms and is worked into a load impedance of 3000 to 10,000 ohms to reduce distortion. If the transformer is of the correct turns ratio, the correct load impedance will be reflected by the

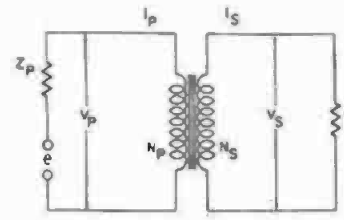


Fig. 8-31. The electrical circuit of an ideal transformer of 100% efficiency.

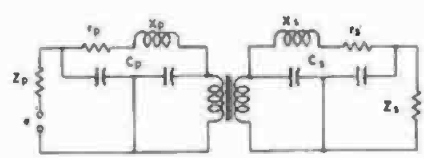
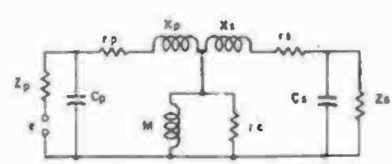
secondary winding load resistance. If the transformer has more than one winding, only one must be terminated, unless the transformer is designed to operate with a double termination. In the practical transformer, the distributed capacity and leakage are also reflected to the primary side. (See Questions 8.31, 8.32, and 8.33.)

8.31 ***What is an ideal transformer?***—A transformer which has no electrical losses. None of the electrical energy is lost in producing the magnetic field in the iron core, nor as heat in the windings. Furthermore, all the lines of flux of the changing current in one winding link all the turns of the other winding. (See Fig. 8-31.) Actually, this is not possible, as there are always some losses regardless of the design and materials used.

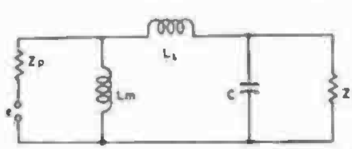
8.32 ***What are the losses of a practical transformer?***—A simple trans-



(a) Physical transformer.

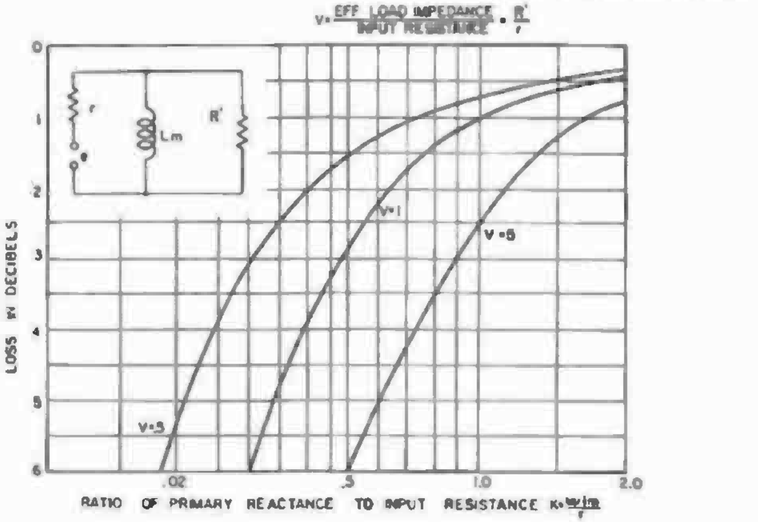


(b) Equivalent "T" network of (a).

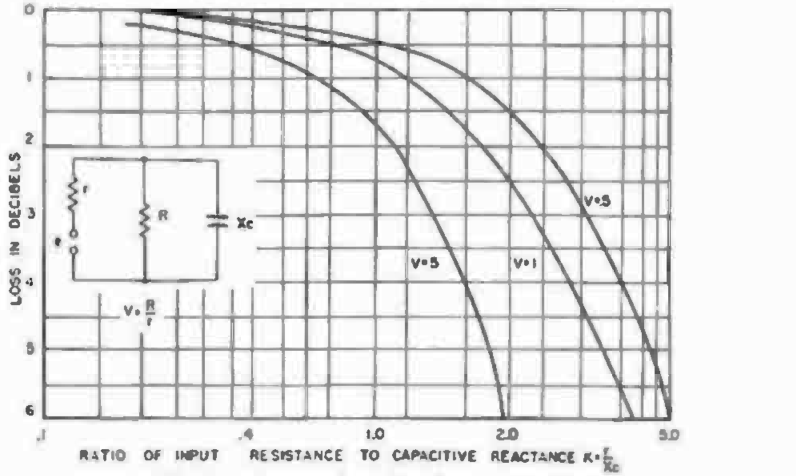


(c) Simplified equivalent circuit of (b).

Fig. 8-32A. Equivalent circuits of an audio transformer.



(a) Loss of power due to shunt effect of the primary.



(b) Loss due to distributed capacity.

Fig. 8-32B. Loss curves of an audio transformer.

former with its various perimeters is shown at parts (a) and (b) of Fig. 8-32A. In addition to the power transfer characteristics, the primary inductance L_m shunts the source impedance, as shown at part (c) of Fig. 8-32A. A leakage reactance L_L which in effect is in series with the load, and a distributed capacity C (due to the winding of the coils) are also in shunt with the source impedance.

As the frequency of the input signal decreases, the primary inductance also decreases. This decrease of inductance may reach a point where some of the power which is normally transferred from the primary to the secondary is shunted through this inductance, as shown at part (a) of Fig. 8-32B. If the frequency of the signal voltage is increased, the impedance of the distributed capacity decreases and shunts a portion of the power which would normally be passed to the load, as shown at part (b) of Fig. 8-32B.

8.33 *What Is leakage reactance?*—The transfer of electrical energy from the primary to the secondary of a transformer depends on the magnetic lines of force linking both the primary and secondary windings. In an ideal transformer, 100 percent of the lines of force would be utilized and the maximum transfer of energy would take place without loss.

The foregoing situation can never be achieved, as a certain amount of the magnetic lines of force leak off into the air. This leakage is called leakage reactance. Leakage reactance is reduced in a transformer by the core material, core design, and the geometry of the coils. (See Question 8.32.)

In conventional push-pull output transformers, the magnetic lines of force do not completely couple both halves of the primary winding. Lines of force coupled to one coil but not to the other cause a counter emf to be generated.

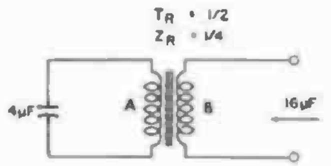


Fig. 8-34. Transformation of a capacitor.

Leakage reactance may be considered to be like an inductance connected in series with the plate of each tube, and is the result of insufficient magnetic coupling between the two halves of the primary winding. When the tubes are driven to cutoff at frequencies above 3000 Hz, the output waveform becomes distorted because of sudden changes in the plate current caused by transients. Output transformers of special design, such as the McIntosh, have been developed to reduce the effects of leakage reactance to where it becomes negligible. The McIntosh amplifier is discussed in Question 12.231.

8.34 Is it possible to transform capacitance?—Yes, this is often done in capacitor-start motor circuits. Referring to Fig. 8-34, a 4-μF capacitor is shown connected across the primary winding of a transformer having an impedance ratio of 1:4. Looking into the secondary winding, an image capacity of 16 μF is seen. (See Question 8.29.)

8.35 What are reflection losses?—The transmission losses resulting from a portion of the transmitted signal being reflected back towards the signal-source. This may be the result of mismatched impedances or of a discontinuity in the transmission line. In the case of an improperly terminated line, not all of the signal energy is transmitted to the load. The portion not absorbed by the load is reflected back towards the source and meets the energy from the source, and causes a loss of power. The greater the mismatch of the termination at the load end of the line, the greater will be the losses because of reflection.

8.36 How may the turns ratio of an unknown transformer be determined?—A known voltage is applied to one of the windings and the voltage is measured across the other winding. The turns ratio is equal to the voltage ratio.

8.37 What is the relationship of the impedance to the turns ratio of a transformer?—The impedance ratio is equal to the turns ratio squared.

8.38 What is the relationship of voltage to the turns ratio of a transformer?—The voltage ratio is equal to the turns ratio.

8.39 What is the relationship of turns ratio to the impedance ratio of a transformer?—The turns ratio is equal to the square root of the impedance ratio.

8.40 Does the mismatch of impedances affect the frequency response of a transformer?—A slight mismatch has little or no effect; however, it is best to measure the frequency response if more than a 15 percent mismatch is known to exist.

8.41 What is the maximum mismatch of impedances that may be tolerated?—Although circuit requirements will control the amount of mismatch that may be tolerated, the mismatch should not exceed 15 percent.

8.42 What is the purpose of a center tap, balanced-to-ground audio transformer?—To reduce the effects of longitudinal currents and also reduce the influence of external magnetic fields and line noises. In Fig. 8-42 is shown a balanced line using two center-tapped transformers balanced to ground. Longitudinal currents are the result of inductive interference induced into both sides of the line simultaneously, as shown by the arrows. The induced currents travel in the same direction in each side of the line. Arriving at the receiving end of the line, the current travels downward to the ground through the center tap of the transformer. As the field reverses, the same action occurs but in the opposite direction. During this action, the audio signals are traveling in opposite directions to their normal manner, as indicated by the solid arrows parallel with the lines. In addition to the center tap on the transformer, electrostatic shields, as

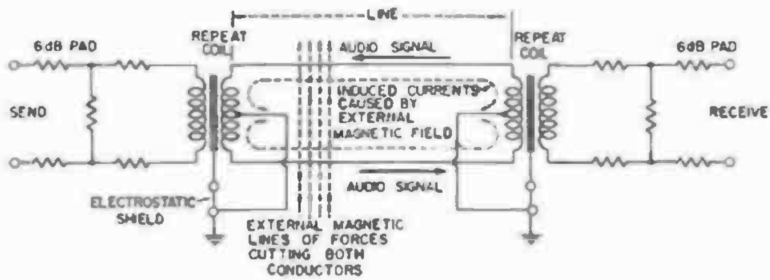

Fig. 8-42. Balanced transmission line using two balanced-to-ground repeat coils, one at each end of the line to reduce the effect of longitudinal currents caused by external magnetic fields.

explained in Question 8.12, are used to prevent capacity coupling between windings, thus, permitting only inductive coupling.

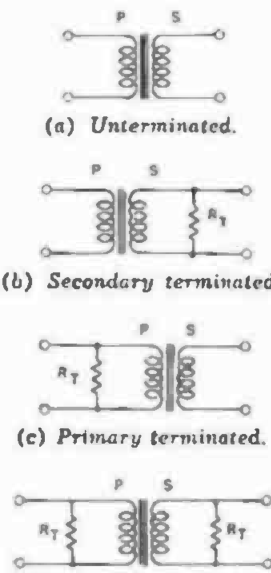
8.43 What is a terminated transformer?—A transformer operating with a resistive load connected across the primary or secondary winding in parallel with the normal load of the winding. Fig. 8-43 shows unterminated and terminated transformers operating with different types of terminators.

8.44 Where are unterminated transformers used?—To feed the grid of a vacuum tube. This connection is often referred to as an open-circuit connection and is generally employed in microphone and photocell preamplifiers. The source feeding the transformer is considered to be the transformer termination. An unterminated transformer should not be used to feed an equalizer, filter, or an amplifier requiring a solid termination.

8.45 Where are terminated transformers used?—In circuits requiring a solid termination such as a line, equalizer, filter, or similar devices.

8.46 What are the characteristics of an unterminated transformer?—The frequency characteristics of an unterminated transformer differ somewhat from those of a terminated transformer and are as follows: Assume a high quality line-to-grid transformer designed to operate from a source impedance of 500 ohms and having a secondary impedance of 50,000 ohms is connected to the grid of a vacuum tube operating as a class-A amplifier. The secondary will be left unterminated.

Under normal operating conditions, when the primary is terminated by a source impedance of 500 ohms, it will be assumed the frequency response



(a) Unterminated.

(b) Secondary terminated.

(c) Primary terminated.

(d) Primary and secondary terminated.

Fig. 8-43. Transformer terminations.

shows a loss of 1 dB at 40 Hz and 12,000 Hz. If the primary is now terminated by a line impedance of 100 ohms rather than 500 ohms, the loss of 1 dB will appear at $\frac{1}{5}$ ($\frac{100}{500}$) of 40 Hz or at 8 Hz. Under these conditions, the high end may resonate at some frequency around 12,000 Hz.

If the primary termination is now changed to 1000 ohms, the frequency response will show a loss of 1 dB at 80 Hz, or the lowest frequency multiplied by the new impedance ratio (1000/500). The high end will start to drop around 7000 Hz.

These values are only approximate but are generally true of unterminated transformers.

8.47 What are the characteristics of a terminated transformer?—Terminated transformers operate with resistive terminations across the primary or secondary, or both, as shown in parts (b) to (d) of Fig. 8-43. If the transformer described in Question 8.46 (500/50,000 ohms) is terminated on the secondary side with 50,000 ohms and connected to the grid of a class-A amplifier, looking into the primary will show an impedance of 500 ohms. The frequency response will show a loss of 1 dB at 80 Hz and 7000 Hz. If the transformer is terminated by a 1000-ohm source impedance, the low-frequency response will still show a loss of 1 dB at the low end, but the high-frequency response will be better than normal, or a loss of 1 dB at around 15,000 Hz. Before operating a transformer either terminated or unterminated, its characteristic should be checked by referring to the manufacturer's specifications. In any case, measurements should be made with the transformer terminated and unterminated to determine whether or not the frequency characteristics of the transformer are affected either by the termination or the method of operation.

8.48 What is a split-terminated transformer? — A transformer terminated on both the primary and secondary sides as shown in part (d) of Fig. 8-43. To illustrate how such terminations are used, assume an input transformer having an impedance ratio of 600/50,000 ohms is terminated on the secondary side with 100,000 ohms or double the secondary impedance.

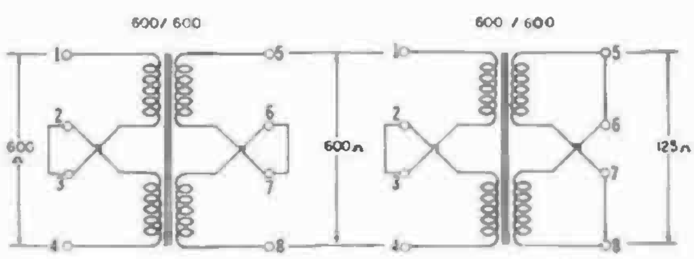
Looking into the normal 600-ohm primary shows an impedance of 1200 ohms. Now, if a 1200-ohm resistance is connected across the primary, the impedance looking into the primary is again 600 ohms. The advantage of such termination is that the transformer primary presents a solid termination to the source impedance. This type termination is of particular value if the primary is being fed from the output of another amplifier. When a transformer using split termination is first connected into a circuit, frequency-response measurements should be made to determine whether the frequency characteristics have materially changed from the original specifications. (See Question 6.113.)

8.49 How are the coils of a four-coil 600-ohm repeat coil connected externally?—A typical four-winding repeat coil is shown at part (a) of Fig. 8-49. If the terminals numbered 2 and 3 of the left-hand coils are connected in series, and terminals 6 and 7 of the right-hand coils are connected in series, the coil will have an impedance ratio of 1:1 or 600/600 ohms.

Leaving terminals 2 and 3 connected in series and connecting terminal 5 to 6 and terminal 7 to 8, as shown at part (b) of Fig. 8-49, the impedance ratio is changed to 600/150 ohms. Leaving the left-hand coils connected in series, either of the right-hand coils alone will present an impedance of 150 ohms. As the four coils are of similar design, any combination may be used by parallel or series connection. It will be observed the internal connections of the coils are crossed over inside the case, and that the ends of a given coil are either odd or even numbered. This is standard procedure for numbering coil terminals.

8.50 What is a nested shield?—An audio-transformer case consisting of alternate iron and copper shields separated by an air space, as shown in Fig. 8-50.

8.51 What is the theory of a nested shield?—Referring to Fig. 8-51, when a magnetic field encounters the outside high permeability iron case (A) of the transformer, it will travel through the case and be deflected around the trans-



(a) 600/600 ohms. *(b) 600/150 ohms.*

Fig. 8-49. Internal connections for a four-coil repeat coil.

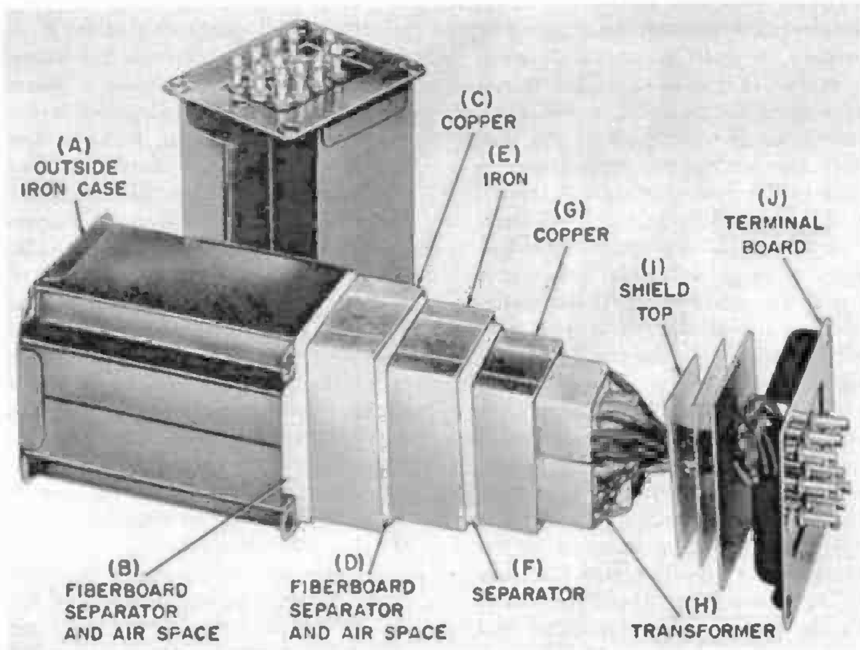


Fig. 8-50. Transformer encased in nested-shield. (Courtesy, Kenyon Electronics Inc.)

former (inside the case) because iron offers a path of lower resistance to magnetic lines of force than air. Also, in passing through the iron case a portion of the field is dissipated in the form of heat due to friction in passing through the iron and the short-circuiting effect of the case. The now reduced field continues through the air space filled by the fiberboard spacers (B), then through the copper shield (C). The field again passes through an air space (D) to a high-permeability iron shield (E) which again reduces the field strength. Leaving this shield, the field passes through air space (F) to copper shield (G) which houses the transformer (H). At the top of each shield are covers (I) (shown in Fig. 8-50) which, in effect, provide watertight shields around the transformer. The copper shields have little or no effect on the reduction of the magnetic field. Their purpose is to reduce the effects of electrostatic fields and disturbances caused by breaking of electrical circuits and radio transmissions.

To secure a further reduction from the effects of external magnetic fields, the coils of the transformer are wound hum-bucking, which neutralizes the effects of any magnetic field that may reach the transformer coils after passing through the multiple shielding.

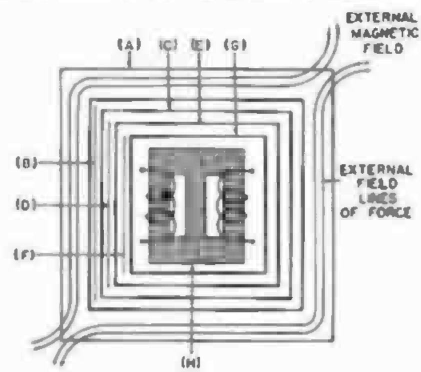

Fig. 8-51. External magnetic lines of force deflected by an iron case and a nested-shield around a transformer. Symbols correspond to those of Fig. 8-50.

Using the construction illustrated in Figs. 8-50 and 8-51 hum and noise pickup may be reduced 120 dB relative to the strength of the interfering magnetic field.

The core of the transformer is brought to a separate terminals for connection to a transmission ground system as described in Question 24.33. The outer iron case is completely insulated from the internal shields and transformer core.

8.52 ***Define the term 120 dB magnetic shielding.***—It means for a given external magnetic field surrounding the transformer, the strength of the magnetic field will be reduced 120 dB at the transformer windings. The amount of reduction is fixed and the actual hum pickup can vary with the change in the external magnetic field strength. However, with 120 dB of hum reduction, generally little difficulty is encountered.

Transformer hum-bucking windings are discussed in Question 8.98, and the measurement of shielding effectiveness is discussed in Question 23.162.

8.53 ***How much is an external magnetic field reduced by a single cast-iron case 1/8-inch thick?***—Approximately 12 dB.

8.54 ***How is the effectiveness of a magnetic field measured?***—By the method given in Question 23.162.

8.55 ***What type transformers require nested shielding?***—Low-level input transformers operating ahead of a considerable amount of gain, microphones, line, repeat coils and others of similar design, or any low-level transformer operating near ac operated equipment.

8.56 ***Should an output transformer be shielded?***—Yes, but an output transformer does not require as heavy a shield as does an input or interstage transformer. As a rule, an output transformer only requires 6 to 10 dB of shielding because it operates at a fairly high level and is not generally affected by extraneous magnetic fields. In many instances, the output transformer is only cased in light metal.

8.57 ***Should an interstage transformer be shielded?***—Yes, about 12 to 40 dB. It is a matter of circuit design and operating levels.

8.58 ***What is an input transformer?***—An audio transformer used at the input of an amplifier or similar device. Input transformers are generally better shielded from magnetic fields, as they are required to operate in low-level circuits. Input transformers, as a rule, are designed to match the low impedance of a transmission line to the grid of a tube. Typical impedance ratios are: 250 or 600 ohms to a 50,000-ohm secondary. (See Question 8.52.)

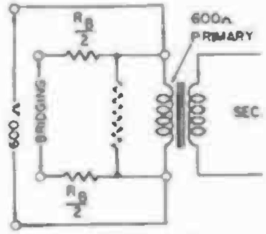
8.59 ***What is an interstage transformer?***—A transformer designed to couple the plate circuit of one vacuum tube to the grid circuit of another. It may be designed to couple either single-ended or push-pull stages.

8.60 ***What is an output transformer?***—A transformer used to transfer the power of an output stage to an external circuit. The primary is of higher impedance than the secondary because it must couple the high impedance of the tube plate circuits to a lower impedance. Output transformers have but one purpose—to transfer the power developed in the plate circuit by the vacuum tubes to an external circuit, without frequency discrimination or excessive power losses. A well-designed output transformer will have similar frequency characteristics, within plus or minus 1 dB, at both high- and low-level power outputs. The insertion loss must be negligible. This is particularly true if a considerable amount of power is to be transmitted.

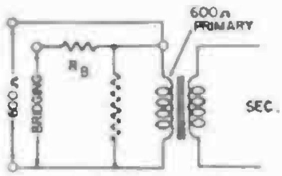
8.61 ***What is a modulation transformer?***—A transformer used for coupling a modulator tube in a radio transmitter to the tubes to be modulated. Such transformers have numerous taps to secure a proper impedance match between the two circuits.

8.62 ***What is a bridging transformer?***—A special transformer with a high-impedance primary designed to be operated from a low source impedance. Many amplifiers used in recording systems and broadcasting make use of bridging transformers, as these transformers permit several amplifiers to be connected across a line without upsetting the impedance match of other equipment. Bridging amplifiers are described in Question 12.87.

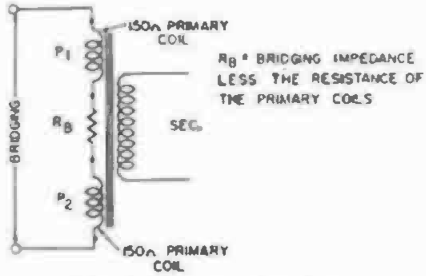
8.63 ***Can a transformer with a high-impedance primary be used for bridging purposes?***—No, uot as a rule. Bridging transformers are of special design. However, a transformer with a low-impedance primary may often be converted for bridging use by the addition of resistors as shown in Fig. 8-63. In part (a) of Fig. 8-63 two resistors R_B have been added in series with a 600-ohm primary, to raise the input impedance to the desired bridging impedance. In part (b) of Fig. 8-63 the same method has been used, except the circuit is unbalanced. In part (c) of Fig. 8-63, resistor R_B has been connected in series witb the return of a split-primary transformer. In this case the transformer may only be used for bridging purposes. Transformers converted to bridging inputs, as shown, will



(a) *Balanced.*



(b) *Unbalanced.*



(c) *Center-tapped primary.*

Fig. 8-63. Methods of converting low-impedance transformers to bridging inputs.

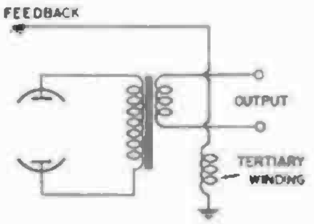
show a considerable insertion loss because of the resistance R_B in series with the windings. This loss will vary depending on the impedance ratio of the transformer and the value of the resistors. Transformers designed expressly for bridging service do not as a rule make use of resistors.

It may be necessary when using a transformer with a 600-ohm primary for bridging purposes to add an additional resistor in shunt with the primary winding as shown by the dotted line resistor in parts (a) and (b) of Fig. 8-63, to preserve the frequency response of the coil. The addition of this shunt resistor will increase the insertion loss of the transformer as a whole, the amount depending on the impedance ratio between the bridging source and the impedance of the transformer primary.

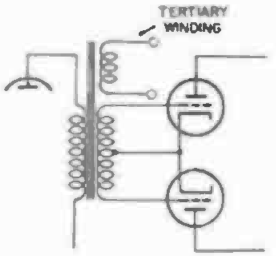
The three resistors, in the case of parts (a) and (b), form a bridging pad. The loss may be computed as described in Question 5.54.

8.64 ***What are the standard bridging input impedances used in the sound recording industry?***—7500, 10,000, 25,000, and 30,000 ohms.

8.65 ***What is a tertiary winding?***—It is a third winding on a transformer. In an output transformer it is generally used for obtaining a negative feedback



(a) *Negative feedback.*



(b) *Interstage transformer.*

Fig. 8-65. Tertiary windings.

voltage. In an interstage transformer, it is used to feed auxiliary equipment, as shown in Fig. 8-65.

8.66 ***What is a hybrid coil?***—A coil consisting of two or more windings, and used in telephone circuits, sound mixers, and test equipment. The geometrics of the coil design are such that the signal can only be transmitted in a given direction when the coil is properly terminated. A typical hybrid coil is shown in Fig. 8-66A. It will be noted the signal can only be transmitted between Z_1 and Z_4, and Z_2 and Z_4. When Z_1, Z_2, and Z_4 are terminated in their proper load impedances and two signals are applied simultaneously to Z_1 and Z_2, the signals do not react on each other and can only be transmitted in the direction of Z_4.

If a voltage is applied to Z_1 and Z_3 (plus-minus to C) by induction, a voltage is developed across Z_2. When Z_3 (a resistance) is adjusted to its correct value, the voltage developed across Z_3 will be *equal* to that developed *across* Z_2, *but of opposite polarity*. Since these two voltages are in *opposition*, the volt-

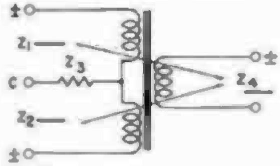


Fig. 8-66A. Conventional hybrid coil.

age applied to Z_1 will be *cancelled* and will not appear across Z_2. Normal transformer action occurs between Z_1 and Z_4, therefore the voltage applied to Z_1 appears across Z_4; the same holds true for a voltage applied to Z_2.

The electrical balance and isolation in a hybrid coil changes somewhat with frequency, the greatest unbalance occurring above 5000 Hz. This causes low-level mixing of the two signals applied to Z_1 and Z_2, and results in *low-level intermodulation*. As a rule, a well designed hybrid coil will indicate a balanced condition of 45 dB, or better, from 30 to 10,000 Hz. (See Ques. 23.72.)

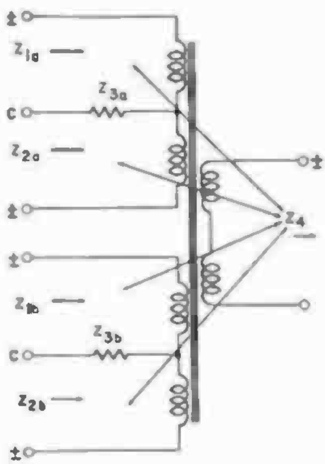

Fig. 8-66C. Sound-mixer hybrid coil.

If a signal voltage is applied to Z_4, it will be transmitted to both Z_1 and Z_2, but *not* to Z_3. The load terminators for Z_1, Z_2, and Z_4 are rather critical, as is the adjustment of the Z_3 resistor.

In Fig. 8-66B is shown how hybrid coils are employed in the telephone industry to permit a single line to be used for two-way conversation. It is the practice to use two amplifiers to make up a repeater station, one amplifier providing amplification in one direction and the second in the opposite direction. When the lines are properly terminated and the balancing networks adjusted, both amplifiers may be used without producing a howl or singing.

The sum of the gains of the two amplifiers must always be less than the sum of the losses across the two hybrid coils to prevent unbalance and singing. For telephone transmission the frequency bandwidth is limited to frequencies between 200 and 3000 Hz. Filters are employed to prevent singing at frequencies outside this band. The balancing networks consist of a resistance and a capacitor connected in series across one pair of terminals of the hybrid coil. In some instances an inductance is employed.

The action of a hybrid coil is somewhat similar to a Wheatstone bridge circuit as described in Question 22.21.

The hybrid coil shown in Fig. 8-66C is typical of such a coil used in sound mixer networks designed for rerecording purposes.

Inputs Z_{1a} to Z_{2b} are connected to the mixer controls. Winding Z_4 feeds equipment following the coil. Resistors Z_{3a} and Z_{3b} are the same as for the coil shown in Fig. 8-66A.

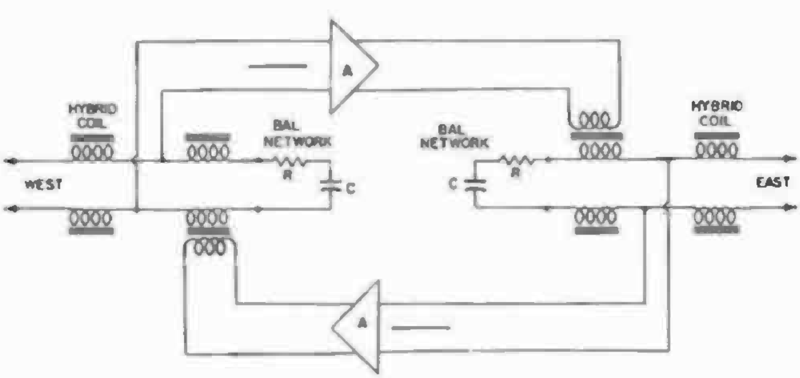

Fig. 8-66B. Hybrid coils used in a telephone-repeater station to permit using a single pair transmission line for East-West conversation.

Sound mixers using hybrid coil design are discussed in Question 9.23.

8.67 ***What are the transmission losses between the windings of a conventional hybrid coil?***—Refer to Fig. 8-66A.

Z_1 to Z_4 — 3 dB	Z_2 to Z_3 — 3 dB
Z_1 to Z_3 — 3 dB	Z_3 to Z_4 Infinite
Z_2 to Z_4 — 3 dB	Z_1 to Z_2 Infinite
Z_4 to Z_3 Infinite	Z_4 to Z_1, Z_2 — 3 dB

The losses given are ideal and will vary somewhat in a practical transformer. Losses between coils, given as infinite, in a practical transformer are approximately 45 to 60 dB. Other losses given are approximately correct.

8.68 ***What is the formula for calculating the balancing resistor Z_3 in a hybrid coil?***—For a mixer hybrid coil:

$$Z_3 = \frac{Z_1(N-1)}{2}$$

where,
- Z_1 equals the input impedance,
- N equals the total number of inputs,
- Z_3 is a noninductive balancing resistor.

8.69 ***How is the insertion loss of a hybrid coil calculated?***

$$dB = 10 \operatorname{Log}_{10} N$$

where,
- N is the total number of inputs.

8.70 ***What is the impedance ratio of each primary to the secondary in a hybrid coil?***

$$Z_r = \frac{2Z_1}{R_L}$$

where,
- Z_1 equals the input impedance,
- R_L equals the secondary load impedance.

8.71 ***What is trans-hybrid loss?***—The degree of isolation provided by the windings of a hybrid coil between the send and receive windings. For a perfectly balanced hybrid coil, this is infinite. However, in practice, this is generally not true as some leakage exists and is particularly noticeable at the high frequencies. Trans-hybrid loss is measured in decibels using a reference level of one milliwatt. The balancing of hybrid coils is discussed in Question 23.72.

8.72 ***Describe a method of measuring the "Q" of a coil.***—Using the circuit of Fig. 8-72 the "Q" of a coil may be easily measured for frequencies up to 1 MHz. Since the voltage across an inductance at resonance equals "QE" (where E is the voltage developed by the oscillator) it is necessary only to measure the output voltage from the oscillator and the voltage across the inductance.

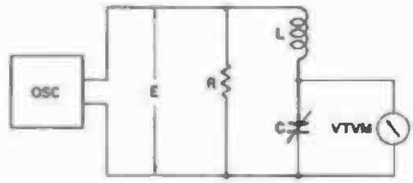

Fig. 8-72. Circuit for measuring the "Q" of a coil.

The voltage from the oscillator is introduced across a low value of resistance, R, about 1/100 of the anticipated radio-frequency resistance of the LC combination, to assure that the measurement will not be in error by more than 1 percent. For average measurements, resistor R will be on the order of 0.10 ohm. If the oscillator cannot be operated into an impedance of 0.10 ohm, a matching transformer may be employed. It is desirable to make C as large as convenient in order to minimize the ratio of the impedance looking from the vacuum-tube voltmeter to the impedance of the test circuit. The voltage across R is made small, an even value on the order of 0.10 volt. The LC circuit is then adjusted to resonate at the resultant voltage measured. The value of "Q" may then be equated:

$$Q = \frac{\text{Resonant Voltage Across C}}{\text{Voltage Across R}}$$

The "Q" of a coil may be approximated by the equation:

$$Q = \frac{2\pi fL}{R} \doteq \frac{X_L}{R}$$

where,
- F is the frequency,
- L is the inductance,
- R is the dc resistance (as measured by an ohmmeter),
- X_L is the inductive reactance of the coil.

8.73 ***What factors affect the Q of a coil?***—The principal factors are frequency, inductance, dc resistance, inductive reactance, and the type of winding. Other factors are the core losses, distributed capacity, and the permeability of the core material.

8.74 What does the term permeability mean?—It is a measure of the ease with which a magnetic material will pass lines of force. High-quality transformers, shields, and other electrical equipment use high-permeability magnetic iron made of various alloys.

8.75 What is the relationship of the turns of a coil to its inductance?—The inductance varies as the square of the turns.

8.76 What effect does a shorted turn have on the inductance of a coil?—The inductance is decreased. In an audio transformer the frequency characteristic will be affected and the insertion loss increased.

8.77 What is the effect of inserting an iron core in a coil?—The inductance is increased; hence, its inductive reactance is increased.

8.78 What is a retard coil?—A choke coil. This is a term used in the telephone industry.

8.79 What is coupled impedance?—The effect produced in the primary of a transformer by the influence of the current flowing in the secondary windings.

8.80 What is meant by the term unity coupling?—If two coils are placed so that the lines of force from one coil cut all the windings of the second coil, it is said that unity coupling exists.

8.81 Why is an air gap used in the core of a choke coil?—To prevent the saturation of the core material with an attendant loss of inductance. Generally, the gap is of the order of a few thousandths of an inch.

8.82 If an air gap is induced in an existing choke, how is the inductance affected?—The inductance will be reduced.

8.83 What is a saturable reactor?—A device similar to a transformer in construction with a third control winding connected to a source of variable direct current. Increasing or decreasing the direct current through the control winding causes a change in the inductance of the coils on the core. In this manner, control of ac devices may be had by the application of direct current to the control winding.

8.84 What is meant by the term flywheel effect?—It is the effect noted in a tank circuit (resonant circuit) which will cause the circuit to continue to oscillate after the excitation voltage has been removed. The higher the Q of the tank circuit, the longer the oscillations will persist and the longer it will take to dissipate the energy and for the circuit to come to complete rest.

8.85 What is the incremental inductance of a coil?—When an alternating current is applied to a coil in which a given amount of direct current is flowing, the inductance will be increased by the superimposition of the alternating current. The inductance will increase (within limits) as the ac component becomes larger.

8.86 Can intermodulation distortion be induced in an audio transformer by the manner in which the core laminations are stacked?—Yes. The manner in which the core laminations are stacked can have quite an effect on the intermodulation distortion induced by a transformer. By the proper design of the coils, the method of stacking, and the use of grain-oriented steel, the intermodulation distortion can be reduced to a negligible amount.

8.87 How may an interstage transformer without a center tap be used for phase-splitting?—In the manner illustrated in Fig. 8-87. Two resistors R_1 and R_2 are connected across the secondary winding to provide the missing center tap. The terminating resistors are selected on the basis of the reflected impedance to the plate of the preceding tube, and the maximum value of resistance permissible for the grid circuit of the particular tube in use. Thus, if a transformer designed for an impedance ratio of 15,000 to 86,000 ohms is to be center-tapped, resistors should be selected which, when connected across the secondary, will not greatly affect the

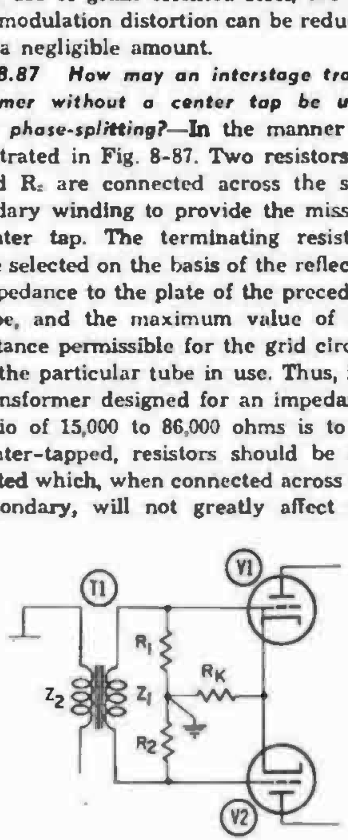

Fig. 8-87. Interstage transformer with resistors connected across the secondary to supply a center tap for push-pull operation.

taps on audio transformers.

where,

R_1 and R_2 are the terminating resistors,

Z_R is the impedance ratio of the transformer,

Z_p is the reflected impedance of the primary winding.

8.88 ***What is the equation for calculating the impedance between taps of a transformer?***—The unknown impedance Z_3, between taps on a transformer (Fig. 8-88A), may be calculated as follows:

$$Z_3 = Z_2\left(\sqrt{\frac{Z_1}{Z_2}} - 1\right)^2$$

$$\text{or } Z_3 = (\sqrt{Z_1} - \sqrt{Z_2})^2$$

where,

Z_3 is the unknown impedance,
Z_2 is the lower impedance tap,
Z_1 is the higher impedance tap.

As an example; assume it is desired to know the impedance (Z_3) between the 250- and 500-ohm taps on the transformer illustrated in Fig. 8-88A.

$$\begin{aligned} Z_3 &= 250\left(\sqrt{\frac{500}{250}} - 1\right)^2 \\ &= 250\,(\sqrt{2} - 1)^2 \\ &= 250\,(1.41 - 1)^2 \\ &= 250 \times .41^2 \\ &= 250 \times .1681 \\ &= 42\Omega \end{aligned}$$

Thus, the impedance between the 250- and 500-ohm taps is 42 ohms. A chart for determining the impedance between taps of a transformer without calculation is given in Fig. 8-88B. The known taps are plotted across the top and the left side of the chart. Assume it is desired to know the impedance between a 600-ohm and a 30-ohm tap. Entering the chart at 30 ohms at the left and reading to the right to the 600-ohm column the impedance is found to be 361 ohms. The square root of various impedances from 2 to 600 ohms is given at the foot of the chart for convenience when calculating an unknown impedance.

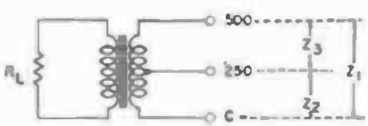

Fig. 8-88A. Transformer for example in Question 8.88.

In Fig. 8-88C is shown a typical output transformer with taps at 15, 250, 500, and 600 ohms, with the impedances between windings indicated, for ready reference.

8.89 ***How are the terminals of a transformer or a coil identified?***—Standard terminal terminology is used to identify the terminals. In Fig. 8-89A is shown the terminal markings used on a typical two-coil repeat coil or isolation transformer. An electrostatic shield is brought out to a separate terminal for connection to a transmission ground system. The core may be brought to a separate terminal or tied internally to the case, or in some instances, the core is left floating. In Fig. 8-89B is shown a coil or transformer employing a single primary center-tapped with multiple secondaries, two of which are center-tapped. The coils may be connected in series or in parallel depending on the impedance requirements.

In Fig. 8-89C is shown a coil consisting of a primary and a secondary with taps at various impedance points. In this design, the taps are unbalanced relative to ground; no center tap is provided.

Fig. 8-89D is that of a four-winding repeat coil. Each coil is identical with the others as to its turns, distributed capacity, inductance, dc resistance, and Q. The four coils are assembled in such a manner that the distributed capacity between them is at a minimum. The coils are generally connected hum-bucking. (See Question 8.98.)

A variety of impedance relations may be obtained by connecting the primaries in series or parallel and the secondaries in a similar manner. Coils of this type are generally cased in a multiple shield (see Question 8.51) to prevent pickup of noise or external magnetic fields. An electrostatic shield prevents the transfer of noise between windings while the signal currents are passed inductively.

The coil shown in Fig. 8-89E is a tapped choke or reactor with one terminal connected as a center tap.

8.90 ***How may the electrical polarity or phasing of transformer windings be established?***—By the use of the test circuit given in Fig. 8-90. Here an oscillator or a source of 60-Hz voltage is connected through a half-wave diode rectifier to the primary of the transformer to distort the waveform of the applied voltage. The oscilloscope is first connected to the primary and the attitude of the waveform is noted. The oscilloscope is then connected across each secondary winding and the attitude again noted.

If the waveform has the same attitude, it is of the same electrical polarity or in-phase with the primary wind-

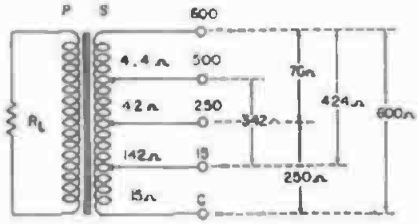

Fig. 8-88C. A typical output transformer with taps at 15, 250, 500, and 600 ohms. The in-between impedances are indicated for ready reference.

ing. If the attitude is reversed by 180 degrees, it is of opposite electrical polarity or 180 degrees *out of phase*. The in-phase terminals are marked plus-minus (±) for identification. This procedure may be used for identifying the polarity of either power or audio transformers.

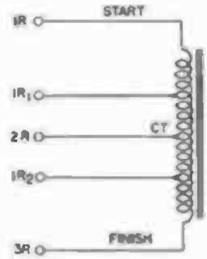

Fig. 8-89E. Center-tapped reactor.

8.91 ***What is the formula for calculating power transfer?***—A 6-volt generator with an internal impedance of 600 ohms connected to a load of 200 ohms is shown in Fig. 8-91A. Applying Ohm's law, the current is:

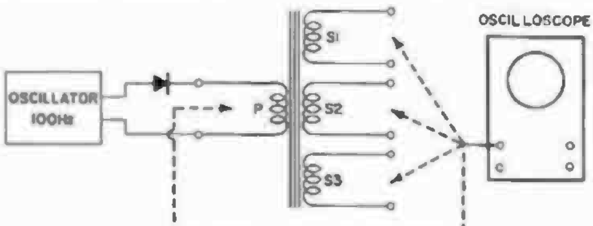

Fig. 8-90. Test circuit for identifying the electrical polarity or phasing of transformer windings.

$$I = \frac{E}{R}$$
$$= \frac{6}{600 + 200}$$
$$= 0.0075 \text{ amp}$$

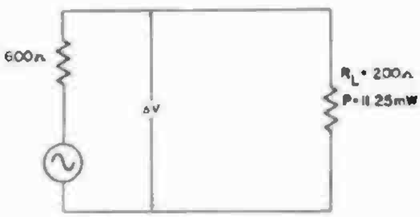

Fig. 8-91A. A 600-ohm generator working into a 200-ohm load.

The power delivered to the load may be calculated:

$$P = I^2R$$
$$= (0.0075)^2 \times 200$$
$$= 0.01125 \text{ or } 11.25 \text{ milliwatts}$$

In Fig. 8-91B the generator is connected to a load of 1000 ohms. The power delivered in this example is 14 milliwatts. In Fig. 8-91C the generator is connected to a load of 600 ohms which is equal to its internal impedance. Solving for I:

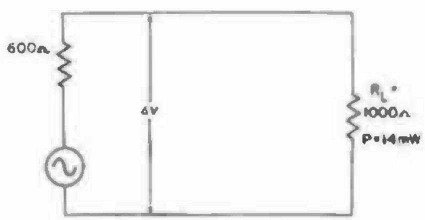

Fig. 8-91B. A 600-ohm generator working into a 1000-ohm load.

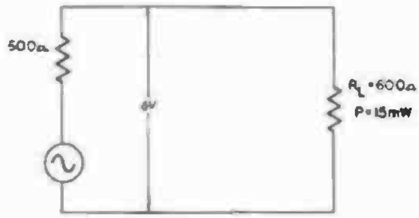

Fig. 8-91C. A 600-ohm generator working into a 600-ohm load.

$$I = \frac{E}{R}$$
$$= \frac{600}{1200}$$
$$= 0.005 \text{ amp}$$

$$P = I^2R$$
$$= (0.005)^2 \times 600$$
$$= 0.015 \text{ or } 15 \text{ milliwatts}$$

The same theory may be applied to a vacuum tube with the plate resistance of the tube acting as the generator impedance and the plate-load resistance acting as the load resistance.

Fig. 8-91D illustrates graphically the power-transfer characteristics of a generator terminated in loads varying from a lesser to a greater amount than the internal impedance of the generator.

At the point where the load resistance equals the internal impedance of the generator, a maximum transfer of power is effected.

8.92 ***What is a toroidal coil?***—This type of coil construction is explained in Questions 6.68 to 6.71.

8.93 ***What is a geoformer?***—A special type transformer designed for use with geophysical measuring equipment. The frequency range of such transformers is limited, generally to the

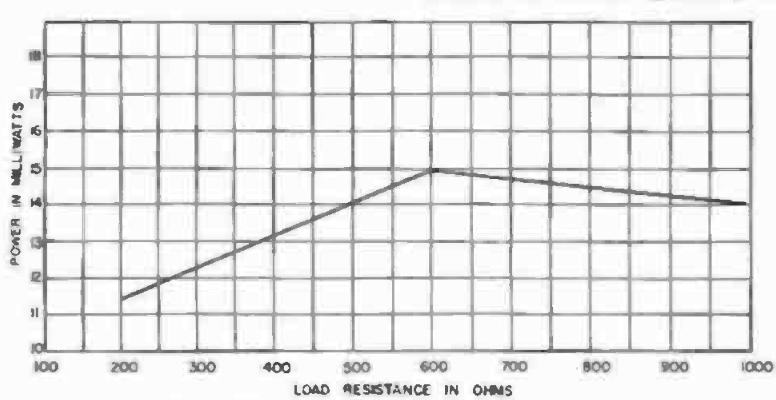

Fig. 8-91D. Power-transfer characteristics.

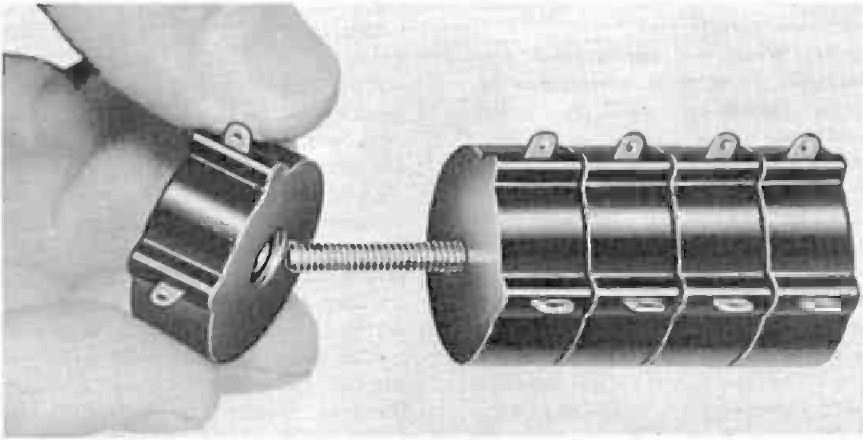

Fig. 8-94. Encapsulated toroidal coils. Because of their design, toroidal coils may be mounted one over the other without fear of intercoupling. Several encapsulated coils are shown using a single nonmagnetic machine screw ready for mounting.

range of 5 to 500 Hz, tapering off slowly after 500 Hz.

8.94 What Is an encapsulated coil?—A coil which after being wound is completely enclosed in a moulded plastic case as shown in Fig. 8-94.

8.95 What are the formulas for calculating the inductance of a single layer, spiral, and multilayer coils?—They may be calculated by the use of either Wheeler's or Nagaoka's formulas. The accuracy of the calculation will vary between one and five percent. Using Wheeler's formula for the single layer coil shown in part (a) of Fig. 8-95, the inductance may be calculated as follows:

$$L = \frac{B^2N^2}{9B + 10A} \text{ microhenries.}$$

For the multilayer coil in part (b) of Fig. 8-95,

$$L = \frac{.8B^2N^2}{6B + 9A + 10C} \text{ microhenries.}$$

For the spiral coil in part (c) of Fig. 8-95,

$$L = \frac{B^2N^2}{8B + 11C} \text{ microhenries,}$$

where,

N is the number of turns in the coil,
A is the length of the winding,
B is the radius of the winding,
C is the thickness of the winding.

8.96 What is a buck-boost transformer?—A transformer used in power-transmission work to increase or decrease the line voltage where a conventional transformer would be impractical or too costly. The connections for boosting the line voltage are shown in Fig. 8-96A and the connections for decreasing the line voltage are shown in Fig. 8-96B. It will be noted that, when reducing the line voltage, the secondary coil is connected to buck the line voltage, thus reducing it. The coils of the booster transformer must be capable of carrying the full-load current. For light loads, a filament or bell-

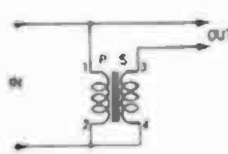

Fig. 8-96A. Booster transformer connections to increase line voltage.

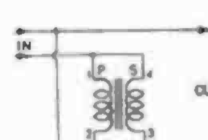

Fig. 8-96B. Booster transformer connections to buck line voltage.

ringing transformer may be used as a buck-boost transformer.

8.97 ***What are the general considerations given to a transformer regarding operating load?***—A power transformer shonld, if possible, be operated at about 90 percent of its normal rated load because the current in the secondary winding or windings will bring the voltage and the current in phase, reducing the phase angle, which results in a power factor closer to unity. The power factor of an ac circuit is the cosine of the phase angle, or the ratio of the true power to the apparent power. Therefore, it is desirable to keep the true power close to the apparent power to reduce excessive voltages and currents in the circuit.

A power transformer loaded to one-fifth its normal load-carrying capabilities can cause arcing and break down the insulation between layers of the coils. Under full-load conditions, the inductive reactance of the primary winding is almost completely cancelled by the opposing magnetizing force caused by the flow of current in the secondary windings. Thus, the phase angle between the true and apparent power is small and the power factor brought close to unity. As a rule, power transformers will show a power factor of 0.90 or more, with efficiencies of 95 percent when properly operated.

8.98 ***How is a hum-bucking audio transformer constructed?***—In modern high-gain amplifiers, the input transformer is generally required to work from a very low-level signal input. Under these conditions of high gain and a low-level signal, it is necessary to make use of specially designed input transformers which will not be affected by extraneous magnetic fields and strong electrostatic fields caused by switching circuits and radio transmissions.

Hum pickup may be reduced to a great extent by the design of the coils, core, and general construction of the transformer.

Two identical coils are wound on opposite legs of the transformer core. The direction of one of the coils is reversed from the other. The two coils are then connected in series by reversing their connections. This type connection does not cause bucking of any current generated by the windings. However, if any hum voltage is induced in the core from an outside source, such as through the chassis or from an adjacent transformer, this will in turn induce a hum voltage in the windings. With the transformer constructed as described, equal hum voltage is induced in the coils on each leg but one voltage will be 180° out of phase with the other, and thus be cancelled out. In addition to the winding construction described in the foregoing, the whole transformer is encased in a nested shield which further reduces the effect of extraneous magnetic fields. Nested shields are discussed in Question 8.51.

8.99 ***Describe how single-phase power may be converted to three-phase power operation.***—Several circuits have been developed for this purpose. The circuits to be described may be used for recording and reproducing equipment motor circuits, or for any other purpose where only a source of single-phase power is available and three-phase power is required.

The basic circuit used in the Westrex RA-1511-A converter, a nonrotating device devised for converting 115-volt

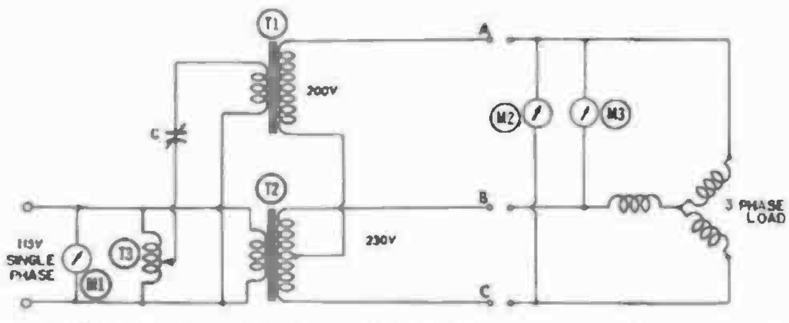

Fig. 8-99A. Basic circuit of Westrex RA-1511-A converter, used to convert single-phase power to three-phase power.

single-phase power to 230-volt three-phase power for driving camera motors, is shown in Fig. 8-99A. The circuit elements provide a means for correcting phase unbalance when motors are changed, and to compensate for changing load conditions.

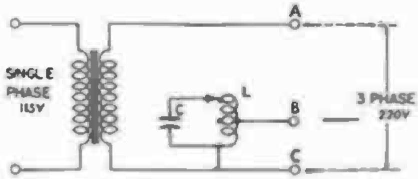

Fig. 8-99B. Schematic diagram showing how single-phase current may be converted to three-phase current by the use of a resonant circuit in the secondary circuit.

Basically, the circuit consists of a Scott transformer connection developed originally for the conversion of two-phase power to three-phase power. Using the circuit shown, the enrrent in the primary of transformer T1 is shifted 90 degrees with respect to the primary of transformer T2 by the connection of a capacitor C of the proper value in series with the primary of transformer T1. Thus, two-phase current is provided from a single-phase source. Three-phase current will only exist when the secondary sides of T1 and T2 are connected to an external three-phase inductive load, such as a motor.

The circuit is adjusted for a given set of load conditions by selecting a value of capacitance which will bring meters M2 and M3 to the same voltage reading (300 V), which is twice the line voltage read on meter M1 (150 V).

A continuously variable autotransformer T3, connected across the primary of transformer T1, permits the incoming line voltage to be adjusted to set the three-phase output voltage to its proper value. Voltmeters across the single- and three-phase voltage circuits permit the voltage to be monitored during actual operation.

In the commercial model, relays and switches are provided for protection to the capacitors and transformers in the event that trouble should develop in the load circuits.

In Fig. 8-99B is shown another circuit developed for converting single-phase current to three-phase current. In this circuit a parallel resonant circuit is connected in series with one leg of the developed three-phase current. This resonant circuit shifts the phase of the output current between 82 and 90 degrees, thus creating a third phase. For proper operation the frequency of the resonant circuit is adjusted under a given set of load conditions to provide the proper voltages to the external load circuits.

A third circuit, developed by William Ashworth, is given in Fig. 9-99C, and is suitable for driving 3-phase Y-connected motors of 1 to 3 horsepower. Here, one side of the single-phase power A is connected directly to phase A of the three-phase motor circuit. The initial current flowing from line B of the single-phase power source flows through a spring-loaded relay winding to phase B of the motor circuit closing the relay contacts and inserting start-

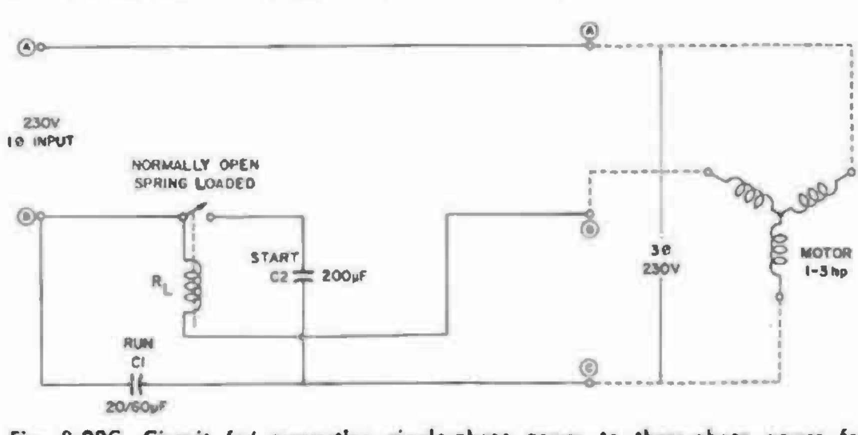

Fig. 8-99C. Circuit for converting single-phase power to three-phase power for motor circuits.

ing capacitor C2 into the circuit. This causes a reduction in the current flow through the relay winding. The spring-loaded action opens the contacts, disconnecting starting capacitor C2, leaving the relay winding connected in series with phase B. With the relay contacts open, running capacitor C1 is in the circuit creating a path from input line "B" of the single-phase, to phase C of the three-phase motor circuit.

Approximately 200 μF of starting capacitance is required, with 20 to 60 μF for the running capacitor C1, or about 20 μF per horsepower. An ammeter should be inserted in each leg of the motor circuit when it is operating under load conditions and the capacitance adjusted for equal current in the three legs.

The most critical part of this circuit is the relay, since its winding must be capable of carrying the motor current, and yet be able to open and close within the normal operating current range of the motor. In some instances the motor may not draw sufficient current when starting to actuate the relay, therefore the motor will not start. In this instance, some experimenting may be required to adjust the relay for the required balance between the starting and running currents. The described circuit will approximate a phase difference of 120 degrees between the three motor leads.

8.100 Describe the construction and operation of a constant-voltage transformer.—Constant-voltage transformers are special type transformers, containing voltage-regulating circuits, which automatically correct for line-voltage

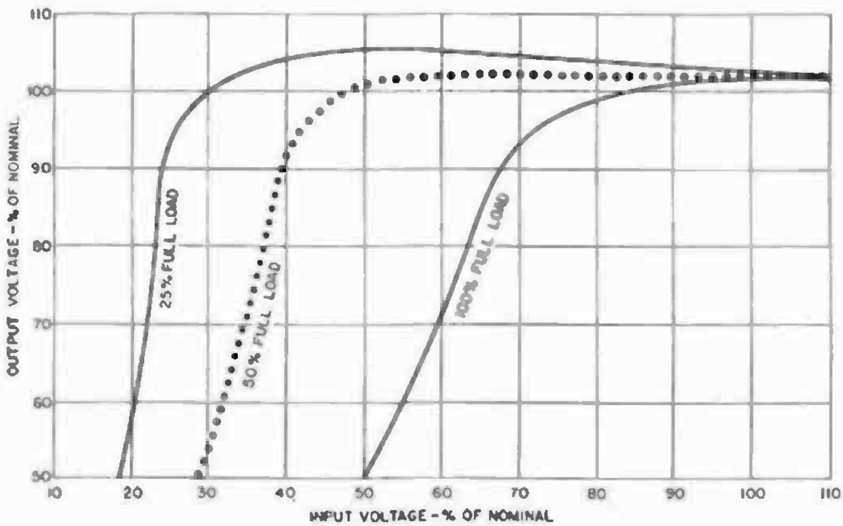

Fig. 8-100F. Characteristics for loads less than 100 percent.

changes, thus maintaining the load voltage constant. These transformers have no tubes or mechanical parts, and except for a slight hum, are noiseless. It should, however, be pointed out, these devices do have fairly strong magnetic fields and when installed, should be placed at some distance from equipment sensitive to such magnetic fields, *particularly magnetic-recording equipment.*

Constant-voltage transformers will be of interest to the audio engineer since many pieces of equipment in a sound installation require voltage regulation to within 1 percent of their normal operating voltages. Among these are transistor amplifiers, vacuum-tube heater and plate voltages, exciter lamps for optical film recorders, projectors, reproducers and similar devices. It is a well-known fact that when vacuum tube heater voltages are maintained within 1 percent, tube life is lengthened and the signal-to-noise ratio is increased. A model CVS constant-voltage transformer, manufactured by Sola Electric, is shown in Fig. 8-100A, and is typical of the type used for the above purposes.

Constant-voltage transformers by Sola are manufactured in two types, the *sinusoidal* type CVS and the *normal-harmonic* type CVN. Both transformers will regulate the output voltage to within 1 percent or less for a line voltage variation between 95 to 130 volts at the primary. The type CVN has about 14 percent THD and is used where line-frequency harmonics are of little consequence. Type CVS contains, besides the voltage regulating circuits, a harmonic-suppression circuit which reduces the internally generated harmonics to 1.5 to 3 percent (depending on the load conditions). Since the basic principle of operation is the same for both type regulators, the normal harmonic type (CVN) will be discussed first.

Referring to Fig. 8-100B, the voltage-regulating circuit involves the use of three coils, a primary (1), compensating winding (3), and a resonant winding (2), connected in parallel with a capacitor (C). A cross-sectional view of the internal construction appears in Fig. 8-100C. Primary winding (1) and compensating coil (3) are layer wound one over the other on part (A), of the center leg of the core. Resonant winding (2) is wound on part (B) of the same leg, but isolated from the primary and compensating winding by a magnetic shunt.

When an alternating current of low voltage is impressed across the primary winding, the resulting magnetic flux,

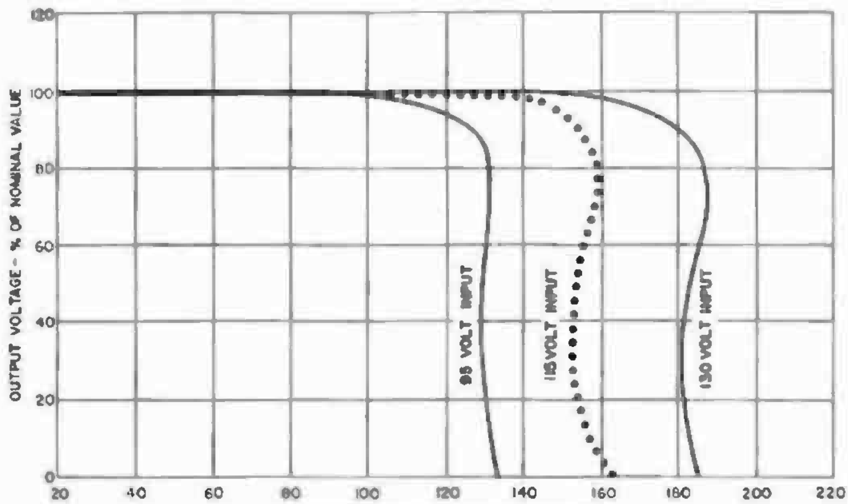

Fig. 8-100G. Effect of increasing the load on the output voltage for Sola constant-voltage transformer.

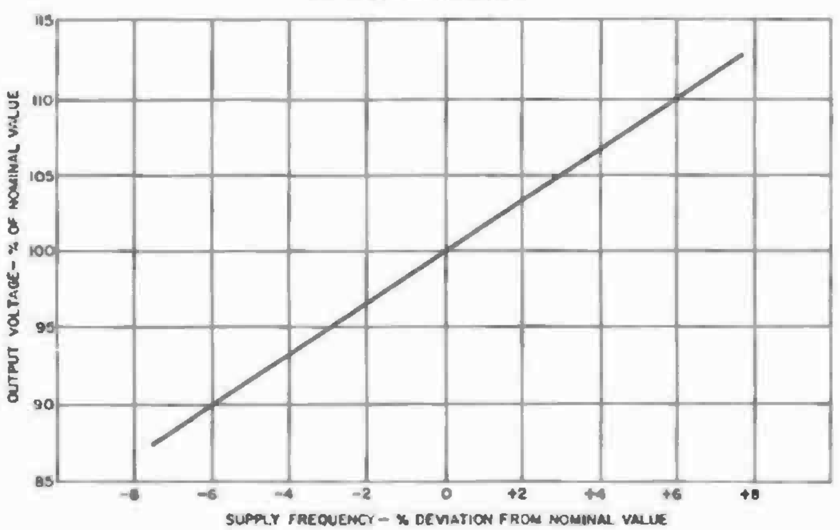

Fig. 8-100H. Effect of frequency on normal output voltage.

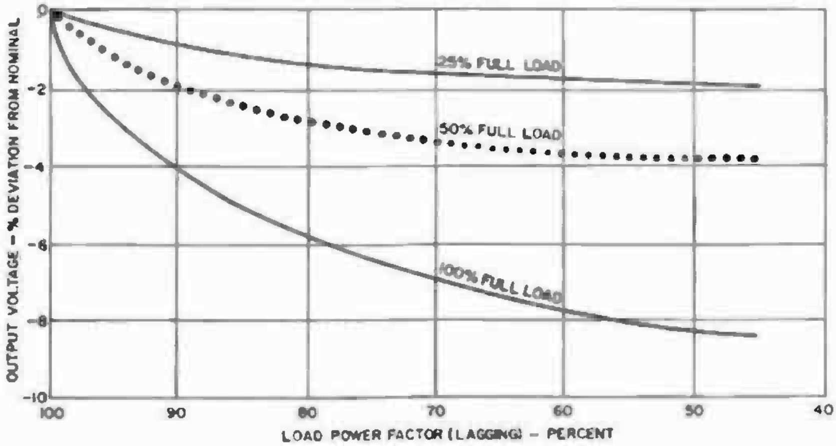

Fig. 8-100I. Effect of the change in median voltage level with changes in load and load power factor.

induces a voltage in winding (2). Because of the reluctance of the air-gaps in the shunt path, this voltage roughly approximates the turn-ratio voltage. As the voltage across the primary is increased, more flux threads through part B of the core structure. When this flux density becomes such that the inductive reactance of winding (2) approaches the value of the capacitive reactance of C at the frequency of the exciting voltage, this circuit becomes resonant and the voltage appearing across winding (2) rises rapidly to a stable, predetermined value which is higher than the calculated turn-ratio voltage. This has the effect of increasing the magnetic density in that portion of the magnetic circuit on which the resonant winding is wound (part B), and of greatly reducing the relative reluctance of the shunt system so that subsequent variations in flux, produced by changes in the primary circuit, are largely absorbed by the shunt system, and the voltage change in the resonant circuit is small. It remains only to compensate for this small change, and that is accomplished by winding (3).

The shunt system also operates to loosen the effective coupling between the resonant circuit and the primary winding so that once resonance is attained, the primary is required to supply only enough energy to overcome the iron and copper losses of the system in order to maintain the oscillation at no load.

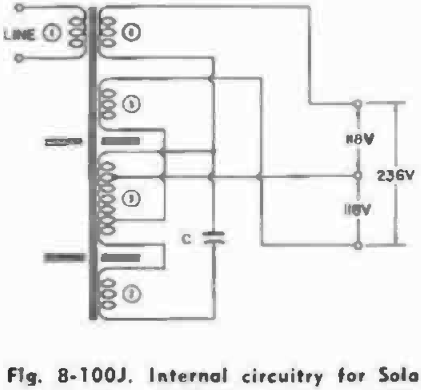

Fig. 8-100J. Internal circuitry for Sola Electric Company three-wire, constant-voltage transformer.

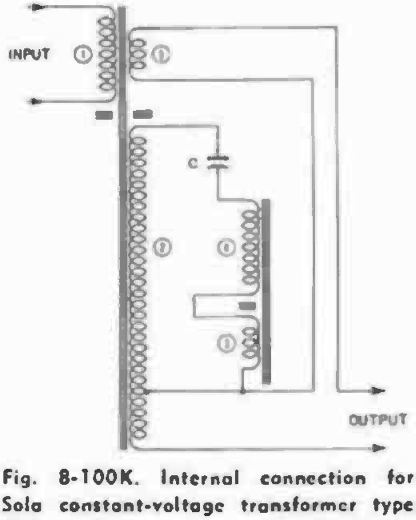

Fig. 8-100K. Internal connection for Sola constant-voltage transformer type CVS, with harmonic-neutralizing circuit.

Since the voltage across winding (2) is stable once resonance is attained, it may be used as a basis of constant-output voltage of the transformer. The output voltage is obtained by tapping across a portion (or all) of the resonant winding coil (2), Fig. 8-100B, or from an additional winding (4), wound over the resonant circuit (Fig. 8-100D). In either case, the compensating winding (3) is connected in series with the output load opposed to it. When this winding is so proportioned that the change in voltage induced by a change in primary voltage is roughly equal to the change appearing in the output, the resultant output voltage remains constant and independent of the voltage variation in the primary circuit.

Once resonance has been established in winding (2), the balance between the magnetic flux in part (A) and (B) of the core is maintained by the buffer action of the magnetic shunt system. Therefore, any load applied to a winding on part (B) will result in a passage of greater amount of useful flux through (B) from (A), exactly compensating for the energy consumed, and at the same time maintaining the oscillation of the circuit (2). The transformer then delivers regulated voltage within its rated capacity.

A regulation curve of 1-percent output voltage is shown in Fig. 8-100E, with regulating curves for loads less than 100 percent shown in Fig. 8-100F. The graph in Fig. 8-100G gives the effect of increasing the load and its effect on output voltage. The effect of changing frequency on a normal output voltage is shown in Fig. 8-100H. The effect of changes in the load power is given in Fig. 8-100I. The circuitry for a 3-wire constant-voltage transformer is shown in Fig. 8-100J. This transformer will supply the same regulation for the following conditions: from the 236-volt terminals alone, from either of the 118-volt legs, from a combination of the 236-volt and 118-volt loads, or from unbalanced 118-volt loads.

Voltage regulation may be obtained from loads other than unity power factor; however, only at the expense of lower output voltage. If the lower voltage under the lagging power factor is objectionable, correction may be made with capacitors connected at the load, or by means of the buck-boost transformer described in Question 8.96. The efficiency of these transformers is on the order of 75 to 90 percent. Power-factor correction is discussed in Questions 3.58 to 3.60. As a rule, constant-voltage transformers are *not* used on motor circuits supplying sound recording and reproducing equipment.

Voltage-regulating transformers of the CVS type, have 1 to 3 percent harmonic distortion, compared to 14 to 20 percent for the standard CVN type. To reduce such distortion, a harmonic-neutralizing circuit (Fig. 8-100K) is used. The primary coil (1), resonant circuit winding (2), buck-coil (5), capacitor (C), and the main core structure all function in the same manner as described for the CVN. Coils (3) and (4) of the neutralizer circuit are wound at opposite ends of the common core, and separated by a high reluctance magnetic shunt. The neutralizer assembly is connected into the resonant circuit, as most of the distortion (third harmonic) is generated in the particular portion of the electromagnetic circuit.

Coil (4) in series with the resonant circuit, when considered alone, will have *three times* the impedance for third harmonic currents as for the fundamental frequency. It thus offers considerable filtering action by its mere presence. The neutralizer circuit also reduces smaller harmonics, consisting of 5th, 7th and higher odd harmonics. Coil (3) connected in parallel with one section of the resonant winding (2), develops voltages proportional to all unwanted harmonics by the selection of a suitable winding and proper polarities. Since the above voltage-regulating transformer isolates the load portion of the circuit from the main ac source, a *separate* ground must be supplied. This is often a distinct advantage for eliminating heavy ground currents.

8.101 What precautions should be observed when using constant-voltage transformers?—They should be installed at least 50 to 100 feet distant from amplifier equipment having a considerable amount of gain. This is particularly true for photocell and microphone preamplifiers. Magnetic recording and reproducing equipment due to its nature should not be placed within less than 50 feet of such transformers, and farther if practical. Voltage readings at the load side must be made using either a *dynamometer* or *thermocouple*-type meter (such as a Weston-662). *Rectifier-type meters or vacuum-tube voltmeters should not be used, as the readings may vary several volts,* depending on the percent harmonic distortion of the voltage. It is possible for a vacuum-tube voltmeter to read 120 to 127 volts for an actual voltage of 117 volts. (See Question 22.103.)

The change in output voltage resulting from a resistive load is usually small, running to less than 1 percent. The power-factor will cause the output voltage to vary from the normal rating of the transformer if the load circuit has a power-factor other than that specified on the transformer data plate. Load regulation will also be relatively greater as the inductive load power factor is decreased.

8.102 Can constant-voltage transformers be connected in tandem to improve regulation?—Yes. However, when two units are connected in tandem, the output of the second unit will show little or no detectable change arising from supply-line variations up to about 15 percent. Cascade or tandem operation is recommended for special applications where the regulation must be in the region of 0.25 percent.

Operating sinusoidal voltage transformers in tandem may increase the harmonic distortion up to about 5 percent. Also, the transformers become more frequency sensitive because of the two resonant circuits, one in each transformer. This alone can cause about 0.25-percent variation in regulation. The first, or driver, transformer must be slightly larger in capacity to overcome the losses of the driven unit. The first transformer may be of the nonsinusoidal type, and the second a sinusoidal type if necessary.

8.103 Can constant-voltage transformers be connected in parallel?—If the transformers are of the same voltage rating and capacity, the primaries or secondaries may be connected in parallel to obtain a greater power output. However, regulation may suffer.

8.104 Describe an electromechanical voltage regulator.—Electromechanical line-voltage regulators combine the power-handling capabilities of a motor-driven variable autotransformer with the fast response and accuracy of an electronic feedback loop. This type regulator introduces no harmonic distor-

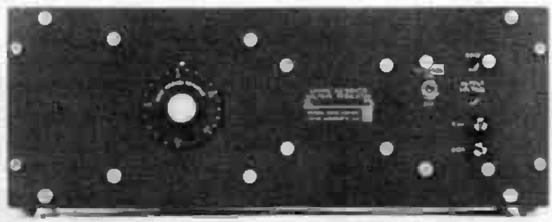

Fig. 8-104A. General Radio Co. Model 1581-A electromechanical voltage regulator.

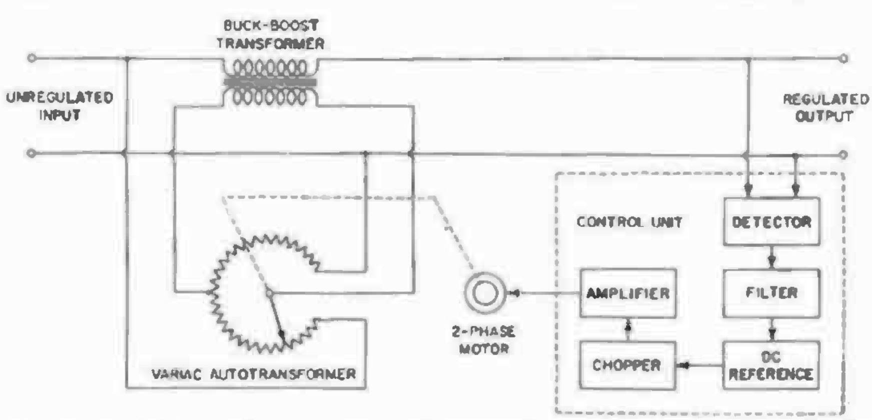

Fig. 8-104B. Block diagram of the electromechanical voltage regulator Model 1581-A manufactured by the General Radio Co.

tion, and is totally unaffected by changes in load power factor, from zero leading, to zero lagging, and is insensitive to load currents. With proper design it can hold the output voltage constant with wide swings of line frequency, a factor most important in the regulation of voltage from portable and emergency generators. It is well suited for applications involving heavy starting currents and can withstand overloads up to 10 times the rated output current. Such regulators may be obtained with power-handling capabilities up to several kVA, for either single or three-phase operation. Such a voltage regulator is pictured in Fig. 8-104A, manufactured by the General Radio Co., with a block diagram of its circuitry shown in Fig. 8-104B. Voltage deviations at the output activate a servo-feedback loop consisting of a control unit, a two-phase motor, a Variac autotransformer, and a step-down buck-boost transformer. The deviation is thus translated into a correction voltage that is added to, or subtracted from, the input to bring the regulated voltage to the correct value. The solid-state control unit converts any small deviation in output voltage into a proportional electrical signal to drive the motor. The deviation is first sensed by an rms detector whose dc output, after filtering, is compared with a 9-volt reference voltage derived from a zener diode. The resultant difference voltage is chopped into an ac error signal, with a magnitude proportional to the output deviation; the phase is determined by the direction of the deviation.

The ac error voltage from the control unit drives the two-phase servo motor, with the phase and magnitude determining the direction of rotation and the motor speed. The motor drives the autotransformer through a gear train. Because the output voltage of the autotransformer is stepped down by the action of the buck-boost transformer, the full adjustment range of the autotransformer can be used to produce a relatively narrow range of control. Remote circuits are provided for connections to the load-line at some selected point. Thus, corrections are made for the voltage drop in the supply line.

Two screwdriver controls on the front panel provide for adjustment of the amplifier gain and output voltage. The dial indicates the percent difference between the input and output voltages and permits manual voltage adjustment ranges from 0.25 to 0.50 percent of the output voltage, with response speed of 20 to 160 volts per second, and a correction range of 82 to 124 percent, depending on the model.

Fig. 8-105B. Comparative grain arrangements. (Courtesy Westinghouse Electric and Manufacturing Co.)

8.105 Show the different type cores and laminations used in the construction of audio transformers. — Transformer laminations and cores are many and varied. It is the trend in the manufacture of high-quality audio transformers to use the "C" and "E" type, grain-oriented steel cores, as shown at parts (a) and (b) of Fig. 8-105A. The particular group of cores shown are manufactured by Arnold Engineering Co., and marketed under the trade name of *Silectron*. Grain-oriented steel is a cold-rolled grade of 3-percent silicon steel, manufactured by the Allegheny Ludlum Steel Corp. It has high-saturation flux density, lower core losses, and lower exciting volt-amperes than regular silicon steel. This high degree of orientation is preserved by the cutting of the core and the *gapless* construction. The steel strip is coated on both sides, which provides good interlamination resistance with a negligible effect on the space factor. The coated strip is slit to the proper width, and wound on a mandril to make a gapless core. The core is then annealed to relieve winding stresses, and cut to produce two core halves, with a highly polished surface. The effective air gap, when the surfaces are placed together, is 0.001 inch.

Similar cores manufactured by Westinghouse are known under the trade name of *Hipersil*. The magnetic properties of grain-oriented steel are achieved by the orientation of the steel crystals through rolling and heat treatment. Individual crystals line up with their edges essentially parallel to each other and parallel to the direction of the rolling sheets. Where crystals are oriented to all face in one direction, the steel has a much higher magnetic permeability in that direction than does steel with crystals pointing at random. Because of this arrangement of the crystals, grain-oriented steel requires a smaller external magnetizing force to produce a given flux than does unoriented steel. This results in a very high high-density permeability, high low-density permeability, high incremental permeability, and very low losses in the direction of the rolling. For comparative grain arrangement of ordinary silicon steel and grain-oriented silicon steel, refer to Fig. 8-105B. Each arrow represents the direction of easiest magnetization of the individual crystals forming the steel.

The "E" shaped cores at Fig. 8-105A, part (b) are used for shell-type transformers, where the coil is placed over the center leg. The "E" and "T" laminations shown in part (c) are used for both audio and power transformers. The powder core shown in part (d) is designed for two halves, one over the other, completely enclosing the coil. The toroidal core shown in part (e) supports the coil, which is shuttle wound around the core. The "C" and "E" cores are also used for pulse transformers and for 400- to 3000-Hz power transformers.

8.106 Describe a plug-in audio transformer.—Because of the small size of solid-state amplifiers, and the fact that they can be plugged into mounting trays, it has become necessary that audio transformers in some instances take the same form. Fig. 8-106 pictures such a transformer, manufactured by McCurdy Radio Industries Ltd, of Canada, designed in module form. The transformer is assembled using a contemporary dual glass-epoxy card design with gold-plated printed circuitry. Internal electrostatic shields are provided with a heavy external magnetic shield, to reduce pickup from stray magnetic fields. The transformer shown is a repeat coil, employing four windings, that may be connected for 150- or 600-ohms impedance.

8.107 How may three-phase loads be controlled using two variable autotransformers?—Two 120-volt autotransformers are connected in open-delta, as seen in Fig. 8-107. Maximum voltage

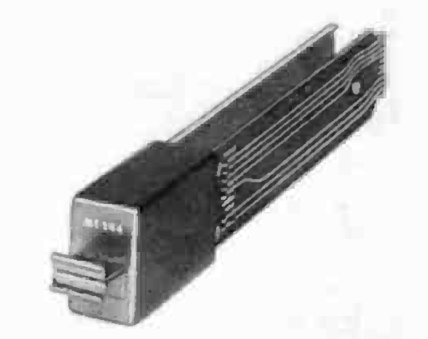

Fig. 8-106. Plug-in repeat coil manufactured by McCurdy Radio Industries Ltd. of Canada.

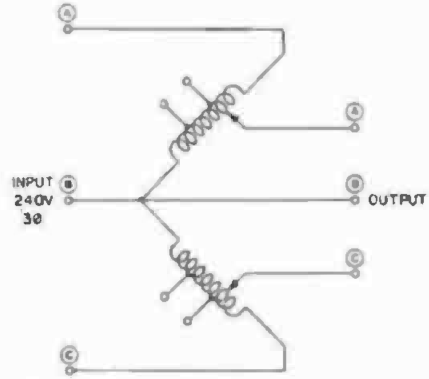

Fig. 8-107. Controlling a three-phase load using two 120-volt autotransformers connected open-delta.

attainable can be either the line voltage, or 17 percent above the line voltage by using the over-voltage connection. The load rating for a single unit is $\sqrt{3}$ or 1.732 times that of a single unit. If 240-volt autotransformers are used, an output voltage of more than double the supply voltage is possible, although the current and power ratings are halved.

8.108 How are three autotransformers connected for three-phase operation? —Three 120-volt autotransformers are wye-connected, as in Fig. 8-108. This connection is possible because the voltage from the line to neutral of the wye-connected assembly is the line voltage divided by the $\sqrt{3}$. Thus, in the case of the 240-volt three-phase line, the voltage across each unit will be 138 volts. Since each single unit is wound for 140 volts across the whole winding, three 120-volt units can be wye-connected if the over-voltage connection is omitted. Although the over-voltage connection cannot be used, the kVA is increased by the ratio of 138/120. The load rating of the wye-connected assembly is 3.47 times that of a single unit. Similarly, 240-volt units can be used on 480-volt three-phase lines.

8.109 Describe the construction of a unity-coupled driver transformer for a class-B transistor push-pull amplifier.— In Figs. 12-255 and 12-256, are shown two transistor amplifiers capable of producing 100 watts of audio power, with low distortion. To drive the output stages, a driver transformer of *low* turns ratio and *low* impedance, having as close to *unity* coupling between windings as possible, is required. To acquire such coupling, the primary and secondary windings must be wound *bifilar* style, that is—the wires must be wound parallel, or side-by-side. (See Question 5.16.) The primary is split into two or more coils and wound along with the secondaries. These windings are termed *bifilar*, *trifilar* and *pentafilar*, depending on the number of wires concerned.

A typical bifilar-wound transformer that may be used as the driver transformer for the amplifier of Fig. 12-255 is wound, using a split-primary bifilar wound with two secondaries. A 600-turn primary is first wound on a nylon bobbin with a ¾-inch square hole, using Number 30 enameled wire. Next,

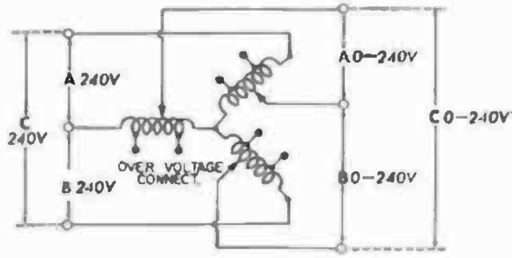

Fig. 8-108. Three 120-volt autotransformers connected for 240-volt, three-phase operation. The over-voltage connection cannot be used.

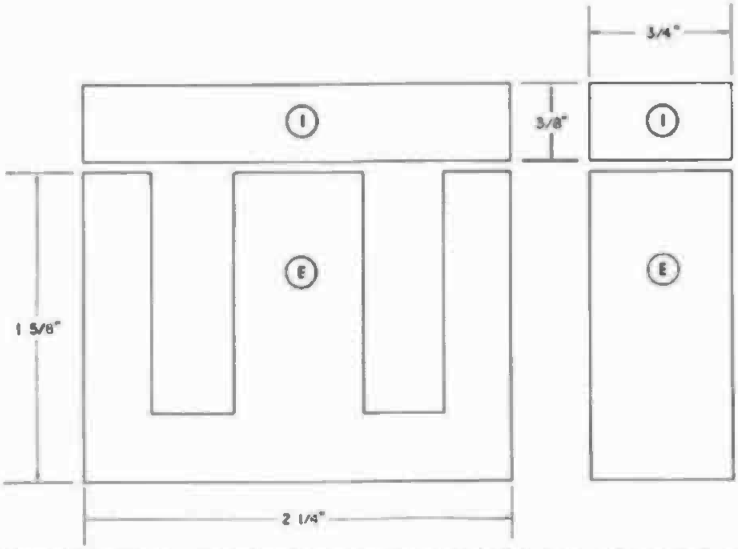

Fig. 8-109A. E and I core laminations used in class-B driver transformers for transistor power amplifier.

two secondaries are wound, using two simultaneous windings (bifilar) of Number 27 enameled wire for 200 turns. The primary is then continued by winding another 600 turns over the top of the other windings. The ends are brought out and the starts and endings indentified. The approximate dc resistance of the primary is 45 ohms, and of the secondaries, 3.3 ohms each. The core is made of EL-75, grade M-19 silicon steel "E" and "I" laminations, using a 1-mil air gap (see Fig. 8-109A). Enough laminations are used to fill the hole in the bobbin (¾-inch). This results in a transformer with a turns ratio of 6:1:1. In using the transformer, the proper polarities must be observed. This may be determined with the use of a compass and a dry cell, or as described in Question 8.90.

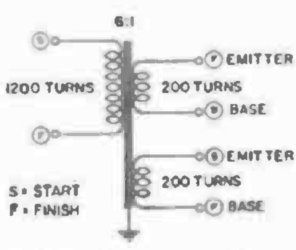

Fig. 8-109B. Driver transformer coil configuration for transistor class-B push-pull amplifier stages.

Section 9

Sound Mixers

The design of todays sophisticated mixing console is quite complex, due to the multiplicity of devices associated with the mixing network. Many will recall when paralleled battery rheostats were used as mixer controls for broadcasting and motion picture sound recording, and will view the modern console as an outgrowth of the basic principles applied at that time. With miniaturization, many components are now included in the mixer network, rather than at a remote position. Printed circuit plug-in designed components facilitate replacement in the event of failure. Any of the vacuum tube designs may be used with solid-state components, with certain considerations.

Several different type solid-state and vacuum-tube mixers are discussed. A twelve-position, three-section, four-bridging bus dubbing mixer is described, with its associated monitoring, talk-back, reverberation, and signal circuitry. Solid-state devices employed in mixing consoles are discussed in Section 12.

9.1 ***What is a sound mixer?***—A resistive network designed to provide a means of combining several separate audio signal sources into one composite signal. The signal sources may consist of dialogue, music, and sound effects. The sources of signal may be from a broadcast line, optical or magnetic film sound tracks, records, a live pickup, or any combination of these sources.

The network is designed so that changing the level of any one of the individual signal sources has no effect on the level or frequency characteristics of the other signal sources in the network. For broadcasting and recording purposes, at least six positions are required. For recording purposes, equalizers, filters, and other devices are included in the mixer console but do not form a part of the mixer network. A mixer console designed for recording and a-m and fm broadcasting is shown in Fig. 9-1.

9.2 ***What is low-level mixing?***—A mixing network similar to that shown in Fig. 9-2 which uses no amplification

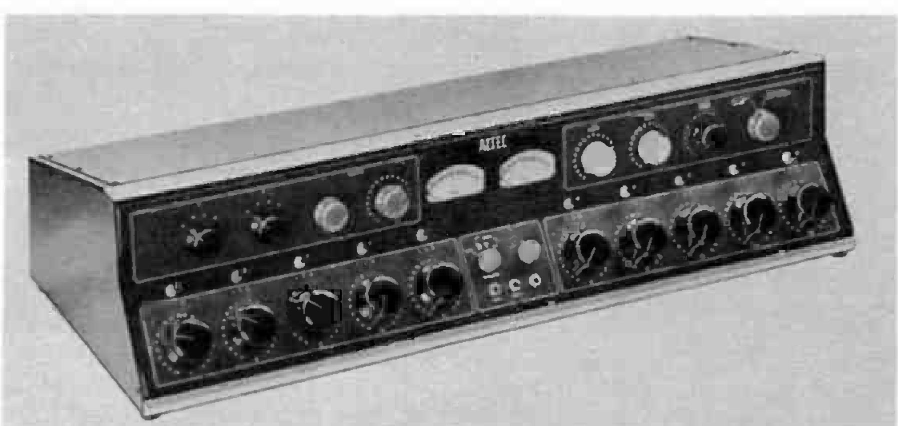

Fig. 9-1. Ten-position mixing console Model 250-SU, manufactured by Altec-Lansing.

between the signal source and the mixer control. The signal-to-noise ratio is low for this system and it is not used in professional installations. This method of mixing is now obsolete.

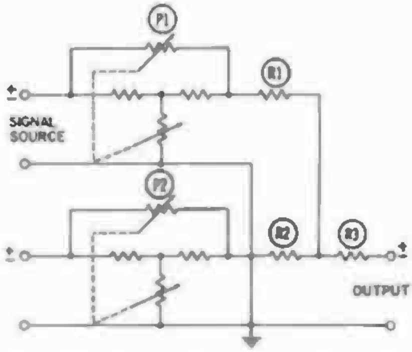

Fig. 9-2. Two-position low-level mixing network. Signal source is fed direct to mixer controls without amplication.

9.3 *What is high-level mixing?*—A mixing network which uses a preamplifier between the signal source and the mixer control as shown in Fig. 9-3. The advantage of high-level mixing is that the signal-to-noise ratio is increased in proportion to the gain of the preamplifier.

9.4 *What is the gain of the average mixer-preamplifier?*—About 40 to 60 dB. In some of the older installations a slight amount of equalization is included in the preamplifiers to compensate for microphone and recording-channel characteristics. However, in modern equipment this is the exception rather than the rule. Preamplifiers are designed to have uniform frequency characteristics from 20 to 20,000-Hz, within plus-minus 0.5 dB or less, with reference to 1000 Hz. This is true for both transistor and vacuum-tube types. Preamplifier design is discussed in Question 12.72.

9.5 *What are the principal components of a mixer console?*—Mixer networks consist of a group of variable controls, building-out resistors, a submaster and overall master control, and isolation coils or hybrid coils. In mixer networks specifically designed for motion picture rerecording, the network will also include low- and high-frequency attenuators (see Questions 6.80 and 6.81). For motion picture rerecording at least 8 mixer-control positions are required, and preferably 12. These are split into groups of four, with a submaster control for a given group of controls. A master control is sometimes included for fading all positions simultaneously; however, this is generally confined to broadcast-type mixer circuits. In addition to the mixer controls, the networks will include equalizer circuits operated by key switches or push buttons, which are not really a part of the mixer network, but are often included as a component part. A typical low-level mixer network is shown in Fig. 9-2, and a high-level mixing circuit is shown in Fig. 9-3.

The minimum requirements for a console might consist of the following components:

4 input circuits.
4 fixed attenuators to prevent overloading of microphone preamplifiers during the recording of high-level program material.
4 mixer controls, straight-line or rotary.

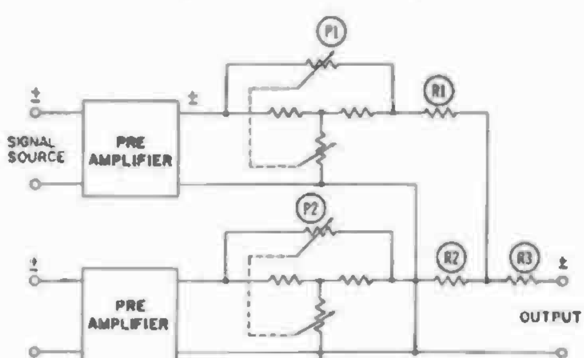

Fig. 9-3. Two-position high-level mixing network. Signal source is amplified then fed to the mixer control.

1 master control.
1 program equalizer (variable).
*1 graphic equalizer.
*1 compressor amplifier.
1 VU meter and attenuator.
* Intercommunication to other parts of the installation.
Monitor gain control.
Headphone jack and control.
Necessary amplifiers and attenuator networks.

*These items may be omitted; however, for good recording they should be included if possible. See Question 9.52.

9.6 *Describe the construction of typical recording and broadcast mixer consoles.*—A small six-position recording console, designed and built by RCA is pictured in Fig. 9-6A. The mixer network consists of two sections, each section containing three vertical ladder configuration mixer controls, and three graphic equalizers that may be connected into the mixer positions by means of push buttons. The outputs of the two mixer sections are combined in a hybrid coil. Two program equalizers, preamplifiers, compressor-limiter amplifiers, dB compression and VU meter, high- and low-pass filters complete the principal components. The system employs a single bridging bus. All amplifiers pertinent to the console are of the plug-in type, accessible at the rear of the console. Remote control for house lighting, ventilation and other functions of the studio are provided on a panel at the left end of the console. Two electrically driven footage counters mounted at the right, and operated from projection machines indicate the footage for both 16 and 35mm film. The operating levels shown on the block diagram of Fig. 9-6B are only approximate, and will vary with the type equipment and installation requirements. The monitor loudspeaker behind the screen is driven from a 40-watt power amplifier in the projection booth.

A mixer console, designed and manufactured by Altec-Lansing, for recording or a-m and fm broadcasting was shown in Fig. 9-1. The console contains 10 plug-in preamplifiers, 3 booster amplifiers, 3 program amplifiers (miniature plug-in), 10 mixer controls, along with the necessary networks, key-switches, and 2 VU meters with their auxiliary controls. The block diagram for this console appears in Fig. 9-6C. At the left are ten external input circuits, which may be from any source of sound, such as a turntable, magnetic tape recorder, telephone lines, microphones, etc. The output of each preamplifier is fed to a separate mixer control, then through combining networks, 3-position key switches, and to three bridging busses. The output circuitry provides for single (monophonic), two-channel stereo, or three-channel/two-channel operation.

Three-channel/two-channel operation consists of using the center position

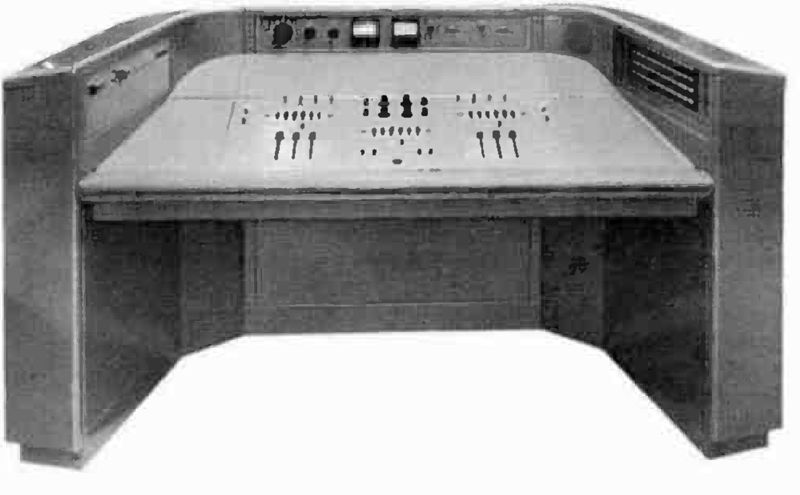

Fig. 9-6A. Small rerecording console which was designed and built by RCA for single track recording.

of the bus-selector key switch to feed a third, or center-channel, mixing bus. The output from this bus is amplified, then divided by means of a splitting pad and introduced into the left and right channels. For stereophonic use, this permits the vocal or dialogue to be picked up on a single microphone and evenly divided between the left and right channels. This reduces the need

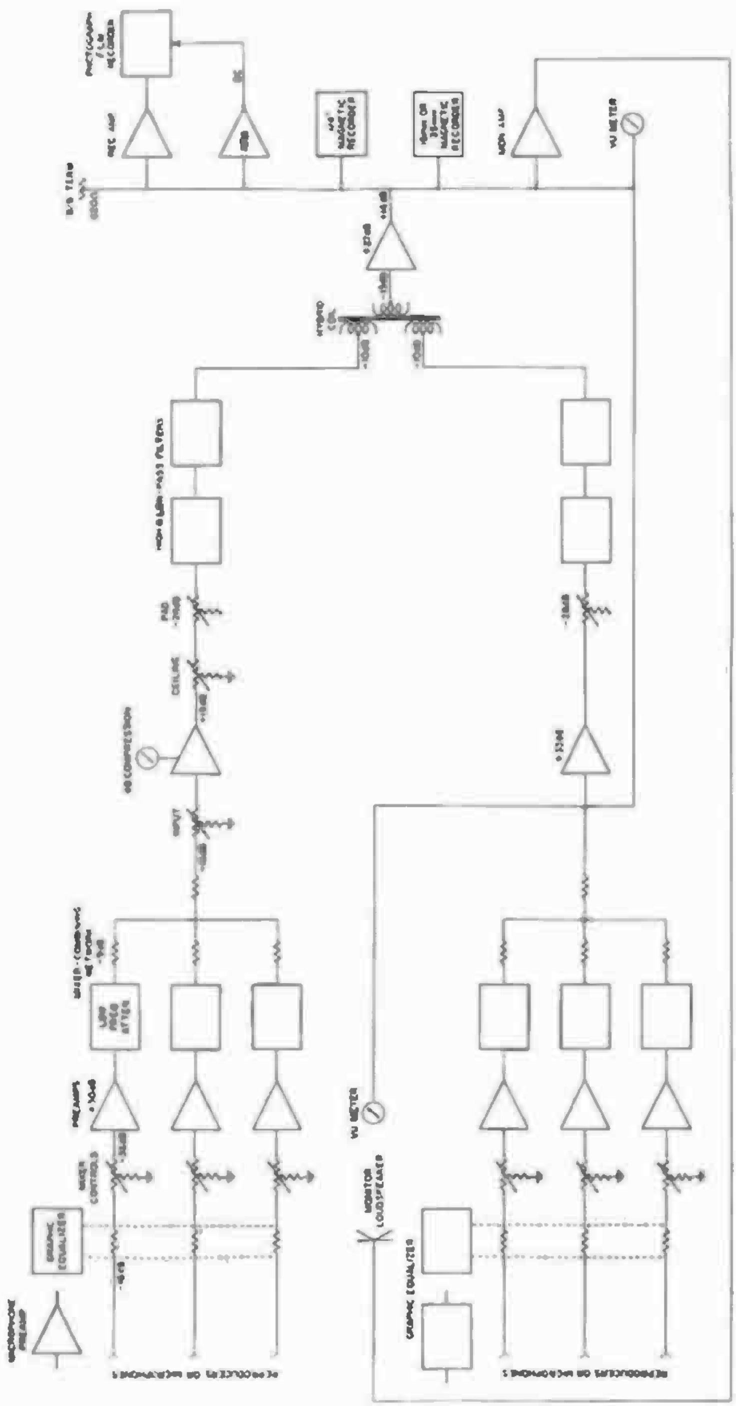

Fig. 9-6B. Block diagram and approximate operating levels for the mixing console which is shown in Fig. 9-6A.

for balancing and microphone matching. In this mode of operation, the variable equalizer is connected in the circuit for dialogue equalization (see Question 18.81). Provision is also made for splitting the center of the channel left and right for use in recording master tapes, where it is recorded on three channels, then reduced to two channels for release on disc or tape. Monitor am-

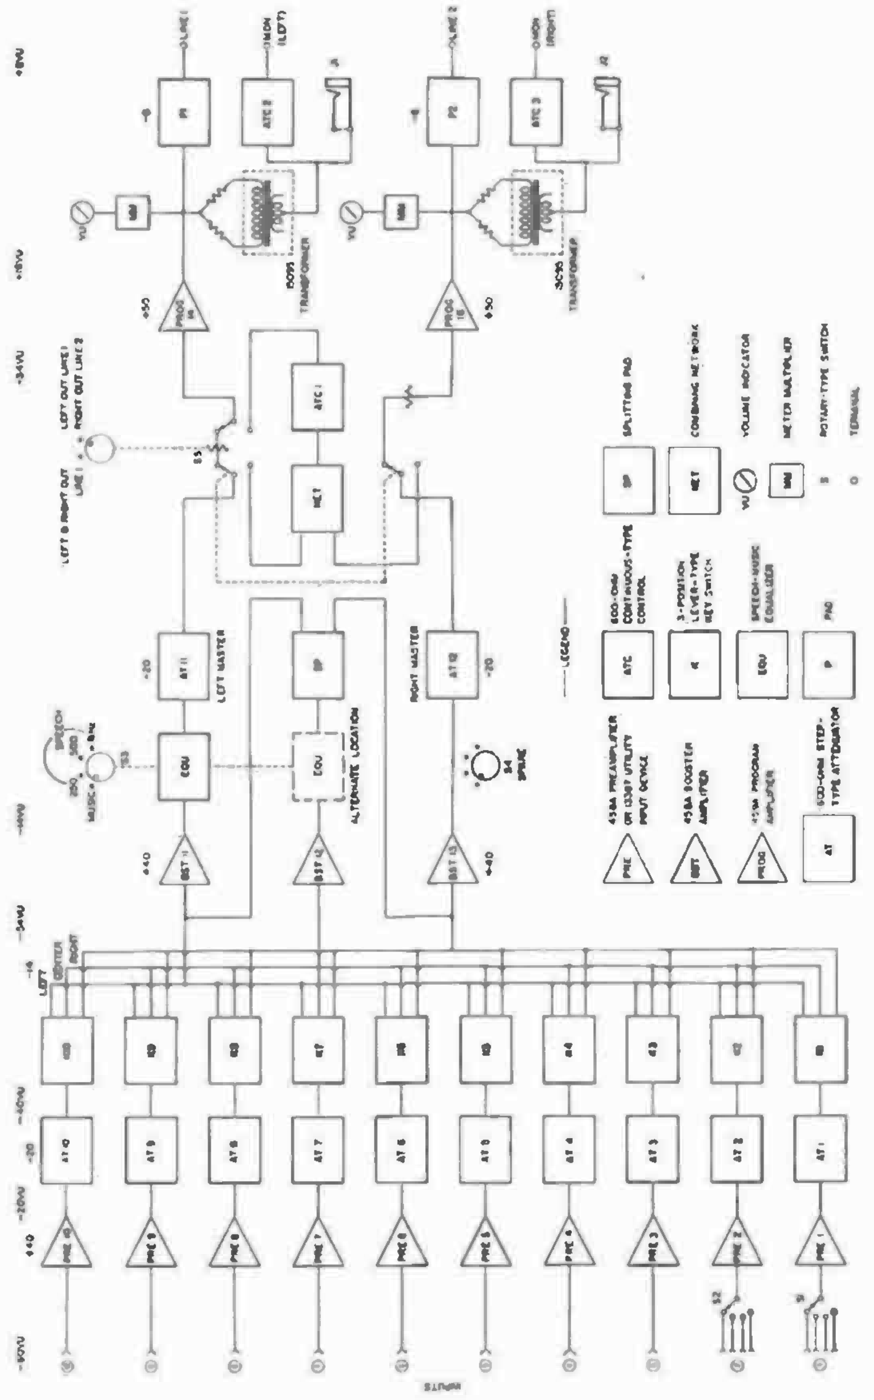

Fig. 9-6C. Block diagram for the Model 250-SU Altec-Lansing mixer console.

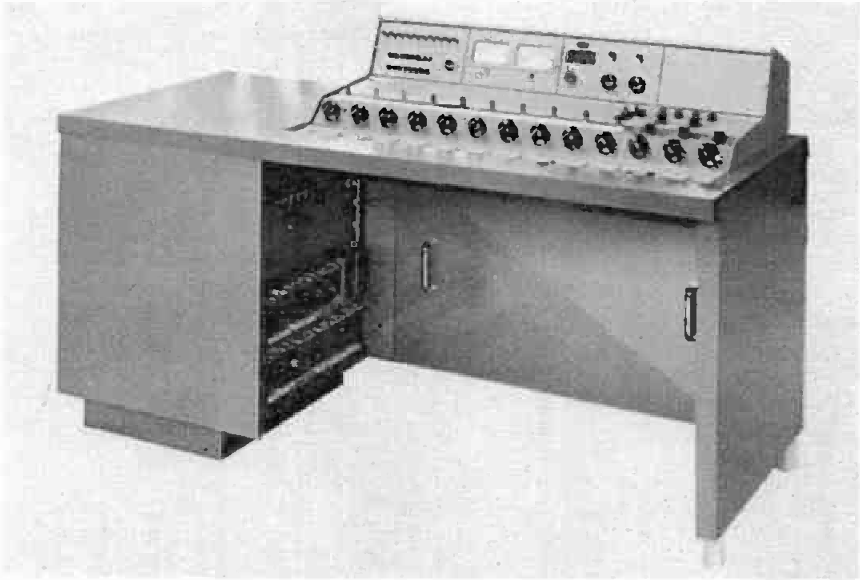

Fig. 9-6D. Ten-position mixing console Model SS4400 manufactured by McCurdy Radio Industries Ltd. Canada.

plifiers are not included in this console, since these items vary with the individual installations. A separate power supply provides the necessary plate and heater voltages. The frequency response is plus-minus 1 dB, 30 to 15,000 Hz. Distortion is 1.0 percent at plus 24 dB, signal-to-noise ratio, minus 70 dB referred to plus 18-dB output, with minus 50-dB input.

The Model SS4400 console, pictured in Fig. 9-6D, manufactured by McCurdy Radio Industries Ltd. (Canada), is designed for recording and a-m and fm broadcasting use. The basic circuit consists of 10 mixing positions (with cueing positions), solid-state preamplifiers, equalizers, VU meters, power supplies, module-type transformers, monitor amplifiers, and the necessary auxiliary controls. A total of thirty input circuits are provided, switchable to the 10 mixer positions, via the three-position key switches. After leaving the key switch, the signal is applied to a microphone preamplifier or a matching transformer. In addition to the thirty inputs, seven remote line inputs are available by push buttons, providing two switchable outputs that may be wired to any of the thirty input circuits. The ten mixer controls are ladder configuration, and feed 10 booster amplifiers. The mixer network outputs are selected by means of key switches for the two program busses. Two of the mixer circuits in-

Fig. 9-6E. Electrodyne Model ACC-1204 12-position mixing console.

corporate relays for remote control of the announcing microphone.

The two program channels employ line amplifiers to raise the level sufficiently to provide two output circuits at plus 18 dBm. Ten-dB pads are used between the output of the line amplifier and the output to provide a solid termination and isolation. An additional output is provided at each output for

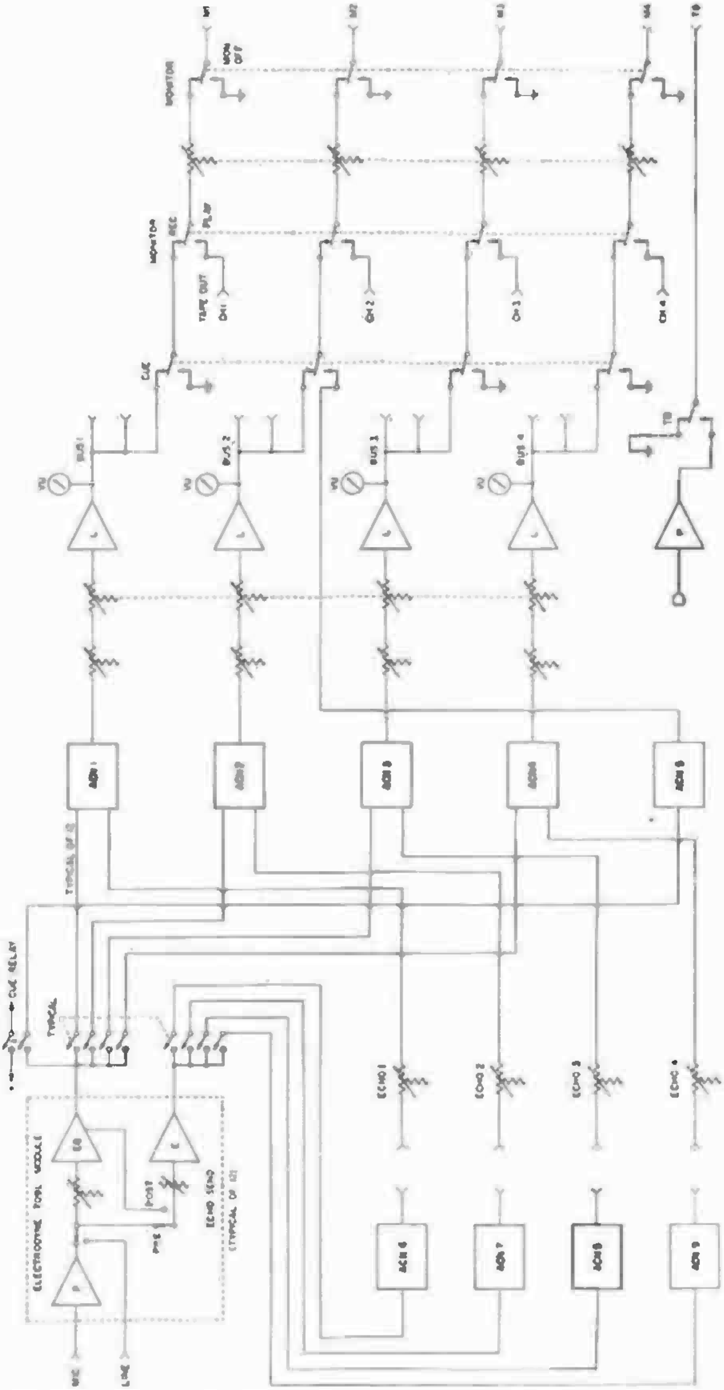

Fig. 9-6F. Block diagram for Electrodyne mixer console. This console was especially designed for use in recording phonograph records.

headphones. One VU meter is connected permanently across program amplifier 1, and the second may be switched to program channel 2 or across four auxiliary VU meter inputs for observing external program levels.

A complete talkback system is included, with push buttons for the selection of the console microphone, or inputs from announce turrets or remote cue and talkback circuits. Although the console shown has only one program equalizer, space has been provided over each mixer control for installing additional equalizers. The equalizers are similar to those discussed in Question 6.100. Circuitry is also supplied for connection to an external reverberation unit, and pre- and post-fades. Shown at the lower left in 9-6D are plug-in transformers (see Question 8.106), preamplifiers, power supplies, and monitor amplifiers.

The overall frequency response of this unit is plus-minus 0.5 dB, 30 to 15,000 Hz. Distortion is less than 0.5 percent for plus 18-dB output. Cross talk between the two program channels is not less than 65 dB. Signal-to-noise ratio is 64 dB for 78-dB gain at plus 18-dB output.

Pictured in Fig. 9-6E is a 12-position mixer console, manufactured by Electrodyne, employing integrated circuit amplifier modules discussed in Question 6.132. Module-design concept is used throughout the console, where practical. The mixing network uses active combining networks as discussed in Question 5.98, thus eliminating the need for booster amplifiers.

This console has been especially designed for recording, using a four-track tape recorder (or other types). Each of the 12 input circuits contain a 6-position high- and low-frequency equalizer-amplifier module, with a straight-line mixer control. Four separate output circuits, each with its own VU meter, provide visual monitoring facilities. A block diagram of its internal circuitry appears in Fig. 9-6F.

9.7 Describe the construction of a single- and multiple-mixer control.—The internal construction of a Model K-1 Gotham Audio Corp., single-element control is pictured in Fig. 9-7A. The control element is straight-line operated, although the attenuator element is a rotary one. The configuration of the control is the ladder attenuator discussed in Question 5.51. The attenuator element is hermetically sealed, with the contacts encapsulated in liquid silicone oil to reduce contact noise. The length of travel is 5¾ inches, employing a total of 56 contacts. In the upper 60 percent of travel (the usual operating range), the attenuation is 0.5 dB per step, with an increasing taper up to 85 dB before reaching infinity.

The attenuator element is actuated by

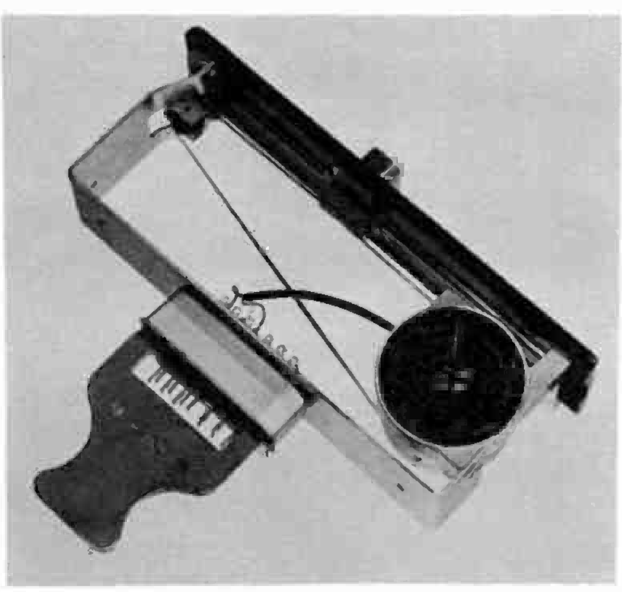

Fig. 9-7A. Interior view of Model K-1 Gotham Audio Corp. vertical mixer control.

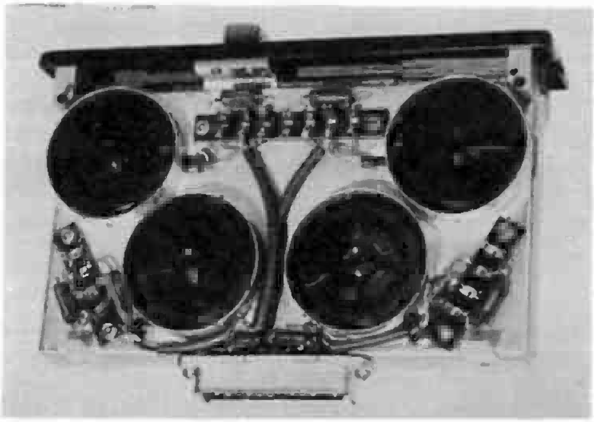

Fig. 9-7B. Interior view of Model K-4 Gotham Audio Corp. vertical mixer control.

a knob connected by a toothed belt imbedded with steel strands, and requiring only 180 to 240 grams of pressure for operation of 1 to 4 controls. A cable connector is provided for easy removal from the console. A Model K-4 mixer control, a four-element version using similar attenuators, is shown in Fig. 9-7B. Mixer controls of this design are quite common in stereophonic mixing consoles. Because of the additional three attenuators in the model K-4, ball bearings are used for ease of operation.

Fig. 9-8. Slide-wire ladder mixer control.

9.8 Describe the construction of a ladder slide-wire mixer control.—Slide-wire mixer controls find their greatest use in rerecording consoles, and are designed using the equation in Question 5.51. Such attenautors may be designed mechanically for either rotary or vertical usage. A typical rotary type is shown in Fig. 9-8. Vertical attenuators are similar in design, except the resistor card is straight, and a finger contact is used. Ladder attenuators have a fixed insertion loss of 6 dB, which must be taken into consideration in designing a mixer network. The signal-to-noise ratio of a ladder attenuator increases with the increase of loss.

9.9 Are balanced configurations used in mixer-pot design?—Yes. In special cases balanced mixer pots are used. These are generally of the balanced bridged-T type as shown in Fig. 5-38. Balanced-H configurations may also be used; however, because of the cost and the fact a balanced-H configuration requires six rows of contacts compared to four for the balanced bridged-T pot, the latter is preferred. A bridged-T pot also has a lower noise level and requires less maintenance.

9.10 What is the maximum attenuation required for a bridged-T mixer control used in a rerecording mixer?—At least 45 dB or greater, in steps of 0.5 dB. After passing 45 dB, the taper increases quite rapidly to afford a fast cutoff. Generally, the last steps are 6, 9, 12 dB, and infinity (see Question 5.80).

9.11 What is the minimum acceptable level of leakage that may be tolerated in a given position of a mixer network?—A minimum of 70 dB. The leakage is measured at a frequency of 10,000 Hz as shown in Question 23.67.

9.12 What does the term fade mean?—To attenuate a signal slowly to infinity.

9.13 What is cross-fading?—The gradual attenuation of one signal as another is gradually brought up to normal level. This is accomplished by closing one mixer pot as another pot is being opened.

9.14 *What is a board fade?*—An expression used in the broadcast industry which means to fade out all signals on the mixer by means of a master control.

9.15 *What is a submaster control?*— A control at the output of a group of mixer controls such as a split mixer. A

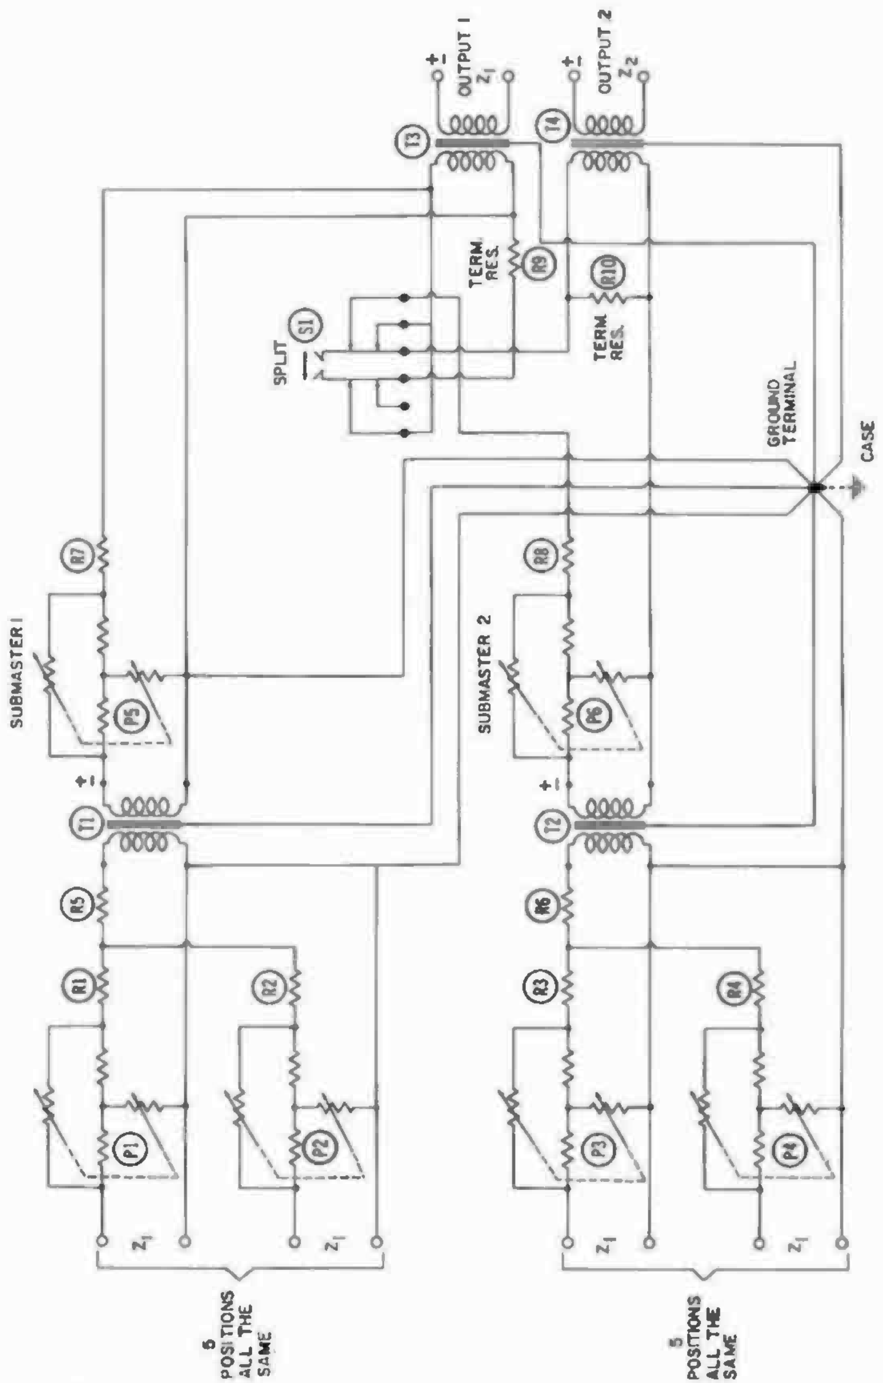

Fig. 9-18. A 10-position split-mixer network with a key switch for combining the two sections into a single network.

submaster control affects only a particular group of controls.

9.16 ***What is an overall master control?***—A control that is located at the output of the mixer network for the purpose of controlling all of the mixer positions simultaneously.

9.17 ***What is a grand master control?*** — It is the same as an overall master control.

9.18 ***What is a split mixer?*** — A mixer network split into two or more sections whereby a given group, or groups, of mixer controls may be controlled individually, yet their outputs may be combined into one composite signal. A typical split-mixer network is shown in Fig. 9-18. Ten positions are shown split into two groups of five each. At the output of each group are building-out resistors (R1 to R8) and a submaster control P5 and P6 for controlling the output level of each group. The two sections of the network may be combined into a 10-position mixer or split by throwing the key switch S1. The output windings of the transformers T3 and T4 are run to separate channels or to a single recording channel.

9.19 ***What is a parallel-connected mixer network?*** — A configuration in which the mixer pots are connected in parallel as shown in Fig. 9-19. It will be noted that the building-out resistors R1 through R4 are connected in series with the output of each mixer control and an extra one (R5) is located at the input to the output coil. The purpose of building-out resistors is to provide an impedance match and isolation between pots. The low potential side of each pot is returned to a common ground connection at the low potential side of the output coil, T1. The purpose of the coil is to provide an impedance match to the line feeding the recording channel and to isolate the mixer ground from the recording circuits.

9.20 ***Show a schematic diagram for a series-connected mixer network.*** — A four-position series-connected mixer network is shown in Fig. 9-20. It will be noted the pots are all above ground. As the circuit is floating, serious leakage at the high frequencies can take place. This circuit has not been used for years and is not recommended.

9.21 ***Show a schematic diagram for a three-channel stereophonic dialogue***

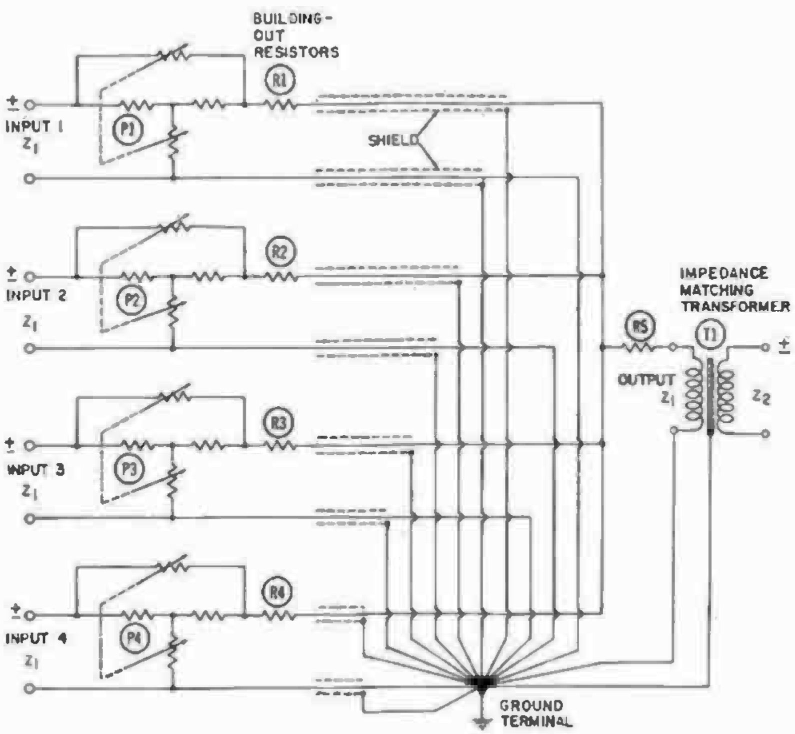

Fig. 9-19. A 4-position parallel-connected mixer network. The ground side of each mixer control is brought to a common ground point.

recording channel.—An elementary circuit diagram for a three-channel stereophonic mixer suitable for motion picture recording is shown in Fig. 9-21A. The mixer is split into three sections: left, center, and right. Each section consists of a conventional parallel-connected two-position mixer which feeds a recording amplifier connected to a magnetic recorder.

At the output of each recording amplifier is a resistive network which ties the three outputs together and feeds two monitor amplifiers connected to a pair of split headphones for the mixer. The left earphone is connected to the left channel and the right earphone to the right channel. Both earphones hear the center channel. Balancing pots are provided for balancing the sound level to each earphone.

Monitoring headphones are connected across the output of each recording channel for the microphone boom oper-

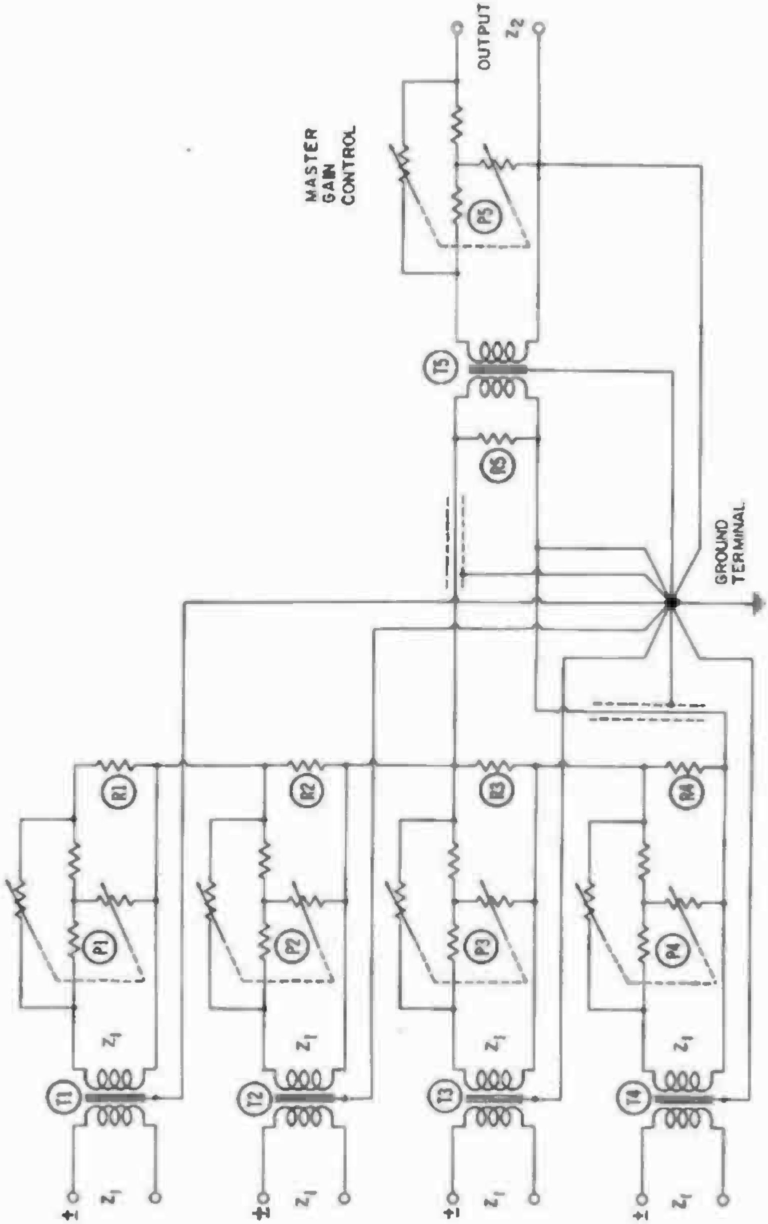

Fig. 9-20. A 4-position series-connected mixer network, not recommended for critical work.

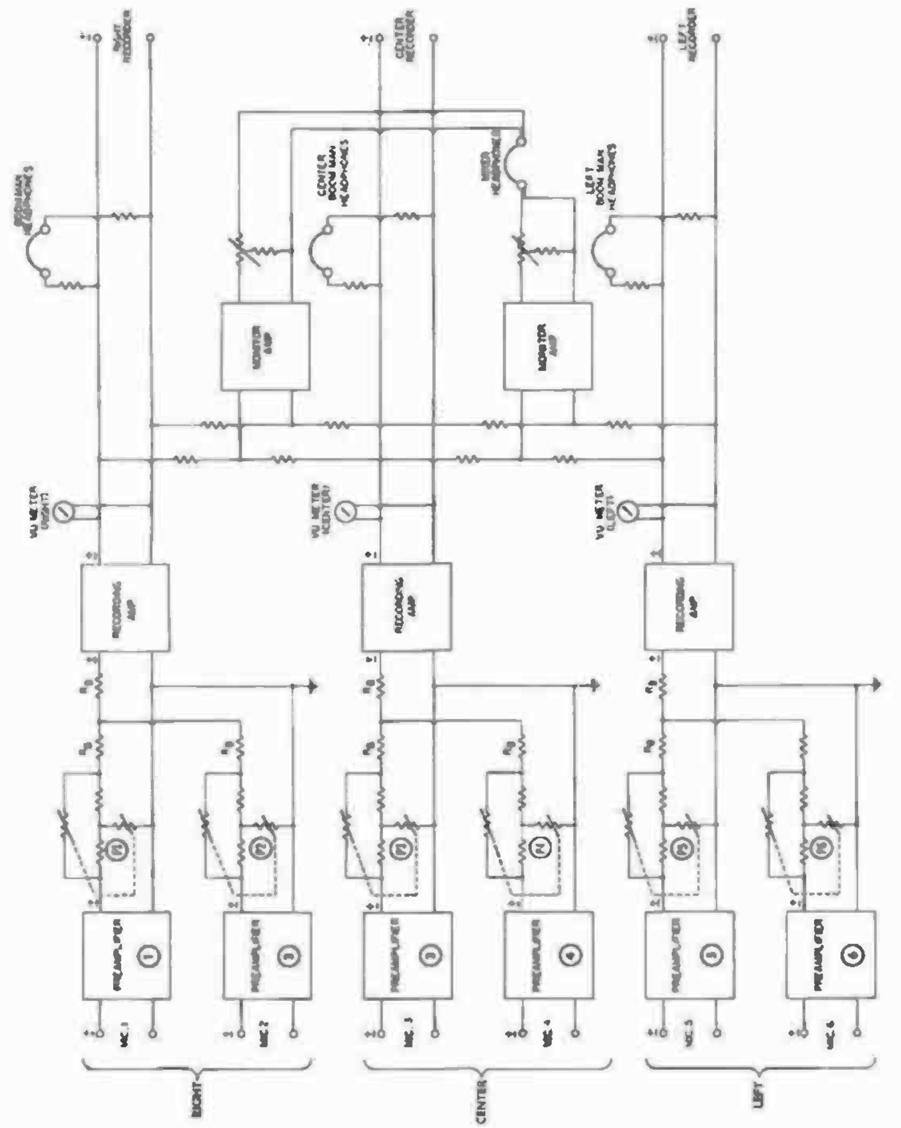

Fig. 9-21A. Simplified diagram for a 3-channel (6 microphone) stereophonic motion picture production mixer. Split headphones are used for the mixer, and individual headsets for the boom operators.

ator. It is highly important that all amplifying equipment be phased relative to the other channels, from the microphone to the magnetic recording head at the recorder. A typical stereophonic production mixer having six microphone inputs is shown in Figs. 9-21B and C.

It will be observed in Fig. 9-21C, that although the mixer controls are of vertical design, they are really two rotary controls ganged together. These controls consist of standard rotary attenuators operated by a system of cords and pulleys. The cords and pulleys may be viewed just below the edge of the panel. At the bottom of the case are microphone preamplifiers and recording and monitor amplifiers.

9.22 ***Show a block diagram for a four-position parallel connected stereophonic rerecording mixer using pan-pots.*** —An elementary block diagram for such a mixer network is shown in Fig. 9-22A. Although only four mixer controls are shown, any number may be connected in the network as long as the proper building-out resistors are used.

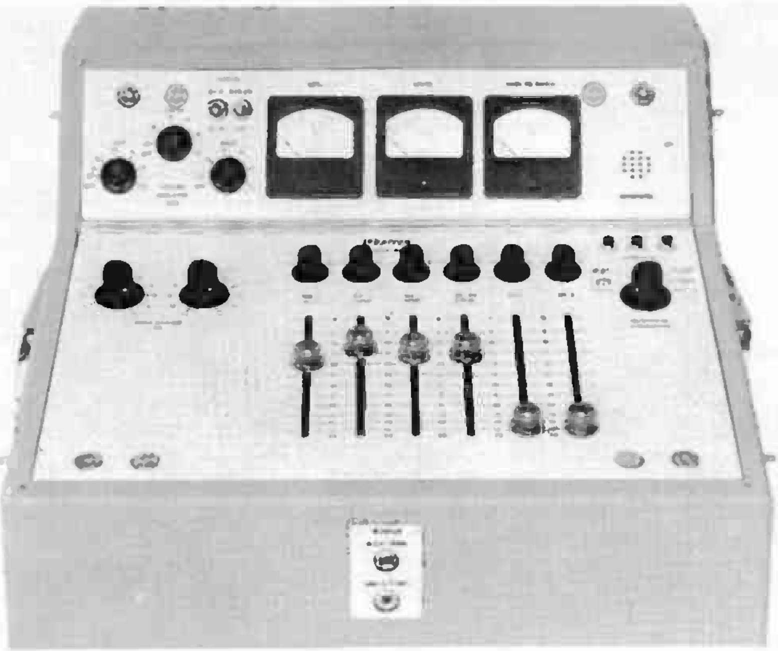

Fig. 9-21B. Exterior view of a Westrex portable stereophonic mixer.

The sound tracks to be spread are connected to the input of the regular monaural mixer network, P1 through P4. At the output of each mixer pot is a booster amplifier to compensate for the insertion loss of the pan pots.

Leaving the booster amplifier, the signal is fed to the input of a pan pot (described in Question 5.73). The output of each pan-pot is combined in a resistive network which feeds the input of three recording channels. The building-out resistors R_b, are to achieve an impedance match between the pan-pots.

The mixer network shown may be used for stereophonic rerecording using

Fig. 9-21C. Interior view of Westrex portable stereophonic production mixer.

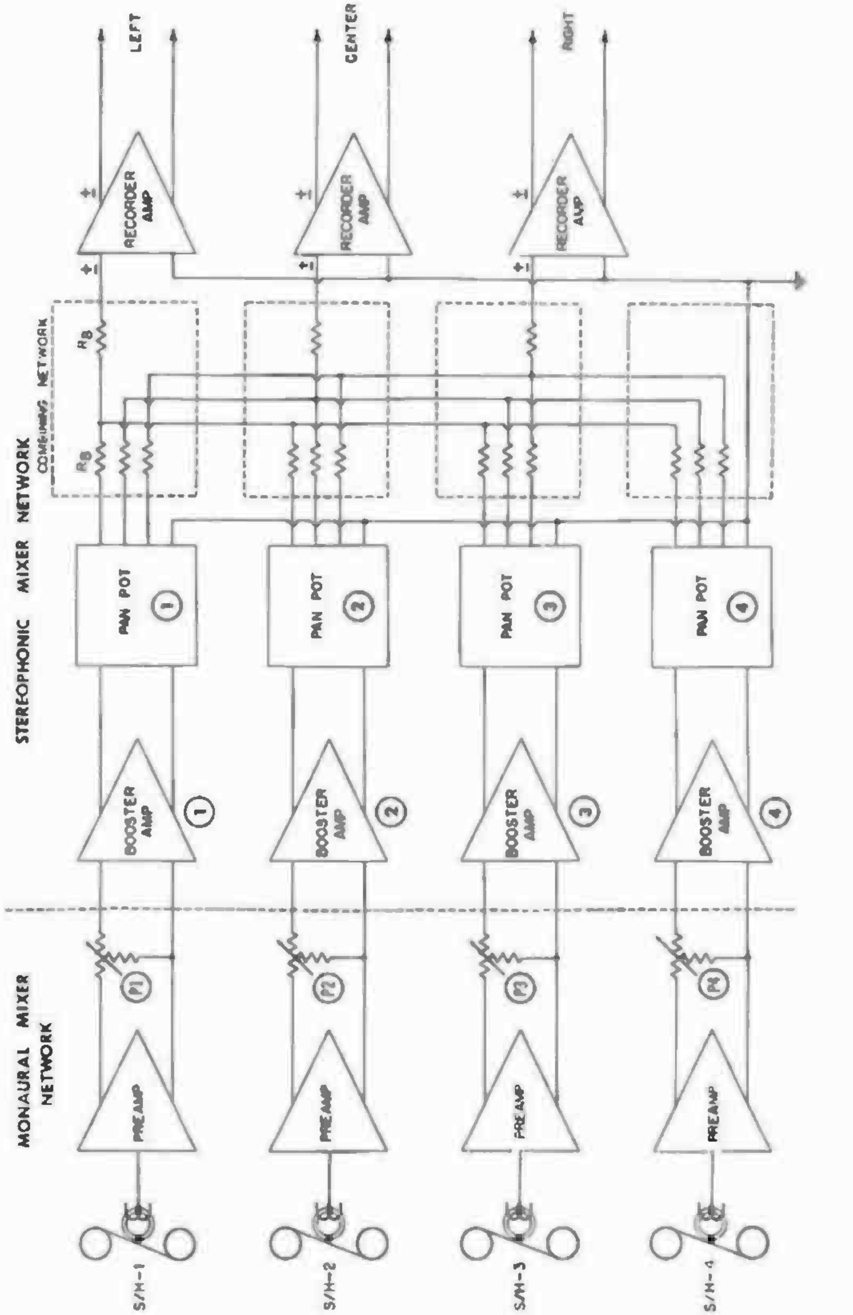

Fig. 9-22A. Simplified diagram for a 4-position pan-pot rerecording mixer network.

original stereophonic sound tracks, or monaural sound tracks. In the latter case, the stereophonic effect is called pseudostereophonic sound and is quite widely used in the motion picture industry.

A stereophonic rerecording mixer console built by RCA for 20th Century Fox Studios is shown in Fig. 9-22B. A similar type built by the sound department of Universal Studios, Universal City, California, is pictured in Figs. 9-22C and D.

The circuitry and controls for this console are typical of that required for rerecording stereophonic sound for motion pictures. Four groups of 8 vertical mixer controls are placed each side of

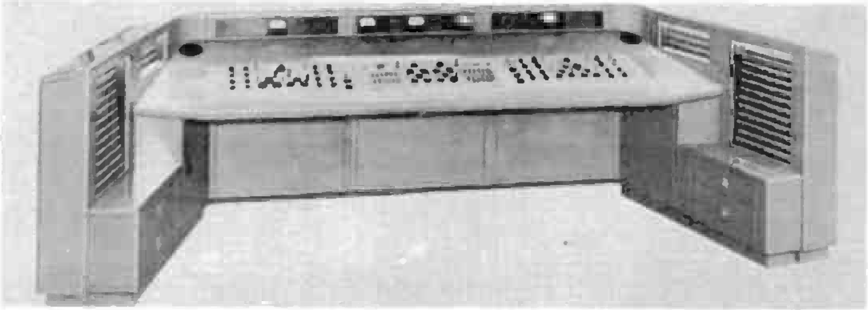

Fig. 9-22B. Stereophonic rerecording mixer console built for 20th Century-Fox Studios by RCA.

Fig. 9-22C. Stereophonic rerecording console at Universal Studios. (Courtesy Universal Studios Sound Department)

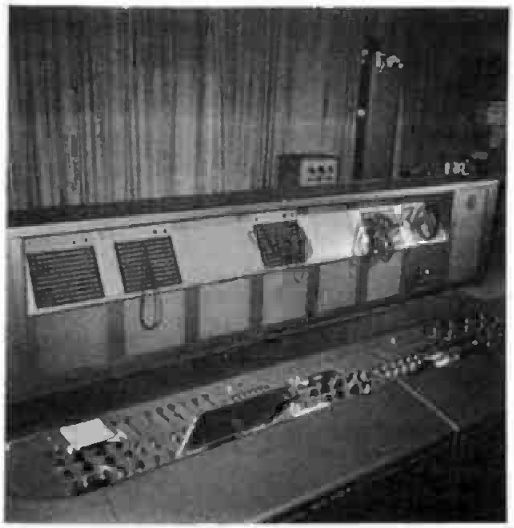

Fig. 9-22D. View taken looking over the console toward the patch bay. Here changes in the method of operation are made by the use of patch cords. (Courtesy, Universal Studios Sound Department) the center. The controls in the center section consist of pan-pots along with other controls for placing the sound in proper perspective. Three of the mixer-control groups have graphic equalizers, with additional equalizers and filters at the other positions. Many of the circuits are operated from push buttons for on-cue effects. No. VU meters are used at the console; instead, three *projection* type, VU meters about 30 inches in diameter, are placed on the floor below the screen.

At the rear of the console is a patch bay, containing 1360 tip, ring and sleeve type jacks. Here, the circuits may be connected by means of patch cords for different modes of operation. The patch bay has a total of 1360 circuits. At the lower right jack bay is a compressor amplifier, for controlling the peak level of dialogue.

9.23 *What is a hybrid-coil mixer?* —A network split into several sections each containing a group of mixer pots. The several sections are combined by means of hybrid coils, as discussed in Question 8.66. Hybrid coils are used in only the most elaborate mixers where unusual recording combinations are required. Typical uses for a hybrid coil mixer are for stereophonic rerecording, and recording large orchestras and choral groups. It is not unusual for such mixers to have up to 20 positions. A block diagram for a 16-position mixer network using hybrid coils appears in Fig. 9-23. Basically, the network consists of four separate, four-position, resistive networks (1 to 4).

Starting at network one at the upper left, the output of this network is connected to one side of the primary of hybrid coil T1. The output of network two is connected to the other side of the primary of the coil. The secondary of this coil feeds a booster amplifier having 30 dB gain. The output of the booster amplifier feeds a submaster control P1 for fading out all of the pots in the four-group mixer network simultaneously. The submaster control terminates in one side of the primary of hybrid coil T3 and from there, to the secondary and a master control P3, and thence to the recording circuits. Normal jacks are connected in all inputs and outputs, for testing and patching. Resistors R1, R2, and R3 are the balancing resistors normally used with hybrid coils. The bottom ends of these resistors are brought to a common ground point. Booster amplifiers 1 and 2 compensate for the insertion loss of the coils and other network components. If the recording circuits are unbalanced, an unbalanced pot may be substituted for the balanced control P3.

The signal levels indicated are based on an assumed signal level, at the input of the four-position mixer group, of a minus 30 dBm which is the output level from an average optical film sound head.

Each hybrid coil induces a loss of approximately 3 dB between the primary and the secondary. An additional loss of 6 dB takes place because of the two-group mixer panels at the primary. It is assumed that no loss will be carried in the sub- and master-gain controls. If the loss occurs, additional gain will be required. (See Question 8.66.)

9.24 *What is a building-out resistor?* —A noninductive resistor used for obtaining an impedance match in a mixer or combining network. The symbol for this resistor is R_{bo}.

Building-out resistors are also used in the output of low-impedance amplifiers to build out the internal output impedance to a given value. This subject is discussed in Question 12.142.

9.25 *What is the equation for calculating the value of a building-out resistor to a parallel-connected mixer network similar to that shown in Fig. 9-19?*

$$R_{bo} = \left(\frac{N-1}{N+1}\right) Z_1$$

where,

N is the number of mixer controls,

Z_1 is the impedance of the mixer control.

9.26 *What causes mixer-network insertion loss?* —Referring to Fig. 9-19, a fixed loss, termed *insertion loss* (IL) is created by the building-out resistors R1 to R5, the impedance-matching transformer T1, and any loss induced by the mixer-control configuration. Insertion loss is measured from the input of one control (control set to zero) to the output of T1. Insertion loss may be overcome by the use of an active mixer-combining network, as described in Question 5.98. (See Question 23.68.) The insertion loss for a mixer network employing ladder-type mixer controls will be 6-dB greater than for one using T-type controls.

9.27 ***How is the insertion loss of the parallel-connected mixer network shown in Fig. 9-19 calculated?***

$$\text{dB loss} = 20 \operatorname{Log}_{10} N$$

where,

N is the number of mixer positions.

9.28 ***How are the terminating resistors in the series-mixer network of Fig. 9-20 calculated?***—The terminating resistors R1, R2, R3, and R4 may be calculated:

$$R_T = \left(\frac{N+1}{N-1}\right) Z_1$$

where,

N is the number of controls,

Z_1 is the mixer-control impedance.

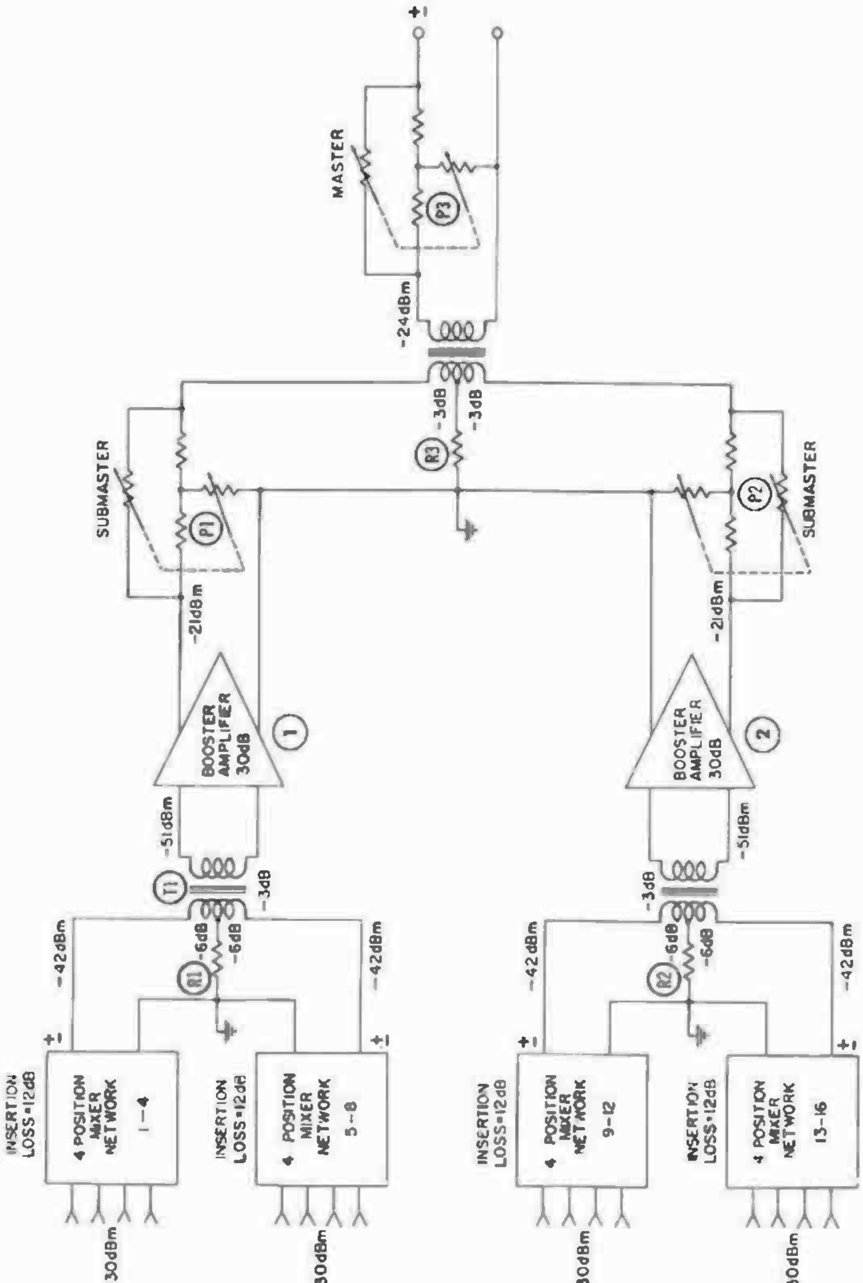

Fig. 9-23. A 16-position hybrid-coil mixer network. Losses are indicated for the coils and control networks.

9.29 What is the impedance at the output of the series-mixer network in Fig. 9-20?—The impedance from the top of the number one control to the bottom of the number two control is:

$$Z_2 = \frac{Z_1 N^2}{2N - 1}$$

where,
N is the number of mixer controls,
Z_1 is the mixer-control impedance,
Z_2 is the output impedance from the top of R1 to the bottom of R4.

Resistor R5 is equal to the output impedance of the four controls. A transformer of the correct impedance ratio may be substituted for the resistor, if desired. If the impedance at the output of the network is of an odd value, a taper pad may be substituted for the coil. The loss of the pad must be included in the insertion loss. Such pads are discussed in Question 5.34.

9.30 How is the insertion loss for a series-connected mixer calculated?

$$10 \text{ Log}_{10} (2N - 1)$$

where,
N is the number of mixer controls.

9.31 How are the balancing resistors for the hybrid-coil mixer network in Fig. 9-31 calculated?

$$Z_3 = \frac{Z_1 (N - 1)}{2}$$

where,
Z_3 is the balancing resistor,
Z_1 is the mixer-control impedance,
N is the total number of mixer controls.

Z_3 is a noninductive resistor. (See Question 8.66.)

9.32 How is the insertion loss of the hybrid-coil mixer network in Fig. 9-31 calculated?

$$\text{dB} = 10 \text{ Log}_{10} N$$

where,
N is the total number of mixer controls.

To this is added the loss of a ladder configuration (if used) and the transfer loss of the hybrid coil (3 dB). (See Question 8.67.)

9.33 How is the impedance ratio of primary to secondary calculated for a mixer-hybrid coil?

$$Z_R = \frac{2 \times Z_1}{Z_4}$$

where,
Z_1 is the impedance of the mixer controls,
Z_4 is the impedance of the hybrid-coil secondary.

9.34 Are plain-T type attenuators used in mixer networks?—Yes. However,

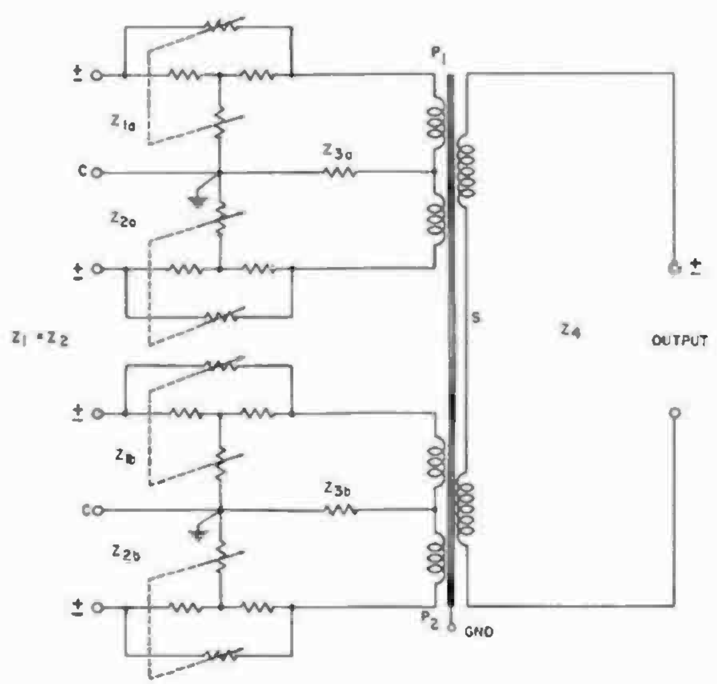

Fig. 9-31. Hybrid-coil mixer network.

as they require three rows of contacts, they have a higher noise level than the bridged-T type and therefore require a greater amount of maintenance. Ladder or bridged-T type mixer controls are recommended for commercial installations.

9.35 ***What is the recommended method of servicing a mixer control?***—If a mixer control becomes noisy while in operation, apply a signal of 40 to 60 Hz to the pot in question, and burnish the contacts (or slide-wire) by a rapid movement of the arm by wrapping a piece of cord around the control knob. The low-frequency signal supplies a signal voltage, yet it is of a low enough frequency that the noise of the contact may be easily heard. A light clear mineral oil such as Nujol may be applied to the contact surfaces to prevent oxidation of the surfaces. *Never use an abrasive on the contact surfaces.*

9.36 ***What is meant by phasing a mixer?***—Phasing a mixer means polarizing the mixer inputs and output so that they are electrically in phase with each other.

The phasing of a mixer network is quite important, particularly if the mixer is to be used for stereophonic or photographic film recording. Optical film-recording systems must be phased from the microphone inpnt to the light modulator unit.

When a pressure wave is applied to a microphone, the diaphragm moves inward. At the same instant the light modulator is deflected and the noise reduction equipment moves toward the maximum cancellation point. Because the human voice is unsymmetrical, the system is phased to prevent the clipping of the modulation peaks by means of the noise reduction equipment. Therefore, the film-recording system must always be in phase for correct operation.

It is good practice with any type recording and reproducing system to observe proper phasing of the various components in the system. This is particularly true for photographic sound track transfer channels. Phasing of multiple-channel mixer networks is discussed in Section 23. Microphone phasing is discussed in Questions 4.84 and 4.85.

9.37 ***What method is recommended for grounding mixer networks?***—The ground side of each mixer control is brought to a common ground point, as shown in Fig. 9-19. Individual twisted shielded pairs are used to connect each mixer control. If balanced-to-ground input circuits are to be used with this network, a repeat coil must be connected between the signal source and the input of the mixer control to isolate the grounding systems.

All interconnecting wiring in the interior of the mixer inclnding the ground wires must be shielded, and the shields returned to a common point. If the shields are covered with cloth braid, the shield is grounded at one end only. If the shield is bare and can make contact with the mixer case, it must be honded together every few inches and securely bonded to the case at short intervals.

9.38 ***When key switches are used in mixer networks, how are clicks prevented when the circuits are broken?***—By the use of a transmission ground system. The switches are of the make-before-break type. If a mixer control is switched out of the circuit, a terminating resistor equal in value to the impedance of the control must be connected in the circuit to maintain the proper impedance relations.

9.39 ***What are low- and high-frequency attenuators?***—Reactive circuits connected ahead of the mixer control for the purpose of attenuating either the low- or the high-frequencies. As a rule, they are set for a characteristic that conforms to the standards used in the motion picture industry. The circuits for such attenuators appear in Fig. 9-39. It will be noted that low-frequency attenuation is secured in the upper control by connecting capacitors in series with the high side of the mixer-control input. Two positions are provided, −8 dB and −12 dB at 100 Hz. When the capacitors are in the circuit, 100 Hz is attenuated the indicated amount with respect to 1000 Hz. High-frequency attenuation is obtained by shunting capacitors across the line. Three positions are provided: −4 dB, −8 dB, and −12 dB at 10,000 Hz, with respect to 1000 Hz.

For purposes of illustration, the high-frequency attenuation in the lower control is obtained by the use of a series resonant circuit. A resistor is shunted around the coil to lower its Q and shape the response curve. High- and low-

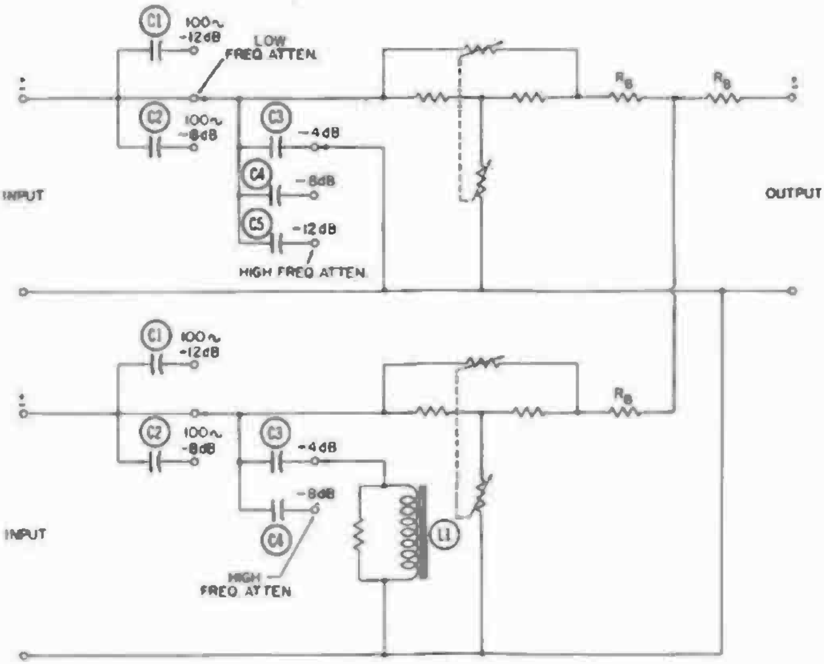

Fig. 9-39. A 2-position mixer.

frequency attenuators are discussed in Questions 6.80 through 6.84.

9.40 *What is the insertion loss of a mixer network when using ladder mixer controls?*—The insertion loss is 6 dB greater than when using plain or bridged-T controls. This loss is due to the configuration of the ladder pot and is independent of the loss setting of the control. Ladder pots are discussed in Question 5.51.

9.41 *How is the insertion loss of a mixer measured?*—This subject is discussed in Question 23.68.

9.42 *Describe a solid-state sound reinforcement and public address mixer-amplifier.*—Sound mixers designed for high-quality sound reinforcement or public-address service generally require a minimum of six positions, and up to 20 positions is not uncommon. A mixer-amplifier of solid-state design, manufactured by the Langevin Co., is shown in Fig. 9-42A. Although this particular mixer has only 6 positions, another 12 positions may be added by the addition of an auxiliary mixer network of Fig. 9-45. The schematic diagram for

Fig. 9-42A. Model AM1A solid-state, 6-position mixer manufactured by the Langevin Co.

the unit of Fig. 9-42A is shown in Fig. 9-42B.

At the left are six microphone inputs, feeding six plug-in, module-type preamplifiers using silicon planar transistors, with individual speech-music equalizer switches in their outputs. From there, the signals are combined into a resistive mixer network and to a booster amplifier, variable equalizer, a second booster amplifier, master gain control and a line amplifier. Provision is

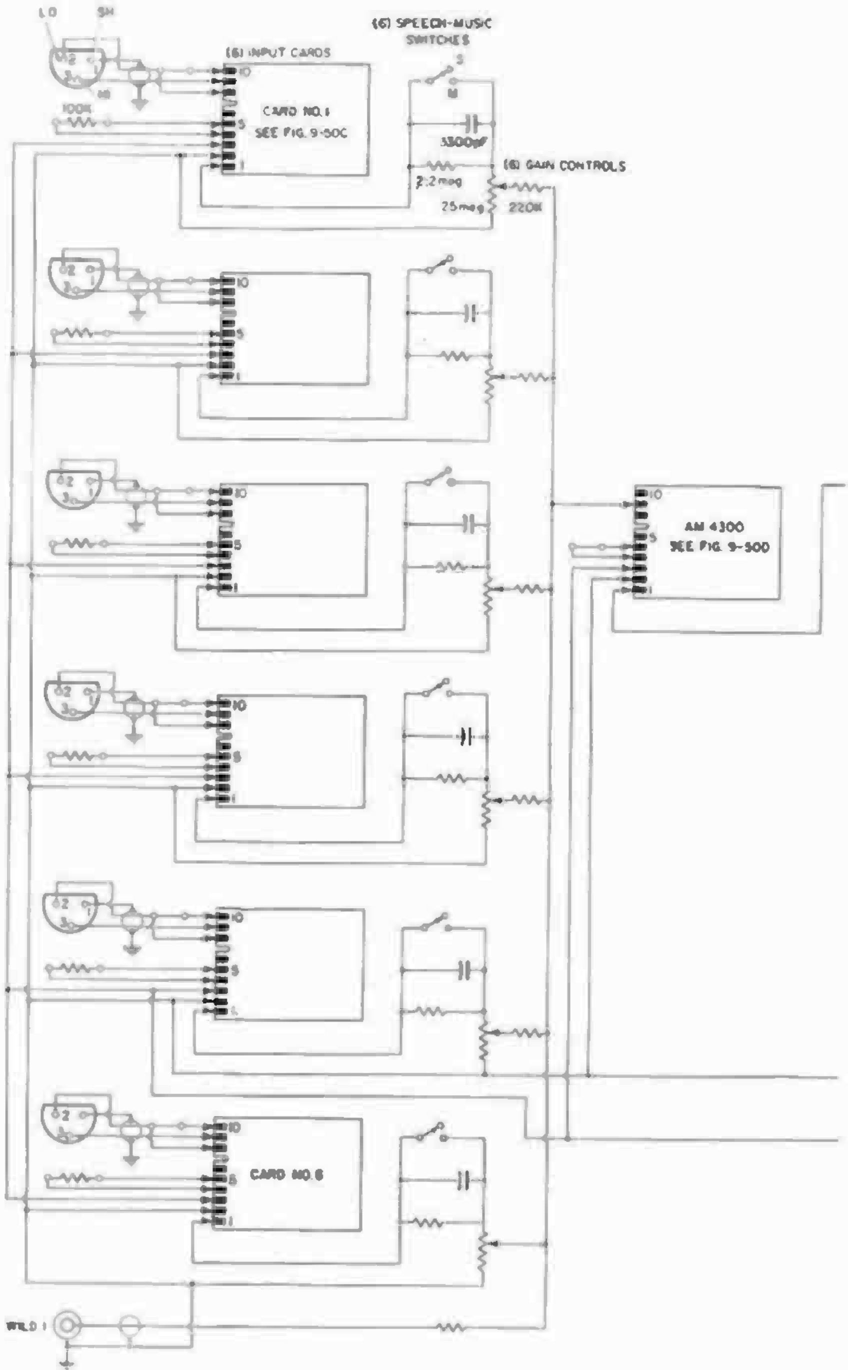

Fig. 9-42B. Schematic diagram for

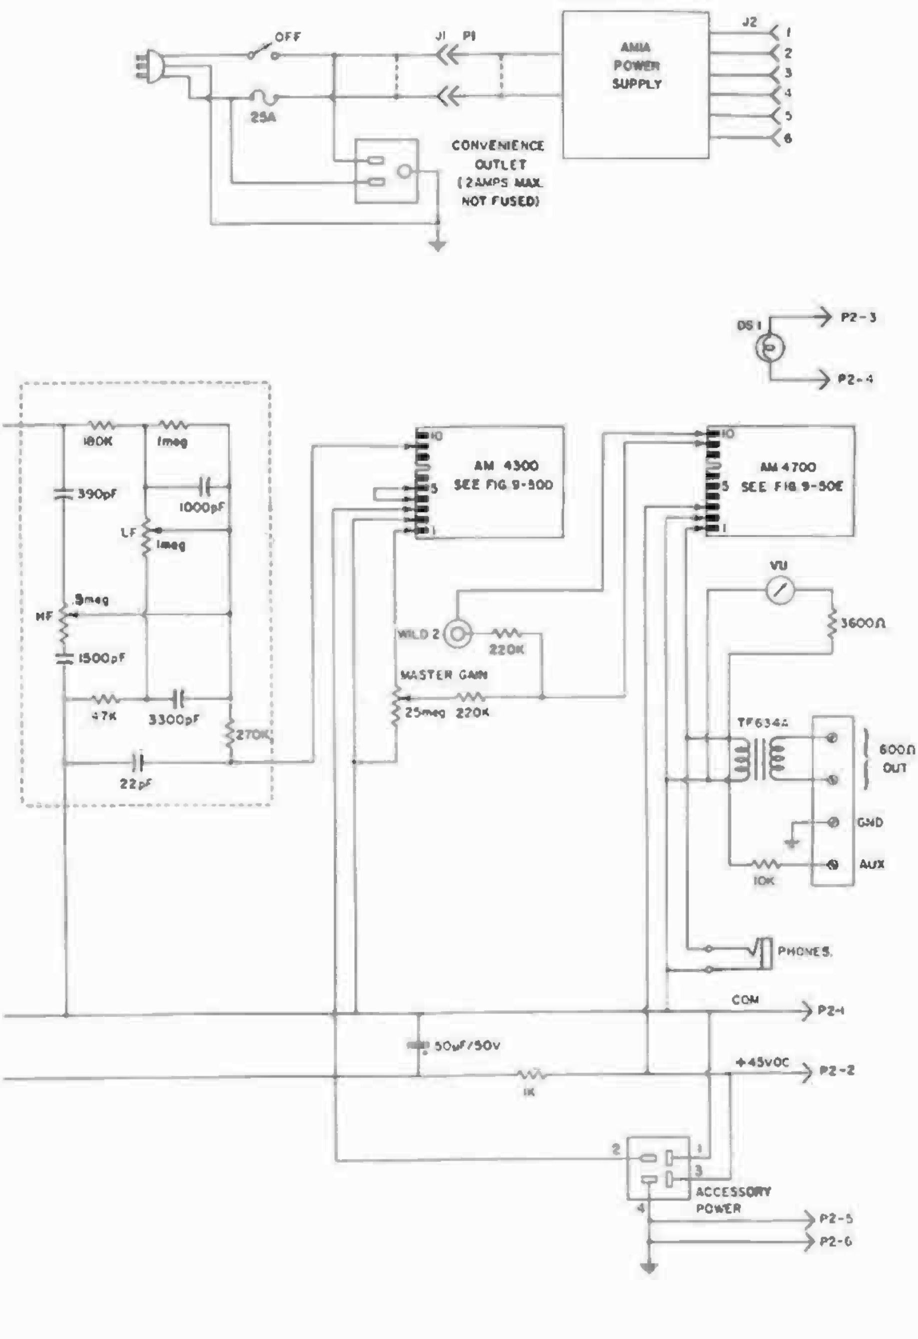
made for headphone monitoring. A regulated solid-state power supply is also contained in the mixer housing. The frequency response is plus-minus 1 dB, 30 to 15,000 Hz, with less than 0.25 percent total harmonic distortion. The equivalent input noise is minus 112 dBm (60 dB signal-to-noise ratio). Total gain is 88 dB, maximum output power is plus 18 dBm.

The internal circuitry for the Model AM-4100 preamplifier, the Model AM-



Langevin AM1A mixer amplier.

4300B booster amplifier, and the Model AM4700 output amplifier, is shown in Figs. 9-42C, D, and E.

9.43 ***What is an electronic mixer?*** —This is a term which is sometimes used to identify a compressor amplifier employed for motion picture recording. Electronic mixers are discussed in Questions 18.84 through 18.102.

9.44 ***What are the values of build-***

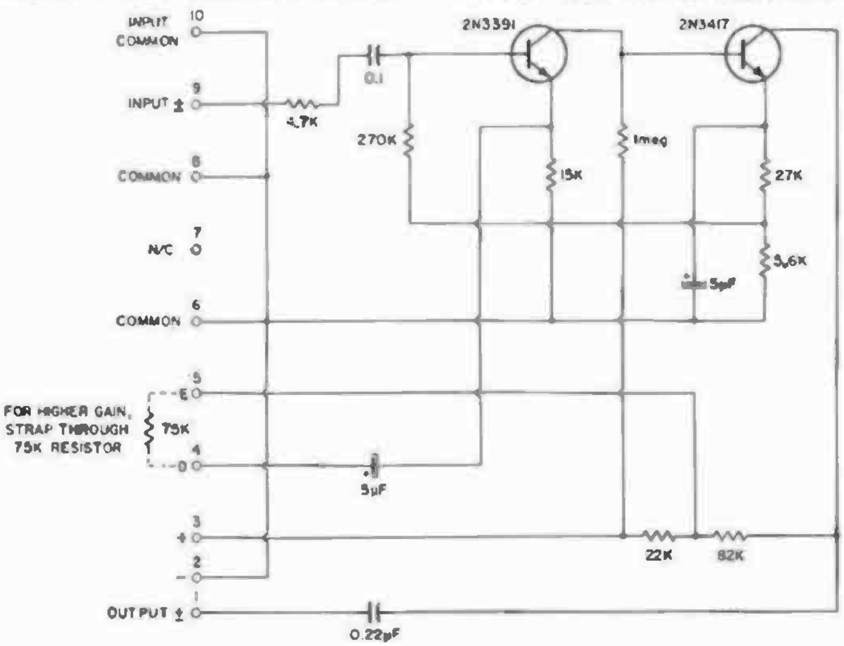

Fig. 9-42D. Langevin Model AM4300B solid-state amplifier for AM1A mixer-amplifier.

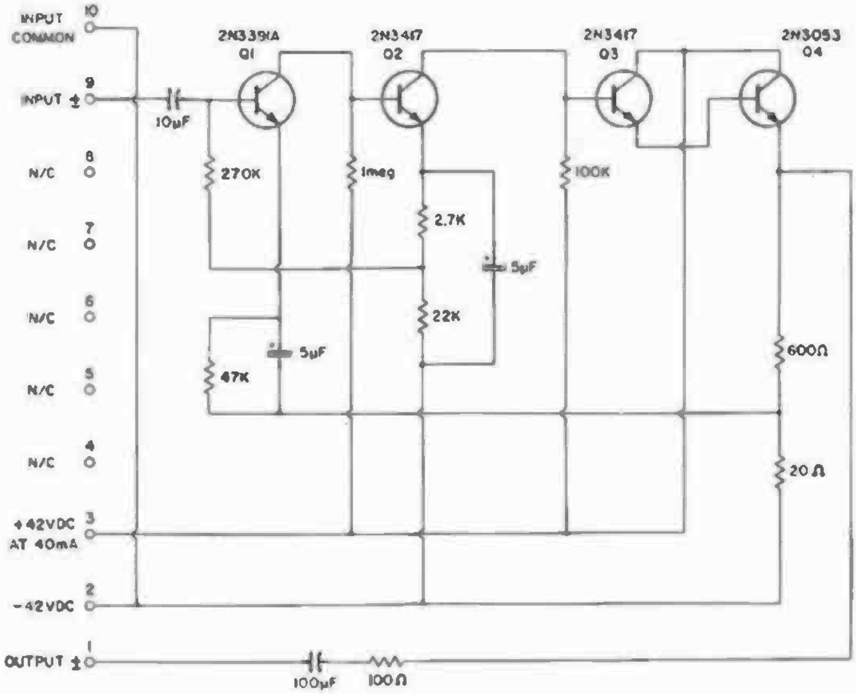

Fig. 9-42E. Langevin solid-state amplifier Model AM4700 used in the Model AM1A mixer-amplifier.

ing-out resistors used for parallel-type mixer networks?—The values of the building-out resistors and the insertion loss for mixers using a parallel mixer network (Fig. 9-19) are given in Fig. 9-44. The number of mixer positions appears at the left and the impedance of the network appears at the top of the chart.

The insertion loss is the loss caused by the building-out resistors, with only a single input at its minimum attenuation. The measurement of insertion loss is discussed in Question 23.68.

9.45 *Describe an auxiliary mixer.*—The auxiliary mixer pictured in Fig. 9-45 is manufactured by Langevin Co., and is designed to be operated as an auxiliary 9-position mixer-amplifier with any existing mixer to provide additional input positions. The circuitry of the unit is quite similar to that of the mixer described in Question 9.42, and is the same up to the booster amplifier. The unit is self-powered and contains the necessary preamplifiers and booster amplifier, which is operated directly into a low-gain position of the master mixer.

9.46 *Describe the mechanical layout and components for a three-section rerecording mixer console.*—Pictured in Fig. 9-46A is a three section rerecording console, designed by the author, and constructed by McCurdy Radio Industries, Canada. This console is designed for use with three-track magnetic film rerecorders or any type single track recorder. Basically, the console consists of three sections, termed dialogue, effects, and music. Each section consists of four mixer controls and a master control, plus two graphic equalizers, high- and low-pass filters, and two low-frequency attenuators. One or both of the graphic equalizers may be connected in any one of the four positions by means of push buttons above the control panel. In addition, key switches are provided for on-cue operation. The low-frequency attenuators provide standard roll-off characteristics as discussed in Questions 6.122 and 6.131. Graphic equalizers are discussed in Questions 6.108 and 6.126. The high-pass filters employ cutoff frequencies of 45, 80, 100, 135, and 150 Hz. The low-pass cutoffs are at 6, 8, and 10 kHz. These may also be cued in as required. The usual practice is to leave in the 45-Hz filter for rerecording, and use the 8-kHz low-pass filter for normal dubbing operation. For original music, the 10-kHz filter is used.

The dialogue position varies in its components, as an additional program equalizer, discussed in Question 6.12, has been added to the upper right, along with three controls for an EMT reverberation unit (installed at a remote point) described in Question 2.130. A remote meter indicates the reverber-

ation time being used, for future reference. At the upper left is a group of on-the-line machine indicators to assure the mixer that all the reproducers and recorders are on the line. The machine indicators light automatically whenever a machine is connected across a distributor bus. A group of intercommunication key switches at the lower left of each section permits the mixer to slate the head end of each take, talk to the machine room, maintenance department, power room, test laboratory, and the music scoring console (in an upstairs monitor room). The intercommunication system is solid-state, installed at a remote position.

It is the practice in the motion picture industry when recording master sound tracks, to record 400-Hz head tone on each roll of magnetic tape or film. This tone is used by the mixer to establish the correct listening level for playback, and later is used by the transfer activity. The output of the 400-Hz oscillator has three separate controls, one at each section. If the manual button is pushed, the tone appears in only the section where the button is depressed. If the button is pushed to automatic in any of the three sections, the tone is automatically recorded on the three sound tracks for a duration of six seconds, starting at the dialogue section. If three tracks were recorded simultaneously, the level at the composite bridging bus would be in error by several dB. The small diagonal panel at the upper left contains a monitor gain control and a 20-dB talk key for reducing the monitoring level while the sound track is running and discus-

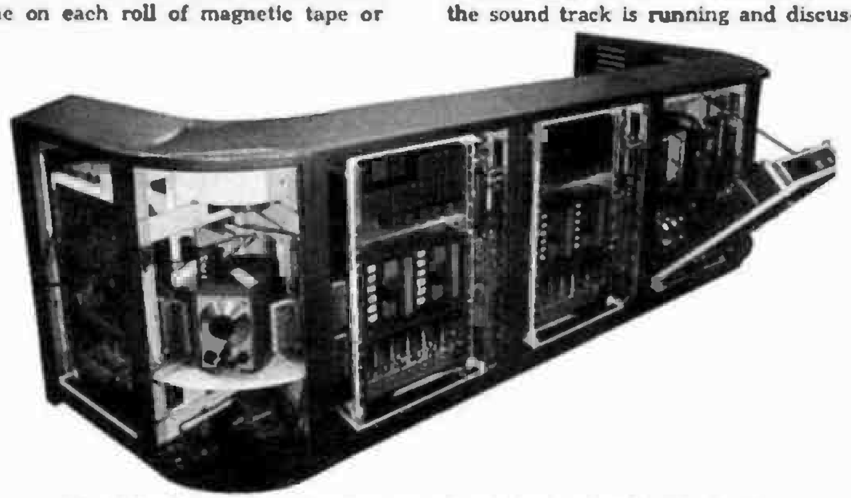

Fig. 9-46D. Rear view of mixer console similar to that in Fig. 9-6A.

sions are in progress. In the panel at the lower left are three controls for a compressor-limiter amplifier, with input and ceiling controls and a de-essing key switch. The playback mode is set by the position of a selector switch, with pilot lights to indicate that the machine is being used. If the recording levels are correct, the playback level will be within plus-minus 0.5 dB, using the head tone as a reference. Two variable sound-effects filters at the bottom of the panel complete the controls in this area. (See Question 18.84.)

The fact that the three sections of the console are termed dialogue, effects, and music, does not mean they are confined to this particular type recording. This terminology has been adopted to identify the sections and is the order in which the three sound tracks appear on a three-track magnetic film recorder. All three sections have the same identical electrical characteristics, except for the compressor amplifier in the dialogue channel.

A remote-control panel at the left side of the console (not shown) contains switches for controlling the house lighting, ventilation, quiet lights, baby spot above the console, dubbing and projection mode, screen curtains and a control permitting the loudspeaker behind the screen to be operated in conjunction with a similar speaker in the music scoring monitor room, or separately. This control is duplicated in the projection booth and at the music-mixer console. Between the second and third VU meters are push buttons for activating a footage counter (mounted at the screen) and resetting to zero. A reverberation time meter is mounted between VU meters three and four, for resetting the reverberation unit, and a push button for measuring the monitor level, using the effects VU meter. All relay control and heater voltages for the amplifiers are supplied from 1 percent regulated dc power supplies located in a remote power room.

The rear of the console houses the compressor amplifier, high- and low-pass filters, relays, pads, and other equipment necessary to its operation. The patch bay is mounted in a steel cabinet directly behind the console, and contains 18 jack strips, with 432 active circuits, using tip, ring, and sleeve type jacks (Fig. 9-46B). It also contains a dip filter for 60 and 120 Hz, and a background suppressor amplifier. The wiring between the console and the patch-bay is carried in a section of 6-cell metal gutter laid in the floor. A similar gutter is described in Question 24.49.

Although the patch bay houses 31 amplifiers, only 22 are directly associated with the mixer circuitry. The others are for microphones, spares, and special setups. The 400-Hz oscillator is also housed in this area, and slides into the amplifier tray at the extreme lower right. When a microphone is required such as for looping, a spare amplifier is patched into the desired input. In this instance, the mixer uses headphones for monitoring. Looping is discussed in Question 17.223. In the drawing of Fig. 9-46C, is shown the mechanical layout of the patch bay. A rear view of a similar console is pictured in Fig. 9-40D. When the rear panels are removed, the equipment falls forward on a frame to facilitate servicing. The placement of a console on a dubbing stage is shown in the drawing of Fig. 2-76D.

9.47 Describe the block diagram for the three-section mixer console of Question 9.46.—Basically, the circuitry (Fig. 9-47A) is divided into three sections, each consisting of four mixer controls, amplifiers, combining networks, equalizers, filters, bridging bus and VU meter. The output from each bridging bus is fed to one track of a three-track magnetic film recorder. For monitoring purposes and for feeding of single-track recorders a composite bridging bus is used, fed from the combined output of the dialogue, effects, and music-bridging busses. A fixed playback system controlled by relays permits the mixer to check the recording levels, in reference to a head-tone recorded at the head end of each roll of magnetic film. To simplify the drawing, only one input is carried through for each group of four mixer controls. Up to the mixer-combining network, each input is identical.

Starting at the extreme upper left are the input circuits for the four controls of the dialogue section. The signal may be from any source having an output level of minus 4 dBm or greater. From the input line, the signal passes through a push-button controlled graphic equalizer, then through a preamplifier (1 to 4), isolation coil (1:1 repeat coil), and to the mixer control. Leaving the control, it passes through a low-frequency attenuator, mixer-combining network, a second isolation coil, booster amplifier (5) where the signal is again amplified and passed to a master mixer control (isolated at its input and output by coils—normal setting zero loss), then to a compressor-limiter amplifier (see Question 18.86). At the input and output of the compressor are two controls, one for setting the correct input level, and a ceiling control for adjusting the amount of compression. Leaving the ceiling control, the signal encounters high- and low-pass filters. At this point, push-button switches are provided for connecting an EMT reverberation unit (described in Question 2.130) into the circuit. Amplifiers (29) and (30) when once set require no further adjustment. The reverberation is available only in the dialogue section; however, it may also be patched in at either the effects or music sections.

At the output of the low-pass filter, the signal is passed to a combining network, where a slating microphone can be keyed into the dialogue channel when required, or the playback signal injected, or the head-tone oscillator signal injected. Normally relays K_1, K_2 and K_3 are in the upper position, supplying a termination for the network. The output of the network feeds the signal to dialogue line amplifier (6), and then to the dialogue bridging bus and VU meter.

From the bus, the signal is amplified by a bridging amplifier (7), which terminates in a three-branch monitor-combining network, and to a composite

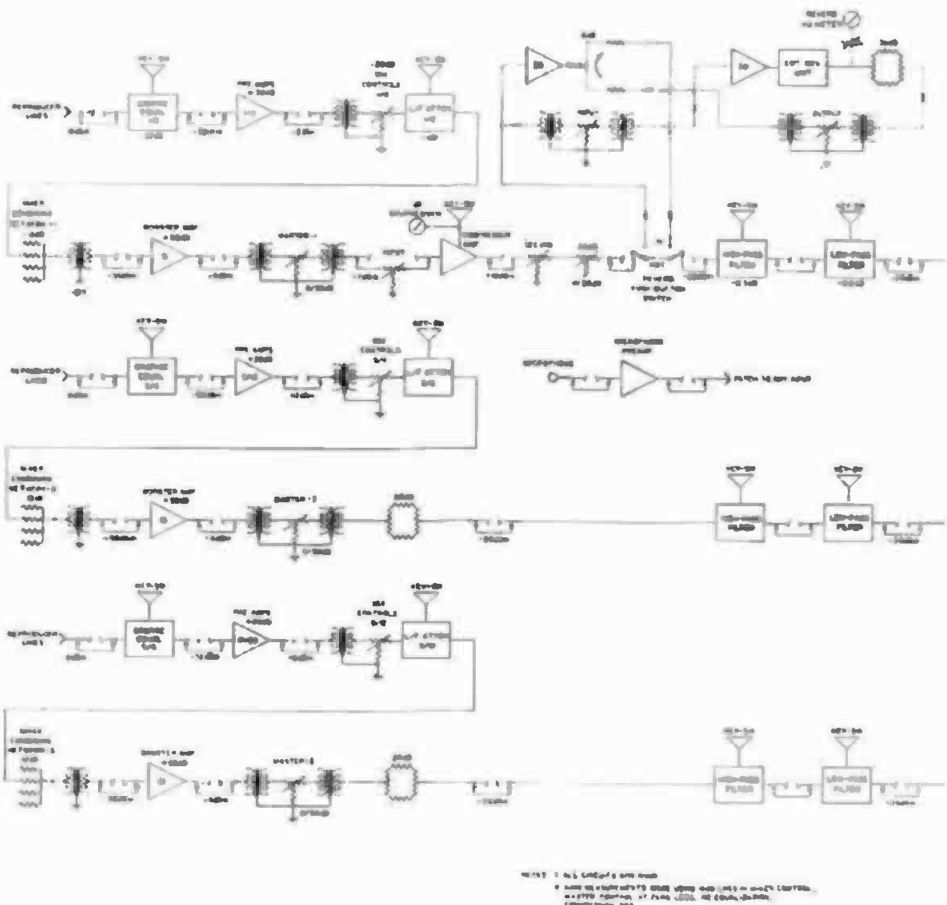

Fig. 9-47. Block diagram for 3-section split-

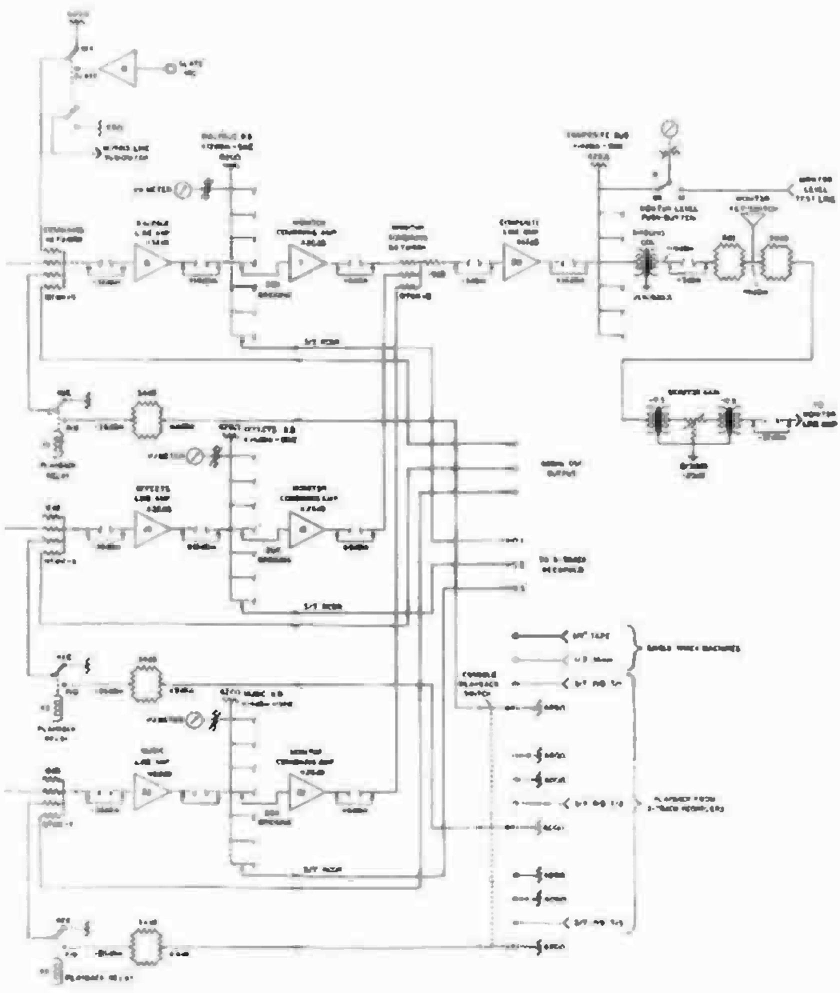
bridging bus amplifier (28), which drives the composite bridging bus and VU meter. The composite bus feeds a bridging coil which terminates in a 6-dB and 20-dB pad to reduce the monitor level while conversing through a key-switch control. The output of the pad is taken to a monitor gain control and then fed to the monitor system—a 50-watt power amplifier in the projection booth. To complete the monitor circuit, a signal is taken from the effects and music bridging busses and fed to two other branches of the monitor-combining network and amplified by the composite line amplifier (28), then the signal is passed on to the composite bridging bus.

The other two sections—effects and music—are identical to the dialogue section up to the output of the master controls. Here a 20-dB pad is connected in these two sections at the input of the high- and low-pass filters. From then on, the circuitry is the same as for the dialogue section, and the circuits feed their respective tracks for three-track recording. Single-track machines are fed from the composite bridging bus.

The gain through the whole system must be balanced within plus-minus 0.5 dB, particularly at the input to the combining network at amplifier (6). The system is lined up by applying a signal to the input or mixer control (1) in the dialogue channel, with 16 dB of loss in the control and the preamplifier, and the booster and line amplifiers adjusted for plus 14 dBm at the three bridging busses. For recording, the VU meters are set for an 8-dB lead by



channel mixer console in Question 9.46.

setting their attenuators back to plus 6 dBm. This is to take care of the unseen peaks that could overload the system while recording. The adjustment of the amplifier gains will vary somewhat from the indicated levels with different equipment, therefore they cannot be taken as absolute value.

When the playback relays are in the playback position, the playback signal is passed through a 34-dB pad before being applied to the combining network. The loss of this pad may have to be altered, depending on the output level from the playback machine. When the 400-Hz head-tone is recorded, the signal passes through the same combining network and is recorded on each sound track for 6 seconds, in its proper sequence, by a cam-driven relay system. In the off position, the oscillator output is shorted to prevent leakage; this circuitry is not shown.

Although the circuitry is for vacuum-tube type amplifiers, transistor types may be used if the gain and impedance matching is observed (see Question 9.45). The gain of the amplifiers should be divided to keep the signal-to-noise ratio high. The frequency response for this particular console is, plus-minus 1 dB, 40 to 15,000 Hz, with a total harmonic distortion (THD) of less than 0.5 percent at any frequency between 40 and 10,000 Hz. The signal-to-noise ratio is 65 dB, or 79 dB below a bus level of plus 14 dBm. Crosstalk between the three sections is greater than 85 dB at 10,000 Hz. All transmission circuits are symmetrical employing "O" type pads throughout. The several isolation coils permit the use of unbalanced mixer-network circuits and controls, with symmetrical input and output circuits. This also provides a means for grounding the various sections to a common ground point, thus reducing the possibility of circulating ground currents. All input and output circuits are 600-ohms impedance. The monitor system is discussed in Question 9.48.

It is of extreme importance that the three sections of the console be in *phase* with each other, to prevent cancellation between the three sections for certain conditions of operation. Phasing of this and other type mixer networks is discussed in Questions 23.106 and 23.107.

It is the policy of some recording activities to patch an optical film recorder across the composite bridging bus and record an optical negative along with the master dubbing track to save transfer time. The magnetic sound track is then held for protection and playback purposes. If the optical recording is to be variable-area direct-positive, it may be advantageous to employ a *cross-modulation compensator-amplifier* with the film recorder, a *film loss equalizer*, and if possible a *limiter-amplifier* to prevent overmodulating the light modulator in the optical film recorder. Cross-modulation compensating amplifiers are discussed in Question 18.246.

9.48 Describe the monitor system and associated equipment for the console in Question 9.46.—Leaving the composite bridging bus of Fig. 9-47, and following the monitor line to the upper left of Fig. 9-48, the monitor signal is amplified by a monitor line amplifier, and fed to a projection changeover relay panel, used for selecting the mode of operation—projection or dubbing. With the relay in the dubbing position, the signal is applied to the input of a monitor compensator panel, consisting of a 10-dB pad and a low-pass filter. The characteristic of this filter is representative of the average theater. Components in the panel provide adjustment for the characteristics of the dubbing stage acoustics, if required. At the output of the compensator panel is a three-branch combining network for driving the input of two 50-watt power amplifiers, one for driving the dubbing loudspeaker behind the screen, and the second for driving a duplicate speaker system in the music scoring monitor room. The output of the amplifiers feeds a speaker selector relay panel for playing the two speakers simultaneously or individually. The selector panel may be operated either from the projection booth or at the console.

From the selector panel, the signal is fed to a loudspeaker crossover network installed at the speaker system, using autotransformers to match the impedance of the network to the voice-coil impedance. It will be observed that the impedance of the monitor line from the amplifiers is 250 ohms. This permits the signal to be transmitted over the line at high voltage, low current, thus reducing

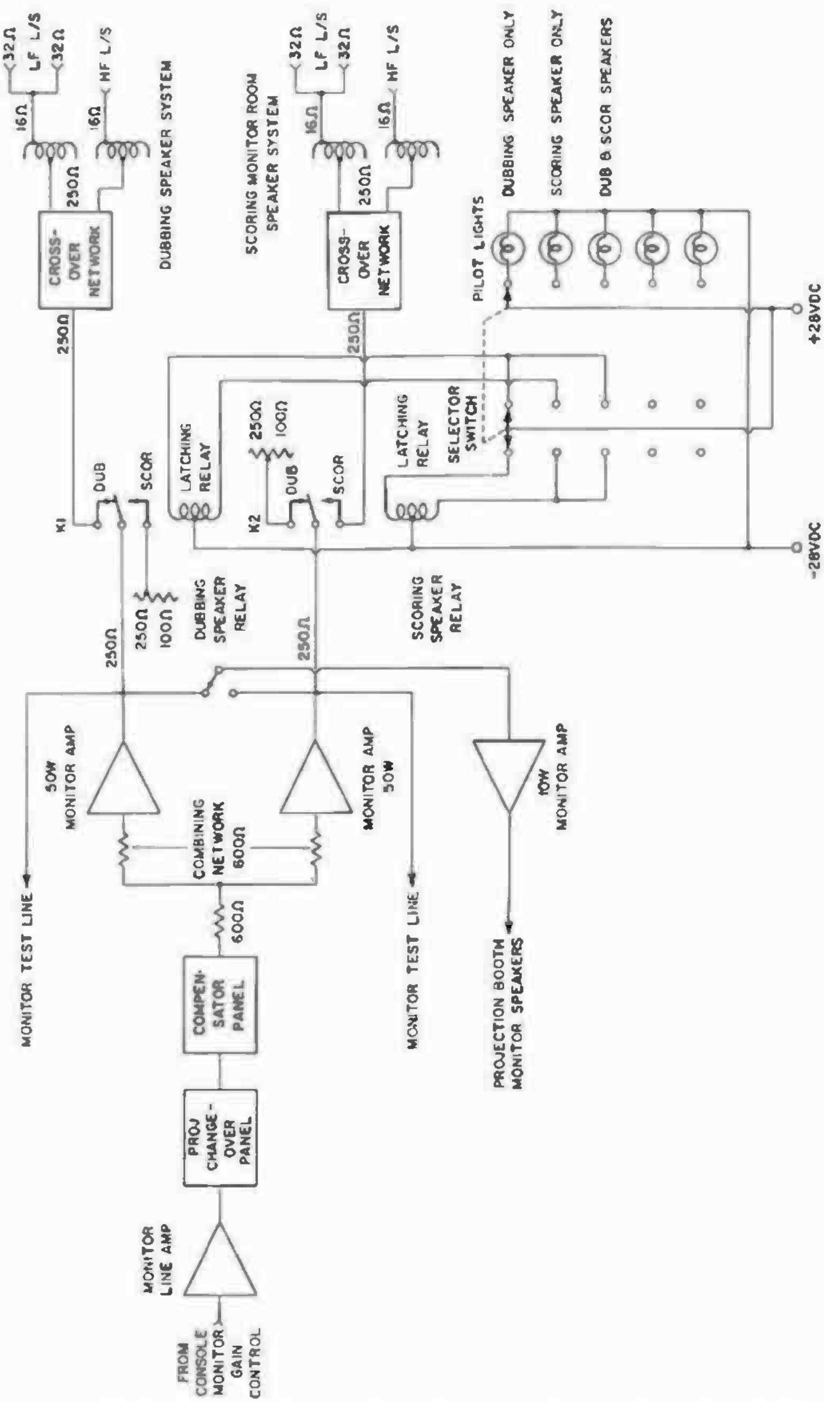


Fig. 9-48. Monitor speaker-selection relay panel for console in Fig. 9-46.

the line losses between the screen and the amplifier system.

Connected at the output of the power amplifiers is a 10-watt monitor amplifier for driving the projection booth monitor speakers. A total of four are employed, one at each projector and one at the operator's rewind bench. Separate talkback speakers are used at each projector control station.

9.49 Describe the operation of the reverberation unit used with the console

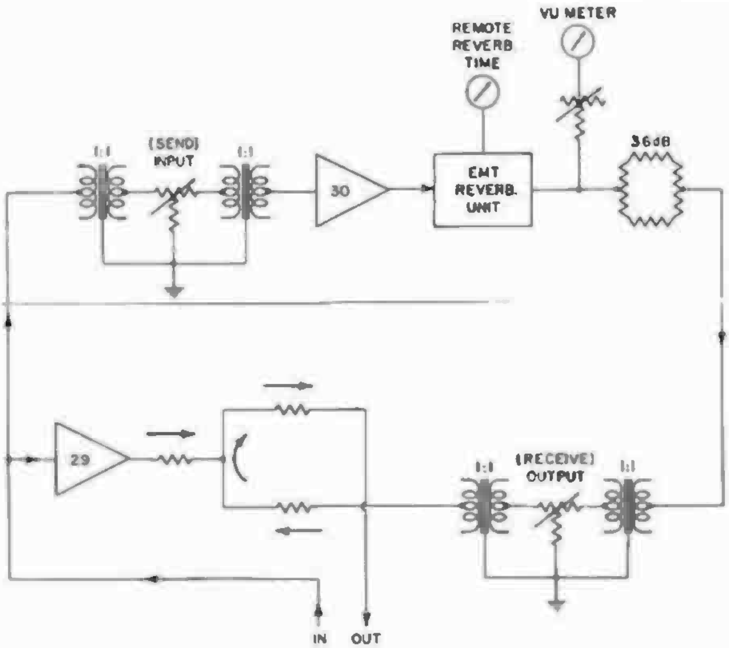

Fig. 9-49. Block diagram for EMT reverberation unit when used with the console of Fig. 9-46. All circuits are 600 ohms.

of Fig. 9-46.—The construction and technical details of the EMT reverberation unit are discussed in Question 2.130. Referring to Fig. 9-49, when the push buttons associated with the reverberation unit are depressed, the direct-signal from the dialogue channel is applied to the input of a two-branch network through amplifier (29). Passing through the upper branch of the network, the direct signal is returned to the recording channel as indicated by the arrows. At the same time, the direct signal is also applied through an input gain control and isolation coils to the input of amplifier (30), and then to the input of the EMT unit. At the output of the reverberation unit is a 36-dB pad and an output gain control which feeds the reverberated signal back to the lower branch of the network indicated by the arrows. As the signal cannot go back through the amplifier, it takes the path of least resistance and flows through the upper branch of the network, returning to the recording channel, in accordance with the arrows. In this manner, the direct and reverberated signals are mixed. After the gains of amplifiers (29) and (30) are determined, they require no further adjustment. The VU meter indicates the reverberated sound level for future reference. A remote meter at the console indicates the reverberation time in seconds.

9.50 ***Describe a solid-state portable mixer-amplifier designed for public address, sound reinforcement, and recording.***—The mixer-amplifier illustrated in Fig. 9-50A, manufactured by Altec-Lansing, is completely solid-state and may be used for public address, recording, and sound reinforcement. The schematic diagram appears in Fig. 9-50B. Starting at the upper left of the diagram, five low-level inputs are available, each connected into a standard octal socket, for use of plug-in microphone and phonograph preamplifiers or line transformers. Tracing the signal from the output of the upper preamplifier socket, the signal passes through an individual speech-music switch (S1). In the music position, the frequency response is flat, and in the speech position the response is rolled off starting at 500 Hz, and continuing downward to 6 dB at 100 Hz, and 16 dB at 30 Hz. The signal is then applied to a 750-ohm mixer control (P1), then to a mixer-combining network consisting of resistors R1 to R5, and to the input of a booster amplifier. At the output of the booster amplifier is a master gain control, which feeds a compressor amplifier having an

Fig. 9-50A. Solid-state portable mixer-amplifier Model 352A manufactured by Altec-Lansing.

attack time of 10 milliseconds, and a fixed compression ratio greater than 5:1. The compressor may be switched in as required. At the output of the booster amplifier is also a connection to feed a magnetic tape recorder. The signal voltage at this point is 0.10 volt, or about minus 55 dB for an input impedance of 10,000 ohms. By taking off the input signal at this point, it is not affected by the master gain control, but only by the mixer controls.

The compressor amplifier is followed by a high- and low-frequency equalizer circuit, then passed on to two voltage amplifier stages (Q2 and Q3), then a phase-inverter (Q4) which drives a compound amplifier (Q5 to Q8). The final amplifier stage consists of four power transistors (Q9 through Q12) operating class-B, and capable of developing 40 watts of output power, with less than 1-percent distortion over a range of 35 to 5000 Hz, and 45 watts with less than 5-percent distortion from 30 to 10,000 Hz. The output transformer is designed to supply output impedances of 4, 8, and 16 ohms, balanced to ground (see Question 8.25). A 70-volt winding is included for use with a loudspeaker distribution system.

The power for the amplifier may be taken from an internal power supply or from external batteries, such as a 12-volt car battery. Provision is also made for a second output to a tape recorder, with a voltage of 0.12 volt. Since this output is taken at the emitter of Q4, it

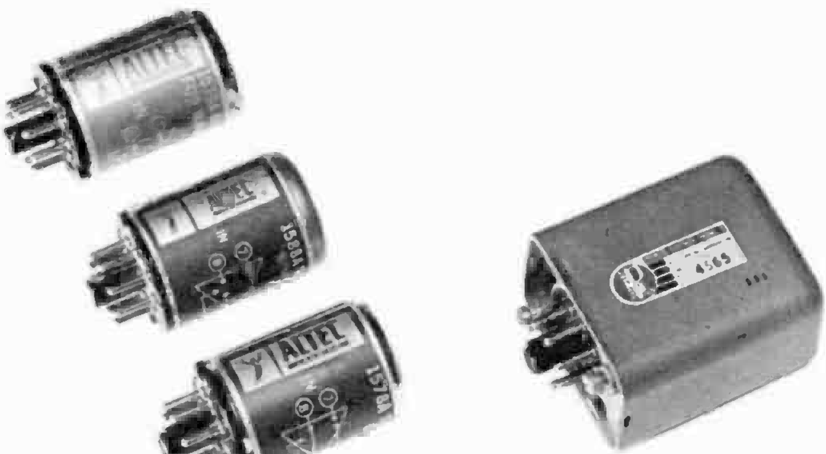

Fig. 9-50C. Plug-in units for the Altec-Lansing Model 352A.

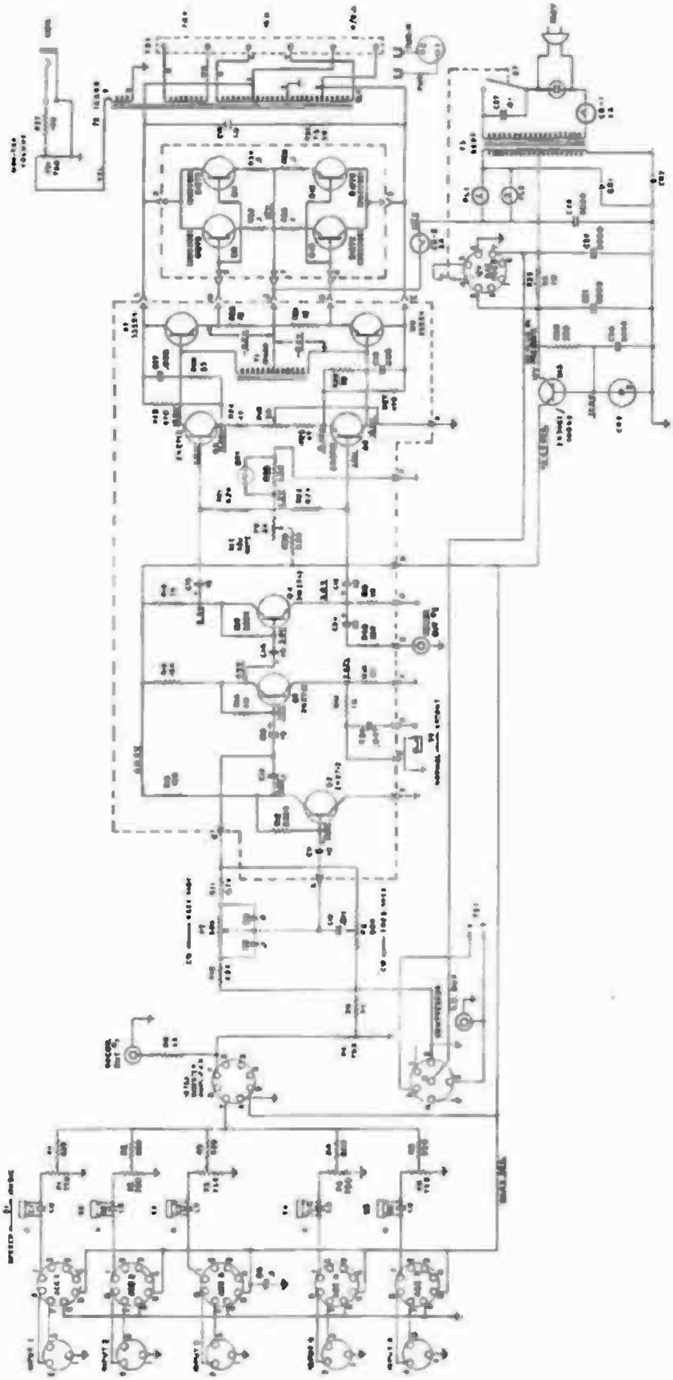

Fig. 9-50B. Schematic diagram for Altec-Lansing Model 352A.

is subject to the adjustments of both the mixer control and the master gain control. A separate winding on the output transformer supplies a means of monitoring the output signal with either headphones or loudspeaker. The VU meter is connected between one side of the 16-ohm output winding and ground, which is also connected to the input of the compressor amplifier. Fig. 9-50C shows the plug-in units. Transistor amplifiers are discussed in Section 12.

9.51 ***How is the output signal from a microphone prevented from overload-***

ing the input of a microphone preamplifier?—When recording program material from a high level source, a 10- to 20-dB network is connected between the output of the microphone and the input of the microphone preamplifier (Fig. 9-51). Many mixing consoles have this feature designed into the circuitry.

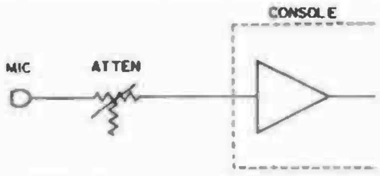

Fig. 9-51. Attenuator network connected in the output of a microphone to prevent overloading the preamplifier.

In a second manner by which preamplifier overloading is prevented, an attenuator network is included in the microphone housing, connected after the transducer element. This reduces the signal level in the microphone itself before it reaches its own preamplifier (if one is used).

Section 10

VU and Volume Indicator Meters

To properly operate a sound recording or reproducing system, some method for determining the signal levels in different parts of the system to avoid overloading and distortion is required. This is the purpose of the VU or VI meter.

VU meters have been standardized and are widely used in various devices. However, when they are improperly used, difficulties may be encountered for different impedance levels.

This Section discusses the various ramifications of such meters, and the pitfalls that are to be avoided. Simple tables have been included for compensating, if the meter is used at other than the designed impedance. A peak-indicating instrument, the Neon VI meter, widely used before the VU meter made its appearance in the motion picture industry, is described as the experimenter might find it most useful. Ballistics, reference terminology, peak-indicating devices and their calibration, and the insertion of VU meter lead in a recording channel are discussed.

10.1 What is a volume indicator meter?—A meter used to measure power levels of audio-frequency signals. The term volume indicator, abbreviated VI, is generally associated with meters calibrated in decibels. Meters designed for program monitoring purposes have special characteristics, as explaned in Question 10.3.

10.2 What is a VU meter?—A meter used for monitoring broadcast and recording circuits. Such meters employ special ballistic characteristics to properly indicate program material levels which are of complex waveforms and vary simultaneously in both amplitude and frequency. The meter consists of a 200-microampere dc, D'Arsonval movement fed from a full-wave, copper-oxide rectifier unit mounted within the meter case. VU meters are calibrated in reference to one milliwatt of power in a 600-ohm circuit. A typical VU meter panel is shown in Fig. 10-2.

10.3 What are the characteristics of a VU meter?—Because of the inaccuracies inherent in the early copper-oxide rectifier power-level meter and because of the fact it was not satisfactory for program monitoring, the development of an entirely new meter was jointly undertaken by the Bell Telephone Laboratories, Columbia Broadcasting System, and the National Broadcasting Company. The results of this research were the development not only of a new type volume-indicator meter but also the standardizing of a new reference level of one milliwatt, a unit which was adopted by the elec-

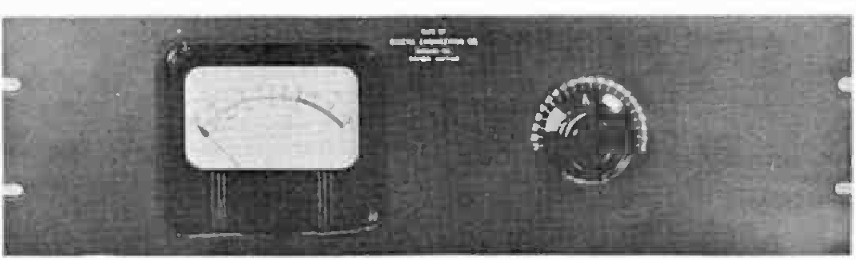

Fig. 10-2. A VU meter panel manufactured by Cinema Engineering Co.

tronics industry in May 1939. The current Standard is USASI (ASA) C16.5-1961.

The characteristics of this meter are as follows:

GENERAL—The meter consists of a dc meter movement with a noncorrosive, full-wave, copper-oxide rectifier unit (mounted in the instrument case) and responds approximately to the root mean square (RMS) value of the impressed voltage. This will vary somewhat depending on the waveforms and the percent of harmonics present in the signal.

INSTRUMENT SCALE—The face of the instrument may have either of the two scale cards shown in Fig. 10-19. Each card has two scales, a VU scale ranging from −20 to +3 VU and a percent modulation scale ranging from zero to 100 percent, with the 100 point coinciding with the zero point on the VU scale. (See Question 10.19.) The normal point for reading volume levels is at zero VU or 100 scale point which is located to the right of the center at about 71 percent of the full scale arc.

DYNAMIC CHARACTERISTICS—With the instrument connected across a 600-ohm external resistance, the sudden application of a sine-wave voltage, sufficient to give a steady-state deflection at the zero VU, or 100 scale point, shall cause the pointer to overshoot not less than 1 percent nor more than 1.5 percent (0.15 dB). The pointer shall reach 99 on the percent scale in 0.3 second.

RESPONSE VS. FREQUENCY—The instrument sensitivity shall not depart from that at 1000 Hz by more than 0.2 dB, between 35 and 10,000 Hz, nor more than 0.5 dB between 25 and 16,000 Hz.

IMPEDANCE—For bridging across a line, the volume indicator, including the instrument and proper series resistor (3600 ohms), shall have an impedance of 7500 ohms when measured with a sinusoidal voltage sufficient to deflect the meter to zero VU or 100 scale point.

SENSITIVITY—The application of a sinusoidal potential of 1.228 volts (4 dB above 1 milliwatt in a 600-ohm line) to the instrument in series with the proper resistance (3600 ohms) will cause a deflection to the zero VU or 100 percent point.

HARMONIC DISTORTION—The harmonic distortion introduced in a 600-ohm circuit, caused by bridging the volume indicator across it, is less than 0.3 percent, under the worst possible condition (no loss in the variable attenuator).

OVERLOAD—The instrument must be capable of withstanding, without injury or effect on the calibration, peaks of 10 times the voltage equivalent to a reading of zero VU or 100 for 0.50 second and a continuous overload of five times that voltage.

10.4 What is a power-level meter? —A VI meter calibrated in decibels. As a rule, this type meter is confined to test equipment for steady-state measurements and is not used for monitoring program material.

10.5 What is a rectifier-type meter? —One which employs a copper-oxide or selenium rectifier unit to rectify the applied ac voltage to dc for operating the instrument movement. This is a very common method employed in meters designed for audio frequency measurements, such as a VU meter, or ac voltmeters for servicing. Such meters have a high input resistance to prevent loading the circuit under measurement.

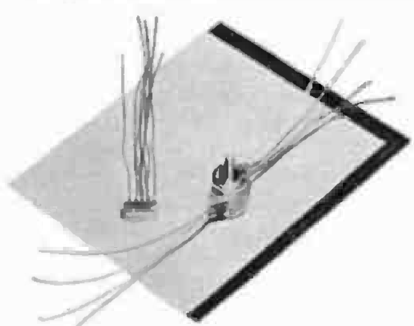

Fig. 10-5. Selenium instrument rectifiers manufactured by Conant Electrical Laboratories.

Two rectifier units manufactured by the Conant Electrical Laboratories are shown in Fig. 10-5. A complete explanation of bridge rectifiers will be found in Questions 21.95 through 21.99.

10.6 Describe a wide range electronic VU meter for program monitoring. —Standard VU meters measure only the upper 23 dB of the signal level. From a practical standpoint this limits the display to about 20 dB below the reference level of the zero indication.

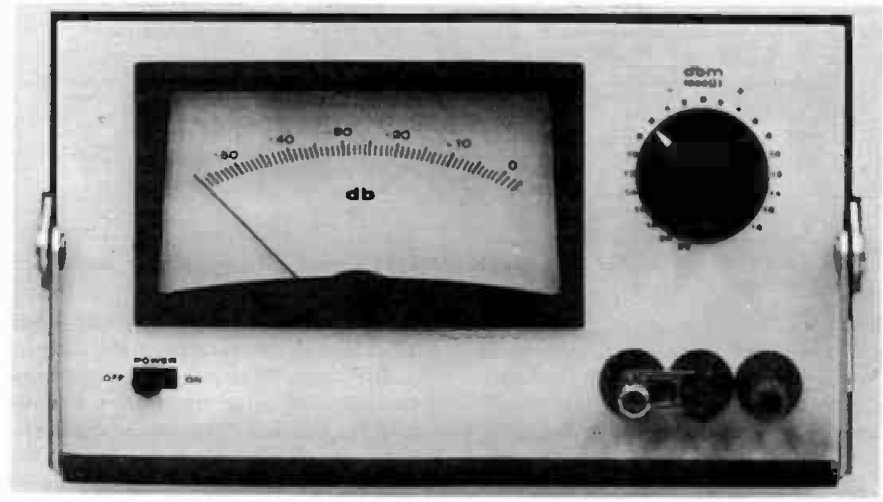

Fig. 10-6A. CBS Laboratories Model 600 wide-range program-monitor meter.

This short range of operation limits its usefulness, particularly when it is connected across a bridging bus for monitoring program information. A wide-range program-monitor meter, Model 600, manufactured by CBS Laboratories, which displays the program information over a 60-dB meter scale, spread from minus 57 dB to plus 3 dB, is shown in Fig. 10-6A. The large spread of program material permits the very low level signals to be observed, and also the noise between program pauses.

This instrument was not designed to replace the conventional VU meter; however, its characteristics are compatible with the present VU meter. In addition, a dc output is provided for connection of a linear tape recorder for logging program levels over a range of 60 dB. The zero-dB indication may be set to represent a reference level from minus 22 dBm to plus 18 dBm.

Referring to the block diagram in Fig. 10-6B, the basic component is a logarithmic solid-state amplifier, with a nonlinear feedback circuit (see Question 12.196), a preamplifier, a 15,000-ohm bridging input transformer, a reference-level selector switch, and a sensitive indicating meter movement. The total range of measurement is 79 dB to plus 21 dB, with a frequency response of plus or minus 1 dB from 50 to 15,000 Hz.

10.7 What is a neon VI meter?— In the early days of motion picture sound recording, and long before the use of magnetic film, sound was recorded directly on photographic film (optical recording). Because the VI meters at that time were not standardized and had radical ballistics, peaks of 8 to 10 dB were not indicated by the meter, and the light modulator could be easily overloaded, causing serious

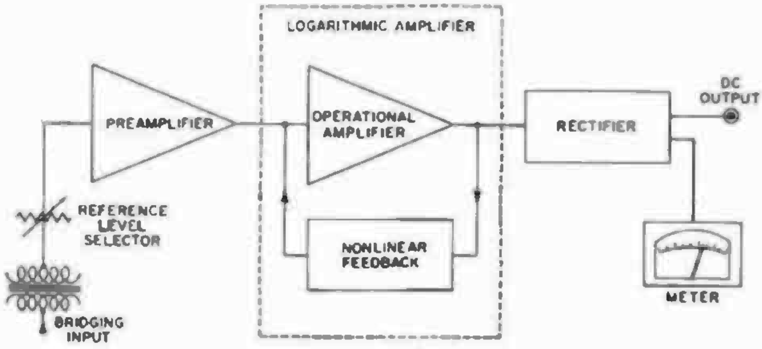

Fig. 10-6B. Block diagram for CBS Laboratories Model 600 wide-range program-monitor meter.

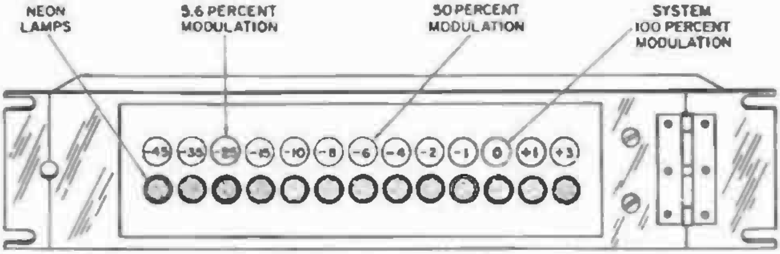

Fig. 10-7A. Front view of RCA Model MI-3176A neon volume indicator meter.

distortion. To provide a meter that would read the peaks and at the same time permit the mixer to see the indications, RCA developed an instrument known as a neon volume indicator meter (no longer manufactured).

The meter consisted of 20 small vacuum tubes and 16 neon lamps, arranged in a circuit to indicate the recording levels from minus 45 dB to plus 3 dB, with reference to 100 percent modulation of the light modulator. The reason for the use of such a device was its sensitivity and ability to read both the negative and positive peak excursions of the light modulator.

As this device is of interest to present day recording and is in some instances still in use, a description of its principles are in order. The mechanical design was such that the neon lights were mounted horizontally in a straight line (Fig. 10-7A). In each hole in the lower line is a neon lamp, which is actuated by the audio signal and made to glow. At the extreme left is a minus 45-dB lamp and at the extreme right the plus 3-dB lamp. Pilot lamps glowing continuously indicate the minus 25-, 6-, and 0-dB levels. The basic circuit for such an instrument is shown in Fig. 10-7B. The revision of this circuit to transistors would be of considerable value to present day recording, as the industry is still faced with the use of monitoring meters that do not indicate the actual peak values of the audio signal.

The block diagram for a neon VI meter is shown in Fig. 10-7B. The signal is applied to the input transformer T1, then amplified by a two-stage amplifier. At the output of the amplifier, the signal is applied to two voltage dividers, P1 and P2. From there the signal passes through several other amplifiers, each with a neon lamp at its output. The gain of each amplifier stage is adjusted by P1 and P2 to fire the neon tube at a given level.

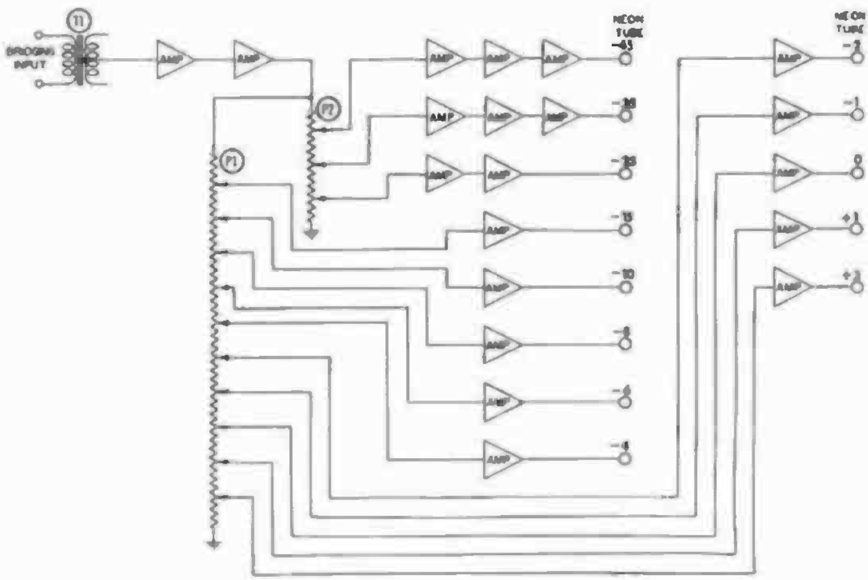

Fig. 10-7B. Basic circuit for neon volume indicator.

10.8 What is the standard reference level used for recording and broadcasting?—Both the recording and broadcasting industries as well as most other electronic industries use the 1-milliwatt reference level. This level was standardized in May of 1939. In a few instances for special purpose devices, the 6-milliwatt reference level is used.

10.9 What does the term dBm mean?—It indicates the stated level is with reference to 1 milliwatt of power in a 600-ohm line.

10.10 What is the reference level when it is stated only in dB?—It is with reference to 6 milliwatts in a 500-ohm line.

10.11 What is the voltage across a 600-ohm line for 1 milliwatt of power?—The voltage equals 0.773 volt.

10.12 What is the voltage across a 500-ohm line for 6 milliwatts of power?—The voltage is equal to 1.73 volts.

10.13 Define the terms volume unit (VU) and decibels (dB).—The volume unit (VU) is a unit of measurement used with volume-indicator meters to specify a change of 1 dB in volume for a complex waveform. Such units are used with the VU meter described in Question 10.3. Complex waveform changes can only be measured in volume units. Meters designed for such use have special characteristics. For complex waveforms, such as speech, a VU meter reads between the average and the peak values of a complex wave. No simple relationship exists between volume measured in VU and the power of a complex waveform. The indicated reading will depend on the particular wave shape at the moment. For sine-wave measurements, a change of one VU is numerically equal to a change of 1 dB.

VU meters are designed to have a dynamic characteristic that approximates the response of the human ear. When a speech waveform is applied to a VU meter the movement will indicate peaks and valleys in the signal. The average of the three highest peaks in 10 seconds (disregarding occasional extremes) is taken to be the indication of the meter movement.

From the above discussion it appears the VU should not be used to interpret steady-state measurements, and is only used with complex waveforms which are constantly changing in amplitude and frequency, and depend on human interpretation of a constantly changing condition. The decibel is used to interpret steady-state conditions. It should be pointed out that many meters indicated as VU meters are not actually such meters, as they are normal sensitive movements without the special characteristics of the standard VU meter. Therefore, they do not indicate a true reading in volume units.

10.14 Why are VU meters calibrated with reference to 1 milliwatt of power in a 600-ohm line?—This reference level was selected as a level which would conform to the Telephone Company's standards of limiting the signal level on a transmission line to a value that would produce a minimum of cross talk and still provide a satisfactory signal-to-noise ratio. Also, the 1 milliwatt reference level is a unit quantity. Hence, it is readily applicable to the decimal system, being related to the watt by the factor 10^{-3} which results in positive values for the majority of measurements.

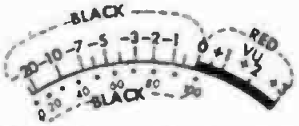
A further advantage is that all meters of this type are exactly alike in construction and characteristics and, when several are connected across the same circuit, may be tested and their operation checked by the application of a 1000-Hz signal.

10.15 What is the maximum signal level that may be applied to a telephone line?—Plus 8 dBm.

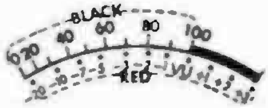
10.16 What does the term zero level mean?—It is a reference power level. Example; for 1 milliwatt of power in a 600-ohm line, zero equals 0.773 volt. For a 500-ohm line, zero equals 1.73 volts (7.78 dB higher than 1 milliwatt).

10.17 Where is 1 milliwatt indicated on a VU meter scale?—For a VU meter of 7500-ohms input impedance connected across a 600-ohm line in which 1 milliwatt of power is flowing, 1 milliwatt will be indicated at the minus 4 VU (or dB) calibration point, for the reason that a VU meter input attenuator has no zero position, but starts its calibration at plus 4 VU. Therefore, 1 milliwatt will be indicated at the minus 4 VU (or dB) calibration point. This will be discussed further in Question 10.24.

10.18 What reference levels have been used other than 1 milliwatt?—In the early days of broadcasting and re-



(a) *Recording and test equipment.*



(b) *Broadcast monitoring.*

Fig. 10-19. VI meter scales.

cording, both 10 and 12.5 milliwatts in a 500-ohm line were used as a reference level. However, later this was changed to 6 milliwatts. In May, 1939 the present standard of 1 milliwatt in a 600-ohm line was adopted. Fifty milliwatts was used at one time by the radio industry for rating the output level of a radio receiver for a given input at the antenna in microvolts. This too has been replaced with other standards.

10.19 Explain the difference between an A and a B scale used on VU meters.—VU meters may be obtained with the upper portion of the scale arc calibrated in either percent modulation or decibels. For recording purposes the A scale is preferred because the levels are read in decibels. For broadcast work, the percent-modulation scale is preferred as it indicates the percent modulation of the radio transmitter. However, both scales are widely used. The two scales are pictured in Fig. 10-19.

10.20 Where is the point of greatest accuracy on the scale of a VU or VI meter?—The accuracy for the full-scale deflection is 2 percent; however, the minus 1 and the plus 1 dB calibration points above and below the zero calibration are generally used when reading levels as they are quite accurately indicated.

10.21 What are the ballistics of a VU meter?—Ballistics are the mechanical and electrical characteristics built into the meter movement. A given characteristic may be obtained by shaping the pole pieces and counterweighting the pointer mechanism. Shunts are sometimes used across the meter terminals, but this will reduce the sensitivity of the movement. (See Question 10.3.)

The ballistics characteristics of a typical old style VI meter and a standard VU meter, when a 1000-Hz signal is applied for a period of one second, are shown in Fig. 10-21. It will be noted the VU meter comes to a steady state at the end of 0.30 second, while the VI meter continues to oscillate showing peaks and valleys over a period of one second.

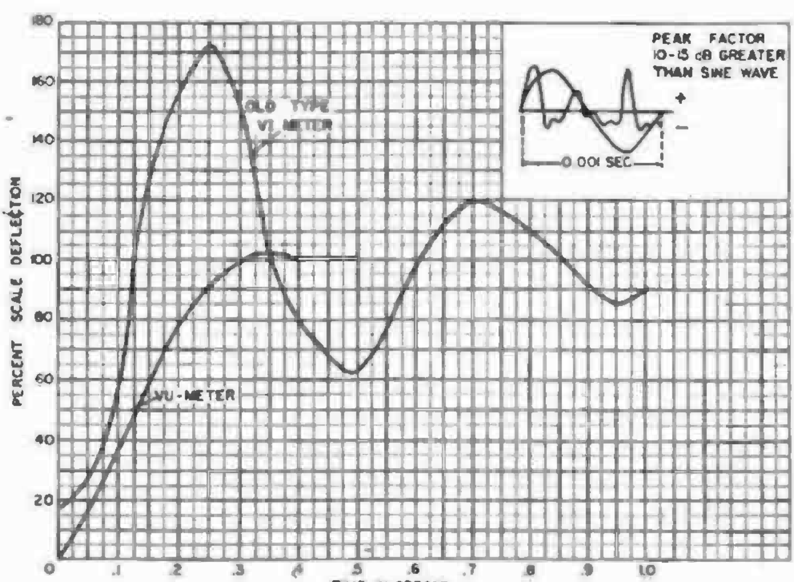


Fig. 10-21. Comparison of the original VI meter and the present VU meter ballistics for a sudden application of a 1000-Hz signal for a period of 1 second. (Courtesy, Proceedings of IRE, now IEEE.)

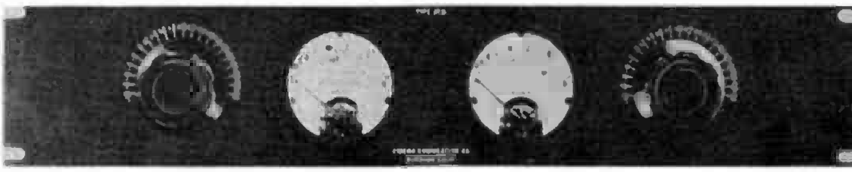

Fig. 10-22. An early type dual volume indicator panel manufactured in 1939 and now obsolete. (Courtesy, Cinema Engineering Co.)

The VI meter movement overshoots about 65 percent in the first 0.25 second, while the VU meter movement has almost reached a steady state. This clearly indicates why the ballistics of the VU meter are more desirable than those of the older-type VI meter for monitoring program material containing complex waveforms.

10.22 What type meters were used before the adoption of the VU meter?—Copper-oxide rectifier meters of the type shown in Fig. 10-22. The characteristics of these meters were not standardized, although they were used extensively in both the recording and broadcasting industries. This meter possessed characteristics which were not suitable for monitoring purposes, although they were quite suitable for sine wave power measurements.

The older-type meters used a reference level of 6 milliwatts in a 500-ohm line as the zero level calibration point (1.73 volts). This appeared on the meter scale slightly to the left of center scale.

Two sensitivities in this meter were used; they were zero equals 1.73 volts and zero equals 0.548 volt. In the latter meter, zero was equal to a minus 10-dB signal in a 500-ohm line. Three movements were available; fast, medium, and slow. The range of measurement was extended by the use of an attenuator as used with the present VU meter.

10.23 How may the ballistics of the older type VI meters be identified?—By the letters appearing on the meter scale. HS indicates high speed, GP is for general purpose, and SS indicates slow speed. The high-speed movement was used for monitoring purposes, the general-purpose movement for test equipment, and the slow speed for acoustic measurements or where an extremely slow response was required.

10.24 What are the recommended connections for a VU meter?—Referring to Fig. 10-24 it will be seen the instrument consists of an indicator movement, a variable attenuator, and a series resistor of 3600 ohms. The meter movement is a 200-microampere D'Arsonval movement with an internal resistance of 3900 ohms. A full-wave, copper-oxide or selenium rectifier is contained within the meter case. The attenuator is variable in steps of 2 dB and presents a constant resistance of 3900 ohms to the meter movement. This design prevents the ballistics of the meter from being affected when the attenuator setting is changed.

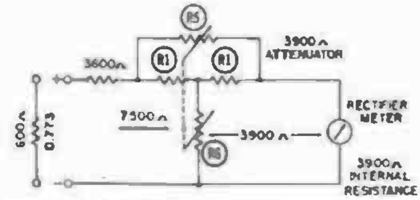

Fig. 10-24. Schematic diagram for a 7500-ohm VU meter, calibrated for one milliwatt reference level or, 0.773 volt across 600 ohms.

Standard VU meters are designed to read zero VU, or 100 percent, with 1.228 volts (+4 dBm) applied to the instrument with the 3600-ohm series resistance connected ahead of the attenuator. If the meter is used with the attenuator but without the 3600-ohm series resistor and is connected across a 600-ohm source in which 1 milliwatt of power is flowing, the movement will be deflected to the 100 percent calibration point.

This method of use is not recommended because the impedance looking back into the meter is only 3900 ohms and is too low an impedance to bridge a 600-ohm circuit. It is the usual practice to keep the impedance of bridging devices at a ratio of 10:1 or greater.

To increase the input impedance of the VU meter from 3900 ohms to 7500 ohms, a 3600-ohm resistor is connected in series ahead of the attenuator. However, in so doing a 4-dB loss is incurred across the 3600-ohm resistor. If a signal of 1 milliwatt (0.773 volt) is impressed across the input terminals of the circuit in Fig. 10-24, it will not deflect the meter to the 100 percent calibration but only to the minus 4 VU (or dB) mark, or approximately 65 percent. This means that if the meter is to be deflected to the 100 percent point, the input signal must be increased to a plus 4 dBm. This is the reason why 1 milliwatt of power will be indicated at the minus 4 calibration mark.

Attenuators used with VU meters have no 0-dBm calibration step but start at a plus 4 dBm. The bridging loss of a 7500-ohm VU meter is quite small (in the order of 0.34 db) when connected across a line of 600 ohms impedance.

10.25 How does the attenuator of a VU meter function?—VU meters are, in reality, voltmeters calibrated in decibels to read with respect to a reference voltage. The attenuator inserts loss ahead of the meter in a manner similar to a voltmeter multiplier, except that in the case of the VU meter, the loss is inserted in steps of one or more dB while the impedance remains constant.

10.26 How are the readings of the input attenuator and the meter scale added?—Algebraically. For example, if the attenuator is set to a plus 10 dBm and the meter indicates a plus 3 dB, the level is plus 13 dBm. On the other hand, if the attenuator is set to a plus 30 dBm and the meter reading is a minus 3 dB, the true level is plus 27 dBm.

10.27 Does a VU meter indicate the true level of a complex waveform?—No. It indicates somewhere between the average and the peak values. Program material is of a complex and transient nature; therefore, the VU meter indicates considerably under the instantaneous peak program level. This means that many peaks present in the program material are not indicated by the meter because the meter movement cannot follow small instantaneous peaks which are varying both in amplitude and in frequency simultaneously. Therefore, the meter must either be set or caused to indicate in a manner that will not overload the system in which it is operating.

Peak voltages of 8 to 14 dB may be occurring above the meter indication but, because of the ballistics of the meter, are not indicated. Even if they could be seen it would be too late to reduce the level. Therefore, a VI or VU meter must be set with at least an 8-dB lead, which is described in Question 10.28.

10.28 What is the procedure for inserting lead into a VU meter circuit to prevent overloading a recording system?—Since VU meters do not indicate the true peak values of program material (complex waveforms) it is quite easy to overload a recording system. To protect against these unseen peaks, a lead or margin of safety is inserted in the VU meter circuit.

To illustrate the procedure for inserting a lead into a VU meter circuit, assume a recording channel employing both photographic film and magnetic recorders is to be adjusted. Further assume that the VU meter is connected across a bridging bus with a sine-wave level of plus 14 dBm. With the VU meter set to plus 14 dBm, a 400- or 1000-Hz signal is sent into the input of the recording console. The mixer control is set to its normal operating range and the signal level adjusted to bring the bus level to plus 14 dBm (the VU meter reads 100 percent or zero dBm). Adjust the recording amplifier for the photographic recorder to deflect the light modulator to *exactly* 100-percent modulation. Assuming the operating level for the magnetic recorder has been determined as set forth in Question 17.163, the recording amplifier is adjusted for 100-percent modulation.

Remove the input signal and return the VU meter attenuator to its plus 6-dBm position. This inserts an 8-dB lead or margin of safety in the VU meter by making it 8 dB more sensitive, thus protecting the system against unseen peaks up to 8 dB. The program material is now mixed in the usual manner. Some recording activities, because of the heavy peaks and overloads encountered in some types of music, use a 10- to 12-dB lead in the VU meter.

Radio transmitters are adjusted in a similar manner, only in this instance the percentage modulation indicated by the VU meter indicates the percent modulation of the radio transmitter.

10.29 What is the input impedance of the older type VI meters described in Question 10.22?—Generally, 5000 ohms for those designed to indicate 1.73 volts across a 500-ohm line. The circuit diagram for the older type meter is shown in Fig. 10-29. This type meter panel uses a 5000-ohm L-type attenuator ahead of the meter movement. Although the L-pad does not present a constant impedance to the meter movement, it does present a constant 5000 ohms to the circuit being bridged. The two arms of the attenuator are ganged together mechanically and are varied inversely to each other. The attenuator is designed to increase the level of the meter readings in steps of 2 dB each, starting at zero level (6 milliwatts).

One of the disadvantages of this type meter, when used for monitoring program material, is the ballistics of the meter which are changed with changes in the setting of the input attenuator. This is due to the shunt arm of the attenuator being reduced in value and acting as a shunt across the meter movement, as the attenuator is set for a higher range The ballistics of this meter are not suitable for program monitoring, and have been obsolete for some years. The ballistics and frequency characteristics also vary with different manufacturers.

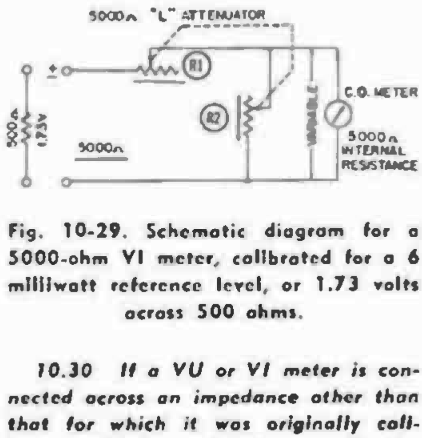

Fig. 10-29. Schematic diagram for a 5000-ohm VI meter, calibrated for a 6 milliwatt reference level, or 1.73 volts across 500 ohms.

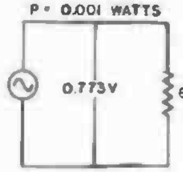
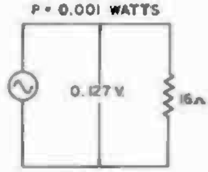
10.30 If a VU or VI meter is connected across an impedance other than that for which it was originally calibrated, will the reading be correct?—No. A correction factor must be applied to the indicated reading to correct for the difference in the impedance.

10.31 Why must a correction factor be applied to a VU meter when connected across an impedance different from that which it was originally calibrated?—VU and VI meters are in reality voltmeters calibrated in decibels with respect to a reference power level. If connected across a line impedance different from that for which it was originally calibrated, the voltage supplied to the meter will either be lower or higher than the original calibration. Therefore, the meter indicates incorrectly. Two circuits are shown in Fig. 10-31, one a 600-ohm circuit and the other a 16-ohm circuit. Both are dissipating the same amount of power, yet the voltage across each circuit is quite different. For the 600-ohm circuit, the voltage is 0.773 volt, and for the 16-ohm circuit it is 0.127 volt. It may readily be seen that if a VU meter is connected across the 16-ohm circuit, it will not deflect the same amount as for the 600-ohm circuit, although the same amount of power is flowing in each circuit. To arrive at the correct power level in the 16-ohm circuit a correction factor must be applied to the meter indication.



(a) *600-ohm line.*



(b) *16-ohm line.*

Fig. 10-31. Voltages across lines of different impedance but with same power in milliwatts.

10.32 Give the equation for VU and VI meter impedance level correction.

$$dB = 10 \operatorname{Log}_{10} \frac{Z_2}{Z_1} \text{ or } \frac{Z_1}{Z_2}$$

where,

Z_1 is the impedance of the circuit bridged,

Z_2 is the impedance for which the meter is calibrated.

When the line impedance is greater, the equation is inverted and the correction subtracted from the indicated level. When the line impedance is low, the correction factor is added. A typical example of applying a correction factor would be as follows: A VU meter calibrated for a line impedance of 600 ohms is bridged across a 16-ohm line as shown in Fig. 10-31. If the meter indicates a level of plus 1 dBm, what is the true level?

$$dB = 10 \,Log_{10} \frac{600}{16}$$
$$= 10 \times 1.574$$
$$= 15.74 \,dB.$$

The correction factor of 15.74 dB is added to the meter reading of plus 1 dBm, which results in a true level reading of plus 16.74 dBm. Typical correction factors are given in Fig. 10-32A.

Shown in Fig. 10-32B is an impedance-level correction graph for meters calibrated with reference to 1 milliwatt, 600 ohms. The new impedance to be bridged is entered at the lower margin and followed upward to the diagonal line. The correction factor is read at the left margin.

Line Impedance (ohms)	Meter Cal. 500 Ohms (dB)		Meter Cal. 600 Ohms (dB)	
600	−0.791	subtract	0.000	
500	0.000		+0.791	
250	+3.010		+3.800

8	+17.960		+18.750	
4	+20.970		+21.760	

Fig. 10-32A. VU and VI meter impedance correction factors.

10.33 Define the term bridging loss when applied to a volume indicator meter.—It is the reduction in signal level experienced when a VU meter is bridged across a circuit. The drop in signal level is caused by the absorption of power by the meter circuit. As a rule, the power absorbed is quite small and may for most purposes, be ignored. However, at high powers, it may become important. Bridging loss may be calculated by the equation:

$$dB = 20 \,Log_{10} \frac{2B_R + R}{2B_R}$$

where,

B_R is the VU meter input impedance,
R is the line impedance.

A table of bridging losses for the more commonly used impedances and meters is given in Fig. 10-33.

10.34 How may a standard VU meter designed for 600-ohm use be employed in a line having an impedance of 150 ohms?—By the use of an input transformer as shown in Fig. 10-34, recommended by the Weston Instru-

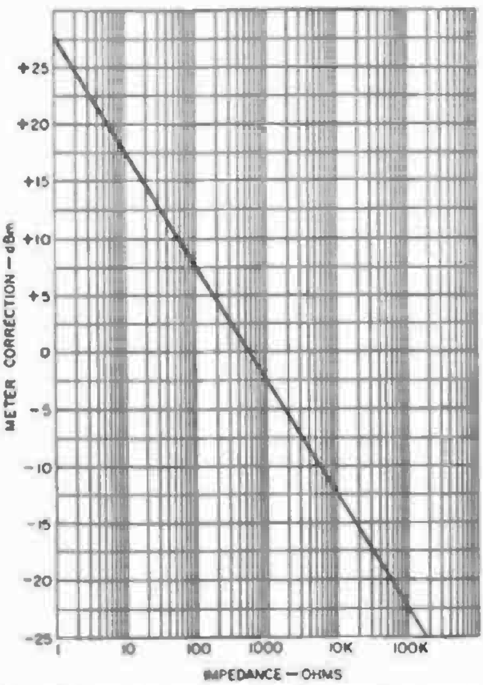

Fig. 10-32B. Impedance-level correction graph.

ment Corporation. The transformer has a turns ratio of 1:2 which results in a gain of 6 dB, and may be used with the switches S1 and S2 set to "T," up to any level for which the transformer is suitable. Switch S3 may be open for ungrounded circuits or omitted entirely. The circuit is closed if a grounded system is necessary.

Meter Impedance (ohms)	*Line Impedance (ohms)*	*Bridging Loss (dB)*
5000	500	0.47
5000	600	0.55
7500	500	0.30
7500	600	0.38

Fig. 10-33. VU and VI meter bridging losses for circuits of 500 and 600 ohms.

However, since any transformer has power limitations and since a 12-dB pad can be arranged to serve as a match between the line and the load, the diagram shows an arrangement whereby the transformer is switched out of the circuit and a fixed pad switched in at the 12-dB or 16-dB point. The two line switches S1 and S2 are transferred to "P" and switch S3 must be closed, if previously left open.

It is convenient to associate these transfer switches with the 12-dB position on the attenuator. The transformer is used for levels up to plus 12 dBm. Above plus 12 dBm, the pad is switched into the circuit.

10.35 What is a power-output meter?—A meter similar to the one shown in Fig. 10-35A which is used for measuring the power output of audio amplifiers and other devices. It may also be used to determine the characteristic and internal output impedance, the effect of load-impedance variation, and other applications involving the measurement of output power and impedance with respect to frequency.

The circuit of the meter (Fig. 10-35B) consists of a load impedance adjusting network composed of resistor R1, impedance-selecting switch S1, multiplier switch S2, frequency-correcting networks, a calibrating pot, and indicating meter M1.

The impedance-adjusting network provides for the selection of 40 different load impedances between 2.5 and 20,000 ohms. The meter scale is calibrated from 1 to 50 milliwatts, and from 0 to 17 dB. The meter multiplier switch extends the power readings from 0.10 to 5000 milliwatts (5 watts), and the dB reading from minus 10 to plus 30 dB in steps of 2 dB. The location of the controls may be seen in Fig. 10-35A.

Fig. 10-35A. A power-output meter manufactured by the Daven Company.

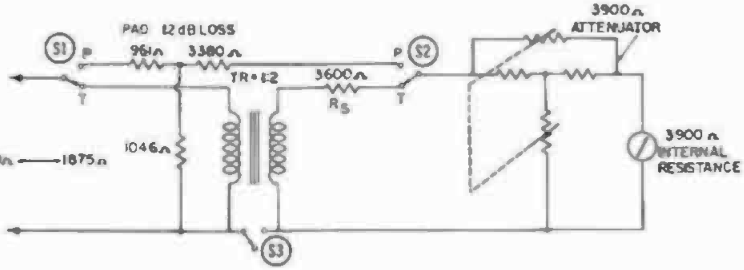

Fig. 10-34. Circuit for a standard VU meter panel, with input transformer and pad, for operation on a 150-ohm transmission line.

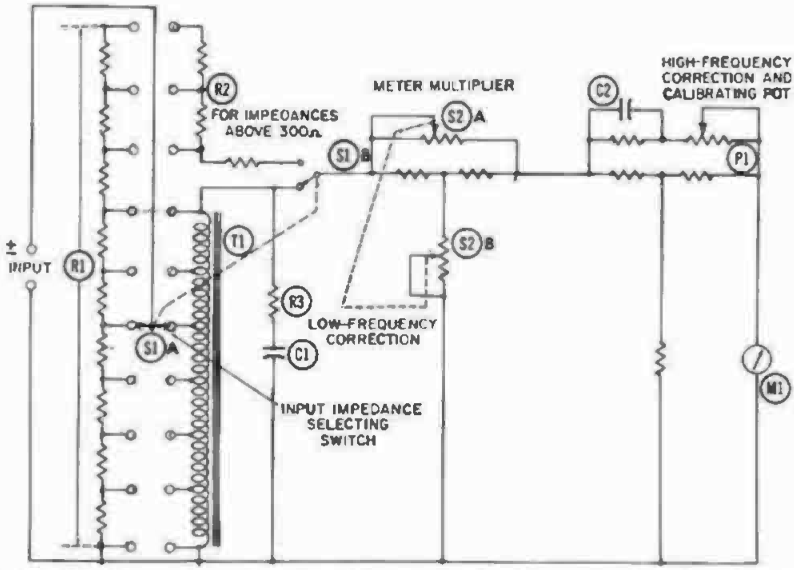

Fig. 10-35B. Elementary schematic diagram of the Daven Model OP-961 power-output meter.

Referring to Fig. 10-35B, the input terminals are shunted by a 40 section noninductive resistance network R1, its value controlled by switches S1A and B. For impedance values up to 300 ohms, resistor R1 is bridged by a high impedance autotransformer T1, the appropriate tap being selected by switch S1A. As the resistance of R1 is increased or decreased, the ratio of transformation of the autotransformer coil is increased or decreased in the proper relation, so that the power dissipated in resistor R1 is directly proportional to the voltage appearing across the meter M1.

To ensure that the input impedance remains essentially noninductive, the bridging impedance presented by the autotransformer to resistor R1 is quite high. For impedances above 300 ohms, switch S1B disconnects the coil and substitutes a noninductive resistor, R2. This resistor then controls the voltage appearing across the meter. The selection of the taps on resistor R1 as well as switching from the autotransformer T1 to resistor R2 is controlled by the positions of switches S1A and B.

The actual value of impedance presented by the meter is the value of R1 in parallel with the autotransformer T1. (The design of such autotransformers is discussed in Question 22.124.) Above 300 ohms, resistor R2 is substituted for the transformer and is shunted by the remainder of the circuit. A frequency-correcting network consisting of resistor R3 and capacitor C1 is connected across the output side of coil T1 to compensate for losses in the coil at the lower frequencies.

The meter-multiplier switch S2A and B consists of a bridged-T network calibrated in power ratio and decibels. A second bridged-T network serves as a combination high-frequency correction network and basic calibration control. The indicating meter is a conventional rectifier meter.

The input impedance and power accuracies are plus or minus 2 percent over a range of 30 to 10,000 Hz. The reference power is 1 milliwatt in a 600-ohm circuit (zero dBm). The device may be used for many different types of measurements; among them are:

(A) *MEASUREMENT OF POWER OUTPUT AT A GIVEN IMPEDANCE AND FREQUENCY.* Adjust the meter for a reading near its center scale. Maximum power output is the meter indication multiplied by the meter multiplier (S2). For variable-impedance devices, set the meter impedance to the required load impedance and note the power output. This same procedure is used for all impedance values of interest.

(B) *MEASUREMENT OF INTERNAL OUTPUT IMPEDANCE.* Vary the meter impedance until a maxi-

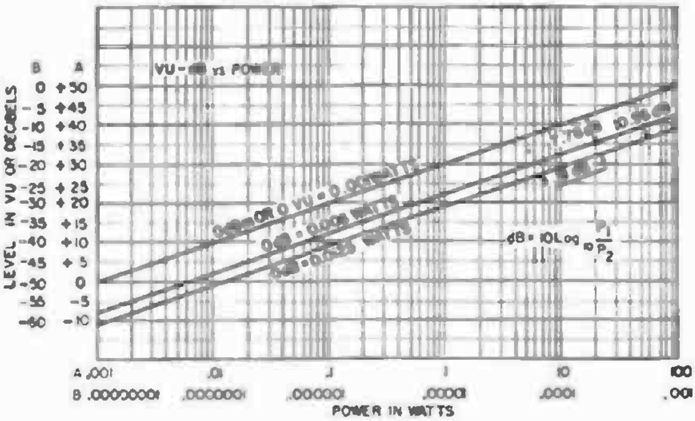

Fig. 10-40. Chart showing the difference in decibels between 1, 6, and 12.5 milliwatt reference power levels.

mum power-output indication is obtained. The internal output impedance of the device under test is equal to the meter impedance.

(C) *MEASUREMENT OF INTERNAL OUTPUT IMPEDANCE WITH RESPECT TO FREQUENCY.* Hold the input signal to the device under test at a constant value. Measure the internal output impedance for each frequency of interest, by noting the maximum power output.

Care must be exercised in assuming that the impedance which develops the maximum power output is the correct load impedance for the device under test. Many devices (such as negative-feedback amplifiers) have an internal output impedance. If known, the correct load impedance should always be used when making measurements involving the use of power output meters.

10.36 What is the reference-level terminology used in the sound and electronic industries?

dB	6 milliwatts, 1.73 volts, 500 ohms.
dBa	Noise measurements (dB adjusted).
dBj	1000-microvolts reference.
dBk	1-kilowatt reference.
dBm	1 milliwatt, 0.0775 volt, 600 ohms.
dBμ	1-microvolt reference.
dBV	1-volt reference.
dBW	1-watt reference.
dBx	Crosstalk measurements.
dBrap	Decibels above the reference acoustical power, 10^{-16} watts.
dBrn	Relationship of noise to a reference level.
dBrnc	Crosstalk measurements.
dBVg	Decibels of voltage gain.
VU	1-milliwatt; complex waveforms varying in both amplitude and frequency.

10.37 What is a transmission unit?—A now obsolete term formerly used for expressing gain or loss. It has been replaced by the term decibel.

10.38 What does the term mile-of-loss mean?—This is an obsolete term formerly used in the telephone industry to express gain or loss in terms of loss

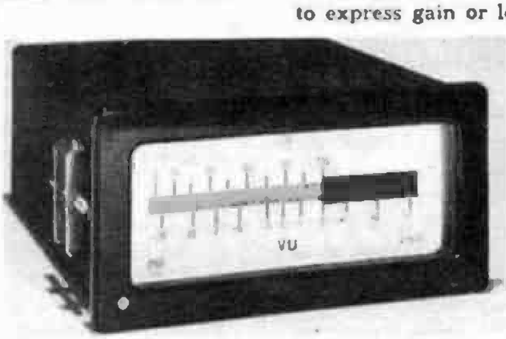

Fig. 10-41. Moving beam of light VU meter. (Courtesy, Gotham Audio Corp.)

for one standard mile of telephone cable or wire. It was replaced by the transmission unit (now also obsolete) and subsequently, by the present term decibel. 1 Mile of Standard cable × 0.947 = 1 decibel.

10.39 ***Define the neper.***—A term used to express gain or loss. Mathematically, the neper is defined:

$$\text{Nepers} = \tfrac{1}{2}\ \text{Log}_\epsilon \frac{P_1}{P_2}$$

where,

P_1 and P_2 are two powers,
ϵ equals 2.718 the base of the Naperian system of logarithms.

The relationship between decibels, nepers, and miles of standard cable may be found as follows:

Multiply	By	To find
decibels	0.1151	nepers
decibels	1.056	miles of standard cable
miles of standard cable	0.947	decibels
miles of standard cable	0.109	nepers
nepers	8.686	decibels
nepers	9.175	miles of standard cable

(Nepers are still used in some parts of Europe.)

10.40 ***Show the relationship in decibels, between a 1, 6, and 12.5 milliwatt power-reference level.***—The difference between these three reference powers may be seen in the graph of Fig. 10-40. The difference between 1 milliwatt and 6 milliwatts is 7.78 dB, and for 12.5 milliwatts 10.96 decibels.

Decibel conversion graphs for 1 and 6 milliwatts sine-wave power are given in Fig. 25-105A and B.

10.41 ***What is a moving light beam VU meter?***—A VU meter employing a straight-line scale, consisting of a d'Arsonval movement and a rectifier. An optical system projects a beam of light through a slot onto a mirror attached to the movement; in turn it casts a narrow beam of light onto a ground glass scale, calibrated in decibels (Fig. 10-41). The frequency response is 20 to 20,000 Hz, 3900-ohms input impedance—normally used with 3600-ohm resistor

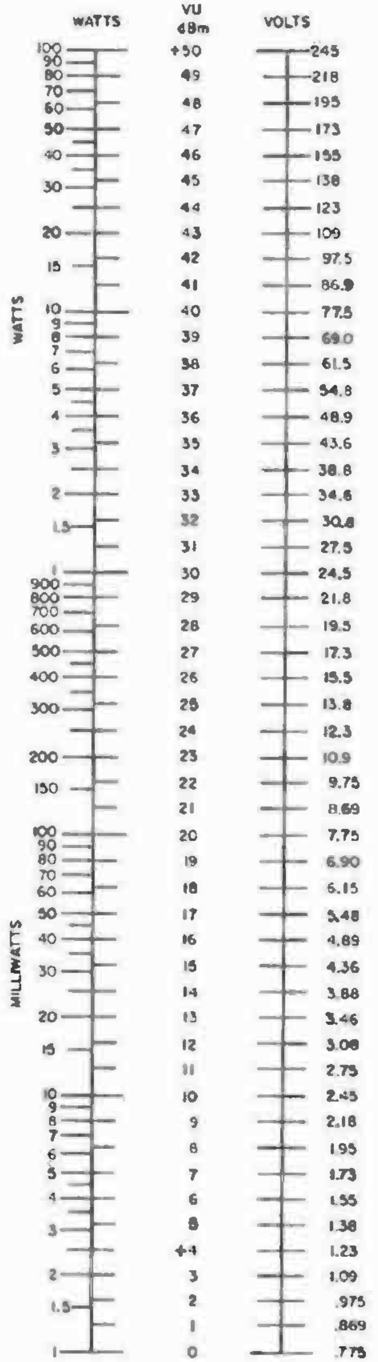

Fig. 10-42. Relationship of VU and dBm to power in watts and voltage in a 600-ohm line.

(see Question 10.24). The ballistics are in accordance with USASI (ASA) Standard C-16.5, 1961. The sensitivity is the same as for a standard VU meter. When the level deflects over zero VU, the light doubles in height and turns

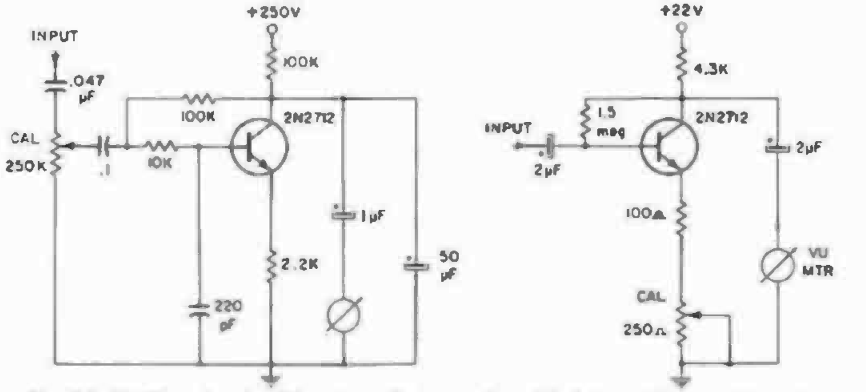

Fig. 10-43. Two simple VU meters that may be added to existing equipment.

red, thus warning the operator that the system is in overload. The scale reads in both percentage modulation and decibels.

10.42 Knowing the level in decibels and line impedance, how is the voltage determined for other line impedances?—If the line voltage for a given level at 600 ohms is known, voltages for other line impedances may be calculated:

$$E_x = V_{600}\sqrt{\frac{Z}{600}}$$

where,

E_x is the unknown voltage,
V_{600} is the voltage for 600-ohms.

As an example, assume voltage E_x is required for a line impedance of 150 ohms at a level of plus 4 dBm. Referring to Fig. 10-42, the voltage for a level of plus 4 dBm is 1.23 volts. The new voltage may now be calculated:

$$E_x = 1.23\sqrt{\frac{150}{600}} = 0.615 \text{ volt.}$$

Voltages for a line impedance of 600 ohms for levels between minus 20 dBm to plus 50 dBm may be taken from Fig. 10-42. Additional information is given in Question 23.167, and in Question 25.115.

10.43 Show a simple circuit for adding a VU meter to existing equipment.—Two such circuits each employing a

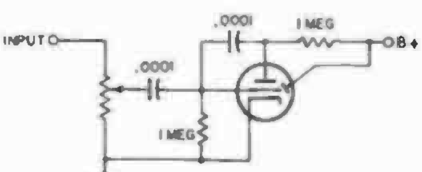

Fig. 10-44. A 6E5 or Magic Eye Tube connected as a volume indicator meter.

2N2712 transistor are shown in Fig. 10-43. Either of the circuits may be added to existing equipment. The meter movement can be the conventional VU meter with its internal rectifier or an inexpensive 200 to 500 microampere movement using a small rectifier similar to those discussed in Question 10.5. The completed meter is calibrated by applying a constant frequency of 1000 Hz to the input, and calibrating the meter movement in decibels. This subject is discussed in Section 23.

When the meter is put to use, the 100-percent modulation of the system is established, and the sensitivity of the meter circuit is increased by 10 dB to provide a 10-dB lead as explained in Question 10.28. It should be understood that unless the meter movement is an actual VU meter, the peak indications will not be compatible with the conventional VU meter. However, with a 10-dB lead, the system should be protected from serious overload.

10.44 How may a magic eye tube be connected for use as a volume indicator?—In the manner shown in Fig. 10-44. The terminal indicated input should connect to a point ahead of the recording device and be adjusted to indicate the peak recording level. (See Question 10.7.)

10.45 How is an oscilloscope used as a peak reading VI meter?—As discussed in Question 10.28, the standard VU meter does not indicate the true peaks of a complex waveform. To protect a recording channel from overload a lead of 8 dB or more is inserted in the VU meter circuit to protect the system from unseen peaks. A peak-reading VI meter may be had by connecting an oscilloscope in parallel with the VU

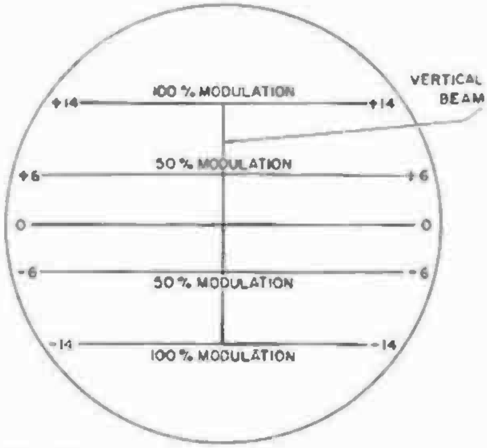

Fig. 10-45A. Oscilloscope screen calibrated for use as a peak-indicating VI meter. The horizontal sweep control is closed-off to present only a vertical line.

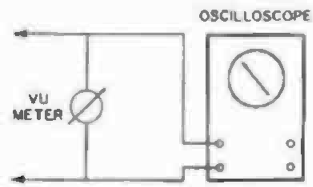

Fig. 10-45B. Oscilloscope connected in parallel with VU meter.

meter (Fig. 10-45B). To align the oscilloscope with the VU meter, two measurements are required.

A 1000-Hz signal is sent into the channel and the bridging bus level set, for example, to plus 14 dBm, and the deflection of the oscilloscope (sweep off) is adjusted for a convenient deflection (100%) on the graticule (Fig. 10-45A). The VU meter is now set for an 8-dB lead by turning its attenuator to plus 6 dBm. This level is also marked on the oscilloscope graticule. Now under normal recording conditions the oscilloscope will indicate the peak modulations. Thus, the readings of the VU meter for a complex waveform may be compared to the actual peak excursions not indicated by the VU meter. This method of monitoring recording levels is often used where the control of recording levels is critical.

Section 11

Vacuum Tubes, Transistors, and Diodes

In 1883, Edison discovered that electrons flowed in an evacuated lamp bulb, from a heated filament to a separate electrode (the Edison effect). Fleming, making use of this principle, invented the "Fleming Valve" in 1905, but when de Forest, in 1907, inserted the grid, he opened the door to electronic amplification with the "Audion." The millions of vacuum tubes are an outgrowth of the principles set forth by these men.

The subject of vacuum tubes is complex, and only design considerations essential to proper use in audio circuitry are entered into. Semiconductors have resulted in the obsolescence of many type tubes; however, tubes will continue to play an important role in electronic circuitry for years to come. Vacuum tubes and transistors may be complementary, and many hybrid devices have been designed utilizing a combination of the two. While entirely different in concept, they may both perform the same function, and with modification of circuitry may be used interchangeably. However, the design engineer must use a different approach when considering devices employing either transistors or vacuum tubes.

Characteristics and variations in vacuum tubes, transistors, diodes, photoconductors, and other devices of the semiconductor family are discussed in this section.

11.1 What is the Edison effect?—The emission of electrons from a heated body. This effect was discovered by Thomas A. Edison in 1883 during his experiments with the electric light.

11.2 What are elements?—The inner electrodes of a vacuum tube.

11.3 What is a filament?—The element in a directly heated vacuum tube which emits electrons.

11.4 What is a heater?—A coiled element used to heat the cathode element in an indirectly heated vacuum tube.

11.5 What is thorium?—A rare mineral used in the manufacture of vacuum-tube filaments. Thorium when mixed with tungsten in the form of a filament is a profuse emitter of electrons, but gradually evaporates during its use.

11.6 What is barium oxide?—A rare earth used in a manner similar to thorium for coating the surface of a cathode or filament of a vacuum tube.

11.7 What is an indirectly heated tube?—One which employs a heater inside the cathode sleeve. The electrons are emitted from the surface of the cathode and not the heater. (See Fig. 11-7.)

11.8 What is a directly heated tube?—One employing a filament which serves the dual purpose of heater and cathode. The operating temperature of such tubes ranges from −900 to 2500 degrees Centigrade.

11.9 What is a getter?—A barium or tantalum disc enclosed in a vacuum

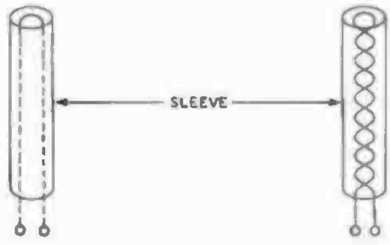

Fig. 11-7. Indirectly heated tube.

tube for the purpose of absorbing gasses released from the elements. The disc is flashed from the exterior during the exhausting process. This generally results in a silver or reddish discoloration on the interior of the glass envelope.

11.10 What is a cathode?—A sleeve surrounding the heater in a vacuum tube. The surface of the cathode is coated with barium oxide or thoriated tungsten to increase the emission of electrons. (See Fig. 11-7.)

11.11 What is a control grid?—A spiral wire element placed between the plate and cathode elements of a vacuum tube to which the input signal is generally applied. This element controls the flow of electrons between the cathode and the plate elements.

11.12 What is a suppressor grid?—A gridlike element situated between the plate and screen elements in a vacuum tube to prevent secondary electrons emitted by the plate from striking the screen grid. The suppressor is generally connected to the ground or cathode circuit.

11.13 What is a screen grid?—An element in a pentode-type vacuum tube which is situated between the control grid and the plate elements. This screen grid is maintained at a positive potential to reduce the capacitance existing between the plate and control-grid elements. It thus acts as an electrostatic shield and prevents self-oscillation and feedback within the tube.

11.14 What is a plate?—The positive element in a vacuum tube. The element from which the output signal is nsually taken. It is also called an anode.

11.15 What is a diode?—A two-element vacuum tube consisting of a plate and a cathode. It is also known as a Fleming valve, after its inventor Dr. J. A. Fleming, an English scientist.

11.16 What is triode?—A three-element vacuum tube.

11.17—What is a dual triode?—A single envelope containing two sets of triode elements.

11.18 What is a tetrode?—A four-element vacuum tube containing a cathode, a control grid, a screen grid, and a plate. It is frequently referred to as a screen-grid tube.

11.19 What is a hexode?—A six-element vacuum tube consisting of a cathode, control grid, suppressor grid, screen grid, injector grid, and a plate.

11.21 What is a heptode?—A seven-element vacuum tube containing a cathode, control grid, four grids, and a plate.

11.22 What is a pentagrid?—A seven-element vacuum tube consisting of a cathode, five grids, and a plate.

11.23 What is an octode?—An eight-element vacuum tube consisting of a cathode, six grids, and a plate.

11.24 Where are multigrid tubes used in audio circuits?—In compressors, expanders, and special applications.

11.25 What is a beam-power tube?—A power-output tube having the advantage of both the tetrode and pentode tubes. Beam-power tubes are capable of handling relatively high levels of output power for application in the output stage of an audio amplifier. The power-handling capabilities stem from the concentration of the plate-current electrons into beams of moving electrons. In the conventional tnbe the electrons flow from the cathode to the plate, but are not confined to a beam. In a beam-power tube the internal elements consist of a cathode, control grid, screen grid, and two beam-forming elements which are tied internally to the cathode element. The cathode is indirectly heated as in the conventional tube.

The internal construction of an RCA 6L6 beam-power tube is shown in part (a) in Fig. 11-25. One of the most important points of the construction of this tube is the method used to form the electron beams. This is accomplished by making the pitch of the winding of the control- and screen-grid elements the same, and in a physical plane relative to the paths of the plate-current electrons. Because of the control-grid winding shadow being in the same plane as the screen-grid winding, fewer electrons strike the windings of the screen-grid element. Thus the screen-grid current is less, permitting a greater number of electrons to reach the plate element, which results in a greater plate current for a given signal voltage at the control grid. The plate current being high results in the plate resistance being relatively low, thus increasing the power-handling capabilities. The beam-forming elements are

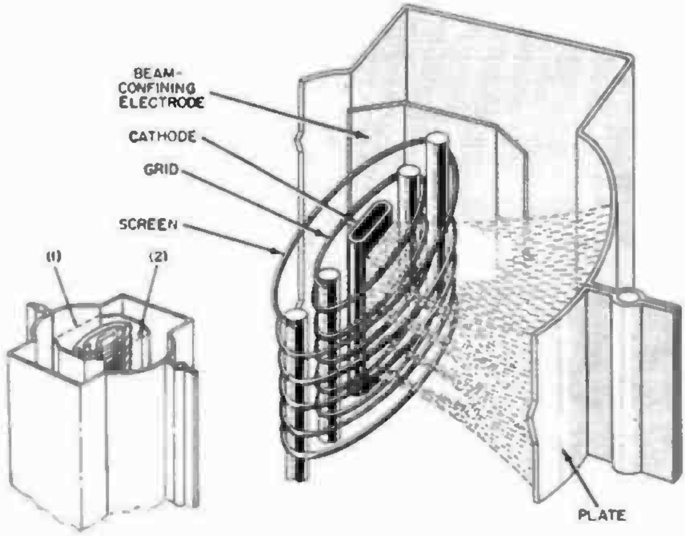

Fig. 11-25. View of the interior of a 6L6 beam-power tube. (Courtesy, Radio Corporation of America.)

connected internally to the cathode element and influence the movement of the electrons in their passage to the plate element. Because the beam-forming elements are at cathode potential, an equivalent space-charge effect is caused between the screen grid and the plate; this charge has an effect similar to that of a surface existing between the ends of one beam-forming plate and the other. This is shown by the dashed lines (points 1 and 2) in part (b) of Fig. 11-25. This effect is referred to as a virtual cathode. This invisible wall also repels secondary electrons from the plate and prevents them from striking the screen-grid element.

11.26 What is an electron-ray tube?—A miniature cathode-ray tube used as an amplitude indicator in recording and test equipment and also as a tuning indicator in radio receivers. Cathode-ray tubes are discussed in Question 11.91. The interior of an RCA 6E5 electron-ray tube is shown in Fig. 11-26.

11.27—Describe the construction of a nuvistor tube.—Nuvistor tubes (6CW4 and 7586) are used quite frequently in sound equipment, particularly where a high signal-to-noise ratio is a necessity. They are often used in the microphone preamplifier circuits with transistorized recording channels. When used as such, the circuitry is termed a *hybrid* circuit. Nuvistors have desirable characteristics for portable equipment, as they only require 0.135 amp at 6.3 volts for the heater, with a plate current of 10 milliamperes at 75 volts. The transconductance is 11,500 micromhos, with an amplification factor of 35. They also have the additional feature of being non-microphonic. An interior view showing the construction of such a tube is given in Fig. 11-27.

11.28 What is an acorn tube?—A small vacuum tube designed for very-high-frequency use and having a low internal electrode capacitance. The element connections are brought out at the sides of the glass envelope. This tube requires a special socket.

11.29 What is a thyratron?—A gas-discharge tube which may be used similarly to a relay. A positive charge is applied to a control grid which starts the control cycle. (See Fig. 11-29.)

11:30 What is a voltage-regulator tube?—A vacuum tube containing two elements, a cold cathode, and a plate and filled with a rare gas such as neon or argon. This tube requires no heater and is used as a voltage stabilizer in power supplies.

There are several different type voltage-regulator tubes (VRT). The two most useful to the audio engineer are the gas-filled and the glow-discharged types. Of these types, the voltage regulator and the voltage-reference tubes are the ones most commonly used. The voltage-reference tube is a special VRT, with a sharply defined voltage drop, which may be used for a source of calibration within limits. Voltage-regulator types are generally used in *shunt* with the circuit to be regulated, and act as a *variable* load, countering the effects of load variation. When there is little or no current drawn from the supply, the VRT conducts heavily. As the load current requirement increases, the VRT takes *less* current and so maintains a constant load on the supply. This effective flatting of the load current provides the voltage stabilization of which a VRT is capable. The average VRT draws from 5 to 30 milliamperes, and over this range of current will maintain the output voltage within 2 to 3 percent of the operating point.

Voltage-regulator tubes will also maintain a constant output voltage, even with variation in power-line voltages supplying the power supply. A rise in line voltage causes the VRT to draw more current, thus lowering the output voltage. Voltage-reference tubes are used where a higher order of control is required, as in recording equipment power supplies. These devices use high gain dc sensing amplifiers, which

control the load current by means of heavy-current regulating tubes that accurately regulate the load current. The accuracy of the regulation is the function of the reference voltage tube. Voltage-reference tubes are similar to voltage-regulator tubes, except they contain certain modifications which restrict them to this form of service. The principal difference is that voltage-reference tubes are limited to a rather narrow range of current operation. However, as the reference tubes are designed to operate at a fixed current, this may be taken advantage of to adjust it to its most stable operating point. A second difference is that reference tubes operate at lower voltages than voltage-regulator tubes.

Voltage-regulator tubes are constructed with an anode consisting of a thin rod mounted in the center of a cylindrical cathode, which is the reverse of the conventional vacuum tube. The cathode in a VRT is cold since there is no heater element. The envelope is filled with an inert gas, such as argon or neon. When a rising voltage is applied across the tube, nothing happens until a critical voltage, called the firing potential or starting voltage, is reached. At this point the tube conducts. At this voltage the inside surface of the cathode becomes partially illuminated with either a purple or reddish glow, depending on the type of gas used. An increase of voltage across the tube causes an increase in current, increasing the area of the glow, which varies with the current and distinguishes it from the reference voltage tube which usually glows over the entire cathode surface.

Voltage-regulator tubes suffer from several inherent problems, the first of which is starting instability. It will be noted on the restarting of such tubes that they do not regulate at the same voltage for each start. This can be as much as plus or minus 2 or 3 volts in 148 volts. Another inherent fault is the flickering of the glow around the cathode as the current is increased from its minimum value to its maximum value. These sudden variations in voltage across the tube are the result of portions of the glow area skipping from one point on the cathode to another. A third form of instability is the operating current accidentally placed at one of the cathode skipping points. Voltage-regulator tubes also have a habit of oscillating at high frequencies or motorboating, depending on the circuit constants.

Although the above discussion does not present a very good picture of such tubes, they are still a valuable tool in the field of regulation. It is good practice to design the supply voltage to be high enough that the tubes will always fire when the initial voltage is applied; this causes a heavy surge of current and will probably regulate at the same voltage. Since a bypass capacitor is required around this tube, it should not be larger than 0.10 μF, since larger values tend to cause the tube to motorboat. Voltage-regulator tubes may also be operated in series or parallel. In series, they may be used as voltage dividers, or where the voltage to be regulated is higher than the specified VRT rating. The use of the voltage-regulator tube in regulated power supplies is discussed in Section 21.

It has been found that both voltage-regulator and voltage-reference tubes when placed in a light-tight box require a higher firing voltage than they do in daylight. In some instances they will not fire at all. For certain types of equipment, a small pilot light is placed near the tube to cause it to fire instantally when the voltage is applied. Typical voltage-regulator and voltage-reference tubes are the OD3/150, 6626, and 6627. Voltage-regulator tubes are also discussed in Section 21.

11.31 What is a phototube? — A two-element vacuum tube containing a cathode and a plate. Light falling on the cathode, which is coated with a light-sensitive substance, causes the tube to conduct. It is used for light control circuits and in the reproduction of sound tracks from motion picture film. The sensitivity of a phototube depends on the frequency or color of the light falling on its elements. Phototubes may be obtained that are sensitive only to certain bands of light. Others respond to the colors common to the human eye. Practical uses of the phototube are discussed in Question 19.93. The name *phototube* is used when referring to a vacuum-type photosensitive tube. The term *photocell* is used for solid-state devices and voltage-generating devices.

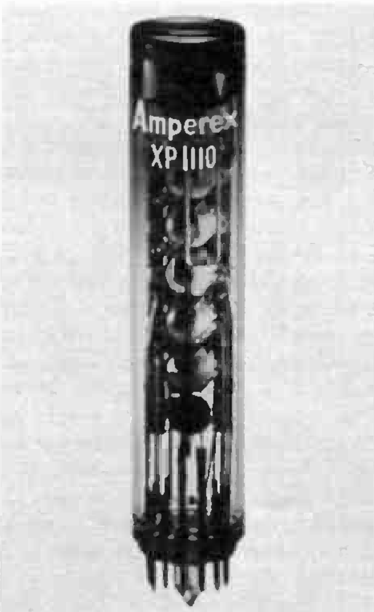

Fig. 11-32A. Amperex Electronic Corp. XP 1110 10-stage, photocathode photomultiplier tube.

11.32 What is a secondary-emission multiplier?—A phototube of extreme sensitivity. The initial electrons emitted from the cathode are directed to strike against a group of plates called dynodes.

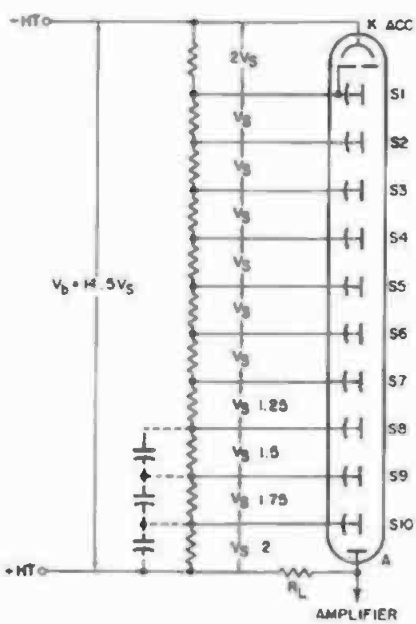

Fig. 11-32B. Voltage divider for Amperex XP 1110, 10-stage photocathode photomultiplier tube.

Each dynode is treated so that it will produce a high secondary-electron emission. When the first dynode is struck, several secondary electrons are released. These, in turn, strike the second dynode, releasing additional electrons. Photomultiplier tubes use 4- to 14-stage dynodes, achieving amplifications up to 100 million, with transit times of 28×10^{-9} to 70×10^{-9}, depending on the number of stages. The total voltage supply will range from 1800 to 7500 volts, again depending on the number of stages. A photocathode-type photomultiplier tube manufactured by Amperex, is shown in Fig. 11-32A, with its internal elements and connections shown in Fig. 11-32B.

11.33 What is the meaning of the term mutual conductance?—It is a term originated by Hazeltine in 1919 to express the conductance of a vacuum tube. This term has now been replaced by the term transconductance, discussed in Question 11.35.

11.34 Give the letter symbols used for identifying the electrical characteristics of vacuum tubes and basing diagrams.—The following symbols are in general usage.

C	Coupling capacitor between stages
C_{g2}	Screen grid bypass capacitor
C_k	Cathode bypass capacitor
E_{bb}	Supply voltage
E_{ff}	Plate efficiency
E_p	Actual voltage at plate
E_{sg}	Actual voltage at screen grid
E_o	Output voltage
E_{sig}	Signal voltage at input
E_g	Voltage at control grid
E_f	Filament or heater voltage
I_f	Filament or heater current
I_p	Plate current
I_k	Cathode current
I_{sg}	Screen grid current
I_{pa}	Average plate current
I_{ka}	Average cathode current
I_{sga}	Average screen grid current
G_m	Transconductance (mutual conductance)
mu	Amplification factor
P_{sg}	Power at screen grid
P_p	Power at plate
P-P	Plate load, plate-to-plate, or push-pull amplifier
R_g	Grid resistor
R_k	Cathode resistor
R_l	Plate load impedance or resistance
R_p	Plate load resistor

R_{sg} Screen dropping resistor
R_d Decoupling resistor
r_p Internal plate resistance
V_g Voltage gain

The above are just a few of the more commonly used symbols. It will be found although such symbols are fairly well standardized, considerable discrepancies exist in their usage. Basing diagrams for the more commonly used tubes are given in Fig. 11-34.

11.35 Define the term transconductance.—It is the change in the value of plate current expressed in microamperes divided by the signal voltage at the control grid of a vacuum tube and expresses its conductance. Conductance is the opposite of resistance and the name mho (ohm spelled backward) was adopted for this unit of measurement.

The basic unit, mho, is too large for practical usage; therefore, the term micromho is used. One micromho is equal to one-millionth of a mho, or 1000 micromhos equal 0.001 mho.

When a vacuum tube is measured in a dynamic transconductance tube tester, all constants of the tube are considered. An ac signal voltage is applied to the control grid and the tube is measured under simulated operating conditions and the actual conductance is measured. Emission-type tube testers do not measure the dynamic characteristics, only the emission of the emitting surfaces of the filament or cathode elements.

The transconductance (g_m) of a tube may be equated:

$$g_m = \frac{\Delta I_p}{\Delta E_{sig}} \ (E_{bb} \text{ held constant})$$

where,

ΔI_p is the change of plate current,
ΔE_{sig} is the change of control-grid signal voltage,
E_{bb} is the plate supply voltage.

A change of one milliampere of plate current for a change of one volt at the control grid is eqnal to one thousandth of a mho or one thousand micromhos.

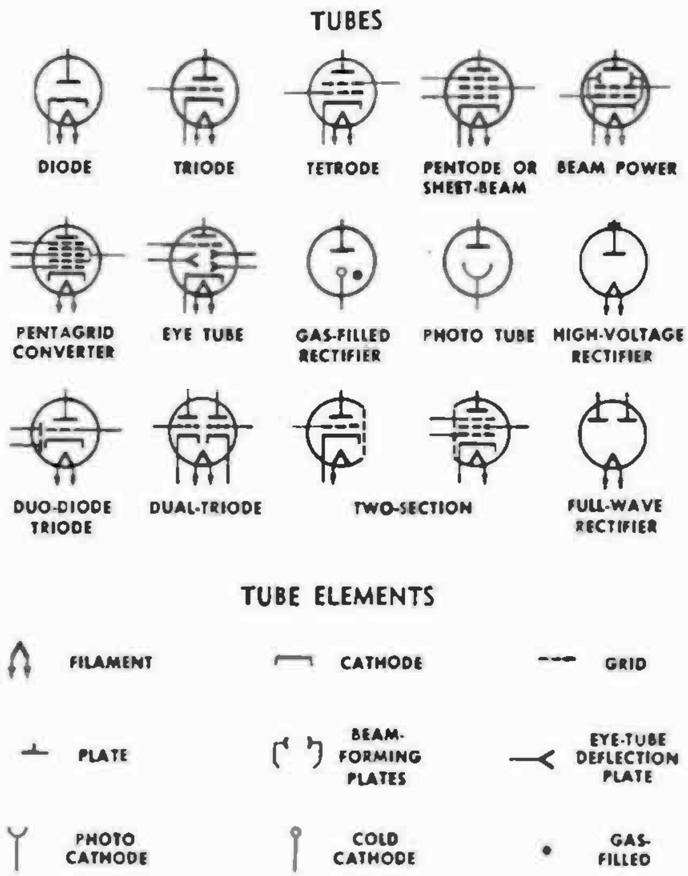

Fig. 11-34. Basing diagrams for vacuum tubes.

To convert mho's to micromhos multiply by 1,000,000. Thus, a tube having a change of two milliamperes plate current for a change of one volt at the control grid would have a transconductance of 2000 micromhos.

11.36 What is the amplification factor or voltage gain of a vacuum tube?—It is the amount the signal at the control grid is increased in amplitude after passing through the tube. This is also referred to as the mu, or voltage gain (V_g) of the tube.

Tube voltage gain may be computed:

$$V_g = \frac{g_m \times r_p \times R_p}{10^6 \times (r_p \times R_p)}$$

or

$$V_g = \frac{mu \times R_p}{r_p \times R_p}$$

where,

g_m is the transconductance in micromhos,
r_p is the plate resistance in ohms,
R_p is the load resistance in ohms,
mu is the voltage gain.

11.37 What does the term gain-per-stage mean?—It is the amount the signal is amplified after passing through a stage of amplification. If the amplifier consists of several stages, the amount of amplification is multiplied by each stage. The gain of an amplifier stage varies with the type tube and the interstage coupling used. The general equation for voltage gain is:

$$V_{gt} = V_{g1} \times V_{g2} \times V_{g3} \ldots$$

where,

V_g is the voltage gain of the individual stages.

11.38 What is the plate resistance of a vacuum tube?—The plate resistance (r_p) of a vacuum tube is a constant and denotes the internal resistance of the tube or the opposition offered to the passage of electrons from the cathode to the plate. Plate resistance may be expressed in two ways: the dc resistance and the ac resistance. The first is the internal opposition to the current flow when steady values of voltage are applied to the tube elements and may be determined simply by Ohm's law:

$$\text{dc } r_p = \frac{E_p}{I_p}$$

where,

E_p is the dc plate voltage,
I_p is the steady value of plate current,
r_p is the plate resistance.

The ac resistance is not so simple to calculate but requires a family of plate-current curves from which the information may be extracted. As a rule, this information is included with the tube characteristics and is used when calculating or selecting components for an amplifier. The equation for calculating ac plate resistance is:

$$\text{ac } r_p = \frac{\Delta E_p}{\Delta I_p}$$

where,

E_p is the voltage at the plate,
I_p is the plate current,
Δ (Delta) is the change in E_p and I_p with the control grid signal voltage (E_{sig}) held constant.

The values of E_p and I_p are those taken from the family of curves supplied by the manufacturer for the particular tube under consideration.

11.39 How is the plate resistance affected by a change of element voltage?—Increasing the plate voltage or decreasing the grid-bias voltage decreases the plate resistance.

11.40 What are steady-state or static characteristics?—The characteristics of a vacuum tube obtained when all normal voltages are applied to the elements with no signal at the input. This is tested when using an emission-type tester.

11.41 What are dynamic characteristics?—Applied to a vacuum tube or transistor, dynamic characteristics are a plot of the steady-state characteristics to which have been added the effect of load impedance. The resultant plate-current and grid-voltage curves are termed *dynamic-transfer characteristics*. Dynamic-transfer curves may be used to determine the linearity and nonlinearity of the input signal compared to the input signal for a specific operating point for a given load resistance or impedance.

11.42 Define the term perveance.—Perveance is a figure of merit for a diode rectifier tube. High-perveance tubes have a lower internal voltage drop for a given fixed current level. This information is generally available in the manufacturer's tube manual.

11.43 What is the cutoff point of a vacuum tube?—A condition when the negative potential applied to the control grid completely stops flow of electrons between the cathode and plate elements.

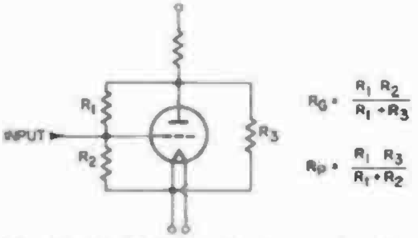

Fig. 11-44. Showing the internal resistance of a vacuum tube which can cause the flow of grid current.

11.44 What is grid current and its cause?—If the control grid is permitted to become positive, with respect to the cathode, it results in a flow of current between the control grid and the cathode through the external circuits. This condition is unavoidable because the wires of the control grid, having a positive charge, attract electrons passing from the cathode to the plate.

Grid-current flow in a vacuum tube is generally thought of as being caused by only driving the control grid into the positive region, and causing the flow of grid current. This is quite true for the operating conditions of an amplifier, but there are other causes of grid current not directly associated with the operation of the tubes. The frequent lack of recognition of grid current hazards is the simplified description of a vacuum tube as a device which operates with a negative grid bias and draws no current from the signal source. This is not entirely true.

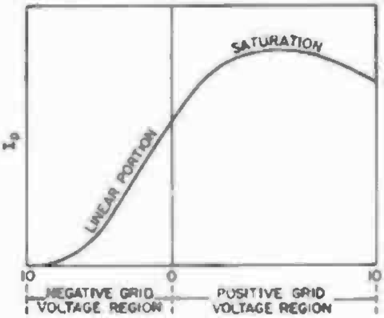

Fig. 11-48. Saturation curve for a typical triode tube.

There are at least eight distinct forms of grid-emission currents, which may be classified: interelectrode resistance, gas-ionization current, grid-emission current, positive grid-electron current, secondary grid-emission current, and negative grid-electron current.

During certain phases of the manufacturing process, such as exhausting and aging, the cathodes are operated at a high temperature which, in turn, produces minute evaporation of the nickel-cathode material and other conductive materials from its coating. The material migrates to a relatively cool surface of the mica supports where it builds up a layer of conductive material and thus shunts a resistance across certain electrodes. In addition, the *getter* material, which is usually a thin coating of barium or magnesium, is deposited on a portion of the glass envelope, or inadvertently deposited on a micro-support area. This resistance is not linear and at higher temperatures and higher voltages, conductance is increased. The leakage paths caused by the foregoing are shown in Fig. 11-44. Grid current is highly undesirable, and can be the cause of considerable distortion.

11.45 How are triode tubes classified for amplifiers?—By their amplification factor (mu or μ). A low-mu tube is one having an amplification factor less than 10. Medium-mu tubes have an amplification factor of from 10 to 50, with a plate resistance of 5 to 15,000 ohms. High-mu tubes have an amplification factor of 50 to 100, with a plate resistance of 50,000 to 100,000 ohms.

11.46 What is anode current?—This is another name for plate current.

11.47 What is secondary emission?—A condition which occurs when electrons are released from a body that is being bombarded by electrons.

11.48 What is meant when it is said a vacuum tube is driven to saturation?—When the maximum emission current has been reached, as shown by the graph in Fig. 11-48.

11.49 What does the term maximum plate dissipation mean?—The maximum power that can be dissipated by the plate element before damage occurs. Plate dissipation can be calculated:

$$\text{Watts dissipation} = E_p \times I_p$$

where,

E_p is the voltage at the plate,
I_p is the plate current.

11.50 What is meant by the expression "a soft vacuum tube"?—A tube in which a small amount of gas remains after evacuation. The retention of gas will often affect the characteristics and cause a blue glow between the plate and other elements due to ionization. This glow should not be confused with the glow seen in mercury rectifiers, gas regulator tubes, and certain type pentode power tubes, as these types of tubes glow when operating normally.

11.51 What is a hard tube?—A vacuum tube having an almost perfect vacuum.

11.52 What are grid-voltage, plate-current characteristic curves for a vacuum tube?—A group of curves, as shown in Fig. 11-52, plotted to show the change in plate current for a change in negative grid bias on the control grid. The curves shown are for a medium-mu triode.

The curves indicate that for a given plate current the plate and grid bias may be determined. For example: the manufacturer states that for a plate voltage of 250 volts and a negative grid bias of 8 volts, the plate current will be 9 milliamperes. This is indicated at Point A on the 250-volt curve. If it is desired to operate this tube with a plate voltage of 150 volts and still maintain a plate current of 9 milliamperes, the grid bias will have to be changed to a negative 3 volts.

11.53 What is ionization?—When an electron in a vacuum tube collides with a gas molecule, the energy imparted by the impact causes the molecule to release an electron. This molecule is called an ion. A gas containing no ions is almost a perfect insulator. Under such conditions no current will flow between elements. However, gases do have some residual ionization due to the action of light falling on the elements and to cosmic rays. If a potential is applied between elements in such a gas, ions migrate between the elements giving the effect of current flow. This current flow is called space, or dark current, because it cannot be observed. This current flow is very small, generally about one to two microamperes in the average tube. Once ionization takes place, the current increases to such proportions that serious damage to the tube can result. Ions are both positive and negative.

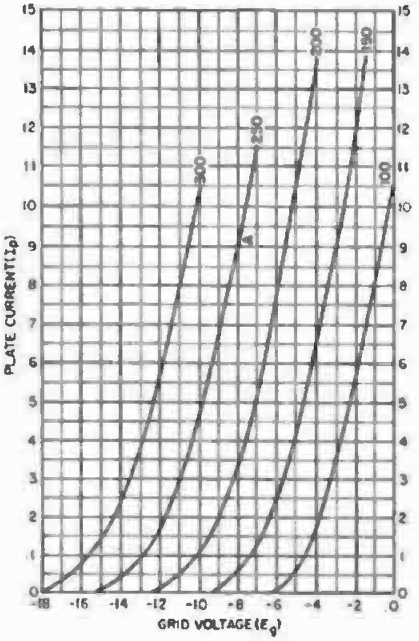

Fig. 11-52. Grid-voltage, plate-current curves for a triode tube.

11.54 What is ionization and deionization potential?—Ionization potential is the potential at which ionization takes place in a gas-filled tube, such as a voltage regulator or voltage-reference tube. Deionization potential is the potential at which ionization of the gas ceases and conductance stops.

11.55 What is the purpose of preheating vacuum tubes?—It is the custom in most plants employing a large number of vacuum tubes in critical places, such as recording and reproducing equipment, to preheat tubes and cook them for at least 100 hours before putting them into service. This is accomplished by connecting the plate, screen grid, suppressor grid, and control grid to one side of the filament or heater circuit (Fig. 11-55). The heater circuit is supplied from a source of voltage regulated to within 1 percent of the rated heater voltage. No plate voltage is used during the cooking period.

After removal from the preheating process, the tubes are individually

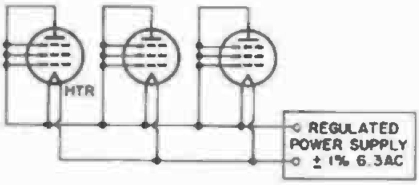

Fig. 11-55. Circuit for cooking vacuum tubes to stabilize their characteristics before putting them into operation.

tested for internal shorts, noise, and leakage, then selected in pairs for devices such as compressors, noise-reduction amplifier, and other equipment requiring matched pairs of tubes.

It has been found from experience when equipment is operated 24 hours a day, tube life is prolonged, internal noise reduced, and the general characteristics are stabilized. (See Ques. 11.71.)

11.56 What is the space charge in a vacuum tube?—In the flow of electrons from cathode to plate, not all the electrons are collected by the plate element. The uncollected electrons congregate in the space between the cathode and plate, and form a negative cloud. Other electrons leaving the cathode have to penetrate this cloud. The clond being negative, uegative charges leaving the cathode on their way to the plate are repelled back toward the cathode. It is these electrons which form the space charge. The space charge around the cathode controls the number of electrons that reach the plate, and therefore, controls the amount of plate current flow. The electron flow can only be increased by increasing the voltage at the plate of the tube.

11.57 Define inverse-peak voltage (IPV).—It is the highest instantaneous plate voltage which a tube can withstand in the *opposite* direction of its normal current flow. In a rectifier tube, it is the maximum value of plate voltage that may be applied, without internal arc-back between the elements, for a given operating temperature.

11.58 What is a microphonic tube?—A tube which, when tapped or vibrated, produces a ringing sound. As a rule, microphonics in a vacuum tube are caused by loose elements within the tube, or these elements may not be sufficiently rugged for the purpose for which the tube is being used.

Special tubes which have no microphonic tendencies are available for use in the low-level stages of an amplifier.

11.59 What causes self-rectification in a vacuum tube?—An increase or decrease in the dc plate current caused by an unsymmetrical waveform. (See Question 12.44.)

11.60 What are the phase reversals that take place between the elements of a vacuum tube?—The phase reversal in electrical degrees between the elements of a self-biased pentode, for a given sine at the control grid is shown in Fig. 11-60A. It will be noted that, for an instantaneous positive voltage at the control grid, the voltage is reversed between the grid and plate 180 degrees and will remain so for all normal operating conditions. The control grid and

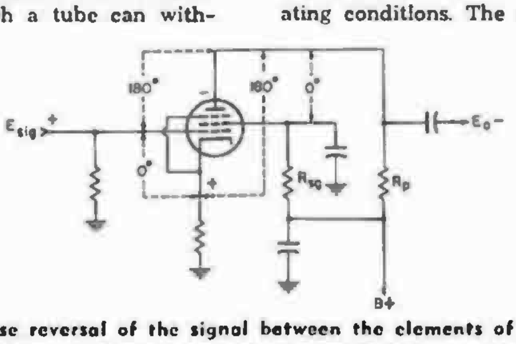

Fig. 11-60A. Phase reversal of the signal between the elements of a pentode vacuum tube. The reversals are the same in a triode for a given element.

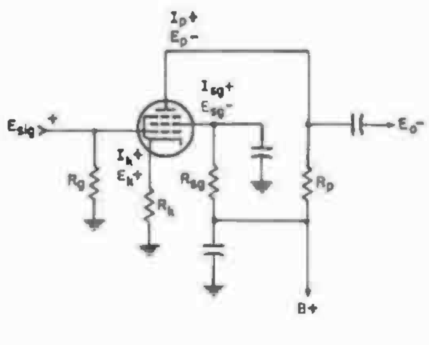

Fig. 11-60B. Phase reversal of the current and voltage in a pentode vacuum tube. The reversals are the same in a triode for a given element.

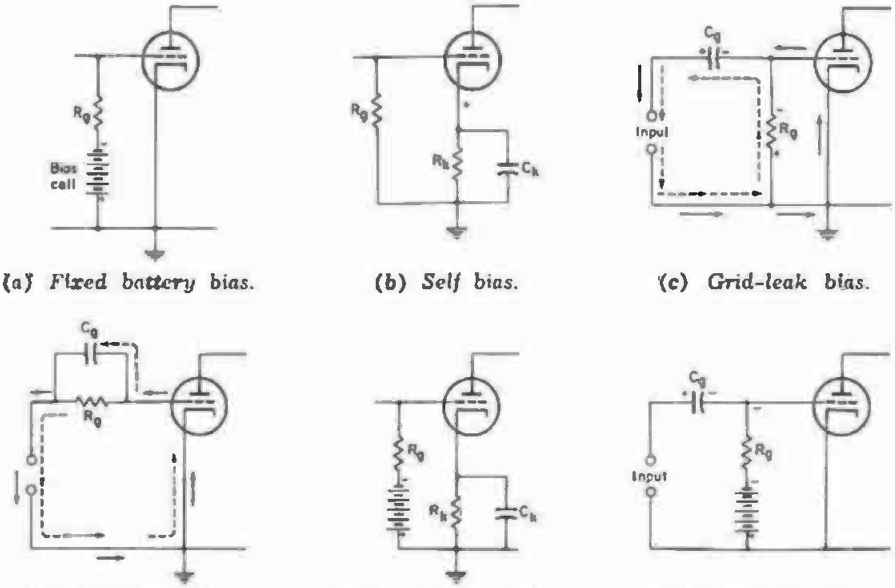

(a) *Fixed battery bias.* (b) *Self bias.* (c) *Grid-leak bias.*

(d) *Grid-leak bias.* (e) *Combination bias.* (f) *Combination bias.*

Fig. 11-62. Various methods of obtaining grid bias.

cathode are in phase. The plate and screen-grid elements are in phase with each other. The cathode is 180 degrees out of phase with the plate and screen-grid elements.

The phase reversal of the voltage and current for each element is shown in Fig. 11-60B. For an instantaneous positive sine at the control grid, the voltage at the plate and screen grid are negative and the current positive. The voltage and current are both positive in the cathode resistor and are in phase with the voltage at the control grid. The plate reversals are the same in a triode for a given element.

11.61 What is the difference between the terms plate voltage and plate-supply voltage?—Plate voltage is the voltage measured between the plate and the cathode elements. Plate-supply voltage is the voltage supplied to the lower end of the plate load. The first voltage is designated by the symbol E_p, the second by the symbol E_{bb}. In resistance-coupled amplifiers, the voltage considered is the plate-supply voltage E_{bb} at the lower end of the plate-load resistance. In a transformer-coupled amplifier, the voltage considered is the plate voltage E_p.

11.62 What are the different methods used for obtaining grid-bias voltage?—The six methods most commonly used are illustrated in Fig. 11-62. At part (a), a bias cell is connected in series with the control grid. At part (b), the tube is self-biased by the use of a resistor connected in the cathode circuit. In part (c), the circuit is also a form of self-bias; however, the bias voltage is obtained by the use of a grid capacitor and grid-leak resistor connected between the control grid and ground. At part (d), the bias voltage is developed by a grid-leak resistor and capacitor in parallel, connected in series with the control grid. The method illustrated at part (e) is called combination bias and consists of self-bias and battery bias. The resultant bias voltage is the negative voltage of the battery and the bias created by the self-bias resistor in the cathode circuit. Another combination bias circuit is shown at part (f). The bias battery is connected in series with the grid-leak resistor in this case. The bias voltage at the control grid is that developed by the battery and the self-bias created by the combination of the grid resistor and capacitor.

11.63 Show how and where the internal capacitance of a vacuum tube is created.—The internal capacitance of a vacuum tube is created by the close proximity of the internal elements as shown in Fig. 11-63. Unless otherwise stated by the manufacturer of the tube, the internal capacitance of a glass tube is measured using a close-fitting metal

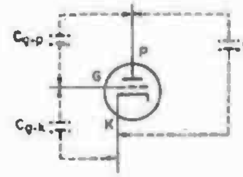

Fig. 11-63. Interelectrode capacitance of a triode.

tube shield around the glass envelope connected to the cathode terminal. Generally, the capacitance is measured with the heater or filament cold with no voltage applied to any of the other elements.

In measuring the capacitance, all metal parts, except the input and output elements, are connected to the cathode. These metal parts include internal and external shields, base sleeves, and unused pins. In testing a multisection tube (dual), elements not common to the section being measured are connected to ground. Input capacitance is measured from the control grid to all other elements, except the plate which is connected to ground. Output capacitance is measured from the plate to all other elements, except the control grid which is connected to ground.

Grid-to-plate capacitance is measured from the control grid to the plate, with all other elements connected to ground.

11.64 What is the terminology for batteries used in connection with vacuum tubes?—"A" battery for filament or heater, "B" battery for plate supply, "C" battery for bias voltages, and "D" battery for screen-grid voltages.

11.65 What is a variable-mu tube?—A pentode vacuum tube constructed with a special grid. In the conventional tube, the mu is constant. The construction of the variable-mu tube is such that the mu may be varied or changed by increasing the negative bias on the control grid. This type of tube is used in compressor amplifiers and expanders. A typical example is the 6SK7 tube.

11.66 What is transit time?—The time required for an electron to travel from the cathode to the plate circuit in a vacuum tube.

11.67 Define contact potential.—In a vacuum tube employing a unipotential cathode, positive grid current begins to flow when the control grid becomes slightly negative, and increases rapidly as the control grid is made more positive (Fig. 11-67). The value of grid voltage at which positive grid current starts to flow, is termed contact potential. Contact potential is caused by the initial velocity of the emission of electrons from the cathode and an electrothermic effect, because of the differences in temperature and the material composition of the control grid and the cathode element.

The value of the contact voltage may reach 1.5 volts. If the operating bias voltage is less than the contact potential, two effects will be present; direct-current flow in the control-grid circuit, and the dynamic input resistance of the tube drops to a relatively low value. The tube should be operated with a value of grid-bias voltage sufficiently high, so that the tube is not operating in the contact potential region. When a tube must be operated to within the contact potential region, care must be taken to avoid undesirable effects in the control-grid circuit, due to grid-current flow, and the lower input resistance. (See Question 11.44.)

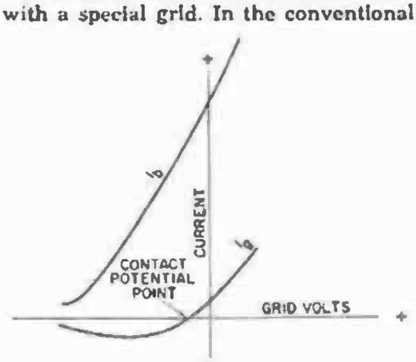

Fig. 11-67. Positive grid-current flow in a tube employing a unipotential cathode.

11.68. What is the direction of current in a vacuum tube?—From the cathode or filament to the anode or plate. This is termed *electron flow*, and is opposite to *conventional current flow*. (See Question 11.109.)

11.69 What is a barretter and a ballast tube?—A barretter is a voltage-regulator tube consisting of an iron-wire filament enclosed in a hydrogen-filled envelope. The filament is connected in series with the circuit to be regulated. For a given voltage variation, the current through the filament is held constant to a given value. Such tubes are used in series with the primary of a transformer and in series-connected filament circuits. Barretters must not be operated uear a strong magnetic field as the filament will vibrate and reduce the life of the filament.

A ballast tube is self-regulating, with its elements enclosed in a glass envelope, without gas, and fitted with an octal tube base. When used, it is connected in series with the circuit it is to regulate. Such regulators as the barretter and ballast tube are rather slow in their reaction to changes in current, compared to other devices. They are used principally in heavy commercial control equipment.

11.70 What is bias voltage?—A dc voltage held constant between the control grid and the cathode of a vacuum tube. (See Question 11.62.)

11.71 How may vacuum-tube characteristics be stabilized?—Tube manufacturers' data sheets generally contain a warning that the heater voltage should be maintained within plus or minus 10 percent of the rated voltage. As a rule, this warning is taken lightly, and little attention is paid to heater voltage variations, which have a pronounced effect on the tube characteristics, internal noise being the greatest offender. Because of heater-voltage variation, emission life is shortened, electrical leakage between elements is increased, heater-to-cathode leakage is increased, and grid currents caused to flow (see Question 11.44). Thus, the life of the tube is decreased with an increase of internal noise. A plot of the loss of tube life compared to percent heater-voltage variation appears in Fig. 11-71.

To reduce the effect of heater-voltage variation, heaters must be operated from a regulated source of voltage, either ac or dc. In large recording plants, it is customary to employ power supplies that furnish a regulated dc voltage, plus or minus 1 percent of the rated heater voltage. Tests have proven that tubes operated for two years or more, using such supplies, have lower internal noise levels than when the tubes were new. (See Question 11.55.)

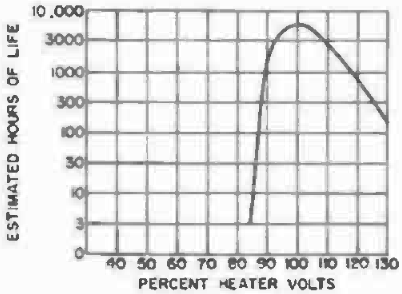

Fig. 11-71. A plot of tube life versus heater-voltage variation in percentage of rated voltage.

11.72 How are vacuum tubes connected in parallel?—As shown in Fig. 11-72. If two tubes of similar characteristics are connected in parallel, the plate current is doubled, the load resistance and bias resistor values halved. The value of the plate voltage remains unchanged. For more than two tubes, the plate current will increase proportionately; the load resistance will decrease in proportion to the number of tubes connected in parallel. This is also true for the bias resistor. As a rule, when vacuum tubes are connected in parallel, resistors of 50 ohms are connected in series with each plate to assist in balancing the plate currents. Also, a resistance of 1000 ohms is connected in series with each control grid (at the socket) to prevent parasitic oscillations. This is particularly important when an odd number of tubes are connected in parallel. The parallel operation of tubes in amplifiers is discussed in Questions 12.60 and 12.111.

11.73 What does the term quiescent mean when applied to a vacuum tube?—A condition that prevails in a vacuum tube when there is no signal voltage at the control grid. The plate current is a steady value.

11.74 Show the interior construction of a typical metal-envelope vacuum tube.—The interior of a metal-envelope vacuum tube with the various elements and their construction marked for identification is shown in Fig. 11-74.

11.75 Show the interior of a typical glass-envelope vacuum tube.—The in-

terior of a typical RCA glass-envelope vacuum tube is shown in Fig. 11-75.

11.76 Show the construction of a miniature tube.—The interior construction of an RCA miniature tube is shown in Fig. 11-76.

11.77 If it is desired to operate a vacuum tube with a plate voltage different from the published data, how are the new bias and screen voltages, plate-load resistance, and other characteristics determined?—By the use of conversion factors F_1, F_2, F_3, F_4, and F_5. Assume the following conditions are specified for a single 6V6 beam-power tube:

Plate voltage	250 volts
Screen voltage	250 volts
Grid voltage	−12.5 volts
Plate current	45 μA
Screen current	4.5 μA
Plate resistance	52,000 ohms
Plate load	5,000 ohms
Transconductance	4,100μmhos
Power output	4.5 watts

The new plate voltage is to be 180 volts. The conversion factor F_1 for this voltage is obtained by dividing the new plate voltage by the published plate voltage:

$$F_1 = \frac{180}{250}$$
$$= 0.72.$$

The screen and grid voltage will be proportional to the plate voltage:

$$E_g = 0.72 \times 12.5$$
$$= 9.0 \text{ volts}$$
$$E_{sg} = 0.72 \times 250$$
$$= 180 \text{ volts.}$$

For calculating the plate and screen currents, factor F_2 is used:

$$F_2 = F_1 \times \sqrt{F_1}$$
$$= 0.72 \times 0.848$$
$$= 0.610,$$
$$I_p = 0.61 \times 45\ \mu A$$
$$= 27.4\ \mu A$$
$$I_{c2} = 0.61 \times 4.5\ \mu A$$
$$= 2.74\ \mu A.$$

The plate load and plate resistance may be calculated by use of factor F_3:

$$F_3 = \frac{F_1}{F_2}$$
$$= \frac{0.720}{0.610}$$
$$= 1.18,$$
$$r_p = 52{,}000 \times 1.18$$
$$= 61{,}360 \text{ ohms},$$
$$R_L = 5000 \times 1.18$$
$$= 5900 \text{ ohms}.$$

The power output is found by the use of the factor F_4:

$$F_4 = F_1 \times F_2$$
$$= 0.72 \times 0.610$$
$$= 0.438,$$
$$\text{Power Output} = 0.438 \times 4.5$$
$$= 1.97 \text{ watts}.$$

The transconductance is determined by the aid of factor F_5:

$$F_5 = \frac{1}{F_3}$$
$$= \frac{1}{1.18}$$
$$= 0.847,$$
$$\text{transconductance} = 0.847 \times 4100$$
$$= 3472 \text{ micromhos}.$$

The foregoing method of converting for voltages other than those originally specified may be used for triodes, tetrodes, pentodes, and beam-power tubes, provided the plate, grid 1, and grid 2 voltages are changed simultaneously by the same factor. This will apply to any class of tube operating such as class A, AB_1, AB_2, B, or C. Although the method of conversion outlined in the foregoing is quite satisfactory in most instances, it should be borne in mind that the error will be increased as the conversion factor departs from unity. The most satisfactory region of operation will be between 0.7 and 2.0. When the factor falls outside this region the accuracy of operation is reduced.

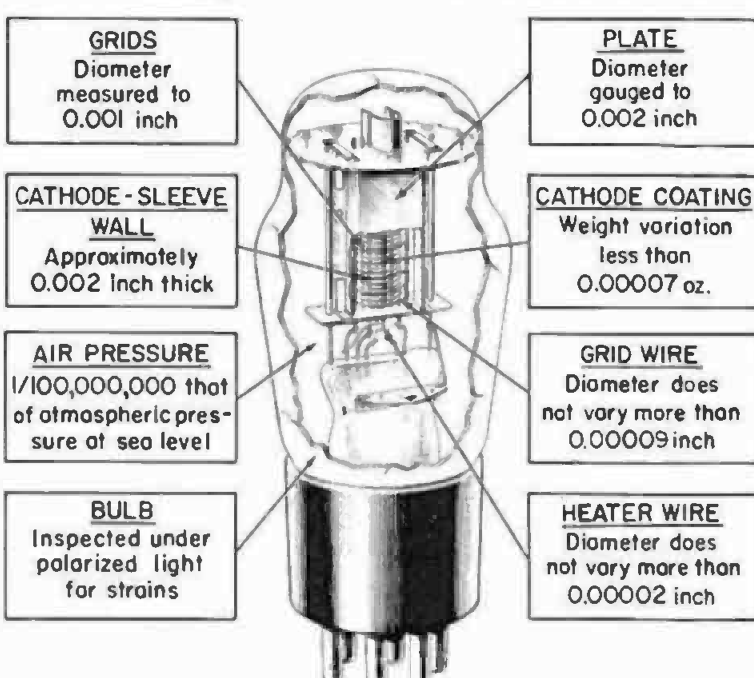

Fig. 11-75. Materials used in the construction of a vacuum tube. (Courtesy, Radio Corporation of America)

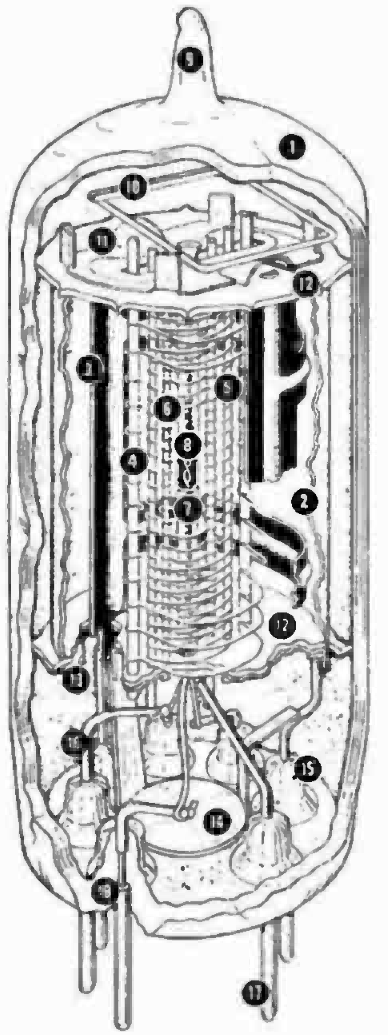

Fig. 11-76. View of the interior of a miniature vacuum tube. (Courtesy, Radio Corporation of America)

The above method of conversion does not take into consideration contact potential or secondary emission effects which become quite noticeable at low operational voltages. When secondary emission effects are noted, the plate voltage must be operated at a higher potential than grid number 2.

The use of low plate voltage and current in a beam-power tube is not recommended. Under normal conditions, the harmonic distortion should be essentially the same as for the originally specified operational voltages.

11.78 How can the heater or filament of a vacuum tube be tested for life reserve?—With a normal indication on the meter of a tube tester, reduce the filament or heater voltage to the values shown in the table below. If the tube with the lowered heater voltage drops and then holds steady within prescribed limits for the tube, it still has a considerable life reserve.

Normal Heater Voltage	*Reduce Heater Voltage to*
1.5	1.1
2.0	1.5
2.5	2.0
3.0	2.5
5.0	4.3
6.3	5.0
7.5	6.3
10.0	7.5
12.6	10.0
25.0	20.0
35.0	25.0
50.0	35.0

11.79 What is heater warmup time and how is it defined?—It is the time required for the voltage across the heater to reach 80 percent of the normal voltage, with four times the normal voltage applied to the heater circuit with a series resistor three times the normal heater operating resistance in series.

11.80 Describe the cause and effect of cathode leakage.—Cathode leakage is caused by internal leakage between the tube elements to the filament or heater circuit. This results in *hum modulation* of the signal voltage, as the heater of a cathode-heater type tube may have one terminal at cathode potential. The opposite heater terminal of a 6.3-volt tube will have a peak negative voltage of approximately 10 volts, at the 60-Hz heater supply. One section of the heater wire, just at the edge or outside on one end of the cathode and electrically near the ungrounded end, may have contaminants deposited during manufacture, which produce leakage and grid emission (see Question 11.44). Even without the contaminants, the 1200° C temperature of the heater wire produces an emission. If such an area is exposed to one of the grid-support side rods outside the mica support, a negative grid bias of less than 10 volts will permit the control grid to pick up the emission at the heater supply frequency.

The effects of cathode leakage can be overcome by the use of a bias voltage on the heater circuit, as discussed iu Question 12.195. A new medium power tube will show a normal leakage between the cathode and heater of about 1 to 2.5 megohms; small receiving tubes show 2 to 3 megohms and higher.

11.81 Why is it necessary to warm up the heater of a mercury vapor rectifier tube before applying the high voltage?—To prevent the active material on the filaments or heater from excessive drain while operating under a subnormal heater voltage.

11.82 When should a tube be considered unsatisfactory and rejected?—When the transconductance (g_m) has fallen to 75 or 80 percent of normal. For some types of tubes and services, they may be permitted to fall to 60 percent of normal.

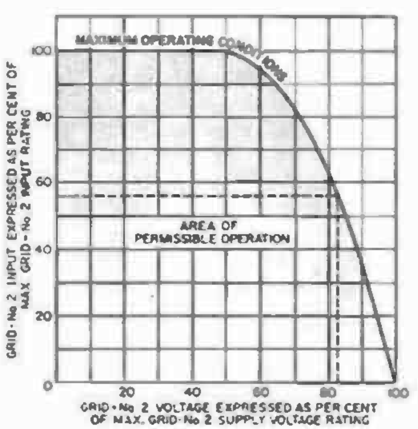

Fig. 11-86. Graph for determining the maximum power that may be dissipated by the screen grid. (Courtesy, Radio Corporation of America.)

11.83 Define the power sensitivity of a tube.—Power sensitivity is the ratio of the power output to the square of the input voltage, expressed in mhos:

$$\text{Power sensitivity (mhos)} = \frac{P_o \text{ watts}}{(E_{in}\text{rms})^2}$$

where,

P_o is the power output of the tnbe,
E_{in} is the rms signal voltage at the input.

11.84 How is plate efficiency calculated?—The plate efficiency (E_{ff}) for any tube may be calculated:

$$E_{ff} = \frac{\text{Watts}}{E_{pa} \times I_{pa}} \times 100$$

where,

Watts is the power output,
E_{pa} is the average voltage at the plate,
I_{pa} is the average plate current.

The measurement is made with a load resistance in the plate circuit equal in value to the plate resistance stated by the manufacturer.

11.85 When measuring the transconductance of a vacuum tube, what is the value of the standard signal voltage applied to the control grid?—Ten millivolts at the control grid. The output cnrrent is measured in ac milliamperes.

11.86 How is a screen-grid series-dropping resistor calculated?—The first step is to refer to the manufacturer's data sheet and find the maximum voltage that may be applied and the maximum power that may be dissipated by the screen grid. These limitations are generally shown graphically as in Fig. 11-86. The value of the resistor may be calculated:

$$R_{sg} = \frac{E_{sg} \times (E_{BB} - E_{s1g})}{P_{sg}}$$

where,

R_{sg} is the minimum value for the screen-grid voltage dropping resistor in ohms,
E_{sg} is the selected value of screen-grid voltage,
E_{BB} is the screen-grid supply voltage,
P_{sg} is the screen-grid input in watts corresponding to the selected value of E_{sg}.

A typical example follows:

Assume the data for a given tube states that a maximum of 300 volts can be applied to the screen grid and that the power dissipation cannot exceed 1 watt. It is desired to operate the screen grid with a voltage of 250 volts between cathode and screen, this voltage to be

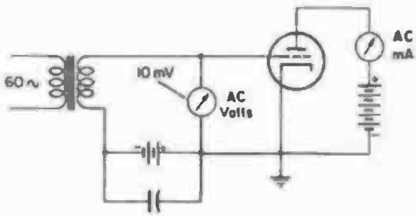

Fig. 11-87. Circuit for measuring the transconductance (G_m) of a typical vacuum tube.

obtained by the use of a series resistance between the power supply and the screen grid.

Because 250 volts is 83 percent of 300 volts, the maximum screen-grid voltage must be limited, as shown on the graph in Fig. 11-86, to 56 percent of the maximum screen-grid input, or 0.56 watt. The minimum value of the series-dropping resistor will be:

$$R_{sg} = \frac{250 \times (300 - 250)}{0.56} = 22{,}320 \text{ ohms.}$$

11.87 How is the transconductance of a vacuum tube measured?—By the use of a circuit such as that shown in Fig. 11-87. Normal grid and plate voltages are applied as indicated. The signal voltage is adjusted at the control grid of the tube. An ac milliammeter, calibrated in transconductance, is connected in the plate circuit.

$$g_m = I_{pac} \times 1000.$$

11.88 Show a circuit for measuring output power.—A circuit suitable for the measurement of power output is shown in Fig. 11-88. The power equals:

$$I_p^2 \times R_L$$

where,

I_p is the plate current in ac units,
R_L is the load impedance in ohms.

11.89 Show a circuit suitable for measuring amplification factor.—A simple test for measuring the ac amplification factor is shown in Fig. 11-89. The ratio of the output voltage to the input voltage is a measure of the amplification factor. This test is used for both triodes and pentodes.

11.90 Show a circuit suitable for measuring only cathode-emission current.—The basic circuit for the measurement of cathode emission is shown in Fig. 11-90. This is the method used in emission-type tube testers. The emission current is measured with all the elements except the cathode and heater tied together.

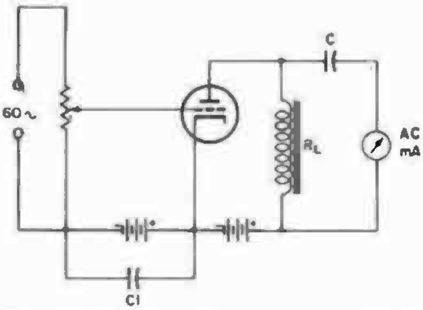

Fig. 11-88. Circuit for measurement of power output.

11.91 Describe a cathode-ray tube.—It is a large vacuum tube used in cathode-ray oscilloscopes, and in television receivers for both black and white and color reception. The cathode-ray tube was developed to its present state of perfection by many different researchers. In 1897 Karl F. Braun perfected the Crookes tube invented by Sir William Crookes for the study of cathode rays. Later, deflection plates were added by J. Thompson, an English physicist, and in 1899 E. Vichart, a German researcher, concentrated the electron beam with coil windings external to the axis of the tube. In 1902 A. A. Petrovski, a Russian, suggested the use of two external coils at right angles to each other to be used for deflecting the beam in the vertical and horizontal planes. Later Boris L. Rosing, also a Russian, experimented with the tube for the transmission of images and letters. Many other researchers have shared in the development of the cath-

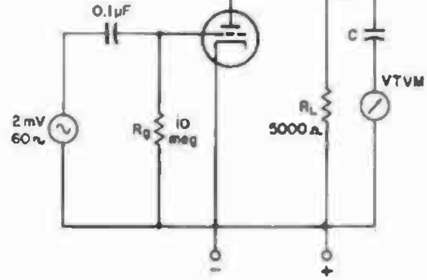

Fig. 11-89. The EIA method of measuring the ac amplification factor of triodes and pentodes. The internal impedance of the signal source should not exceed 2500 ohms.

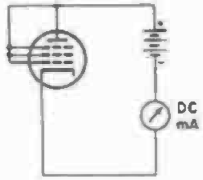

Fig. 11-90. Circuit for measurement of cathode emission current.

ode-ray tube, notably V. K. Zworykiu of the Uuited States for his work in the invention of the iconoscope and iunage orthicon tubes, and Allen B DuMont in his work of developing commercial oscilloscopes.

The cathode-ray tube is the heart of a cathode-ray oscilloscope and is operated in conjunction with quite complicated circuitry for the deflection of the beam and amplification of the applied signal voltages (see Question 22.69.) The tube employs an assembly, termed an *electron gun*, for projecting the electron stream, and a phosphor screen at the other end for displaying the waveform image (Fig. 11-92). The gun consists of a thermionic cathode, with various accelerating electrodes for directing and focusiug on the display screen the emitted electrons from the gun. The resulting narrow beam of electrons strike the screen in the form of a small round spot, with enough energy to cause fluorescence of the phosphor screen.

Cathode-ray tubes may be considered to he extremely fast x-y plotters, which plot input voltage versus time. The stylus of this plotter is a luminous spot which traces the image. In the conventional oscilloscope, the voltage to be observed is applied to the y-axis (vertical) input which moves the spot up and down in accordance with the instantaneous values of the input voltage. The x-axis voltage is supplied from an internally generated ramp voltage, which moves the spot uniformly from left to right across the display area of the screen. The spot then traces an image which displays input-voltage variation (amplitude) as a function of time. When the y-axis is repeated at a fast rate, the display appears as a steady straight line. Oscilloscopes may also be used to display mechanical motion with the proper transducer.

11.92 How are the electrons in a cathode-ray tube caused to strike the fluorescent screen?—Referring to Fig. 11-92, it will be seen that the heart of a cathode-ray tube is its electron gun. The gun is mounted at the end of a glass envelope and projects its electron stream towards the opposite end of the envelope, which contains a fluorescent screen. The construction of the gun is not simple, but consists of a number of parts that must be accurately manufactured and aligned.

The electrons are emitted by a heated cathode A which surrounds a heater element B. The electrons in leaving the cathode pass through a control grid C. The control grid determines the number of electrons that can pass and, consequently, the intensity of the light emitted by the fluorescent screen L. After leaving the control grid, the electrons are focused into a pencillike beam by the focusing anode D. Their velocity is further increased by the accelerating anodes E and F. At this point the electron stream is caused to

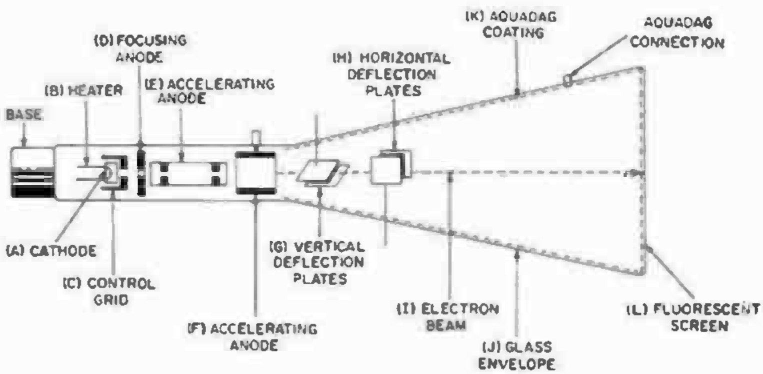

Fig. 11-92. Arrangement of the elements in an electrostatically deflected cathode-ray tube.

be deflected over various portions of the fluorescent screen by means of the horizontal and vertical deflection plates G and H.

Starting at the last anode F and continuing to the screen, the interior of the glass envelope is covered with a grounded graphite coating called aquadag. Its purpose is to bleed to ground stray electrons caused by secondary emission. (See Question 11.47.)

11.93 What is the method used to deflect the electron stream across the screen of a cathode-ray tube?—Two methods are used—the electrostatic and the electromagnetic. For oscilloscope work, the beam is generally deflected by the electrostatic method.

A front-end view of the deflecting plates, as would be seen looking through the fluorescent screen is shown in Fig. 11-93. The deflecting plates are arranged in pairs, two horizontal and two vertical. The electron beam passes through the center of the four plates as indicated by the spot in the center.

If a negative charge is applied to the left horizontal plate and a positive charge applied to the right horizontal plate, the beam will move to the right. When the charge is removed, the beam will return to the center again.

Removing the charge from the horizontal plates and charging the upper vertical plate negative and the lower vertical plate positive will move the beam downward. Reversing the polarities of the horizontal or vertical plates results in the beam moving in the opposite direction. Thus, if an alternating current is applied to the plates, the spot can be caused to oscillate back and forth either in a vertical or horizontal direction. The distance the spot is moved for either set of plates is directly proportional to the applied voltage. If equal voltages are applied to both the vertical and horizontal plates, the beam will be centered. With various combinations of voltage applied to the vertical and horizontal plates, the beam may be caused to move to any position on the screen. This is the basic principle on which a cathode-ray oscilloscope operates.

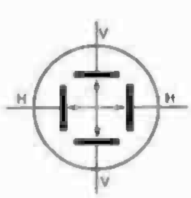

Fig. 11-93. The deflecting plates as seen when looking into the screen end of a cathode-ray tube.

11.94 How is the electron beam caused to draw out a pattern on an oscilloscope?—All oscilloscopes have an internal sawtooth oscillator for deflecting the beam in a linear manner across the screen. This motion is applied to the horizontal plates, while the signal is applied to the vertical plates. If the signal is an alternating one, and the sawtooth oscillator is adjusted for the fundamental frequency or a multiple of the applied waveform, one or more cycles of the waveform may be drawn out on the screen. This subject is further discussed in Question 22.69.

11.95 How is the sensitivity of a cathode-ray tube rated?—It is rated in terms of the voltage required to deflect the beam a given distance on the screen in millimeters or inches, with the signal applied directly to the deflecting plates (without amplification). Sensitivity is rated in rms volts per millimeter or peak-to-peak volts. For dc deflection, it is rated in a similar manner.

11.96 Are the characteristics of fluorescent screen the same for all types of cathode-ray tubes?—No. Tubes may be obtained with different degrees of persistence—long, medium, and short. Also, they may be obtained to reproduce the image in green, blue, or white.

11.97 What does the term "persistence" mean? — The various types of phosphor used in the manufacture of cathode-ray tubes (CRT) are many and varied. Basically there are at the present time 35 types, designated P1 to P35, although there are many more that are unregistered. The persistence of the cathode-ray tube screen is classified by the time it takes for the screen to fade to 10 percent of its original brightness.

The most common phosphors used for oscilloscopes are: P1, P2, P5, P31, and P35 with a grain size of 10 microns, with colors being yellowish-green, blue, green, and blue-white. Phosphors P8, P9 and P30 are no longer used. Luminescence occurs during the excitation of the screen. Luminescence that persists more than *ten nanoseconds* after the excitation has ceased is termed *phos-*

Phosphor	Trace Color		Low-Level Persistence	Writing Rate (aluminized 5BH at 10 kV)	Relative Burn Resistance	Relative Visual Brightness			Trace Contrast (without filter)
	Under Excitation	After-Glow				5AQ 2.5kV	5AM 5kV	5BH 10kV	
P1	green	green	180 ms	200 cm/μs	100	100	600	3000	good
P2	blue	yellow	1 s	600 cm/μs	150	90	550	2000	fair
P7	blu-wht	yellow	3 s	200 cm/μs	75	50	400	1500	poor
P11	blue	blue	20 ms	700 cm/μs	75	20	200	800	poor
P31	blu-grn	lt grn	0.5 s	400 cm/μs	250	110	1300	5000	fair to poor

Phosphor	Phosphor Application	Advantages	Disadvantages
P1	General purpose phosphor for visual observation of repetitive signals.	Good trace to background contrast; color near center of visual spectrum.	Lack of persistence; color too yellow for fast writing rate photography.
P2	General purpose phosphor for visual and photographic observation of slow and normal repetitive signals.	Persistence characteristic may be intensified with an amber filter; short persistence bluish trace very good for photography.	Low trace to background contrast; trace brightness lower than P1 and P31.
P7	For observation of low repetition rate and nonrepetitive phenomena.	Very long persistence; wide spectral separation between blue and yellow so that filters may emphasize either characteristic.	Sepcialized characteristics limit general use.
P11	For photographing all signal types, particularly those requiring fast writing rate.	Blue trace color near maximum sensitivity of film.	Specialized characteristics limit its general use.
P31	General purpose phosphor for visual and photographic observation of repetitive signals.	Provides highest visual brightness—particularly at 5 kV and above in aluminized tubes; listed characteristics combine to make it a good general purpose phosphor.	Low trace to background contrast under bright ambient light conditions.

Fig. 11-97. Characteristics of phosphors used for cathode-ray tube screens.

phorescence. The chemical composition of typical CRT screens is: zinc orthosilicate, zinc cadmium sulphide, zinc sulphide, and many other combinations.

Screens are available with variable persistence which will hold images from 0.1 second to several minutes, hours, and even days. Thus, multiple images may be recorded and held or wiped off with the push of a button. To eliminate parallax in photography and when viewing an image at an angle, CRT's may be obtained with a flat screen and an internal graticule. A table of CRT phosphor characteristics is given in Fig. 11-97 with their advantages and disadvantages.

11.98 How is electromagnetic deflection used with a cathode-ray tube?—It is an electronic system of deflecting the electron beam in the cathode-ray tube by means of electromagnets placed around the exterior of the neck near the front end of the electron gun. The gun construction is the same as that used in the electrostatically deflected one, except that the focusing anode is replaced by an external focusing coil and the deflection plates are replaced by deflection coils.

11.99 What is aquadog?—A graphite coating used on the inside of a cathode-ray tube to collect secondary emission electrons and conduct them to ground.

11.100 What is an intensifier element?—An element in a cathode-ray tube, consisting of a band of graphite (aquadag) on the inner surface of the glass envelope, connected to a source of high voltage. Its purpose is to accelerate the electron beam after it has been deflected.

11.101 What is an ultor element in a cathode-ray tube?—It is the element which receives the highest dc voltage for acceleration of the electron beam prior to its deflection.

11.102 What is a post-ultor element in a cathode-ray tube?—It is the element to which is applied a dc voltage higher than the ultor element voltage to accelerate the electron beam after its deflection.

11.103 What is germanium?—A rare metal discovered by Winkler in Saxony, Germany in the year 1896. Germanium is a by-product of zinc mining. Germanium crystals are grown from germanium dioxide powder. Germanium in its purest state behaves much like an insulator because it has very few electrical charge carriers. (See Question 11.111.) The conductivity of germanium may be increased by the addition of an impurity in small amounts.

11.104 What is the purpose of inducing impurities in semiconductor material?—To control its conductivity characteristics. By introducing arsenic or antimony in germanium, its free or negative mobile charges are increased. The use of gallium, indium, or aluminum in germanium, increases the number of positive mobile charges (called holes). This characteristic is taken advantage of in the manufacture of transistors. The adding of an impurity to a semiconductor is termed doping. (See Question 11.114.)

11.105 When was the phenomenon of asymmetric conduction in solids first observed?—The first known observation was by Munck and Henry in 1835, and later in 1874 by Braun. In 1905, Col. Dunwoody invented the crystal detector, used in the detection of electromagnetic waves. It consisted of a bar of silicon carbide or carborundum held between two contacts. However, in 1903, Pickard filed a patent application for a crystal detector in which a fine wire was placed in contact with the silicon. This was the first mention of a silicon rectifier, and was the forerunner of the present day silicon rectifier. Later, other minerals such as galena (lead sulphide) were employed as detectors. In 1883, Edison observed the flow of current between a hot filament and an anode placed in an evacuated bulb (Edison effect). In 1903 Fleming made use of Edison's discovery and devised the first vacuum diode detector. In 1906, Dr. Lee DeForest invented the three-element vacuum tube. During World War II, intensive research was conducted to improve crystal detectors used for microwave radar equipment. As a result of this research, the original point-contact transistor was invented at the Bell Telephone Laboratories in 1948. Thus, it may be seen that semiconductor devices preceded the vacuum tube by many years.

11.106 Name different type devices classed as semiconductors.—A few of the more commonly known devices are:

Chronistor—A high-speed switching transistor.

Contact protector—A device consisting of one or more diodes, which are connected across the circuit to reduce the effects of surge currents. For ac circuits, two diodes are connected in series back-to-back. For dc circuits, a single diode is used. (See Question 24.67).

Epitaxial annular transistor—A transistor in which a high resistivity silicon is epitaxially grown on a low resistivity silicon substrate in a single crystal relationship. (See Question 11.118.)

Field-Effect Transistor (FET) — A single-junction majority-carrier device and similar in several respects to a vacuum tube. The FET has a high input impedance, is voltage controlled, and has a high output impedance although in the latter respect, by different manufacturing processes, it can have a lower output resistance than a vacuum tube.

Photofet—A light-sensitive field effect transistor fitted with a lens system and used similarly to a photocell. (See Questions 11.161 and 19.170.)

Phototransistor—Similar to the above, except it is of the conventional transistor type, fitted with a lens system.

Photoconductive cell—Similar to the above.

Silicon controlled rectifier (SCR)—A three-element device used for changing alternating current to direct current. The third element is used to control the action of the rectifying elements. (See Question 11.150.)

Selenium transient-voltage suppressor—A selenium diode having a controlled reverse-breakdown characteristic. Connected across rectifier circuits to protect the rectifying devices from heavy transient currents. (See Question 11.158.)

Stabistor—A single- or multiple-pellet diode with controlled forward voltage characteristics, and always used in a forward biased condition. Stabistors are used in computer circuits and in low-voltage regulating circuits.

Thyrector—A protector similar to a zener diode. (See Question 11.148.)

Lumistor—A four-terminal high-temperatnre semiconductor

Thermistor—A thermally sensitive resistor that exhibits a change in electrical resistance with a change in its body temperature.

Raysistor—A device in which a source of light and photosensitive resistive elements are enclosed in a single light-tight case, and used for circuit control by controlling the illumination of light falling on the photosensitive surface.

Voltage-sensitive capacitor—A voltage-controlled diode that functions as a variable capacitor.

Varactor diode—Similar to the above.

Tunnel diode—So named from the nature of its characteristics, a process wherein a particle can disappear from one side of a barrier, and reappear on the other side instantaneously, as if the particle had tunneled under the barrier element.

Transistor—A device that may be used as an amplifier, oscillator, modulater, and many functions performed by vacuum tubes.

Zener diode—A semiconductor device, the equivalent of the gaseous voltage regulator tube. They may be obtained to operate over a wide range of voltages.

Thyrite varistor—A nonlinear resistor in which the current varies as the power of the applied voltage, and used as a surge protector.

The symbols used with semiconductors, and their construction, are shown in Fig. 11-114J.

11.107 Describe the basic structure of a transistor—The transistor is a semiconductor device, invented by Dr. Wm. Shockley, Dr. John Bardeen, and Dr. Walter H. Brattain of the Bell Telephone Laboratories in 1948. The name "Transistor" is coined from two words, transfer and resistor. The first transistor consisted of a particle of semiconductor material, such as germanium, mounted in a holder with two point contacts (Fig. 11-107A).

In this type structure, connections to the emitter and collector were made by means of leads with sharp points in contact with the surface of the crystal (much like the crystal detector used in the early days of wireless telegraphy). During the manufacturing process, two

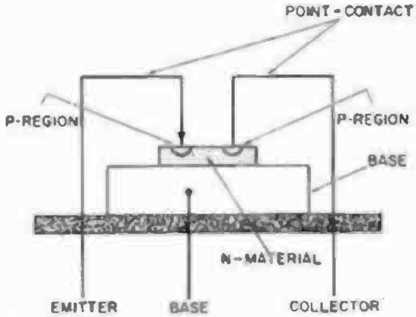

Fig. 11-107A. Cross-sectional view of point-contact transistor. This type of transistor was the original design, but has now been replaced by the junction-type transistor.

small areas of p-type material are produced. Therefore, the contact points of the leads are actually in contact with a p-type material. The n-material is between the p-material and the base. Point-contact construction is now obsolete, having been superseded by the junction-type construction.

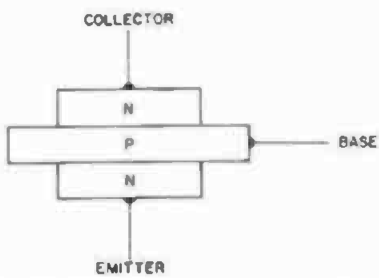

Fig. 11-107B. Basic construction for an npn transistor.

Junction transistors may be constructed using one of two methods, as shown in Figs. 11-107B and C. In the junction-type construction, the connecting leads are fused to the surface of the semiconductor material (Fig. 11-107D). The characteristics are control-

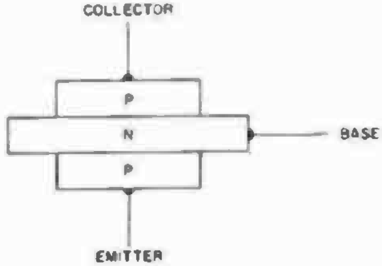

Fig. 11-107C. Basic construction for a pnp transistor.

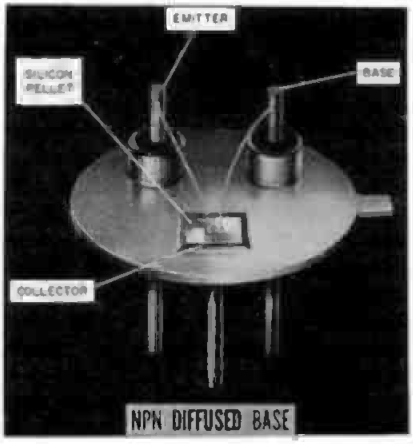

Fig. 11-107D. Interior view of General Electric diffused-base transistor.

led by doping the semiconductor material with impurities.

Since most semiconductor materials are photosensitive, it is necessary that the envelope enclosing the structure be opaque. Transistors do not require a vacuum for their operation. The characteristics of transistors are treated elsewhere in this section.

11.108 Does radiation affect the operation of transistors?—Yes, however the radiation caused by cathode-ray tubes or high-voltage rectifiers has little or no effect if the distance is greater than 12 inches. Radiation causes the semiconductor material to become *conductive*. Silicon devices are less affected than germanium. Cosmic, gamma, and nuclear radiations increase the leakage current and permanently affect the characteristics.

11.109 What is the difference between electron and conventional current flow?—In the field of electronics, two methods of dealing with current flow prevail. In the conventional school of thought, the current flows from *positive* to *negative*, while in the electronics

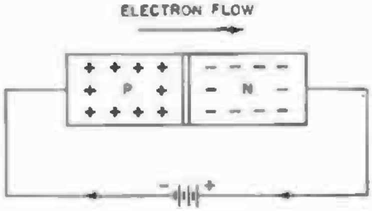

Fig. 11-109A. Direction of current flow in a reversed-biased junction diode.

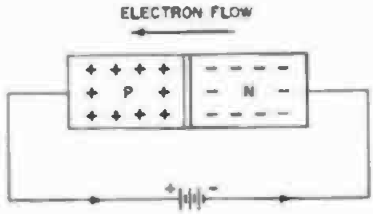

Fig. 11-109B. Direction of current flow in a forward-biased junction diode.

school of thought, the current flows with the electronic drift or *negative* to *positive*. Since the development of semiconductor devices, yet another theory of current flow has been developed—the hole movement positive to negative. In addition to this term are others such as forward current, reverse current, leakage current, saturation current and many others. Semiconductors with their opposite natures of npn and pnp combinations, and many more of multiple construction add to this confusion.

A better understanding of semiconductor current principles may be had by the diode concept. With an external battery connected across a pn junction (Fig. 11-109A), the current flow is determined by the polarity of the applied voltage and its effect on the space-charge region. In the illustration, the positive terminal of the battery is connected to the n material and the negative terminal to the p material. In this arrangement, the free electrons in the n material are attracted to the positive terminal of the battery and *away* from the junction. At the same time, holes from the p-type material are attracted *toward* the negative terminal of the battery and *away* from the junction. As a result, the space-charge region at the junction becomes effectively wider, and the potentional gradient increases until it approaches the battery potentional. Under these conditions the current flow is extremely small because

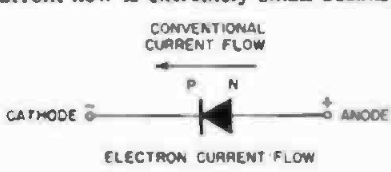

Fig. 11-109C. Symbol for a diode rectifier. The plus and minus terminals may be identified by arrow and bar.

no voltage difference exists across either the p-type or the n-type region and the pn junction is said to be *reverse-biased*.

If the connections are reversed as in Fig. 11-109B, the electrons in the p-type material near the positive terminal of the battery break their bonds and enter the battery, creating new holes. At the same time, electrons from the negative terminal of the battery enter the n-type material and diffuse toward the junction. The space-charge region then becomes effectively narrower, and the energy barrier decreases to an insignificant value. Excess electrons from the n-material can then penetrate the space-charge region, flow across the junction and move by way of the holes in the p-type material toward the positive battery terminal. This flow will continue as long as the external potential is applied. Under these conditions it is said the junction is *forward-biased* and maximum current will flow. In the construction of a diode (Fig. 11-109C), the anode is always positive and it consists of p-type material, and the cathode consists of n-type material. Thus, if a positive potential is applied to the anode (arrow symbol) conventional current flow is from the anode to the cathode, through the external circuit and back to the anode. Electron flow is in the opposite direction. (See Question 11.148.)

11.110 What is silicon?—A nonmetallic element used in the manufacture of diode rectifiers and transistors. Its resistivity is considerably higher than that of germanium.

11.111 Where does the resistance of germanium and silicon fall on the resistance scale of semiconductor material?—The relative position of pure germanium and silicon is given in Fig. 11-111. The scale indicates the resistance of conductors, semiconductors, and insulators per cubic centimeter. Pure germanium has a resistance of approximately 60 ohms per cubic centimeter. Germanium has a higher conductivity or less resistance to current flow than silicon, and is used in the majority of low- and medium-power diodes and transistors.

11.112 Define the terms, majority and minority carriers.—A majority carrier is the type of charge carrier that constitutes more than half of the total

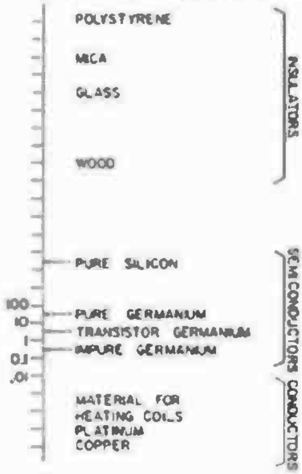

Fig. 11-111. Resistance of various materials per cubic centimeter. Pure germanium has about 60-ohms resistance per cubic centimeter.

charge-carrier concentration. Minority carriers constitute less than half the charge carriers.

11.113 Define the term junction as applied to semiconductors.—The term junction refers to the region between semiconductor regions of different properties, between metal and semiconductor material. An alloy of fused junction is formed by recrystallization on a base crystal from a liquid phase containing doping materials. A diffused junction is formed by a solid or vapor diffusion of an impurity within the semiconductor. Doped junctions are produced by the addition of an impurity that melts during the crystal growth. A grown junction is a junction produced during the growth of a crystal from a smelt. (See Question 11.118.)

11.114 What is the basic theory of a semiconductor?—To understand the theory of operation of a semiconductor device, it must be approached from the standpoint of its atomic structure.

The outer orbit of a germanium atom contains four electrons. The atomic structure for a pure germanium crystal is shown in Fig. 11-114A. Each atom containing four electrons forms covalent bonds with adjacent atoms. Therefore, there are no "free" electrous, and germanium in its pure state is a poor conductor of electricity. (See Fig. 11-111.) If a piece of "pure" germanium (the size used in a transistor) has a voltage applied to it, only a few microamperes of current will flow in the circuit. This current is caused by electrons which have been broken away from their bonds by thermal agitation, and will increase at an exponential rate with an increase of temperature.

Introducing into the germanium crystal an atom with five electrons, such as antimony or arsenic, changes the atomic structure to that of Fig. 11-114B. The extra electrons (called free electrons) will move toward the positive terminal of the external voltage source.

When an electron flows from the germanium crystal to the positive ter-

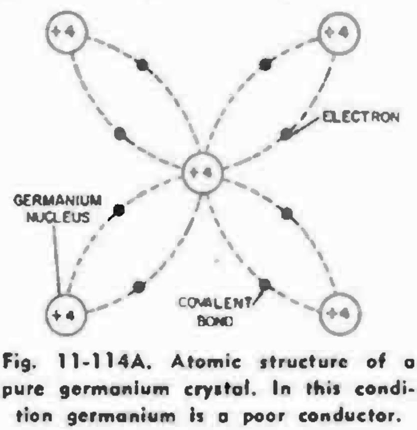

Fig. 11-114A. Atomic structure of a pure germanium crystal. In this condition germanium is a poor conductor.

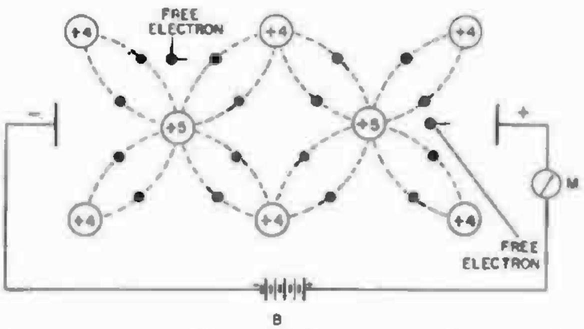

Fig. 11-114B. Atomic structure of a germanium crystal when a doping agent containing five electrons is induced. This type crystal is classified as n-type germanium.

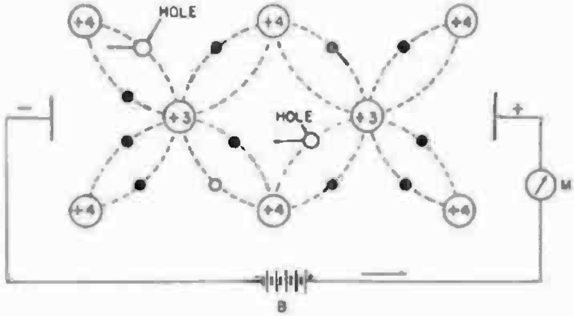

Fig. 11-114C. Atomic structure of a germanium crystal when a doping agent containing three electrons is induced. This type crystal is classified as p-type germanium.

minal of the external voltage source, another electron enters the crystal from the negative terminal of the voltage source. Thus, a continuous stream of electrons will flow as long as the external potential is maintained.

The atom containing the five electrons is called a "doping agent" or "donor." Such germanium crystals are classified as n-type germanium.

Using a doping agent of indium, gallium, or aluminum, which contain only three electrons in their outer orbit causes the germanium crystal to take the atomic structure of Fig. 11-114C. In this structure, there is a "hole" or "acceptor." The term hole is used to denote a mobile particle having a positive charge, and simulates the properties of an electron having a positive charge.

The use of the term hole is relatively new, but it is as useful as the term electron to explain the manner in which electricity is conducted by electrons. Electrons in semiconductors are also referred to as "carriers."

Pure germanium is also referred to as "intrinsic germanium," which means that the germanium has an equal number of donors and acceptors.

When a germanium crystal containing holes is subjected to an electrical field, electrons jump into the holes, and the holes appear to move towards the negative terminal of the external voltage source.

When a hole arrives at the negative terminal, an electron is emitted by the terminal and the hole is canceled. Simultaneously, an electron from one of the covalent bonds flows into the positive terminal of the voltage source. This new hole moves toward the negative terminal causing a continuous flow of holes in the crystal.

Germanium crystals having a deficiency of electrons are classified p-type germanium. Insofar, as the external electrical circuits are concerned, there is no difference between electron and hole current flow. However, the method of connection to the two types of transistors differs.

With an electrical field of one volt per centimeter in germanium, an electron will move at a velocity of 3600 centimeters per second, whereas a hole will move at a velocity of 1700 centimeters per second.

When a germanium crystal is so doped that it abruptly changes from an n-type to a p-type, and a positive potential is applied to the p region, and

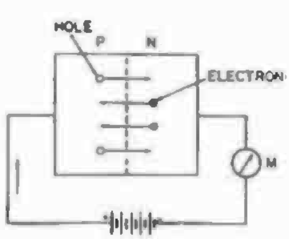

Fig. 11-114D. A germanium junction which consists of a p- and an n-type crystal.

a negative potential to the n region, the conditions will be as shown in Fig. 11-114D.

The holes move through the junction to the right and the electrons to the left, resulting in a voltage-current characteristic as shown in Fig. 11-114E. If the potential is reversed as shown in Fig. 11-114F both electrons and holes move away from the junction until the electrical field produced by their displacement counteracts the applied electrical field. Under these conditions zero current flows in the external circuit. Any minute amount of current which might flow is caused by thermal generated hole pairs. It will be noted in Fig. 11-114G, a plot of the voltage versus current for the reversed condition, the leakage current is essentially independent of the applied potential up to the point where the junction breaks down.

The basic construction of an npn-type transistor is shown in Fig. 11-114H. The left-hand n and center p section is forward-biased, and is termed the emitter junction. The other junction formed by the p and right-hand n section is reverse-biased, and is termed the collector junction. The p- type base is "lightly" doped in comparison to the n-type emitter; therefore, the majority of the current flowing from the emitter to the base is electron current with very little hole current. The major portion of the electrons emitted by the base diffuse across the collector junction and pass to the collector circuit. The ratio of emitter current to collector current is termed the "alpha" of a transistor.

It is essential that the value of alpha be as great as possible. This is achieved by a light doping of the base using a thin base region of the order of 1 mil, and minimizing the unwanted impurities in the germanium that might cause recombination of electrons before they transverse the base region. Alpha's of 0.95 to 0.99 are common in commercial transistors.

Only a small amount of leakage current flows in the collector circuit unless current is induced in the emitter. A small voltage of the order of 0.10 to 0.50 volt is all that is required to cause an appreciable amount of current flow; thus, the input power is quite small.

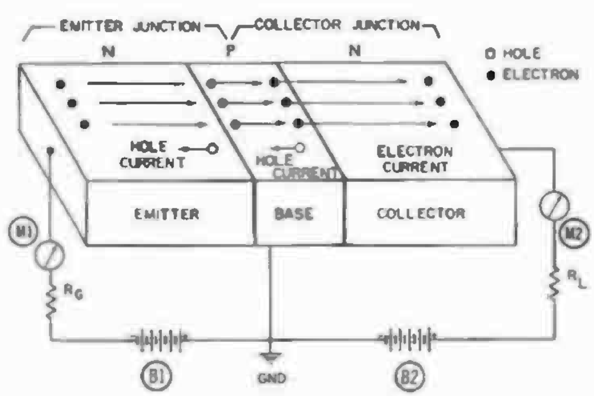

Fig. 11-114H. Basic construction and connections for an npn junction-type transistor.

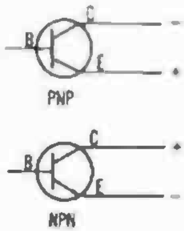

Fig. 11-114I. Symbols for a pnp and an npn transistor.

This permits a relatively large amount of power to be controlled in the external load circuit by a small amount of power at the input circuit.

The power gain of a transistor may be calculated:

$$P_o = \frac{P_{out}}{P_{in}}$$

$$P_{in} = \frac{E_{in}^2}{R_{in}}$$

$$P_{out} = \frac{E_{out}^2}{R_L}$$

where,

P_{out} is the output power,
P_{in} is the input power,
E_{in} is the voltage at the input,
E_{out} is the voltage at the output,
R_{in} is the input resistance of the transistor,
R_L is the load resistance.

The materials used in the manufacture of semiconductor devices are germanium and silicon. As germanium has a higher conductivity than silicon, it is used in most low- and medium-power diodes and transistors. Silicon is more suitable for high-power devices than is germanium since it may be used at much higher temperatures. Considerable research is being done in the development of gallium arsenide, which combines the most desirable characteristics of both germanium and silicon.

The npn-type junction transistor corresponds to the conventional triode vacuum tube using negative (electron) carriers. The pnp-type might be compared to a vacuum tube operating (if it were possible) with the electrons flowing from plate to cathode.

Graphical symbols for diodes and transistors are given in Figs. 11-114I and J. The arrows on the diagrams indicate the direction of electron flow. The base in a transistor corresponds to the control grid in a vacuum tube, the emitter to the cathode or filament, and the collector to the plate of a tube. However, transistors are entirely different from vacuum tubes as they are current-controlled devices, where a vacuum tube is voltage controlled and has a high input impedance. Transistors may have either a high- or low-input impedance, depending on the circuit design. The load impedance has a direct effect on the input impedance and vice versa. Although transistors will perform functions of the vacuum tube, their design requires a new concept in circuit design compared to that used for vacuum-tube circuit design. In Fig. 11-114J are given the symbols used for the more common types of transistors and diodes. However, this list is by no means complete, as the semiconductor field is undergoing continuous change.

11.115 What are the letter symbols used with semiconductor devices for identifying their electrical characteristics?—Although the letter symbols for transistors and diodes have not been completely standardized throughout the electronic industry, many symbols have become fairly well established by common usage. A tabulation of the symbols in use at the present time is given in Fig. 11-115. For letter symbols not given, the basic symbol is used and modified to suit the particular requirement.

Nomenclature used for the classification of semiconductor devices use the prefix 1N for diodes followed by the type number, such as 1N3493. Transistors use the prefix 2N followed by the type number. Letters appearing after the type number indicate a modification of the original design.

11.116 How are the polarities of semiconductor devices identified?—For diodes, the symbol representing an arrow and base is imprinted on the housing if large enough. The arrow always indicates the direction of *conventional current flow*, and is the *positive* (+) terminal. Electron flow is in the direction *opposite* to the arrow. If the device is too small for the symbol to read, a red dot is sometimes used to denote the positive terminal. For miniature-type diodes, the type number is indicated using the standard electronic industry color code. In this case the negative or cathode terminal is at the start of the nnmber, as shown in Fig. 11-116A. Diodes of early manufacture used a black ring or bar to denote the

negative terminal. Top-hat types are marked as shown in Fig. 11-116B.

Transistors, due to their many types and shapes are sometimes hard to identify; therefore, it is good practice to consult the manufacturer's data sheet for the correct terminals and polarity. For three lead types, the center lead is usually the base. A dot indicates the collector; therefore, the remaining lead is the emitter.

11.117 What is the approximate resistance that may be expected between the elements of a transistor?—The ap-

Fig. 11-116. Diode polarity markings. The arrow indicates *conventional* current flow. *Electron* flow is in the opposite direction.

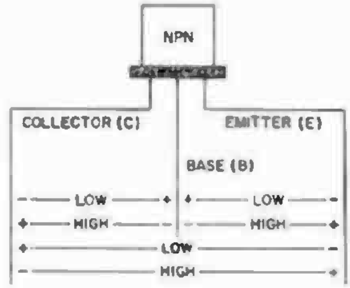

Fig. 11-117A. Approximate resistance between the elements of a transistor when measured with an ohmmeter. The polarities will be reversed for a pnp transistor.

proximate resistance that may be expected between any two elements of an npn transistor known to be operative is shown in Fig. 11-117A, and may be measured using a low current volt-ohmmeter. Before using the ohmmeter, the current flow between the leads of the ohmmeter must be measured with a microammeter or milliammeter; also measure the open-circuit voltage using a 1000 ohm-per-volt meter. For a typical 20,000 ohm-per-volt service meter on the $\times$ 100 resistance scale, the current measured 76 microamperes; on the $\times$ 1.0 scale, 800-microamperes; and 70 milliamperes on the 1/100 scale. The highest scale measured 16 volts, and the two lower scales 1.6 volts. Thus, it can be seen that a *good transistor could be damaged if measured on the low-resistance scale.*

Referring again to Fig. 11-117A, it is indicated that for a given polarity of the ohmmeter, either a high or low resistance may be expected between a given pair of terminals. Generally the ratio of high to low will be on the order of 200,000 ohms or greater; on the low side between 1 to 2 ohms. For a pnp type, the polarities are reversed from those shown. The effects of an internal short circuit for an operating transistor is shown in Fig. 11-117B, with a tabulation of the effect on the operating voltages shown in Fig. 11-117C. The operating voltages should, for accuracy, be measured with a meter of extremely high resistance, or better yet, with a dc vacuum-tube voltmeter.

11.118 Describe the methods of construction used in the manufacture of

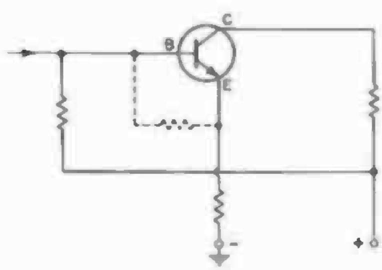

Fig. 11-117B. An npn-type transistor with its components. If two of the elements are shorted, as shown by the dotted line, the effects tabulated in Fig. 11-117C may exist.

transistors.—The principal difference in the manufacturing of transistors is the method used in the construction of the junctions. Certain types of transistors employ up to eight elements, and there appears to be no limit to the various combinations possible. In Fig. 11-118A is shown the construction of a grown-junction transistor. An alloy-junction transistor is shown in Fig. 11-118B. During the manufacture of the material for a grown junction, the impurity content of the semiconductor is altered to provide npn or pnp regions. The grown material is cut into small sections and contacts are attached to the regions. In the alloy-junction type, small dots of n- or p-type impurity elements are attached to either side of a thin wafer of p- or n-type semiconductor material. After heating, the impurity dot alloys with the semiconductor material to form regions for the emitter and collector junctions. The base connection is made to the original semiconductor material. Drift-field transistors employ a modified alloy junction in which the impurity concentration in the wafer is diffused or graded, as shown in Fig. 11-118C. The drift field speeds up the current flow and extends the frequency response of the alloy-junction transistor.

A variation of the drift-field transistor is the microalloy diffused transistor (Fig. 11-118D). Very narrow base dimensions are achieved by etching techniques, resulting in a shortened current path to the collector. Mesa transistors, shown in Fig. 11-118E, use the original semiconductor material as the collector, with the base material diffused into the wafer and an emitter dot alloyed into the base region. A flat-topped peak or mesa is etched to reduce the area of the collector at the base junction. Mesa devices have large power-dissipation capabilities and can be operated at very high frequencies. Double-diffused epitaxial mesa transistors are grown by the use of vapor deposition to build up a crystal layer on a crystal wafer, and will permit the precise control of the physical and electrical dimensions independently of the nature of the original wafer. This technique is shown in Fig. 11-118F.

The planar transistor is a highly sophisticated method of constructing transistors. A limited area source is used for both the base diffusion and emitter diffusion, which provides a very small active area, with a large wire contact area. The advantage of the planar construction is its *high dissipation, lower leakage current, and lower collector-cutoff current,* which increases the stability and reliability. Planar construction is also used with several of the previously discussed base designs. A double-diffused epitaxial planar transistor is shown in Fig. 11-118G.

11.119 What are the general precautions to be observed with the use of semiconductor devices?—Limit the maximum junction temperature to prevent excessive leakage currents. Use low values of stability factors, such as using resistance in the emitter circuit. Reduce the value of the shunt resistance from base to emitter to a value as low as possible (taking into consideration the gain requirements). Use large values of collector current to minimize temperature changes. Use low values of source resistance to keep the stability factor low. In temperature-compensated circuits, provide a common heat sink for all semiconductor devices. *Do not* use an ohmmeter for checking a transistor or diode without first measuring the current flow between the ohmmeter leads. When soldering, use heat-sink pliers on the leads. Use a thermal derating factor when operating at temperatures above 25 degrees centigrade. The foregoing are but a few precautions to be observed in the use of semiconductor de-

vices. When in doubt, consult the manufacturer's data sheet.

11.120 What is meant by the term "punch-through"?—It is the widening of the space charge between the collector element and the base of a transistor. As the potential V_{cb} is increased from a low to a high value, the collector-base space charge is widened. This widening effect of the space charge, narrows the effective width of the base. If the diode space charge does not "avalanche" before the space charge spreads to the emitter section, a phenomenon termed "punch-through" is encountered. (See Fig. 11-120.)

The effect is: the base disappears as the collector-base, space charge layer contacts the emitter, creating a relatively low resistance between the emitter and the collector, causing a sharp rise in the current. The transistor action then ceases. As there is no voltage breakdown in the transistor, it will start functioning again if the voltage is lowered to a value below where punch-through occurs.

When a transistor is operated in the punch-through region, its functioning is not normal, and heat is generated internally which can cause permanent damage to the elements.

11.121 Define breakdown voltage in a transistor.—Breakdown voltage is that voltage value between two given elements in a transistor at which the crystal structure changes and current begins to increase rapidly. Breakdown voltage may be measured with the third electrode open, shorted, or biased in either the forward or reverse direction. A group of collector characteristics for different values of base bias are shown in Fig. 11-121. It will be observed the collector-to-emitter breakdown voltage increases as the base-to-emitter bias is decreased from the normal forward values through zero to reverse. As the resistance in the base-to-emitter circuit decreases, the collector characteristics develop two breakdown points. After the initial breakdown, the collector-to-emitter voltage decreases with an increasing collector current, until another breakdown occurs at the lower voltage.

Breakdown can be very destructive in power transistors. A breakdown mechanism, termed second breakdown, is an electrical and thermal process in which current is concentrated in a very small area. The high current, together with the voltage across the transistor, causes intense heating, melting a hole from the collector to the emitter, caus-

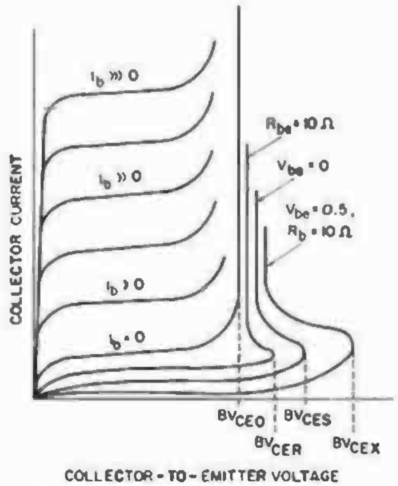

Fig. 11-121. Typical collector characteristic curves showing locations of various breakdown voltages. (Courtesy Radio Corporation of America)

ing a short circuit and internal breakdown of the transistor.

The fundamental limitation to the use of transistors is the breakdown voltage, ($BV_{..r}$). Because the breakdown voltage is not sharp, it is necessary to specify the value of collector current at which breakdown will occur. This data may be obtained from the manufacturer's data sheet.

11.122 Define the term "extrinsic transconductance."—It is the quotient of a small change in collector current divided by a small change in emitter-to-base voltage producing it, under the condition that other voltages remain unchanged.

11.123 Show the flow of current through a transistor.—The current flow paths for both pnp- and npn-type transistors are given in Fig. 11-123. It will be observed that the flow of current is reversed from one type to the other.

11.124 What are the equivalent circuits for transistors?—Transistors may be considered to be a "T" configuration active network. Three such networks are given Fig. 11-124.

11.125 What are the phase relationships between the input and output of a transistor?—For the conventional transistor the *only* configuration that will provide a 180-degree phase reversal between input and output is the *grounded or common-emitter* configuration (Fig. 11-125A). Phase relations for the grounded or common-collector and common-base configurations are shown in Figs. 11-125B and C. These configurations have the same phase for both input and output. Equivalent vacuum tube circuits have been included for comparison. In the instance of the field-effect transistor (FET), Fig. 11-125D, for a given instantaneous polarity of the input signal at the gate, the output signal at the drain is reversed by 180 degrees. The signal at the source is of the same phase as the gate. This makes the FET ideal for phase-inverter applications.

11.126 What is the relationship between the input and output impedance of a transistor?—The input resistance for the common-collector and common-base configuration increases with an increase of the load resistance R_L. For the common-emitter, the input resistance decreases as the load resistance is increased; therefore, changes of input or output resistance are reflected from one to the other. Typical variations of output resistance for changes in generator impedance are given in Fig. 11-126. Voltage, power, and current gains are shown for a typical common-emitter configuration in Fig. 11-128.

(c) Grounded collector.

Fig. 11-126. Junction-type transistor circuits showing the input and output impedances. The impedances shown are typical and will vary with different type transistors.

11.127 Show typical amplifier circuits for transistors.—Three simple amplifier circuits are shown in Figs. 11-127A, B, and C. In Fig. 11-127A is shown a two-stage resistance-capacitance (RC) coupled amplifier. In Fig. 11-127B, the circuit is direct-coupled, eliminating the coupling capacitors. Today's trends are toward the use of direct-coupled circuitry, since it reduces the phase-shift, extends the frequency range in both directions, and reduces the number of components. However, on the other hand, the gain is somewhat reduced over that of the RC coupled types, and the number of stages that can be direct-coupled is limited. Variations in the bias voltage are also reflected in the other stages. The term direct-coupled does not imply that it may be used for the amplification of direct current, as the extremely low-frequency signals are limited by factors other than the coupling method.

A transformer-coupled amplifier is shown in Fig. 11-127C. Although either pnp- or npn-type transistors may be used if the correct polarities are observed, it is quite important that the transformers match the transistor input and output impedances. Transistors are not necessarily confined to the circuits shown, but may be used in any amplifier configuration, such as single-ended types, push-pull, class-A, -B and -C, and other subscripts. Transistors may also be used for radio-frequency amplification up to several hundred megahertz. In fact, transistors may be used in almost any application where vacuum tubes are used, and in many circuits where it would be impractical to use tubes. Transistors may be used in an impedance-coupled circuit or with autotransformers. However, these circuits are generally only employed for special-purpose amplifiers.

Transistors may also be operated in parallel, similar to vacuum tubes, but unfortunately transistors, although of the same type and manufacture, do not always have similar characteristics. If the transistors are unmatched, when connected in parallel one transistor may be carrying most of the load. Two solutions are apparent—either use matched pairs of transistors or employ emitter resistors to balance the load. It has been found that for power transistors rated at 5 amperes or greater, a resistance of about 0.2 ohm connected in each emitter will generally be satisfactory. A rule of thumb is to use a resistor that will

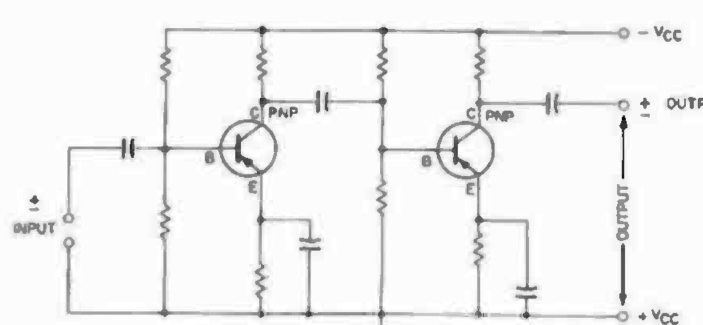

Fig. 11-127A. Typical resistance-capacitance coupled audio amplifier.

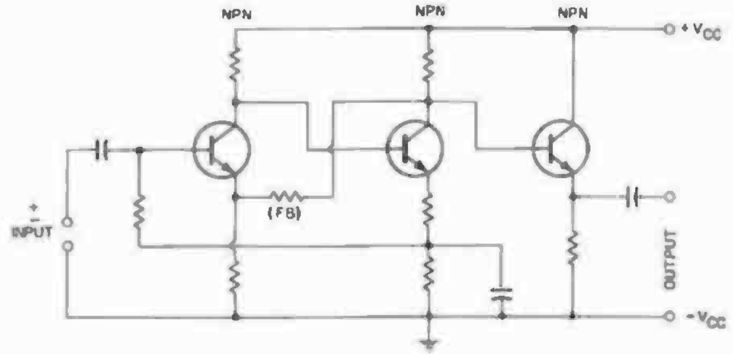

Fig. 11-127B. Direct-coupled amplifier using negative feedback between first and second stages.

cause a voltage drop of 1 volt at the maximum collector current. If possible, measure the characteristics of each transistor and then select two having nearly the same characteristics; also insert the resistor in the emitter circuits. If these precautions are not observed, one transistor can be badly damaged.

11.128 Show the voltage, power, and current gains for a typical transistor.—Typical curves for a conventional transistor using a common-emitter configuration are shown in Fig. 11-128. It will be noted the current gain decreases as the load resistance is *increased*. The voltage gain *increases* as the load resistance is *increased*. Maximum power gain occurs when the load resistance is approximately 40,000 ohms, and it may exceed unity. For the common-collector connection, the current gain decreases as the load resistance is increased, and while the voltage gain increases as the load resistance is increased, it never exceeds unity. Curves such as these help the designer to select a set of conditions for a specific result.

11.129 How is power gain for a transistor calculated?—The power gain varies as the ratio of the input to output impedance, and may be computed:

$$dB = 10 \operatorname{Log}_{10} \frac{Z_{out}}{Z_{in}}$$

where,

Z_{in} is the input impedance in ohms,
Z_{out} is the output impedance.

11.130 Can negative feedback be applied to transistor amplifiers?—Negative feedback is employed extensively in transistor amplifiers much in the same manner as vacuum tubes. One of the most common methods being used is to omit bypassing the emitter circuits. Referring to Fig. 11-130, here two feedback circuits are employed, one from the output to the emitter of Q1 and a second from the collector of Q2 to the emitter of Q1. In this manner a total of 40 dB of negative feedback is acquired —16 dB between Q1 and Q2, and 24 dB from the output of the emitter of Q1. If an output transformer is used, the feedback is taken from the output winding and returned to the proper phase point in the early amplifier stages. The subject of negative feedback and the amplifier circuit shown is further discussed in Question 12.255.

11.131 Define the terms alpha and beta as applied to transistors.—An im-

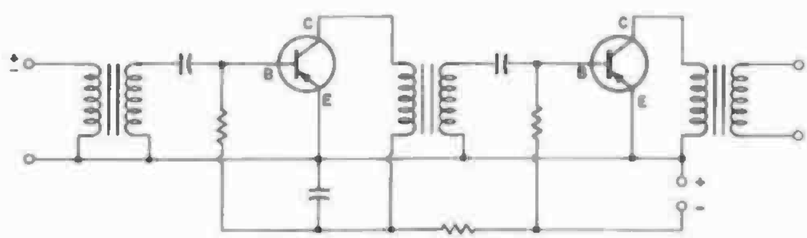

Fig. 11-127C. Typical transformer-coupled audio amplifier. The transformers are selected to match the impedance between stages.

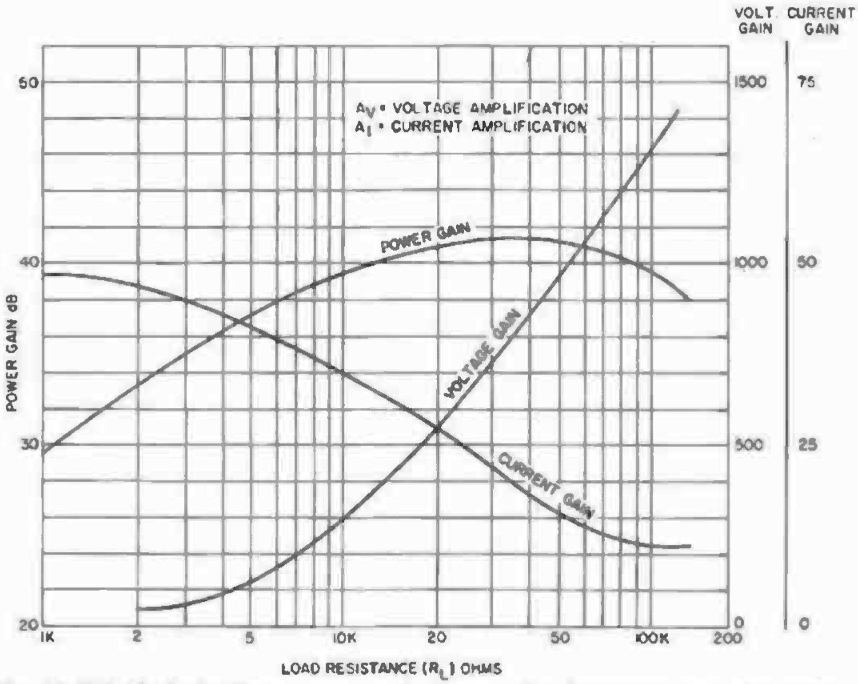

Fig. 11-128. Typical voltage, power, and current gains for a conventional transistor using a common-emitter configuration.

portant characteristic of a transistor is its forward current-transfer ratio, or the ratio of the current in the output to the current in the input element. Because of the many different configurations for connecting transistors, the forward transfer ratio is specified for a particular circuit configuration. The forward current-transfer ratio for the common-base configuration is often referred to as alpha (α) and the common-emitter forward current-transfer ratio as beta (β). In common-base circuitry, the emitter is the input element and the collector is the output element. Therefore, the dc alpha is the ratio of the dc collector current I_C to the dc emitter current I_E. For the common-emitter, the dc beta is then the ratio of the dc collector current I_C to the base current I_B.

Because the ratios are based on the dc currents, they are termed alpha and

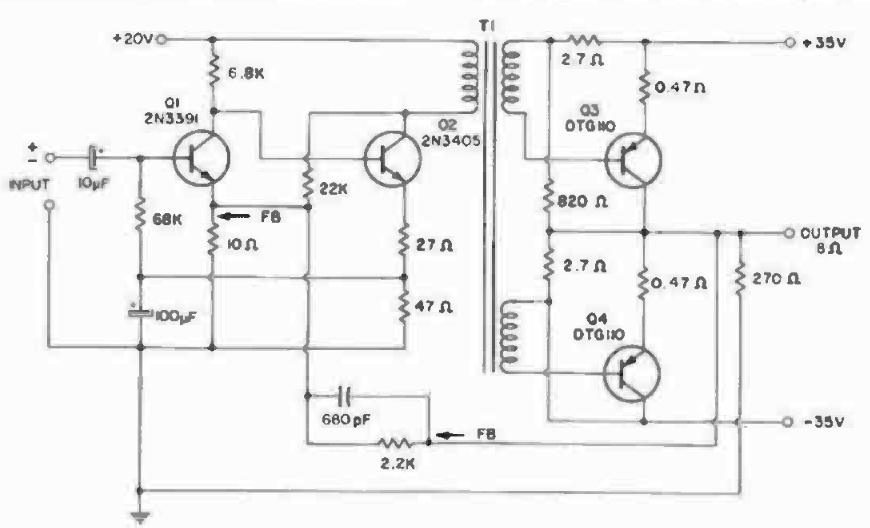

Fig. 11-130. A 50-watt push-pull amplifier. (Courtesy, Delco Radio Corp.)

beta. The ratios are also given in terms of the ratio of signal current, relative to the input and output, or as a ratio of change in the output current to the input current which causes the change.

The term alpha is also used to denote the frequency cutoff of a transistor, and is defined as the frequency at which the value of alpha for a common-base configuration, or beta for a common-emitter circuit, falls to 0.707 times its value at a frequency of 1000 Hz.

Gain bandwidth product is the frequency at which the common-emitter forward current-transfer ratio beta is equal to unity. It indicates the useful frequency range of the device and assists in the determination of the most suitable configuration for a given application.

11.132 What is cutoff current in a transistor?—When a transistor is biased to a nonconducting state, small reverse dc currents flow, consisting of leakage currents which are related to the surface characteristics of the semiconductor material and saturation currents. Saturation current increases with temperature and is related to the impurity concentration in the material. Collector-cutoff current is a dc current caused when the collector-to-base circuit is reverse-biased, and the emitter-to-base circuit is open. Emitter-cutoff current flows when the emitter-to-base is reverse-biased and the collector-to-base circuit is open.

11.133 Describe the various methods used for biasing transistors.—Several different methods of applying bias voltage to transistors are shown in Fig. 11-133A, with a master circuit for aiding in the selection of the proper circuit shown in Fig. 11-133B. Comparing the circuits shown in Fig. 11-133A their equivalents may be had by making the resistors in Fig. 11-133B equal to zero or infinity, for analyzation and study. As an example, the circuit of Fig. 11-133A, part (d) may be duplicated in Fig. 11-133B by shorting out resistors R4 and R5.

The circuit in part (g) of Fig. 11-133A employs a split voltage divider for R2. A capacitor connected at the junction of the two resistors shunts any ac feedback current to ground. The stability of circuits (a), (d), and (g) in Fig. 11-133A, may be poor unless the voltage drop across the load resistor is at least one-third the value of the power supply voltage V_{cc}. The final determining factors will be gain and stability. Stability may be enhanced by the use of a thermistor (see Question 11.157) to compensate for increases in collector current with increasing temperature. The resistance of the thermistor decreases as the temperature increases; thus, the bias voltage is decreased and the collector voltage tends to remain constant. Diode biasing may also be used for both temperature and voltage variations. The diode is used to

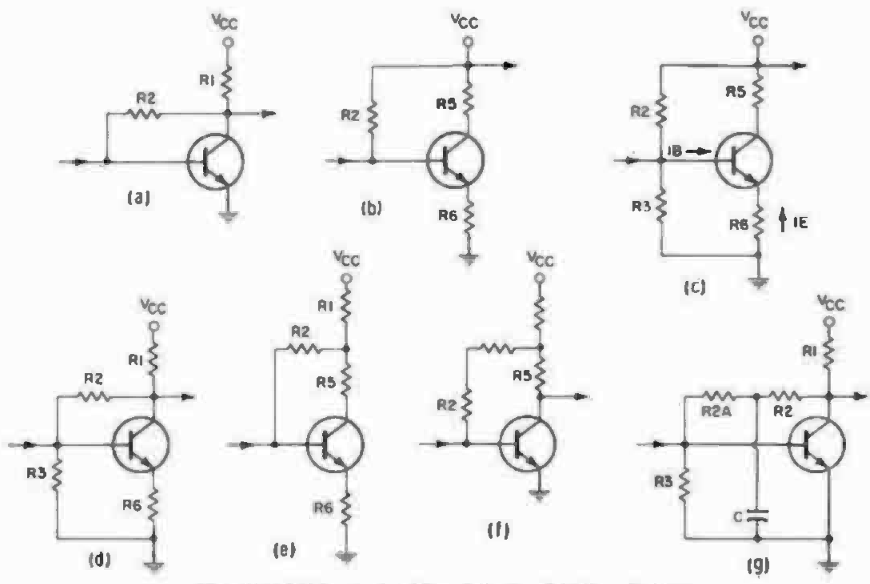

Fig. 11-133A. Basic bias circuits for transistors.

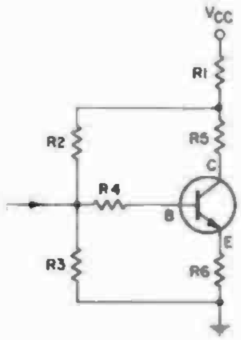

Fig. 11-133B. Basic design circuit for transistor bias circuits.

establish the bias voltage which sets the transistor idling current, or the current flow in the quiescent state. This subject is discussed at further length in Section 12.

11.134 Describe the distortion characteristics of a transistor.—The harmonic distortion increases in a transistor as the operating voltages and currents are increased and approach their maximum values. Output stages should be operated class-B push-pull whenever possible. A small amount of collector current must be permitted to flow at all times to reduce the effects of crossover or notch distortion at the zero signal point.

The addition of large amounts of negative feedback can be used to further reduce distortion. Transistor amplifiers have been developed to where both the harmonics and intermodulation are almost immeasurable.

Harmonic and intermodulation measurements must be made at levels 3 to 20 dB below the rated output of the stage under measurement. This procedure is discussed in Question 23.39.

11.135 How are gain controls connected in transistor circuits?—Three commonly used methods are shown in Figs. 11-135. The control should be connected in such a manner so that it has little or no effect on the transistor impedance, and not in a feedback loop.

11.136 Define the terms, small signal and large signal, in relation to a transistor.—The transistor like the vacuum tube is nonlinear, and can be classified as a nonlinear active device. Although the transistor is only slightly nonlinear, these nonlinearities become quite pronounced at very low and very high cnrrent and voltage levels. If an ac signal is applied to the base of a transistor without a bias voltage, conduction will take place on only one-half cycle of the applied signal voltage, resulting in a highly distorted output signal. To avoid high distortion, a dc bias voltage is applied to the transistor and the operating point is shifted to the linear portion of the characteristic curve. This improves the linearity and reduces the distortion to a value suitable for small signal operation. Even though the transistor is biased to the most linear part of the characteristic curve, it can still add considerable distortion to the signal if driven into the nonlinear portion of the characteristic. (See Question 11.139.)

Small signal swings generally run from less than 1 microvolt to about 10 millivolts under normal operation conditions. Therefore, it is highly important that the dc bias voltage be of sufficient value so that the applied ac signal is small compared to the dc bias current and voltage. Transistors are normally

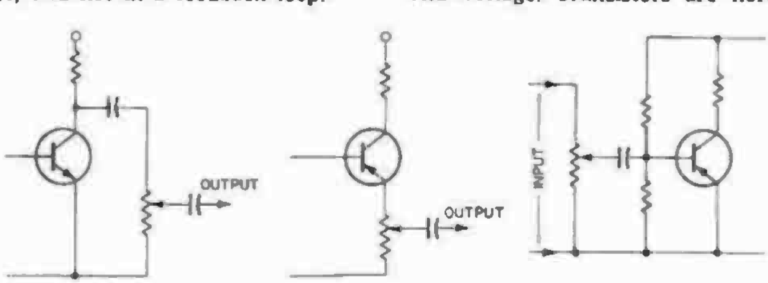

Fig. 11-135. Three methods used for connecting gain controls in transistor circuits.

biased at current values between 0.1 and 10 milliamperes. For large signal operation, the design procedures become quite involved mathematically and require a considerable amount of approximation and the use of nonlinear circuit analysis.

11.137 On what basis are audio transformers selected for transistor use? —Because of the wide difference of impedance between the input and output circuits of transistors, care must be taken to provide an impedance match between cascaded stages, or an appreciable loss of power will take place.

The maximum power amplification is obtained with a transistor when the source impedance matches the internal input resistance, and the load impedance matches the internal output resistance. The transistor is then said to be "image matched."

If the source impedance is changed in value it affects the internal output resistance of the transistor, necessitating a change in the value of the load impedance. When transistor stages are connected in tandem, except for the grounded-emitter connection, the input impedance is considerably lower than the preceding stage. Therefore, the interstage transformer must supply an impedance match in both directions.

When working between a grounded-base and a grounded-emitter circuit, a step-down ratio transformer must be used. Working into a grounded-collector stage, a step-up ratio is used. Grounded-collector stages are sometimes used as an impedance-matching device between other transistor stages. When adjusting the battery voltages for a transistor amplifier employing transformers, the battery voltage must be increased to compensate for the dc voltage drop across the transformer windings. The manufacturer's data sheets should be consulted before selecting a transformer, to determine the source and load impedances. Standard transformers are available, as for vacuum tubes. (See Question 11.139.)

11.138 How is the noise factor (NF) for a transistor amplifier calculated?— In a low-level amplifier such as a preamplifier, noise is the most important single factor, and is stated as the signal-to-noise ratio or *noise factor*. Most amplifiers employ resistors in the input circuit, which contribute a certain amount of measurable noise because of thermal activity. This power is generally about 160 dB below the power of 1 watt for a bandwidth of 10,000 Hz. When the input signal is amplified, the noise is also amplified. If the ratio of the signal power to noise power is the same, the amplifier is noiseless and has a noise figure of unity or more. However, in a practical amplifier some noise is present, and the degree of impairment is called the noise figure (NF) of the amplifier, expressed as the ratio of signal power to noise power at the output:

$$NF = \frac{S_i/N_i}{S_o/N_o}$$

where,

S_i is the signal power,
N_i is the noise power,
S_o is the signal power at the output,
N_o is the noise at the output.

The NF in dB is 10 times the logarithm of the power ratio. Thus, for an amplifier with a 1-dB noise figure, it decreases the signal-to-noise ratio by a factor of 1.26; a 3-dB NF by a factor of 2; a 10-dB NF by a factor of 10; and a 20-dB NF by a factor of 100. Amplifiers with an NF below 6 dB are considered excellent.

Low noise factors can be obtained by the use of an emitter current of less than 1 milliampere, a collector voltage of less than 2 volts, and a signal-source resistance below 2000 ohms.

11.139 Describe the procedure for using transistor load lines.—The use of transistor load lines is similar in every respect to that used with vacuum tubes. The transistor selected in this question has the following characteristics: maximum collector current, 10 milliamperes; maximum collector voltage, minus 22 volts; base current, zero to 300 microamperes; maximum power dissipation, 300 milliwatts. The base-current curves are shown in Fig. 11-139A. The amplifier circuit is to be class-A, using a common-emitter circuit (Fig. 11-139B). By proper choice of the operating point, with respect to the transistor characteristics and supply voltage, low distortion, class-A performance is easily obtained within the transistor power ratings.

The first requirement is a set of collector-current, collector-voltage curves for the transistor to be employed. Such curves can generally be obtained from the manufacturer's data sheets. Assum-

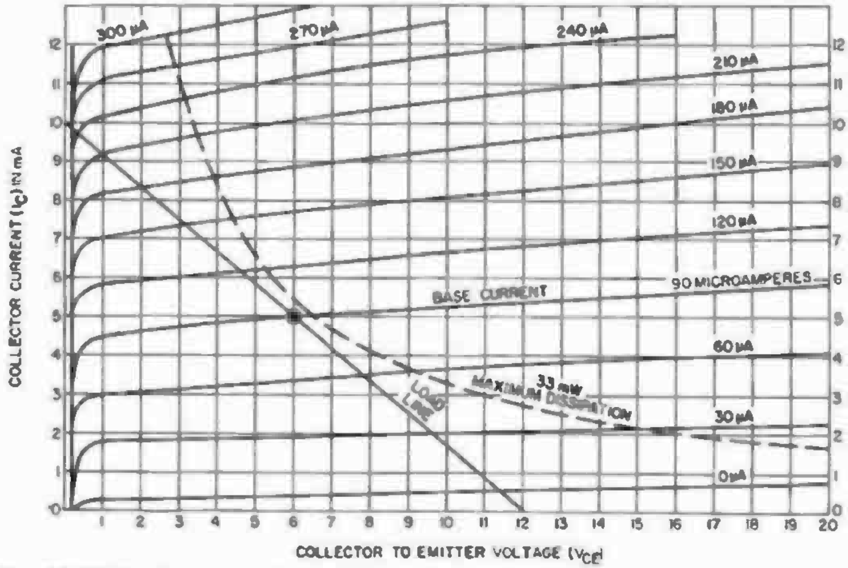

Fig. 11-139A. Common-emitter-collector family of curves, with load line and maximum dissipation power curve.

ing such data are at hand, and referring to Fig. 11-139A, a curved line is plotted on the data sheet, representing the maximum power dissipation by the use of the equation:

$$I_c = \frac{P_c}{V_c} \quad \text{or} \quad V_c = \frac{P_c}{I_c}$$

where,

I_c is the collector-current,
V_c is the collector-voltage,
P_c is the maximum power dissipation of the transistor.

At any point on this line at the intersection of V_cI_c, the product equals 0.033 watt or 33 milliwatts. In determining the points for the dissipation curve, voltages are selected along the horizontal axis and the corresponding current equated:

$$I_c = \frac{P_c}{V_{CE}}$$

The current is determined for each of the major collector-voltage points, starting at 16 volts and working backward until the upper end of the power curve intersects the 300 microampere base-current line.

After entering the value on the graph for the power dissipation curve, the area to the left of the curve encompasses all points within the maximum dissipation rating of the transistor. The area to the right of the curve is the overload region and is to be avoided. The operating point is next determined. A point that results in less than 33-milliwatts dissipation is selected some-

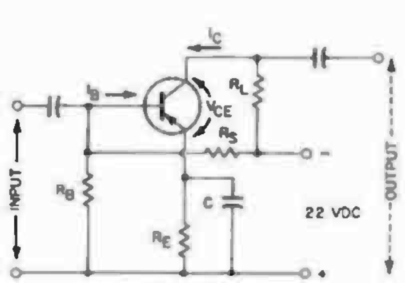

Fig. 11-139B. Amplifier circuit used for load-line calculations.

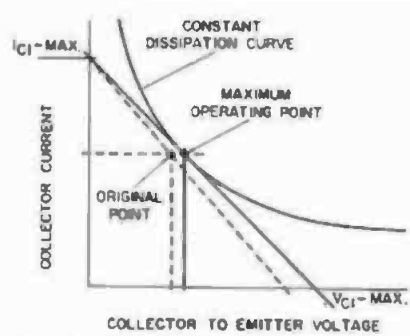

Fig. 11-139C. Load line moved to right for maximum power output. Dotted lines are the original load line and operating point.

where near the center of the power curve. For this example, 5 milliamperes collector current at 6 volts, or a dissipation of 30 milliwatts, will be used. The selected point is indicated on the graph and circled for reference. A line is drawn through the dot to the maximum collector current, 10 milliamperes, and downward to intersect the V_{CE} line at the bottom of the graph, which, for this example, turns out to be at 12 volts. This line is termed the load line. The load resistance R_L may be computed:

$$R_L = \frac{dV_{CE}}{dI_C} = \frac{0-12}{0-0.01}$$
$$= \frac{12}{0.01} = 1200 \text{ ohms}$$

where,

R_L is the load resistance,
dV_{CE} is the range of collector to emitter voltage,
dI_C is the range of collector current.

Under these conditions, the entire load line dissipates less than the maximum value of 33 milliwatts, with 90 microamperes of base current and 5 milliamperes of collector current. The required base current of 90 microamperes may be obtained by means of one of the biasing arrangements shown in Fig. 11-133.

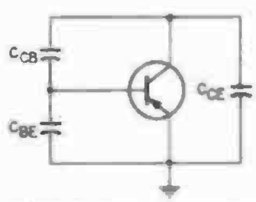

Fig. 11-140A. Internal capacitance of a transistor.

To derive the maximum power output from the transistor, the load line may be moved to the right and the operating point is placed in the maximum dissipation curve, as shown in Fig. 11-139C. Under these conditions, an increase in distortion may be expected. As the operating point is now at 6.5 volts and 5 milliamperes, the dissipation is 33 milliwatts. Drawing a line through the new operating point and 10 milliamperes (the maximum current), the voltage at the lower end of the load line is 13.0 volts; therefore, the load impedance is now 1300 ohms. It should be borne in mind, values shown on the graph are for a particular type transis-

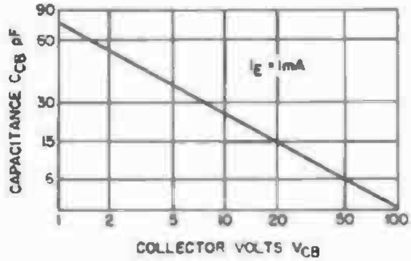

Fig. 11-140B. Variation of C_{CB} with collector voltage.

tor; other types will have a similar family of curves, but not of the same value.

11.140 How does the internal capacitance of a transistor affect its operation?—The paths of internal capacitance in a typical transistor are shown in Fig. 11-140A. Since the width of the p-n junction in the transistor will vary in accordance with voltage and current, the internal capacitance also varies. Variation of collector-base capacitance (C) with collector voltage and emitter current is shown in Figs. 11-140B and C. The *increase* in the width of the p-n junction between the base and collector, as the reverse bias voltage (V_{CB}) is increased, is reflected in lower capacitance values. This phenomenon is equivalent to increasing the spacing between the plates of a capacitor. An increase in the emitter current, most of which flows through the base-collector junction, *increases* the collector-base capacitance (C_{CB}). The increased current through the p-n junction may be considered as effectively *reducing* the width of the p-n junction. This is equivalent to decreasing the spacing between the plates of a capacitor, therefore increasing the capacitance.

The average value of collector-base capacitance (C_{CB}) varies from 2 pF to 50 pF, depending on the type transistor and the manufacturing techniques. The

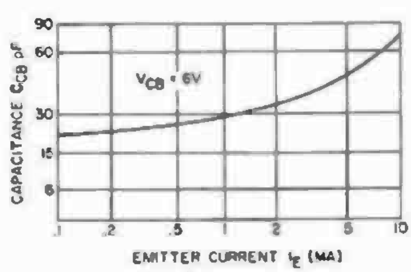

Fig. 11-140C. Variation of C_{CB} with emitter current.

collector-emitter capacitance is caused by the p-n junction, and normally is 5 to 10 times greater than that of the collector-base capacitance, and will vary with the emitter current and collector voltage. For certain applications advantage is taken of this effect for control purposes.

11.141 How is stability factor (SF) calculated for transistors?—The current through a transistor tends to increase with temperature; therefore it is necessary in the design of transistor circuits to include a stability factor (SF) to limit the current dissipation to a safe value, under the expected highest operating temperatures. Stability is expressed as the ratio between a change in dc collector current (I_C) and the corresponding change in dc collector cutoff current, with the emitter open circuit current (I_{CBO}). For a given set of operating voltages, the SF can be calculated for a maximum permissible rise in dc collector current from the ambient temperature value:

$$SF = \frac{I_{CMax} - I_{C1}}{I_{CBO2} - I_{CBO1}}$$

where,

- I_{C1} and I_{CBO2} are measured at 25 degrees centigrade,
- I_{CBO1}, at the maximum expected ambient or junction temperature,
- I_{CMax} is the maximum permissible collector current for a specified collector-to-emitter voltage at the maximum expected ambient or junction temperature.

The maximum value SF can never be *greater* than the value of beta. The stability from a feedback standpoint can be increased by the use of decoupling circuits in the power supply circuits, much in the same manner as for vacuum tubes, discussed in Question 12.36.

11.142 What are the frequency characteristics of transistors used for audio amplifiers?—As a rule, conventional transistors used for audio-amplifier application have bandwidths up to 4 MHz, the average being 1 to 2 MHz. When connected in complex circuitry, the response may be considerably reduced because of circuit capacitance and other design factors. This is particularly true for high-power output stages. If audio transformers are used, naturally the response is limited to the frequency range of the transformers.

Using a well designed circuit and mechanical layout, the frequency response may be designed to cover a spectrum from 5 to 50,000 Hz. In amplifiers using field-effect transistors, (FET) bandwidths from 5 to 250,000 Hz have been achieved. Generally speaking, the high frequency limit of a diode or transistor is a function of the base thickness.

Because of the wide frequency response of transistor amplifiers, precautions must be observed to prevent positive feedback (oscillation). Oscillation may occur in the megahertz range, and is often the cause of failure. By the use of properly designed printed circuit boards, oscillation can be prevented.

11.143 What type push-pull amplifier circuit is recommended for transistors?—One of the disadvantages of using transistors class-A, either single-ended or push-pull, is that the collector current flows at all times, and dissipation is the highest when no ac signal is present. This dissipation of power can be greatly reduced by the use of class-B push-pull operation. To achieve the full power output and economy of operation, the transistors should be biased to full cutoff. However, in so doing, a serious distortion problem arises, as shown in Fig. 11-143. Assuming that the transistors have identical characteristics, the variation in the collector currents are plotted against the base current under normal load conditions.

The overall dynamic characteristics are obtained by plotting individual curves of the two transistors back-to-back, and combining them as shown. Applying a sine wave to the input,

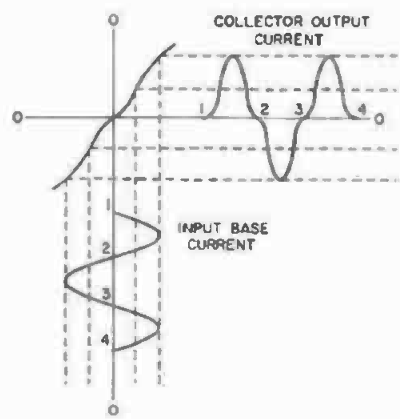

Fig. 11-143. Dynamic transfer characteristics curves of a class-B, transistor push-pull amplifier with zero bias, showing the distorted output waveform.

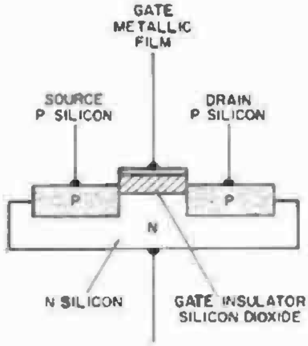

Fig. 11-144A. Internal construction of an insulated-gate transistor (IGT).

points of the input base current are projected into the dynamic transfer characteristics curve. Correspouding points are then projected to form the output collector-current waveform. It will be observed that severe distortion is generated at the *crossover* points, where the signal passes through the zero value. This is termed *crossover distortion* or *notch distortion*, and increases in severity as the signal level is lowered. Crossover distortion is eliminated or greatly reduced by the use of a small bias voltage on both transistors, resulting in a smooth crossover (applies to both transistors and vacuum tubes). In addition to the bias correction, negative feedback is used to further reduce the distortion. (See Question 12.230.)

11.144 Describe an insulated-gate transistor. (IGT) — Insulated-gate transistors (IGT) are also known as a field-effect transistor (FET), metal-oxide silicon or semiconductor field-effect transistors (MOSFET), metal-oxide silicon or semiconductor transistors (MOST), and insulated-gate field-effect transistors (IGFET). All of these devices are similar, and are simply names applied to them by the different manufacturers.

The outstanding characteristics of the IGT is its extremely high input impedance, running to 10^{18} ohms. IGT's have *three elements, but four connections.* The type elements are the gate, drain, and the source. The fourth connection goes to an n-substrate. The construction consists of an n-type substrate, into which two identical p-type silicon regions have been diffused. The source and drain terminals are taken from these two p regions, which form a capacitance between the n substrate and the silicon-dioxide insulator and the metallic gate terminals. A cross-sectional view of the internal construction appears in Fig. 11-144A, with a basic circuit shown in Fig. 11-144B. Because of the high input impedance, the IGT can easily be damaged by static charges. Strict adherence to the manufacturer's instructions must be followed, since the device can be damaged even before putting it into use.

IGT's are used in electrometers, logic circuits, and ultrasensitive electronic instruments. They should not be confused with the *conventional FET*, used in audio equipment and discussed in Question 11.145.

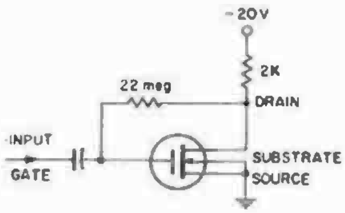

Fig. 11-144B. Typical circuit.

11.145 Describe the basic principles of a field-effect transistor (FET).—The field-effect transistor, or FET as it is commonly known, was developed by the Bell Telephone Laboratories in 1946, but was not put to any practical use until about 1964. The FET is often

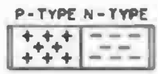

Fig. 11-145A. Creation of depletion region without bias voltage.

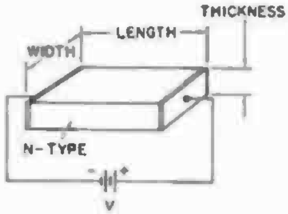

Fig. 11-145D. Plain semiconductor bar.

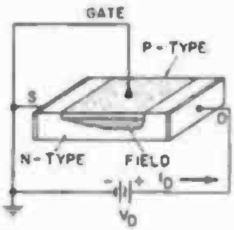

Fig. 11-145E. Bar with gate added and drain voltage applied.

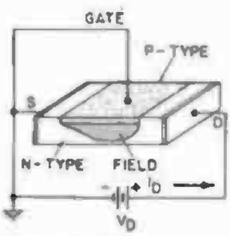

Fig. 11-145F. Field increases with increase of drain voltage.

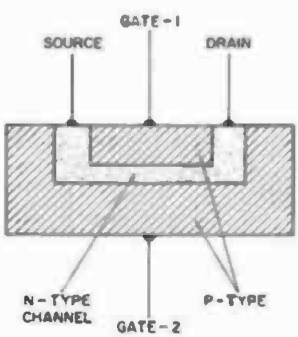

Fig. 11-145G. Cross-sectional view of the construction for a single- or double-gate FET.

quoted as being the semiconductor counterpart of the vacuum tube. The principal difference between a conventional transistor and the FET lies in the fact that the transistor is a *current-controlled* device, while the FET is *voltage-controlled*, similar to the vacuum tube. Conventional transistors also have a low input impedance, which may at times complicate the circuit designer's problems. The FET has a *high* input impedance with a *low* output impedance; this characteristic caused it to be likened to the vacuum tube.

The basic principles of the FET operation can best be explained by the simple mechanism of a p-n junction. The control mechanism is the creation and control of a depletion layer, which is common to all reverse-biased junctions. Referring to Fig. 11-145A, atoms in the n-region possess excess electrons which are available for conduction, and the atoms in the p-region have excess holes which may also allow current to flow (the reader is referred to Question 11-114 for the theory of holes and carriers in semiconductors.) Reversing the voltage applied to the junction, Fig. 11-145B, and allowing time for stabilization, very little current flows but a rearrangement of the electrons and holes will occur. The positively charged holes will be drawn toward the negative terminals of the voltage source, and the electrons which are negative will be attracted to the positive terminal of the voltage source. This results in a region being formed near the center of the junction having a majority of the carriers removed. This is true for both the p and n sides of the junction. The areas near the junction where the carriers have been removed are called the *depletion regions.*

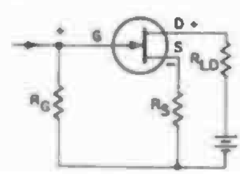

Fig. 11-145H. N-channel FET circuit.

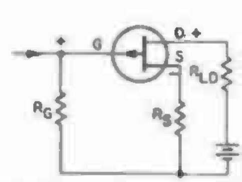

Fig. 11-145I. P-channel FET circuit.

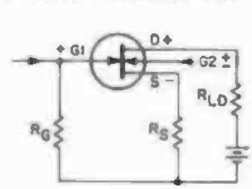

Fig. 11-145J. N-channel double gate FET circuit.

After stabilization, there will be an equal number of holes removed from the p region as there are electrons from the n region. Thus, the distauce that the depletion area extends from the junction is the fuuction of the relative carrier densities. For purpose of illustration, it will be assumed that the n region has less electrons than the p region has holes. The depletion region must then extend further into the n region to have the same number of electrons as there are holes, and in a much smaller volume of p-type material.

Increasing the reverse voltage causes the depletion region to reach farther into the semiconductor material. The result of increasing the voltage is shown in Fig. 11-145C. Referring to Fig. 11-145D, a simple bar composed of n-type semiconductor material is shown, with two nonrectifying contacts at each end. As there is always a certain amount of resistance (R) between the two end electrodes, (P) will be the function of the material sensitivity, (L) the length of the bar, (W) the width and (T) the thickness. Resistivity may be equated:

$$R = \frac{PL}{WT}$$

By varying one or more of the variables of the resistance of the semiconductor, the bar may be changed. Assume a p region in the form of a sheet is formed at the top of the bar shown in Fig. 11-145E. This may be accomplished by diffusion, alloying, or epitaxial growth, and a p-n junction is formed. Thus, a reverse voltage appearing between the p and n material produces two depletion regions. Current in the n material is primarily by means of excess electrons. Reducing the concentration of electrons or majority carriers, the resistivity of the material is increased. Removal of the excess electrons by means of the depletion region causes the material to become practically nonconductive.

Disregarding the p region and applying a voltage to the ends of the bar causes a current and creates a potential gradient along the length of the bar material, with the voltage increasing toward the right, with respect to the negative end or ground. Connecting the p region to ground causes varying amounts of reverse-bias voltage across the p-n junction, with the greatest amount developed toward the right end of the p region. A reverse voltage across the bar will produce the same depletion regions. If the resistivity of the p-type material is made much smaller than that of the n-type material, the depletion region will then extend much farther into the n material than into the p material. To simplify the following explanation, the depletion of p material will be ignored.

The general shape of the depletion is that of a wedge, increasing in size from left to right. Since the resistivity of the bar material within the depletion area is increased, the effective thickness of the conducting portion of the bar becomes less and less, going from the end of the p region to the right end. This indicates the overall resistance of the semiconductor material is larger, because the effective thickness is being reduced. Increasing the voltage applied to the ends of the bar (Fig. 11-145F) extends the depletion region, and further decreases the resistance. Continuing to increase the voltage across the ends of the bar, a point is reached where the depletion region is extended practically all the way through the bar, reducing the effective thickness to zero. Increasing the voltage beyond this point produces little change in current.

Because of the controlling action of the p region, it is termed a *gate*. The left end of the bar being the source of majority carriers, it is termed the *source*. The right end being where the electrons are drained off, it is called the *drain*. A cross-sectional drawing of a typical FET is shown in Fig. 11-145G, and three basic circuits are shown in Figs. 11-145H to J. Double-gate FET's are also in use. The chief advantage of the FET is its low internal noise, simplicity of construction, and its similarity to a vacuum tube, which makes it highly desirable for voltage-amplifier stages. One of the interesting characteristics of a FET is its ability to operate over a wide range of temperature. It has been stated by one manufacturer that FET's have been developed that perform satisfactorily even when submerged in liquid nitrogen at a temperature of minus 200 degrees centigrade, and have also been operated at a temperature of plus 150 degrees centigrade.

11.146 What is the procedure for derating a transistor? — Ratings have

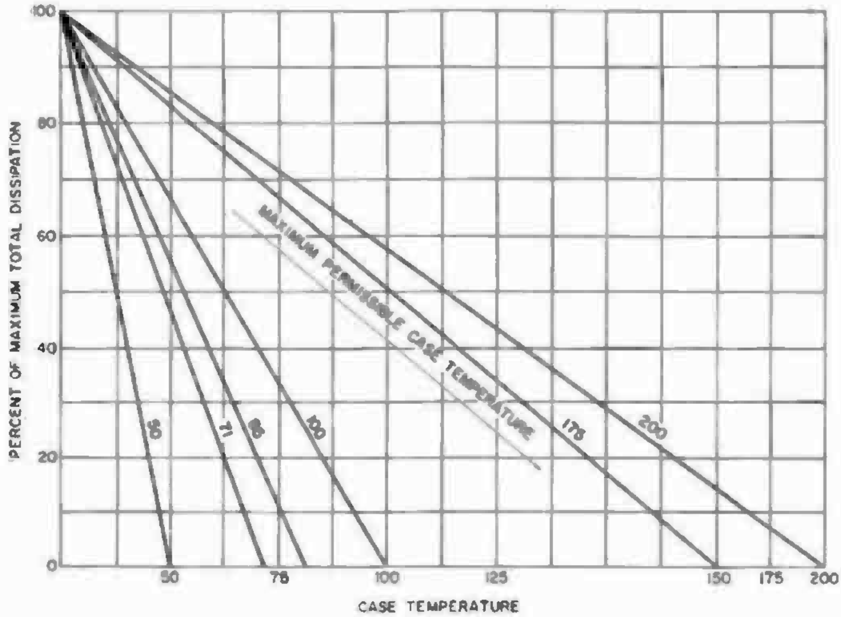

Fig. 11-146. Derating chart showing the maximum permissible percentage of maximum rated dissipation as a function of temperature.

been established for transistors and other semiconductor devices to prevent the overloading and possible damage to such devices, and have been defined by the Joint Electron Device Engineering Council (JEDEC) and the National Electrical Manufacturers Association (NEMA) and Electrical Industries Association (EIA). Absolute maximum ratings, electrode voltage, and current ratings are the limiting factors. Transistor dissipation is the power dissipated in the form of heat by the collector element. It is the difference between the power supplied to the collector and the power delivered by the transistor to the load. For many types of transistors the maximum dissipation is specified for ambient temperature, case, and heat-sink temperature up to 25°C. If the maximum operating temperature is to be higher than that specified by the manufacturer, the device must be *derated*. This may be done quite conveniently by the use of the chart in Fig. 11-146. Knowing the maximum dissipation rating and maximum operating temperature, a vertical line is drawn at the desired operating temperature on the abscissa to intersect the curve representing the maximum operating temperatures specified for the particular transistor. A horizontal line is drawn from this intersection to the ordinate establishing a new maximum dissipation for the device at the new operating temperature.

As an example: The maximum permissible dissipation for a transistor at a case temperature of 100°C is to be determined. The transistor in question has a maximum dissipation rating of 75 watts at a case temperature of 25°C, and a maximum permissible case temperature of 200 degrees. A perpendicular line is drawn from the 100-degree point to the 200-degree curve. The point is projected to the left and indicates a percentage of 57.5. Therefore, the maximum dissipation for this particular transistor at a case temperature of 100° C is 0.575 times 75, or approximately 43.2 watts.

11.147 Describe the basic construction of a solid-state diode rectifier.—Diodes are two element devices consisting of a pellet of either germanium or silicon, using point-contact or junction construction. However, the majority of diodes manufactured at the present time use the junction-type construction. A small diode pictured in Fig. 11-147 is used in radio and television receivers, harmonic generators, frequency discrimiuators and many applications too numerous to mention. Diodes require no heater or filament and have no contact potential, but have a

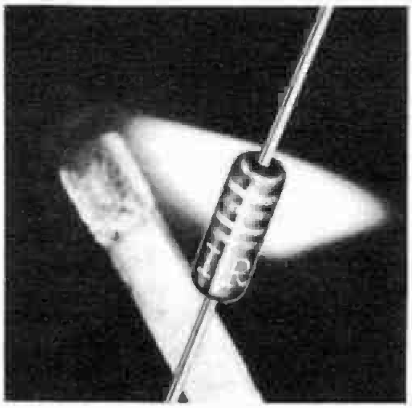

Fig. 11-147. External appearance of a silicon or germanium diode.

high forward conductance, with a high reverse or back resistance. Diodes that will carry a few milliamperes up to several hundred amperes over a wide range of voltages are available. The diode concept is discussed in Question 11-114. Applying a positive voltage to the plus terminal of the diode causes a current through the junction and back to the source. Reversing the voltage, the current is blocked by the high back resistance of the junction.

The conduction characteristics of a silicon diode differ from its counterpart, the germanium diode. Silicon diodes have unusually high back resistance, thereby passing a much lower reverse current. As an example, a 1N251 silicon diode passes in the reverse direction only 0.2 microampere at 10 volts. Applying the same voltage to a 1N34 germanium diode of similar characteristics, 50 microamperes of current are passed in the reverse direction. However, germanium diodes are employed extensively in many different types of equipment. (See Questions 11.148 to 11.155.)

11.148 Describe the characteristics of a zener diode.—The zener diode, named for Dr. Carl Zener, is a semiconductor equivalent of the gaseous regulator tube discussed in Question 11-30. Whereas the gaseous tube regulator is confined to a limited range of voltage operation, zener diodes are available in a wide range of operating voltages, ranging from 2 to several hundred volts, with large power-dissipation capabilities.

A zener diode is a semiconductor device with a substantially constant reverse-voltage characteristic over a wide range of reverse current or temperature. When the reverse voltage of a semiconductor diode is increased, its internal resistance remains at a high value for a short time. When a critical voltage is reached, the resistance falls suddenly. The current flow up to the critical point is on the order of microamperes; however, at breakdown it may be several millamperes, or in the instance of a large diode, it may be several amperes.

The point of breakdown is termed the zener or avalanche point (see Question 11.149). Once this point is reached, the voltage drop across the diode remains fixed, and the current changes only if more voltage is applied. The breakdown of a diode should not be construed as damaging, as such diodes are designed to be operated in and out of the breakdown region without damage or a change in their characteristics. In this manner the diode may be used to provide a constant voltage drop or reference voltage across its internal resistance.

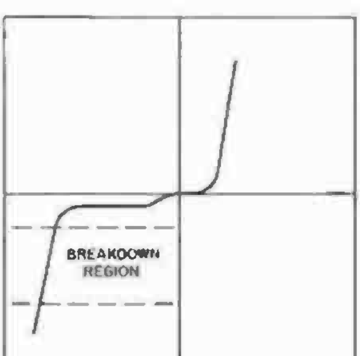

Fig. 11-148A. Zener forward and reverse current characteristics.

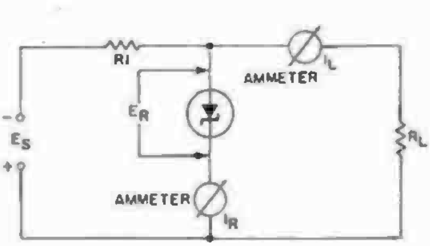

Fig. 11-148B. Voltage-regulator circuit using a zener diode.

WHERE:

R_1 IS THE SERIES RESISTOR
E_S IS THE SOURCE VOLTAGE
E_R IS THE REGULATOR VOLTAGE
I_R IS THE REGULATOR CURRENT
I_L IS THE LOAD CURRENT
P_R IS THE REGULATOR POWER DISSIPATION

$$R_1 = \frac{E_S - E_R}{I_R + I_L}$$

$$I_R = \left(\frac{E_S - E_R}{R_1}\right) - I_L$$

$$P_R = \left(\frac{E_S - E_R}{R_1} - I_L\right) E_R$$

FOR VARIABLE SOURCE VOLTAGE AND LOAD CURRENT:

$$R_1 = \frac{E_S(MIN.) - E_R}{I(MAX.) + .1I_L(MAX.)}$$

$$P_R(MAX.) = \left(\frac{E_S(MAX.) - E_R}{R_1} - I_L(MIN.)\right) E_R$$

FOR CONSTANT LOAD CURRENT BUT VARIABLE INPUT VOLTAGE:

$$R_1 = \frac{E_S(MIN.) - E_R}{I_L + .1I_L}$$

$$P_R(MAX.) = \left(\frac{E_S(MAX.) - E_R}{R_1} - I_L\right) E_R$$

FOR CONSTANT INPUT VOLTAGE BUT VARIABLE LOAD CURRENT:

$$R_1 = \frac{E_S - E_R}{I_L(MAX.) + .1I_L(MAX.)}$$

$$P_R(MAX.) = \left(\frac{E_S - E_R}{R_1} - I_L\right) E_R$$

NOTE:

THE ABOVE EQUATIONS ALLOW A TOLERANCE OF 10% TO COMPENSATE FOR LOAD REGULATION. IF BREAKDOWN IMPEDANCE IS A SIGNIFICANT PERCENTAGE OF THE VALUE OF R, THIS MUST BE TAKEN INTO CONSIDERATION. A HIGH IMPEDANCE SOURCE PRESENTS ADDITIONAL PROBLEMS AND MUST BE CONSIDERED IF IT IS SIGNIFICANT COMPARED TO R_1.

Fig. 11-148C. Equations for designing zener-diode regulator circuit of Fig. 11-148B.

Zener diodes may be constructed using germanium or silicon, with point-contact or junction construction. However, the majority are of the junction type. The conduction characteristics of the silicon diode differ from its counterpart, the germanium diode. Silicon diodes have unusually high back resistance, passing much lower reverse current than the germanium diode. A typical plot of the conduction characteristics for a germanium and silicon diode is shown in Fig. 11-148A. As a comparison, a 2N251 silicon diode passes in the reverse direction only 0.20 microampere at 10 volts, while a germanium diode type 1N34 passes 50 microamperes for the same voltage.

A voltage regulator circuit, employing a silicon diode is given in Fig. 11-148B. It can be seen that a relatively small increase in voltage across the diode causes a large increase in current through resistor R1, thus increasing the voltage drop. This voltage drop across R1 effectively maintains a constant volt-

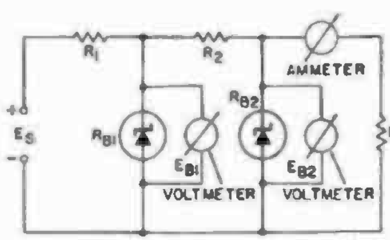

Fig. 11-148D. Zener-diode regulator circuit using a two-stage regulator.

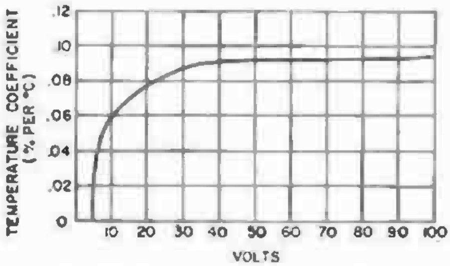

Fig. 11-148G. Temperature coefficient versus zener volts.

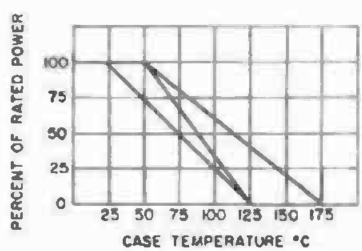

Fig. 11-148H. Typical zener derating curves.

age across the load. The value of resistor R1, regulator current, and power rating, is given in the equations in Fig. 11-148C. The circuitry shown will compensate for the normally encountered variations of input and output load voltages. Extreme variations may require the addition of a second diode regulator as shown in Fig. 11-148D.

Breakdown impedance offers a reasonable measurement to the diode's ability to maintain a nearly constant breakdown voltage, and, consequently, its regulation characteristics. The breakdown voltage and current for a 1-watt 7.5-volt regulator diode is plotted in Figs. 11-148E and F respectively. Variations with temperature are shown in Fig. 11-148G for a range of 5.6 to 100 volts. The curve, as will be noted, is quite constant above 50 volts, then changes rapidly at the lower voltages.

Silicon diodes are rated relative to their case temperature, therefore the manufacturer's data sheet should be consulted and the diode derated accordingly. Typical derating curves are given in Fig. 11-148H. Stud-type diodes require cooling fins to dissipate the heat. Cooling fins will dissipate about 8 milliwatts per square inch, per degree centigrade. Therefore, a 10-watt regulator diode operating close to maximum rating would require an area of $10/0.008 \times 60 \times 20$ square inches to limit the rise to 60 degrees centigrade. Since both sides of the fins radiate, the dimensions would be approximately 3⅛ inches by ⅛-inch thick.

Zener diodes are also used as reference voltage devices and are quite useful in voltage-regulated power supplies or any place requiring an accurate source of reference voltage. The standard tolerance for voltage-reference diodes is plus-minus 10 percent, but may be obtained for 1 and 5 percent accuracy. In a silicon reference diode, the reverse current remains quite small until the breakdown voltage point is reached, then increases rapidly with little further increase in voltage. The breakdown point being the function of the semiconductor material and its construction, it can be controlled in manufacture to supply a given voltage ranging from one to several hundred volts, at various current and power ratings and the cooling method used. Design procedures for zener diodes are given in Question 21-118.

11.149 Define the term "avalanche" as applied to semiconductor devices.— Avalanche is the breakdown point in a semiconductor material caused by the multiplication of the carriers through ionization, and is termed the avalanche point. The avalanche point was proposed by McKay, and elaborated on by many others.

In the early development stages of the zener diode, it was believed the breakdown was due to the Zener effect, thus its name. However, it is now thought that both the Zener effect and avalanche are operative, with the latter process being the most predominant, especially at voltages greater than 6 volts. Zener diodes are sometimes referred to as avalanche diodes; however, the name zener diode prevails.

Both the inverse-peak voltage and avalanche point increase with temperature; therefore, as a safety measure the circuitry is designed for an inverse-peak voltage about 20 to 25 percent *lower* than the breakdown voltage of the diode. Manufacturers take advantage of these characteristics, using doping techniques to control the resistivity, thus controlling the breakdown-voltage point and operating temperature.

11.150 Describe the basic principles of a silicon controlled rectifier (SCR).—

Silicon controlled rectifiers (SCR) are semiconductor devices that may be used as a latching static switch, a sensitive amplifier, a controlled rectifier, and many devices where the precise control of output current is required. An SCR may be turned on in 1 to 4 microseconds and turned off in 10 to 20 microseconds. Units with current capabilities of ½ ampere to several hundred

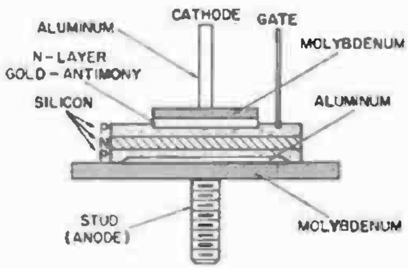

Fig. 11-150A. Cross-sectional view of the interior construction of a silicon controlled rectifier (SCR).

amperes are available with comparable voltage ratings. The basis of the SCR is a disc of four alternate layers of n- and p-type silicon (Fig. 11-150A). Besides the two terminals of the conventional diode (a cathode and anode), the SCR has a gate terminal for controlling the conduction cycle. A cutaway view of its interior construction is shown in Fig. 11-150B.

Referring again to Fig. 11-150A, to protect the silicon junction against thermal and mechanical injury, the silicon discs are braised between plates of molybdenum or tungsten. These plates have the same coefficient of expansion as the silicon. In the small lead-mounted type SCR, the bottom plate acts as the base of the housing enclosure. In the larger types, above 1 ampere, the bottom plate is soldered to a copper stud which acts as the anode terminal and a thermo path for the heat losses to the outside ambient temperature. For this reason, the stud is usually screwed into the base of a cooling fin or heatsink, as shown in Fig. 11-159B.

The operation of the SCR may be explained as follows. On the forward-blocking region of the characteristic, increasing the forward current does not tend to increase the current until a point is reached where avalanche multiplication begins. Beyond this point, the current increases rapidly until the total current through the device is sufficient to maintain itself. At this point, the SCR will go into high conduction, provided the current through the device remains greater than the minimum current, called the holding current. If the current through the device drops below the holding current, the SCR will return to the forward-blocking region again. In the reverse direction, the SCR has essentially two back-biased p-n junctions in series, so that it exhibits

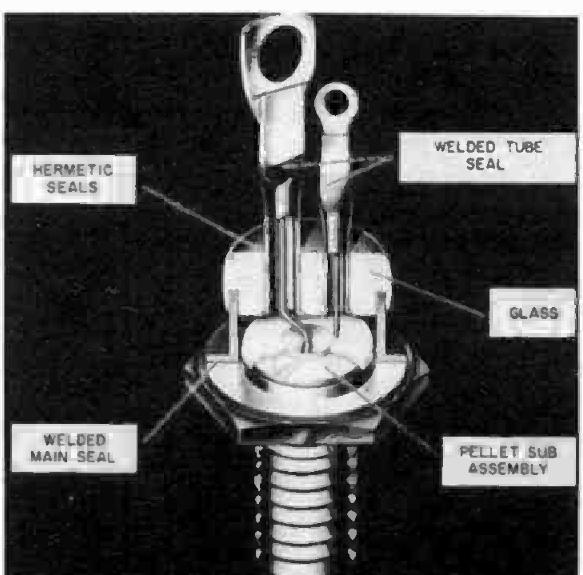

Fig. 11-150B. Interior view of a silicon controlled rectifier (SCR) as manufactured by General Electric Co.

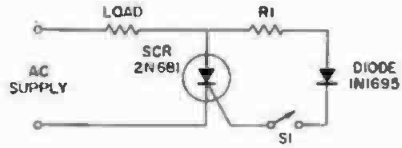

Fig. 11-150C. Firing circuit for a silicon controlled rectifier. (SCR)

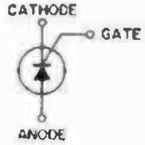

Fig. 11-150D. Symbol for a silicon controlled rectifier.

characteristics very similar to the ordinary back-biased silicon rectifier.

A simple method of obtaining gate current for firing an SCR from the main ac supply whenever the anode is positive with respect to the cathode is shown in Fig. 11-150C. As soon as the SCR 2N681 has fired, the anode voltage drops to the conduction value and the gate current decreases to a low value. Resistor R1 limits the peak gate current and has a value greater than the ac peak voltage divided by two amperes. The 1N1695 diode in the gate circuit is provided to prevent reverse voltage from being applied between the cathode and gate during the reverse half of the cycle. If desired, the diode may be connected between the gate and cathode rather than in series with resistor R1. Conduction in initiated by closing switch S1. Interruption of the load current occurs within one half cycle after opening switch S1.

11.151 What factors determine the selection of a silicon or selenium rectifier?—The selection of a suitable rectifier depends on a number of factors, namely the voltage and current requirements, temperature range of operation, and the space availability. In addition, the type circuit and equipment it is to be operated with must be taken into consideration. The subject is discussed more fully in Section 21.

11.152 Describe the basic principles of a tunnel diode.—Tunnel diodes are two-terminal semiconductor devices consisting of a single p-n junction. The basic difference between the conventional diode and a tunnel diode is in its conductivity. The p-n material used in tunnel diodes has a conductivity of over 1000 times greater than the conventional diode. Such high conductivity is obtained by increasing the amount of donor and acceptor impurities in the semiconductor material during its formation.

The tunnel diode takes its name from the tunnel effect, a process wherein a particle can disappear from one side of the barrier and reappear on the other side instantaneously, as though it had tunneled through the barrier element. Such devices are used at very high frequencies in radio receivers, in computers, and in many other devices. An interior view of a typical tunnel diode is pictured in Fig. 11-152. Although three leads are shown coming from the base, only two terminals are connected to the diode; the third lead is connected to the case for grounding. The tunnel diode was first introduced in 1959, by General Electric.

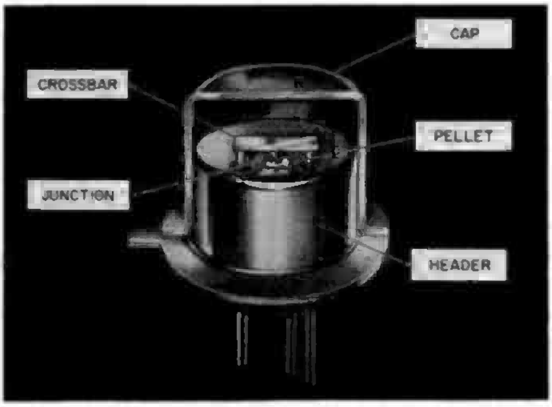

Fig. 11-152. Interior view of a tunnel diode. (Courtesy, General Electric Co.)

11.153 What is the rectifying efficiency of silicon diodes?—Because of the high forward-to-reverse current of the silicon diode, the efficiency is on the order of 99 percent. When properly used, silicon diodes have long life and are not affected by aging, moisture, or temperature when used with the proper heat sink.

11.154 Can diode rectifiers be connected in series or parallel?—Yes, the connection of several diodes in series is permissible when the applied voltage exceeds the peak-inverse voltage (PIV) for a single unit. As an example, four individual diodes of 400-volts PIV may be connected in series to withstand a PIV of 1600 volts. In a series arrangement, the most important consideration is that the applied voltage be equally distributed between the several units. The voltage drops across each individual unit must be very nearly identical. If the instantaneous voltage is not equally divided, one of the units may be subjected to a voltage exceeding its rated value.

Uniform voltage distribution can be obtained by the connection of capacitors or resistors in parallel with the individual rectifier unit. Shunt resistors are used for steady-state applications,

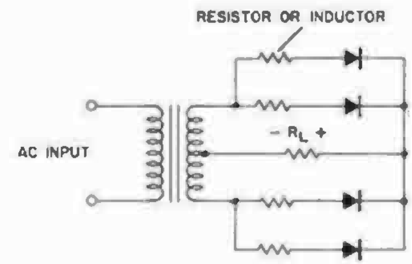

Fig. 11-154D. Diode rectifiers connected in parallel, with series resistances or small inductors.

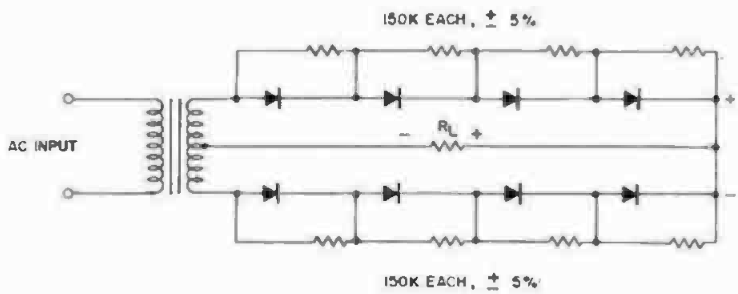

Fig. 11-154A. Diodes connected in series, with balancing resistors connected across each rectifier.

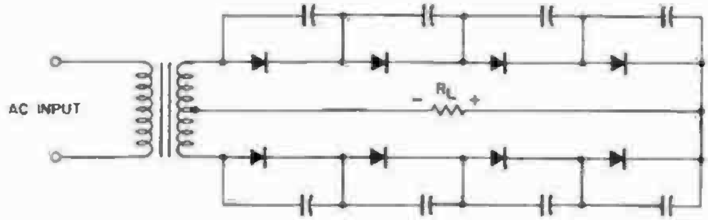

Fig. 11-154B. Diode rectifiers connected in series, with capacitors connected in parallel to reduce the effect of transient voltages.

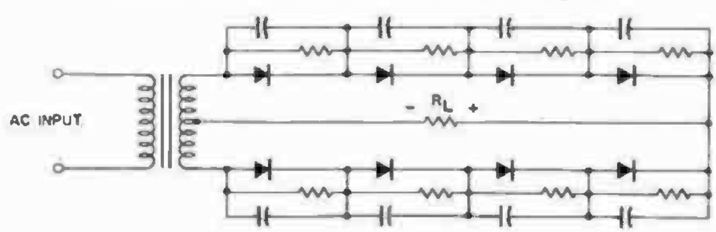

Fig. 11-154C. Diode rectifiers connected in series, with both resistors and capacitors in parallel to equalize voltage distribution and transient effects.

and shunt capacitors are used in applications where transient voltages are expected. If the circuit is exposed to both dc and ac, both shunt capacitors and resistors should be employed.

When the maximum current of a single diode is exceeded, two or more units may be connected in parallel. To avoid differences in voltage drop across the individual units, a resistor or small inductor is connected in series with each diode. Of the two methods, the inductance is favored because of the lower voltage drop and consumption of power. Parallel arrangements should be avoided if possible, by the employment of polyphase circuits or the use of rectifier units large enough to handle the required current.

Series-resistor values will vary with the current ratings of the diodes; however, resistors ranging from 1 to 10 ohms are the usual value, with the dc resistance of series chokes held to 1 ohm or less. The four methods of connection are given in Figs. 11-154A to D.

11.155 What are hot carrier diodes? —The hot carrier diode is distinguished from the more conventional semiconductor devices in that the junction consists of a metal and a semiconductor rather than two different semiconductors. The junction in a hot carrier diode is made to be rectifying rather than ohmic-resistant through a choice of materials, with suitably related work functions. In diodes thus formed, current occurs mainly by means of majority carriers. When the diode is forward biased, the majority carriers injected into the metal have a much higher energy level than those that are in thermal equilibrium with the metal. Such diodes have extremely rapid recovery time, and are used for fast switching circuits, detectors, mixers and many other uses, particularly at high frequencies. A cross-sectional view of its construction is given in Fig. 11-155.

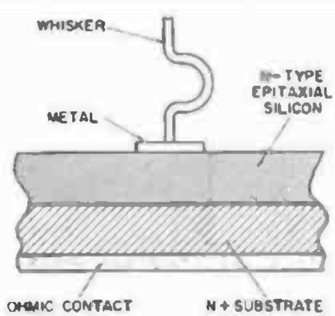

Fig. 11-155. Cross-sectional view of a hot carrier diode construction.

11.156 What is a triac semiconductor? —It is a three-lead, eight-element semiconductor developed by RCA, that passes both halves of the ac waveform when properly triggered. It is similar to an SCR, the difference being the bi-polarity of the Triac assembly, which amounts to having two SCRs back-to-back. The construction of the junctions and an experimental circuit are shown in Fig. 11-156.

11.157 Describe the construction and characteristics of a thermistor. —Thermistors are thermally sensitive resistors whose primary function is to exhibit a change in electrical *resistance* with a change of body *temperature*. They are passive semiconductors, with their electrical resistance being between that of a conductor and an insulator. An important characteristic is their extreme sensitivity to relatively minute temperature changes. While most metals have small positive coefficients of resistance, thermistors exhibit a wide range of either negative or positive temperature coefficients. This unique characteristic permits them to be used in electronic apparatus for control of

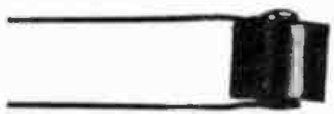

Fig. 11-157A. Thermistor manufactured by General Electric Co.

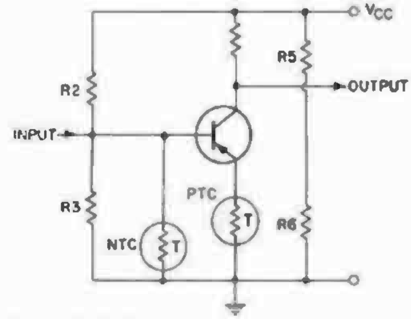

Fig. 11-157B. Thermistor used for temperature compensation in a transistor circuit. A thermistor with a negative temperature coefficient may be connected in parallel with R3, or one with a positive temperature coefficient in place of R6.

voltage and current. A typical thermistor, manufactured by General Electric Co., is shown in Fig. 11-157A.

Thermistors are widely used in transistor circuitry for voltage-temperature compensation, particularly in bias circuits, as seen in Fig. 11-157B. Here a transistor is connected in parallel with a resistor R3 for control of the bias voltage, or it may be connected in the emitter circuit for stabilization. The characteristics for parallel and series connection are shown in Fig. 11-157C, with their change in resistance for a change in temperature in Fig. 11-157D.

The standard reference temperature for thermistors is 25°C. Thermistors are manufactured in a variety of sizes and shapes, such as rods, cubes, washers, discs, beads, etc.

11.158 Describe a surge or transient-voltage suppressor.—Silicon rectifiers are sensitive to voltage, and overvoltage conditions for even a short period of time can cause their failure.

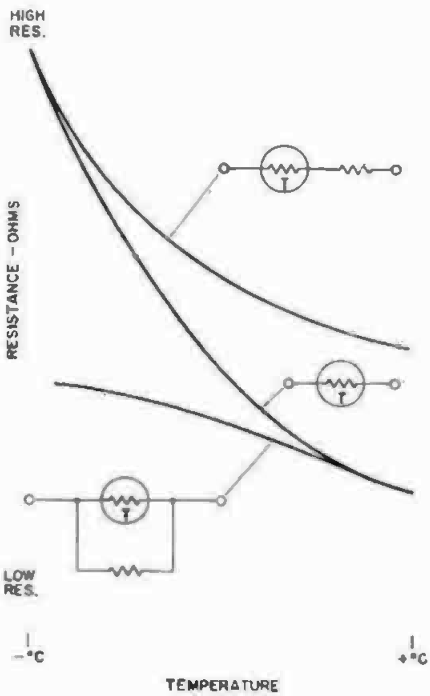

Fig. 11-157C. Temperature versus resistance for parallel series connection. (Courtesy, General Electric Co.)

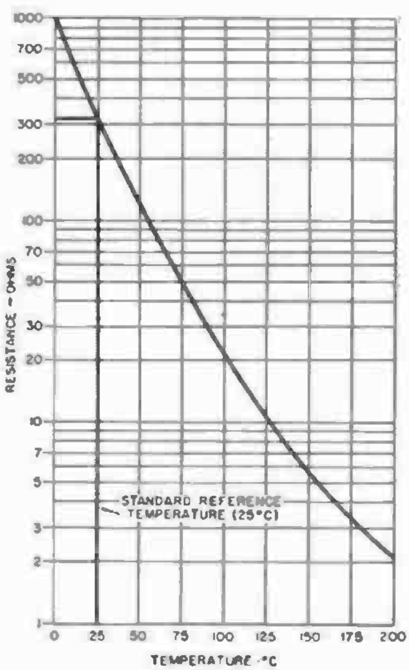

Fig. 11-157D. Resistance in ohms versus change in temperature. (Courtesy, General Electric Co.)

Magnetic devices like transformers, reactors, and relays generate voltage-transient peaks far in excess of the normal input, and are frequently the cause of rectifier failure. As a result, voltage suppressors or clippers are used to increase the reliability of rectifier units, without affecting the circuit operation.

Transient suppressors are selenium devices with *nonlinear* reverse characteristics. The thick dielectric barriers, large area dissipation, and the polycrystalline structure make them capable of handling transient peak voltages of two orders of magnitude or more, above their steady-state rating, and for in-rush currents far in excess of normal densities. The characteristics for a typical *nonpolarized* suppressor are shown in Fig. 11-158A. The similarity of wave shape on both halves of the input circuit will be noted. The characteristic for a *polarized* suppressor are shown in Fig. 11-158B. Nonpolarized

(b) *Polarized.*

Fig. 11-158. Typical reverse characteristics for surge suppressors.

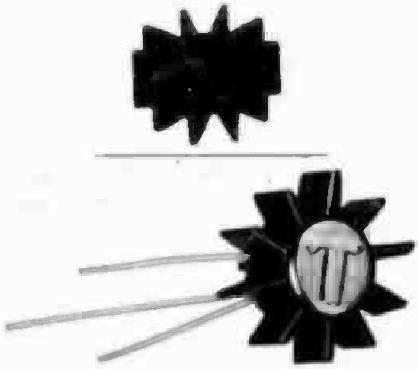
suppressors may be used in either ac or dc applications. Polarized suppressors can be used only in dc circuits, with the suppressor in a normally nonconducting state, but offering a low-impedance discharge path for a collapsing field. Nonpolarized suppressors will clip transient voltages to approximately twice the peak-inverse voltage ratings. Nonpolarized suppressors with low impedance in the nonblocking direction will clip to very low voltage values.

The most common cause of transients is when a switch is opened in the load side of a rectifier circuit at nearly the maximum instantaneous current, generating a high voltage. The peak of the voltage spike can be *hundreds of times the peak of the steady-state voltage.* In this case, the suppressor is connected across the inductance. In rectifier circuits where only the primary circuit of the transformer is broken, the suppressor is connected across the transformer primary. The recovery time for the suppressor is within microseconds. Typical devices of this nature are the Klipvolt, manufactured by Sarkes-Tarzian Inc., and Klip-Sels, manufactured by the International Rectifier Corp. The use of such devices is discussed in Section 21.

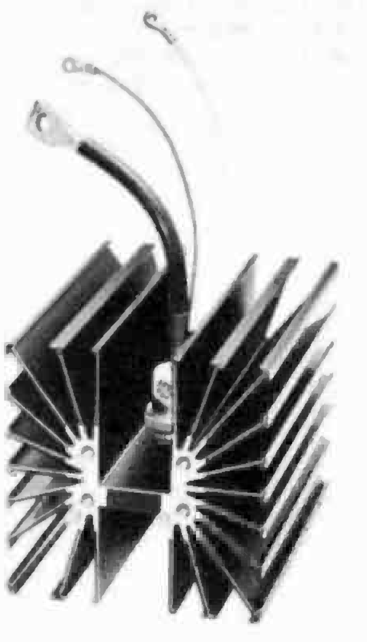
11.159 Describe the different type heat sinks used with semiconductor devices.—Two types of heat sinks used with semiconductor devices are shown in Fig. 11-159. The units in part (a) are used with small low-power transistors, and are smaller in diameter than a dime. The large unit shown in part (b) is used with high-current silicon diodes where considerable heat must be dissipated. The stud of the diode unit is screwed into the center piece of the heat sink. Heat-sink design is discussed in Questions 21.125 to 21.127.

11.160 What are steering diodes?—Diodes connected in a circuit for the purpose of permitting circuit operation only when the actuating signal is of a given polarity. In Fig. 11-160 is shown a steering diode connected in the input of a transistor amplifier to allow the circuit to respond only when a positive-going signal is applied to the input. If negative-signal operation is required, the diode polarity is reversed.

11.161 Describe a photofet or phototransistor.—A photofet is an epitaxial semiconductor photocell, using a



(a) Small heat sinks used with diodes and transistors. Their diameter is less than a dime.



(b) Large heat sink for use with heavy-current diode rectifiers. The stud of the diode is screwed into the center fin of the sink.

Fig. 11-159. Conduction-type heat sinks used for cooling diodes and transistors. (Courtesy, Wakefield Engineering Co.)

field-effect transistor, manufactured by Crystalonics Inc. Incident light is focused on the gate element of the FET through a lens, an integral part of the device. When light strikes the gate area, the electrons on the outer valence of the impurity atom are excited and flow out of the junction through the gate.

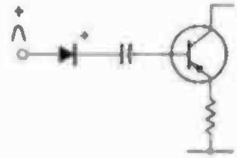


Fig. 11-160. Steering diode connected in the input of a device for permitting its operation only from a positive-going signal. For negative-signal operation the polarity of the diode is reversed.

To state it simply, a given amount of incident light generates a proportional amount of gate current, known as a λ I_g. Thus, the gate junction acts as a current generator and will continue to deliver the same amount of current, regardless of the load, for a fixed source of illumination. It is claimed for such devices that the sensitivity is greater than 10:1 over conventional bipolar photosensitive devices, with 4:1 increases in bandwidth. Such devices are used for high-speed switching, logic, and for many other various control functions.

A circuit suitable for a light-controlled attenuator is shown in Fig. 11-161. The circuitry is designed to take advantage of the photofet's ability to function as a variable resistor. Here, the drain-to-source resistance is a function of the light input obtained from a small incandescent lamp. The bias voltage is adjusted for the desired drain-to-source resistance under quiescent conditions. The spectral response extends from 4000 to 12,000 angstroms, with maximum sensitivity occurring at 9500 angstroms. The recommended light source is a tungsten lamp operated at 2000 degrees Kelvin color temperature.

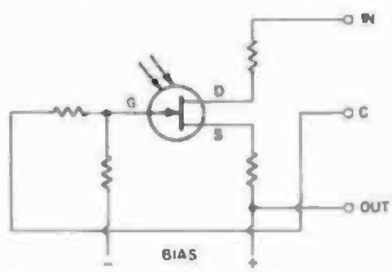

Fig. 11-161. Control circuit for a remote light-operated attenuator using a photofet manufactured by Crystalonics Inc. To distinguish the photofet from a conventional transistor, two arrows are placed above the gate.

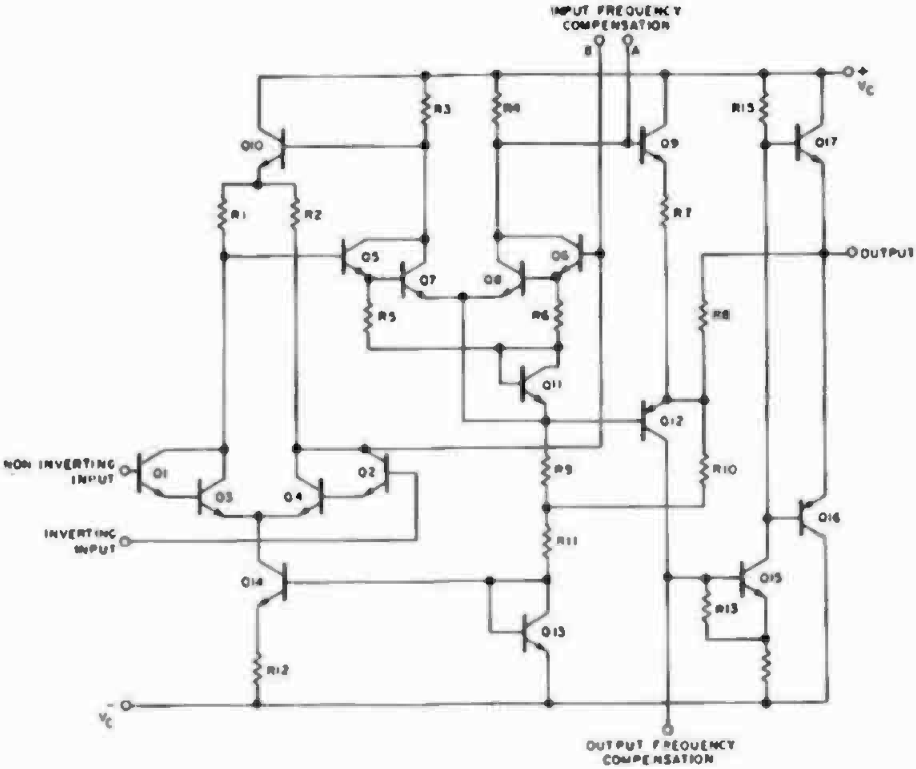

Fig. 11-162. Typical schematic circuit for a monolithic integrated amplifier similar to that used in operational amplifiers.

Because of the light sensitivity of certain semiconductor materials, it is necessary to encase the standard transistor in an opaque container. If this is not done, it is possible to pick up hum from lighting fixtures. This effect has been observed when painted plastic envelopes are used and the paint has become scratched. (See Question 19.169.)

11.162 Describe the basic concept of an integrated circuit (IC).—It is a combination of active and passive semiconductor components fabricated on a single semiconductor chip. The internal components may consist of several transistors, diodes, and resistors. External reactive components can be connected to the internal circuits to form amplifiers, oscillators, and a multiplicity of devices. Negative feedback is generally induced for stability. Integrated circuits are employed in operational amplifiers, although they may also be used for other purposes.

A typical schematic circuit for a monolithic integrated circuit similar to that used in operational amplifiers is given in Fig. 11-162. Operational amplifiers are discussed in Questions 12.196 and 12.261.

Section 12

Audio Amplifiers

The subject of audio amplifiers seems to be endless because of the many designs and functional aspects. In this Section both theoretical and practical amplifier circuits are given for semiconductor and vacuum tube types, with simplified design equations. Resistance and transformer coupled amplifiers with different types of negative feedback are explained. The latter are the outgrowth of the research of H. S. Black, I. G. Wilson, and others.

Of special interest to the audio engineer will be the discussion of semiconductor ac and dc operational amplifiers suitable for adoption to sound mixer console design. Covered are such items as compressor amplifiers, graphic equalizers, high- and low-frequency equalizers, bandpass filters, oscillators, mixer and line amplifiers, and many others. Also discussed are field-effect transistors (FET's) and the possibility of their direct use in place of vacuum tubes.

12.1 What is a resistance-coupled amplifier?—One of the most widely used methods of coupling vacuum tubes is by means of resistance coupling. Resistance-coupled amplifiers are characterized by their simplicity of design, construction, wide frequency range, and their low cost of manufacture. In addition, they are less susceptible to hum and noise pickup from surrounding electrical fields and are especially suited for use with high-mu triode and pentode tubes. A typical two-stage resistance-capacitance coupled amplifier is shown in Fig. 12-1A.

It will be noted that a load resistor R_p is connected in the plate circuit of tube V1 and is used for developing the signal voltage for the following stage. The developed signal is conducted from the plate of V1 to the control grid of V2 through the coupling capacitor C. A grid resistor R_g returns the control grid of V2 to ground. The sole purpose of the coupling capacitor C is to isolate the control grid of V2 from the high positive voltage on the plate of V1.

When a tube in a static or quiescent state (no signal) is connected to the proper grid, cathode, and plate resistors (screen resistor if a pentode is used), and supplied with plate voltage, there is a steady voltage drop across the plate-load resistor. If an instantaneous positive-going signal is applied to the control grid, the plate current will increase. This causes the steady plate voltage to increase in a negative direction (voltage drops at the plate) and generate a negative signal voltage at the plate. Now, if an instantaneous negative-going signal is applied to the control grid, the plate current decreases and the voltage at the plate increases in a positive direction, thus generating a positive signal.

When applying a sine-wave signal to the control grid, the voltage at the plate will rise and fall in accordance with the signal at the control grid, but it will be reversed 180 degrees. Therefore, if the tube is not driven into overload the signal at the plate will be an inverted replica of the signal voltage at the control grid, but of greater magnitude depending on the amplification factor of the tube. The quiescent plate current is selected for a value in the most *linear portion* of the plate-current characteristic. (See Questions 11.52 and 12.101.

As a rule, resistance coupled amplifiers are designed to use self-bias; that is, they have a resistance R_k connected in the cathode circuit through which

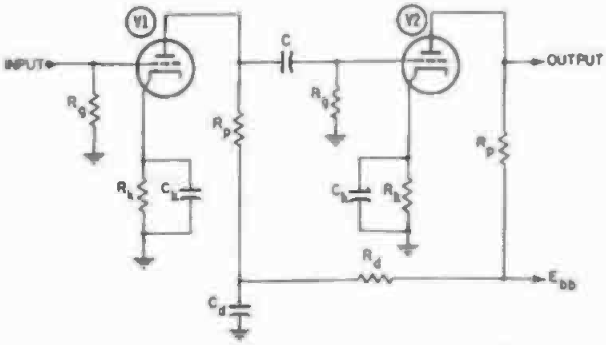

Fig. 12-1A. A two-stage, resistance-capacitance coupled triode amplifier.

the plate and screen-grid (pentode tube) currents pass. This flow of current through resistor R_k to the plate causes the cathode to become positive, with respect to the ground, by the amount of the voltage drop across R_k.

The control grid of V1 is returned to ground through the grid resistance R_g which places the grid at ground potential. This makes the control grid negative with respect to the cathode by the amount of voltage drop across the cathode resistor R_k. This same reasoning is also true for the control grid of V2. Large values of capacitance are connected across the cathode resistors to provide a low impedance path for the signal voltage in the cathode circuit to ground.

In multistage amplifiers, decoupling circuits consisting of capacitors C_d and resistor R_d are connected in the plate circuits of each amplifier stage to prevent common coupling of the tubes through the power supply.

A two-stage resistance-capacitance coupled amplifier using pentodes is shown in Fig. 12-1B. The circuit is similar in design to Fig. 12-1A, except for the addition of the screen-grid dropping resistor R_{sg} and the screen-grid bypass capacitor C_{sg}.

12.2 What are the symbols used for the design of resistance-capacitance coupled amplifiers?

C (C_c)	Coupling capacitor between stages
C_k	Cathode bypass capacitor
C_{sg} (C_{g2}) (C_{sc})	Screen-grid bypass capacitor
E_{bb}	Supply voltage
E_p	Actual voltage at the plate
E_{sg}	Actual voltage at the screen grid
I_p (I_b)	Plate current
I_{sg} (I_{g2})	Screen grid current
R_k	Cathode self-biasing resistor
R_{sg} (R_{g2}) (R_{sc})	Screen-grid dropping resistor
R_g	Grid resistor
R_p (R_L) (R_L)	Plate load resistor
E_{sig} (E_{sg})	Signal voltage at the control grid
V_g	Voltage gain of the stage
E_o	Output signal voltage

Variations of these symbols are given in parentheses. (See Question 11.34.)

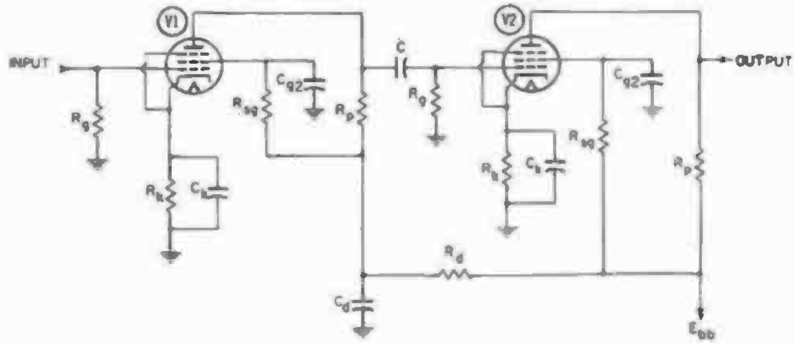

Fig. 12-1B. A two-stage, resistance-capacitance coupled pentode amplifier.

12.3 What are the gain-frequency characteristics of a resistance-capacitance coupled amplifier?—Generally speaking, resistance-capacitance coupled amplifiers have three sets of frequency characteristics. They are: low, medium, and high frequency. With proper design the frequency response may be made quite uniform over a range from direct current to several megahertz. Resistance-coupled amplifiers for audio use are designed to cover a frequency range from 10 to 20,000 Hz and above. (See Question 12.6.)

12.4 What are the factors governing the gain of a resistance-coupled amplifier?—To obtain a large voltage gain in a resistance-coupled amplifier stage, the plate-load resistor R_p must have as large a value as is practical. The higher the value of the plate-load resistance, the greater will be the dc voltage drop across it and the lower will be the actual voltage at the plate of the tube. Therefore, there is a practical limit to the value of the load resistance.

The dc voltage drop across the plate-load resistor must be subtracted from the supply voltage E_{bb} to arrive at the actual value of voltage at the plate of the tube. If the value of the load resistance is high, only a small portion of the supply voltage is available at the plate. This may be too low for proper operation.

Fig. 12-4 illustrates how the supply voltage is distributed in a triode resistance-coupled amplifier. It will be noted that for a supply voltage of 300 volts and a plate-load resistance of 30,000 ohms, 180 volts of the supply voltage is lost in the dc voltage drop across the load resistance and only 117 volts appear between the cathode and the plate, with 3-volts drop across the cathode resistor R_k.

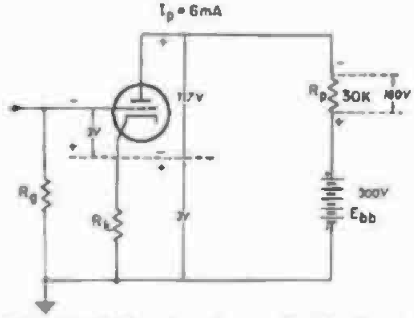

Fig. 12-4. The dc voltage distribution in a resistance-coupled amplifier.

From this illustration it may be readily seen that with a 300-volt supply, increasing the plate-load resistance to a high value results in an excessive voltage drop across the load resistance, and that for a very high value of resistance, the supply voltage would have to be increased to a value out of proportion to the small amount of increased gain achieved by increasing the plate-load resistance.

12.5 What is the relationship between gain and the value of plate-load resistance?—Under the best conditions, only about 80 percent of the tube amplification can be attained. This relationship is shown in Fig. 12-5. It will be noted that, after a certain value of resistance has been reached, the gain increases very slowly and never quite reaches the full amplification factor of the tube.

12.6 What is the variation in the frequency characteristics for different values of plate-load resistance?—Typical gain-frequency characteristic curves for a resistance-coupled amplifier using different values of plate load are shown in Fig. 12-6. As will be seen, the frequency response falls off at both the high and low frequency ends as the plate-load resistance is increased. A

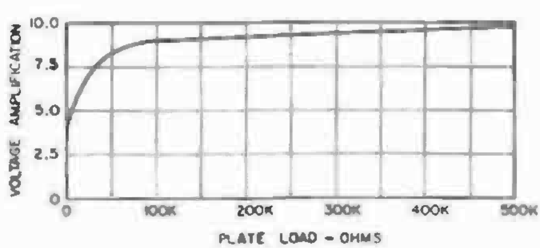

Fig. 12-5. Voltage amplification versus load resistance for a triode having a plate resistance of 10,000 ohms, an amplification factor of 10, and a transconductance of 1000 micromhos.

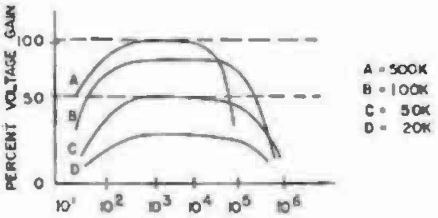

Fig. 12-6. Variation in voltage gain of an RC coupled amplifier for different values of R_p.

wide frequency response can only be obtained with low values of plate load resistance and at the expense of gain.

12.7 What factors affect the gain at the lower frequencies in a resistance-coupled amplifier?—Referring to Fig. 12-1A, a loss of gain at the low frequencies is caused by the high reactance of the coupling capacitor C. The equivalent circuit for a single stage, triode, resistance-coupled amplifier is shown in Fig. 12-7. At the low frequencies, the signal voltage across R_p appears across the series combination of capacitor C and the grid resistor R_g, which is applied to the input of the following stage (μE_g represents the vacuum tube.)

The lower the frequency, the higher becomes the reactance of the coupling capacitor C and more and more of the signal voltage developed across R_p appears across the capacitor C. Therefore, less voltage is applied to the grid of the following stage because of the voltage divider action of R_g and C. The best low-frequency response is obtained when the coupling capacitor C is large in value, so that its reactance is negligible at the lowest frequency to be amplified.

12.8 What are the gain-frequency characteristics at the midfrequencies in a resistance-coupled amplifier?—At the midfreqnencies little or no frequency discrimination is noted because the reactance of the coupling capacitor C is

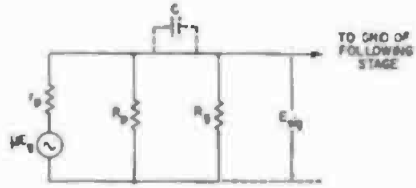

Fig. 12-8. Equivalent circuit for a triode RC coupled amplifier at the mid-frequencies.

small. In Fig. 12-8 (an equivalent circuit) the coupling capacitor has been omitted as its reactance is negligible and may be considered to be a short circuit. Under these conditions, all the voltage (E_{sig}) developed across the plate-load resistor R_p is delivered to the following stage, resulting in a uniform frequency response.

12.9 What are the gain-frequency characteristics at the high frequencies in a resistance-coupled amplifier?—The high-frequency response falls off because of the interelectrode capacitance of the tube and the distributed capacitance of the tube socket and associated wiring. These capacities are considered to be in shunt with the plate and control-grid circuits and act as a low-impedance path to ground at the higher frequencies. (See Fig. 12-9.) As the frequency increases, the reactance of the shunt capacitance C_s becomes less and less, eventually reaching a value equal to that of the load resistance R_p. As a result, the impedance is lowered, a lower voltage is developed across the load resistor R_p, and thus less voltage appears across the input of the following stage. Therefore, the gain falls off as the frequency is increased. Because the reactance of the coupling capacitor is small at the high frequencies, it may be considered to be out of the circuit.

12.10 What is the equation for calculating the amplification of a resistance-coupled amplifier stage at the mid-

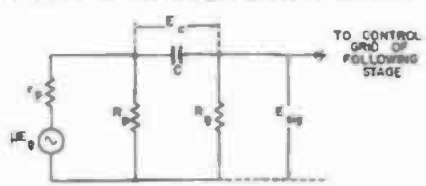

Fig. 12-7. Equivalent circuit for a triode RC coupled amplifier at the low frequencies.

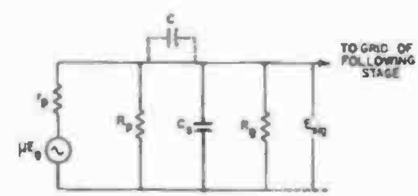

Fig. 12-9. Equivalent circuit for a triode RC coupled amplifier at the high frequencies.

frequencies?—The general equation for a triode tube is:

$$A = \frac{R_p}{r_p + R_p}\mu$$

where,

R_p is the plate load resistor,
r_p is the plate resistance of the tube,
μ is the amplification factor of the tube.

The foregoing equation will give the gain of the tube when the plate-load resistor R_p is not shunted by the grid resistance R_g and coupling capacitor C of a second stage. If the plate resistor R_p is shunted by the components of a second stage, this must be taken into consideration when computing the gain.

The equation is then written:

$$A = \frac{R_{eq}}{r_p + R_{eq}}\mu$$

where,

r_p is the plate resistance of the tube,
R_{eq} is the equivalent resistance of the second stage grid resistor R_g, and the coupling capacitor C, in parallel with the plate load resistor R_p.

A practical example using the above equation would be: Assume a triode is to be operated using a plate-load resistor R_p of 47,000 ohms. The plate resistance of the tube is 7700 ohms and the mu is 17. If the grid resistor R_g of the second stage is several times the value of the plate load resistor R_p, only the value of R_p need be considered. The reactance of the coupling capacitor C, is generally small at the midfrequencies and for practical purposes may be considered to be a short circuit. Therefore, the amplification will be:

$$A = \frac{47,000}{7700 + 47,000} \times 17$$
$$= \frac{799,000}{54,700}$$
$$= 14.62$$

12.11 What is the equation for calculating the amplification of a resistance-coupled amplifier stage at the low frequencies?—The gain of a resistance-coupled amplifier at the low frequencies is more difficult to compute because the reactance of the coupling capacitor to the second stage must be included. The amplification at the low frequencies for a triode tube may be computed:

$$A = \frac{1}{\sqrt{1 + (X_c/R_{eq})^2}}$$

where,

X_c is the capacitive reactance of the coupling capacitor C at the lowest frequency to be passed by the amplifier,
R_{eq} is the equivalent resistance of the plate load resistor R_p in parallel with the reactance of the coupling capacitor in series with the grid resistor R_g of the second stage.

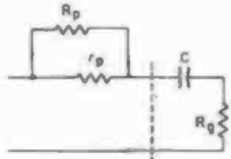

Fig. 12-11. Equivalent circuit for a triode RC coupled amplifier at the low frequencies.

An equivalent diagram for the foregoing equation is shown in Fig. 12-11.

The reactance of the coupling capacitor C increases with a decrease of frequency and is in series with the grid resistor R_g of the second stage. The control grid of the second stage is fed from the junction of these two circuit elements; therefore, less signal voltage is applied to the secoud stage control grid as the frequency is lowered, because of the voltage-divider action of these two circuit elements.

At a frequency where the capacitive reactance of capacitor C is equal to the value of the grid resistor R_g, the signal voltage at the control grid of the second stage will be reduced 3 dB. This is called the half-power point and is taken to be the lower frequency limit of the amplifier. The response at the lower frequencies may be extended by the methods described in Questions 12.21 and 12.37.

12.12 What is the equation for calculating the amplification of a resistance-coupled amplifier stage at the high frequencies?—For a triode the amplification is:

$$A = \frac{1}{\sqrt{1 + (R_{eq}/X_c)^2}}$$

where,

R_{eq} is the equivalent resistance as described in Question 12.10,
X_c is the capacitive reactance of the stray capacitance due to wiring, sockets, and the internal capacitance of the tube.

At the high frequencies the reactance of the coupling capacitor C, is quite small and may be neglected. At a frequency where the reactance of the stray capacitance equals one-third the value of R_{eq}, the gain will drop 3 dB. This is called the upper half-power point and is taken as the upper frequency limit of the amplifier.

12.13 What is the equation for calculating the amplification of a resistance-coupled pentode amplifier stage?—Because of the high plate resistance of a pentode tube (generally of the order of 1 megohm), the value of the plate load resistor R_p is not important. The formula then becomes:

$$A = G_m R_{eq}$$

where,

G_m is the transconductance of the tube in micromhos,

R_{eq} is the equivalent load resistance.

The transconductance is equal to mu/r_p.

12.14 What type tubes are recommended for resistance-coupled amplifiers?—Pentodes or high-mu triodes. For high-frequency amplification, the pentode is preferred because of its lower internal-electrode capacitance. This keeps the shunt capacitive reactance high in comparison to the load resistance R_p. As a rule, the load resistance is made low enough that it is lower than the shunting impedance of the distributed capacitance caused by the wiring, socket, and internal capacitance of the tube.

Lowering the load resistance R_p also decreases the amplification of all frequencies passed by the amplifier, but such design is necessary if the amplifier is to cover a wide frequency band.

The data supplied by the tube manufacturers cover the audio frequency range from 20 to 20,000 Hz. If the low-frequency end is to be extended, the coupling capacitor must be increased in size as discussed in Question 12.21. Also, compensating circuits are generally added as described in Question 12.37.

12.15 How are the circuit constants for resistance-coupled amplifiers selected?—The circuit constants may be calculated individually; however, charts are available from the tube manufacturer that provide all the necessary data except for very special cases. Typical charts are shown in Fig. 12-15. Values for the circuit elements are selected on the basis of the plate supply voltage E_{bb}, plate-load resistance R_p, and the grid resistance R_g, remembering that the higher the plate-load resistance, the greater the loss at the high frequencies. Referring to Fig 12-15, chart 2, it will be noted that under a given plate-load resistance are tabulated the value of the cathode resistance R_k, the screen-grid dropping resistor R_{c2} (or R_{sg}), the coupling capacitor C, and the screen grid and cathode bypass capacitors C_{c2} (or C_{sg}) and C_k.

The values of capacity given are the minimum values for a given set of conditions. The circuit constants are predicated on a given signal voltage E_o at the plate for a given value of harmonic distortion. The amplification or voltage gain V_g given in the charts may be converted to decibels by the equation:

$$dB = 20 \operatorname{Log}_{10} V_g$$

where,

V_g is the voltage gain stated in the charts.

As an example, a given tube has a voltage gain of 14. What is the gain in decibels?

$$\begin{aligned} dB &= 20 \operatorname{Log}_{10} 14 \\ &= 20 \times 1.46 \\ &= 22.92 \text{ dB.} \end{aligned}$$

12.16 Explain how the circuit constants given in a resistance-coupled amplifier design chart are determined.—They are based on a given frequency response, distortion, gain, and signal output voltage. The frequency response on which the circuit constants are predicated is shown in Fig. 12-16. The frequency f_2 is that value at which the high-frequency response begins to fall off. The frequency f_1 is that value at which the low-frequency response drops below a satisfactory value, as discussed in the questions to follow. For most of the types shown, the data pertain to the use of a cathode bias resistor where feasible, a series screen-dropping resistor where applicable, and offers several advantages over fixed voltage operation. These advantages are:

Operation over a wide range of plate supply voltages without appreciable change in gain;

The effects of possible tube differences are minimized;

The low frequency at which the amplifier cuts off is easily changed;

The tendency toward motorboating is minimized.

●– At 2 volts (rms) output. ■ At 3 volts (rms) output. ★ At 4 volts (rms) outpt.
• One triode unit.

Fig. 12-15. A typical resistance-coupled amplifier data chart. (Courtesy, Radio Corporation of America)

The output peak voltage E_o is the voltage available across the grid resistance R_g of the following stage at any frequency within the flat portion of the frequency response, and where the input signal is of such magnitude as to swing the control grid to a point where grid current just starts to flow.

12.17 How critical is the supply voltage for a resistance-coupled amplifier?—For supply voltages differing by 50 percent from those listed in the

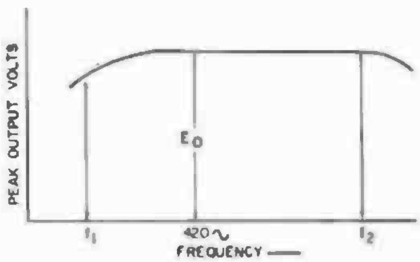

Fig. 12-16. Frequency response for the design of RC amplifiers. (Courtesy, Radio Corporation of America.)

charts of Fig. 12-15, the voltage gain is approximately the same.

12.18 How critical are the values of the circuit components in a resistance-coupled amplifier?—The values of the circuit components in the charts are approximately correct for changes up to 50 percent of the stated supply voltage. Ten-percent tolerance capacitors and resistors are quite satisfactory to be used.

12.19 What is the frequency response when the data in the tube charts are used with a directly heated triode amplifier?—Capacitors C and C_k have been chosen to give a signal output voltage equal to 0.8 E_o for a frequency f_1 of 100 Hz (Fig. 12-16). For any other value of f_1 multiply C and C_k by $100/f_1$. The values given for C_k are for an amplifier using direct current on the heaters. When alternating current is used, it will be necessary to increase the value of C_k to minimize hum disturbances. The voltage at f_1 of "n" stages equals 0.8^n E_o, where E_o is the peak signal voltage at the final stage for any value of R_p.

12.20 What is the frequency response when the data in the tube charts are used with a filament-type pentode tube?—Capacitors C and C_{sg} have been chosen to give an output signal voltage equal to 0.8 E_o for a frequency f_1 of 100 Hz (Fig. 12-16). For any other value of f_1, multiply values of C and C_{sg} by $100/f_1$. The voltage output at F_1 for "n" like stages equals 0.8^n E_o, where E_o is the peak signal output voltage of the final stage. For an amplifier of typical construction and for R_p values of 100,000, 250,000, and 500,000 ohms, approximate values of f_2 are 20,000, 10,000, and 5,000 Hz, respectively. The values of the input coupling capacitor C in microfarads and of the grid resistor R_g in megohms should be such that their product lies between 0.02 and 0.10.

12.21 What is the frequency response when the data in the tube charts are used with a heater-type pentode?—Capacitors C, C_k, and C_{sg} have been chosen to give an output voltage equal to 0.7 E_o for a frequency f_1 of 100 Hz (Fig. 12-16). For any other values of f_1, multiply values of C, C_k, and C_{sg} by $100/f_1$. In the cases of capacitor C_k, the values shown in the charts are for an amplifier with dc heater excitation. When ac is used, depending on the character of the associated circuits, voltage gain, and the value of f_1, it may be necessary to increase the value of C_k to minimize hum disturbances. The voltage output at f_1 for "n" like stages equals 0.7^n E_o, where E_o is the peak output signal voltage at the final stage. For an amplifier of typical construction and for R_p values of 0.1, 0.25, and 0.5 megohm, approximate values of f_2 are 20,000 10,000, and 5000 Hz, respectively.

12.22 Is it necessary to bypass a self-bias resistor?—No, not unless the maximum gain is required from the tube. When the cathode or self-bias resistance is left unbypassed, degeneration (negative-current feedback) is developed by the flow of the audio signal through the bias resistor because of the ac component of the plate current flowing through the bias resistor.

The flow of signal current causes a voltage drop across the bias resistor, which increases the normal bias voltage on the control grid. This increase of bias voltage reduces signal voltage at the control grid and reduces the stage gain from 4 to 6 dB. This requires the input signal amplitude be increased to produce a given output signal level at the plate circuit by the factor:

$$E_{sig} = \frac{A \times R_k}{R_{eq}}$$

where,

- A is the amplification factor of the tube with the cathode resistor bypassed,
- R_{eq} is the combined resistance of the plate-load resistor, R_p and the grid resistor R_g of the following stage,
- R_k is the cathode resistor.

Leaving the cathode resistor unbypassed results in a more uniform frequency response with lower distortion for a given set of conditions, but with higher plate impedance. Unbypassed cathode circuits are more susceptible to hum pickup from ac heater circuits.

The foregoing statements apply to single-stage amplifiers only. For push-pull amplifiers see Question 12.106.

12.23 What is the relationship between the coupling capacitor C and the grid resistor R_g?—When the reactance of the coupling capacitor C at the lower frequencies becomes equal to the grid resistor R_g, the frequency response will be down 3 dB, compared to a reference frequency of 420 Hz.

When designing a capacitive-coupled circuit, it is useful to be able to predict what proportion of the voltage across the plate resistor R_p will appear across the grid resistor R_g. This may be determined by the use of the nomograph in Fig. 12-23. A straight edge is laid from the load resistance at the left to the value of the capacitive reactance at the right. The loss in voltage gain, relative to 100-percent gain, is read from the percentage scale at the center. The loss in dB for a range of 0.5 to 6 dB may be read at the left of the center scale. The capacitive reactance is that of the coupling capacitor at the highest and lowest frequency of interest.

12.24 How does the cathode capacitor C_k affect the frequency response?—Normally the cathode capacitor size is selected for a value that will have a reactance of one-tenth the resistance of the cathode resistor. Practical sizes are 25 to 50 μF. The purpose of the cathode capacitor is to provide a low impedance path for the signal voltage to ground and remove it from the cathode resistor so far as possible. As the size of the cathode-bypass capacitor is reduced, degeneration (negative-current feedback) is increased and, if this capacitor is made small enough, the gain begins to fall at the lower frequencies and the frequency characteristic starts to rise at the higher frequencies. A small capacitor across a cathode resistor is often used to increase the high-frequency response. This subject is discussed in Question 6.96.

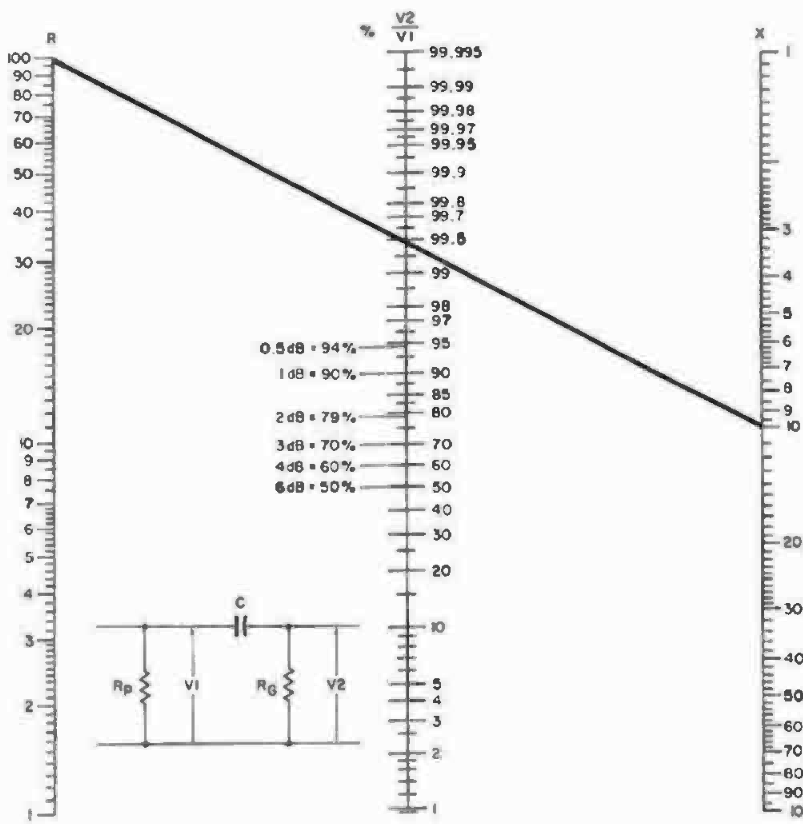

Fig. 12-23. Nomograph for determining the loss in gain that occurs through a capacitive-coupled circuit.

12.25 How may the size of the coupling, screen, and cathode capacitors be approximated?—By the use of the equations:

$$C = \frac{1.6 \times 10^6}{f \times R_g} = \mu F$$

$$C_k = \frac{1.6 \times 10^6}{f \times R_k} = \mu F$$

$$C_{sg} = \frac{1.6 \times 10^6}{f \times R_{sg}} = \mu F$$

$$X_c = \frac{10^6}{2\pi f}$$

where,

C is the coupling capacitor,
C_k is the cathode-bypass capacitor,
C_{sg} is the screen-bypass capacitor,
f is the lowest frequency to be amplified,
R_g is the grid resistor,
R_k is the cathode resistor,
R_{sg} is the screen grid dropping resistor,
X_c is the capacitive reactance.

This statement does not take into consideration effects of phase shift.

12.26 What effect does a volume control have on the frequency response of an amplifier?—It adds to the impedance seen by the input of the following tube reducing the high-frequency response; however, generally it is of no great consequence. Volume controls should not be included in a negative-feedback loop of an amplifier because of its internal capacitance. (See Question 12.191.)

12.27 What factors affect the distortion characteristics of a resistance-coupled amplifier?—They are the same as for any other type amplifier and are a function of the signal amplitude and operating parameters. Negative feedback may be used over a number of stages to obtain the most desirable distortion characteristics.

12.28 How is self-bias achieved in an amplifier?—By connecting a resistor in series with the cathode element to ground. The flow of plate current (and screen grid in the case of a pentode) through this resistor causes a voltage drop across the resistor making the cathode positive with respect to ground. The control grid is connected to ground making the grid negative with respect to the upper end of the cathode. Thus, the control grid is made negative by the amount of voltage drop across the cathode resistor. The value of the cathode resistor, R_k, may be calculated:

$$R_k = \frac{E_g}{I_k}$$

where,

I_k is the total current through the cathode resistor,
E_g is the required grid-bias voltage.

For pentodes, the screen-grid current is added to that drawn by the plate. (The screen-grid current also flows through the cathode resistor.)

The cathode capacitor may be eliminated by use of the circuit shown in Fig. 12-28 in which the cathode element is connected to the junction of a voltage divider circuit formed by a resistor R_d and the cathode resistor R_k.

This circuit places the cathode close to ground and eliminates the need for the usual heavy bypass capacitor. This circuit is quite useful in low-level high-gain amplifier stages in reducing hum. As an example: a given tube requires a bias voltage of 1.2 volts. Connecting a 68,000 ohm resistor from a source of 200 volts dc, to a cathode resistor of 390 ohms places the cathode element only 390 ohms above ground.

Because the cathode resistor is not bypassed, degeneration will take place across the cathode resistor; however, the benefits gained by the reduction in hum in this stage offsets the loss of gain suffered from the degeneration.

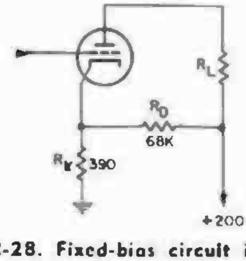

Fig. 12-28. Fixed-bias circuit in a low-level, high-gain amplifier stage.

12.29 What is a grid-leak resistor?—A high-value resistor connected from the control grid of a vacuum tube to ground or the negative side of the circuit. Its purpose is to permit excessive electrons on the control grid to leak off to ground and thus prevent the tube from becoming blocked due to an excessive negative charge on the grid. Grid-leak resistors are used in amplifiers, oscillators, radio detectors (demodulators), and similar devices.

12.30 What is a stopping capacitor?—It is another name for a coupling capacitor used between the stages of a resistance- or impedance-coupled amplifier.

12.31 What is the effect of a leaky coupling capacitor?—Referring to Fig. 12-1A, if the coupling capacitor C is leaky, the positive potential at the plate of the tube V1 will be applied to the control grid of tube V2. The positive potential will offset the negative bias on the control grid of V2 causing the tube to draw grid current and an excessive amount of plate current which may cause the tube to be permanently damaged. In addition, because the tube will not be operating on the linear portion of its characteristic curve, excessive distortion will result.

12.32 What are the limiting factors for determining the maximum resistance that may be inserted in the control-grid circuit of a vacuum tube?—The space current. Because of the current flow, electrons collect on the control grid forming a negative charge. This charge has no way of leaking off except through the resistance between the grid and ground. If the grid resistance is in the order of one-fourth to one-half megohm, a considerable bias voltage is created, ranging from 0.25 to 2.0 volts. The effect of the space charge relative to the grid resistance is often referred to as contact potential because of its similarity to the condition resulting when dissimilar metals placed in contact generate a current.

The maximum value of resistance that may be used with a particular tube may be obtained from the manufacturer's sheet. Higher values of grid-circuit resistance may be used with cathode bias (self-bias) than fixed bias. The reason for this difference is that in a self-bias or automatic-bias circuit, the bias voltage increases with an increase of plate current, thus preventing the creeping of plate current, because of grid emission and gas, between the grid and cathode elements. (See Questions 11.44 and 11.62.)

12.33 What is the overall frequency response of two resistance-coupled amplifier stages connected in tandem?—If two amplifier stages each having a frequency response of 0.80 at a given frequency (f_1) and relative to a reference frequency of 420 Hz are connected in tandem, the overall frequency response for the two stages will be:

$$0.8^2 \text{ or } 0.8 \times 0.8 = 0.64$$

Therefore, the frequency (f_1) will show a loss of 4 dB compared to the reference frequency of the response at (f_1) and is 64 percent of the reference frequency. This will hold true regardless of the type of interstage coupling employed. Percentage compared to decibel loss may be read directly from the chart in Fig. 25-133.

12.34 What is the permissible variation of supply voltage (E_{bb}) for resistance-coupled amplifiers?—Using a given group of circuit components, the supply voltage may vary up to about 50 percent without seriously affecting the operation of the amplifier. However, this should be the exception rather than the rule, as the distortion will be increased and the output signal voltage will drop.

The change of output signal voltage with a change of supply voltage (E_{bb}) may be calculated:

$$E_{o1} = \frac{E_o E_{bb2}}{E_{bb1}}$$

where,

E_{o1} is the new output signal voltage,
E_o is the original output signal voltage,
E_{bb1} is the original supply voltage,
E_{bb2} is the new supply voltage.

12.35 What are the practical factors affecting the frequency response of a resistance-coupled amplifier?—Low-frequency response can be affected by any one or more of the components of the circuit. The reactance of the coupling capacitor C rises rapidly below a frequency of 100 Hz causing a loss at the lower frequencies. As an example, a 0.10-μF capacitor has a reactance at 50 Hz of 30,000 ohms and a reactance at 20 Hz of 80,000 ohms. This increase of reactance reduces the signal voltage at the control grid of the second stage. Increasing the capacity of the coupling capacitor to reduce its reactance increases its physical size adding to the shunt capacities of the circuit and reducing the high-frequency response. This is particularly true if the coupling capacitor is in a metal case. The loss at the lower frequencies causes phase shift which rises to an appreciable amount. One microfarad appears to be the practical limit of a coupling capacitor.

To obtain a uniform frequency response at a frequency of 20 Hz will require a cathode-bypass capacitor of at least 100 μF and preferably 1000 μF. Such values are practicable as they are of low voltage and the units are small in physical size. If these values are impractical, the cathode-bypass capacitor may be eliminated, with a resulting loss of gain because of degeneration in the cathode circuit. However, this will reduce frequency discrimination and phase shift. In some instances it may be desirable to use battery bias with the cathode connected to ground.

Another offender is the screen-grid bypass capacitor. If of insufficient size, degeneration is induced in both the screen and control grid circuits, reducing the stage gain. The screen-grid bypass capacitor should be at least 10 μF and larger if practicable. In any case, the reactance of the capacitor should be one-tenth the resistance of the screen-grid dropping resistor.

Another source of trouble is common coupling of the amplifier stages through the internal impedance of the power supply causing low-frequency motorboating. If the power supply is of the regulated type, the greater portion of the trouble is eliminated. The use of a large bypass capacitor at the output of an unregulated power supply will reduce common coupling. (See Question 12.36.)

12.36 What is a decoupling circuit? —When three or more resistance-coupled stages are used, decoupling resistors R_d and capacitors C_d are connected in the plate-circuit returns of each stage as shown in Fig. 12-36A. The purpose of these decoupling networks is to prevent common couplings between the stages through the common impedance of the power supply. Decoupling may be dispensed with if the amplifier consists of only two stages, as the plate current for the two tubes is out of phase and will not couple through the power-supply impedance.

In a three-stage amplifier, the plate currents of the first and third stages are in phase and will couple through the power supply. This condition manifests itself by a low-frequency oscillation called motorboating. This undesirable coupling is eliminated by the decoupling capacitor C_d which offers a low impedance path to ground to the signal voltage, while the resistor R_d offers a high impedauce to ground through the power supply route. If the ratio of capacitance C_d to resistance R_d is high, the sigual is forced to return

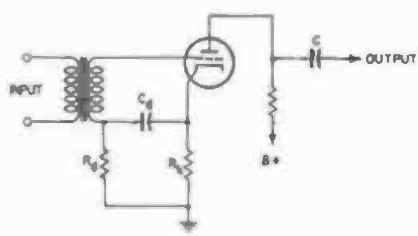

Fig. 12-36B. Decoupling circuit in the control-grid return circuit of a transformer-coupled amplifier.

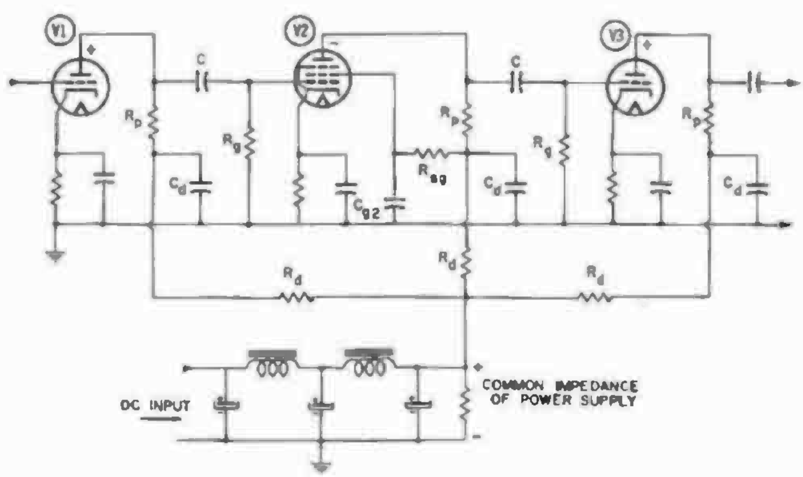

Fig. 12-36A. A three-stage, resistance-coupled amplifier with decoupling circuits C_d and R_d.

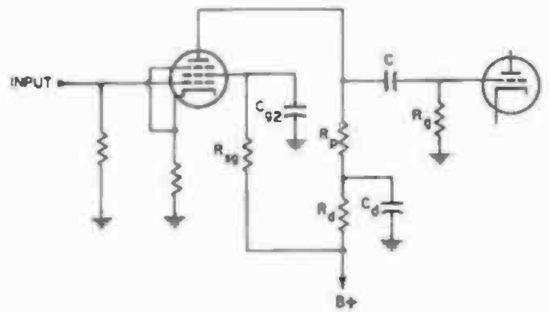

Fig. 12-37. A resistance-coupled amplifier with a low-frequency compensating circuit consisting of resistor R_d and capacitor C_d.

to ground through capacitor C_d rather than through the power supply. Practical values of resistance for R_d are 10,000 to 25,000 ohms. Capacitance values for C_d are 10 μF or greater.

The internal impedance of the power supply may be lowered by shunting the output with a capacitor of 100 microfarads; however, this is often impractical. Another form of decoupling is shown in Fig. 12-36B. A resistor R_d and capacitor C_d are connected in the grid return of the input transformer. The capacitor C_d has a low reactance to the signal voltage while the resistor R_d offers a high-impedance path forcing the signal to return back to the cathode circuit.

12.37 What is a low-frequency compensating circuit in a resistance-coupled amplifier?—Elements connected in the plate circuit to increase the low-frequency response. The circuit elements are those of the decoupling circuit shown in Fig. 12-37. By the proper choice of values, the circuit may be used for both decoupling and compensation. As a compensator circuit it serves two purposes; (1) it introduces phase shift in the plate circuit, compensating for the phase shift of the coupling circuit C and R_g, and (2) it effectively increases the plate-load impedance at the lower frequencies, thus maintaining the gain at the lower frequencies.

The resistor R_d should be kept as large as practicable, say 10,000 to 20,000 ohms. The larger the R_d, the lower the compensation may be carried; however, the value must not be made too great or the drop in voltage at the plate will be excessive. The most effective compensation is obtained when the time constant of the compensating circuit is the same as for the coupling capacitor C and the grid resistor R_g.

12.38 How is the time constant for the compensating circuit in Fig. 12-37 controlled?—For compensation down to 20 Hz, time constants of 0.02 to 0.5 are used. Knowing the time constant desired, the capacitance may be calculated:

$$C_d = \frac{T}{R_p}$$

where,

T is the time in microseconds,
R_p is the plate-load resistance in ohms,
C_d is the decoupling capacitor in microfarads.

The grid resistance may be calculated:

$$R_g = \frac{T}{C}$$

where,

C is the coupling capacitor,
R_g is the grid resistor,
T is the time in microseconds.

12.39 What is a direct-coupled amplifier?—A resistance-coupled amplifier in which the coupling capacitor C has been omitted. In such amplifiers, the plate of the driving tube is connected directly to the control grid of the following stage. This type coupling is shown in Fig. 12-39. The only function of the coupling capacitor is to isolate the control grid of the second stage from the dc potential on the plate of the preceding stage.

In direct-coupled amplifiers, the cathode of the second stage is made sufficiently positive above ground that the difference in potential between the cathode and plate is equivalent to the normal grid bias for the control grid of the second stage.

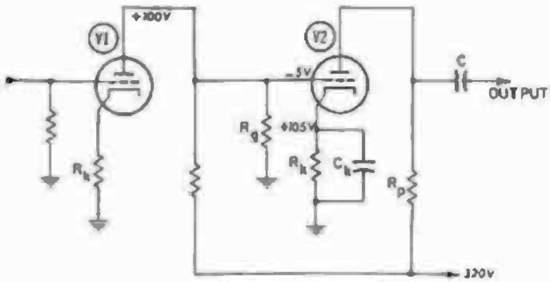

Fig. 12-39. A direct-coupled amplifier. The negative bias voltage at the control grid of V2 is the cathode voltage of V2 minus the plate voltage of V1.

In the circuit shown the cathode is made plus 105 volts above ground. The actual voltage at the plate of V1 is 100 volts positive. The control grid of V2 is returned to ground. Subtracting the plate voltage of V1 from the cathode voltage of V2 makes the control grid minus 5 volts, its correct bias voltage.

12.40 What is a Loftin-White direct-coupled amplifier?—This well known amplifier is shown in Fig. 12-40. The plate of V1 is directly connected to the control grid of V2. The voltage distribution may be traced by starting at the negative end of the power supply. The grid of V1 is connected to ground through the grid resistor R_g. The proper bias for this tube is obtained by connecting the cathode to point A on the voltage divider so that when the circuit is in operation, the total current flow through the resistance between the negative end of the voltage divider and point A gives the required voltage drop.

The plate of V1 is connected to point C on the voltage divider through the plate load resistor R_p which also serves as a grid resistor for the following tube V2. Since plate current flows through resistor R_p, it must be returned to a point on the voltage divider which will supply the proper voltage to the plate; therefore, it is returned to point C.

The plate of V2 is returned through a suitable load resistance or transformer to the positive end of the voltage divider. The cathode of V2 is returned to a point on the voltage divider where the proper bias voltage is obtained. The bias voltage at the control grid will be the voltage drop across the plate load resistor R_p minus the 53-volt drop across the voltage divider between points B and C. This results in a negative voltage (minus 16 volts) at the control grid of V2.

With the proper voltages established and the amplifier operating class-A, a low-distortion amplifier with a wide frequency range is possible.

Direct-coupled amplifiers of the foregoing type can be used to amplify very low frequencies and are particularly suited to pulse amplification, as the phase shift is reduced to a minimum.

12.41 What is a cathode follower?—A vacuum-tube circuit in which the signal voltage is applied to the control grid and the output signal is taken from the cathode circuit. The characteristics of a cathode follower are high input

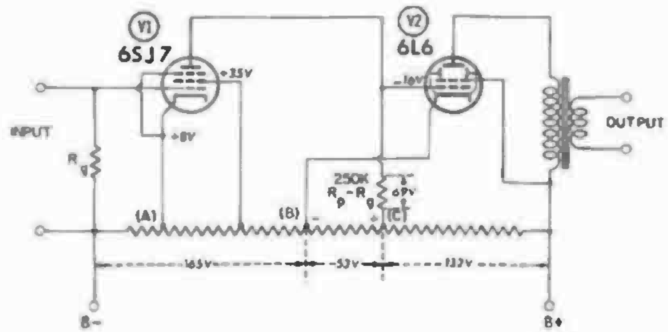

Fig. 12-40. The Loftin-White direct-coupled amplifier.

impedance and low output impedance. Because of degeneration in the cathode circuit, the amplification is always less than one. The circuit in Figs. 12-41A, B, and C are typical cathode-follower circuits. Cathode followers are practically distortionless if they are operated with the correct load impedance. However, if they are overloaded, limiting occurs and the distortion increases.

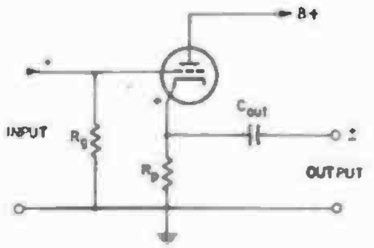

Fig. 12-41A. A cathode follower with 100% negative-current feedback.

In Fig. 12-41A the output signal is taken across the full load resistance R_p (the load resistance is the cathode resistor). In this circuit, 100-percent feedback exists because all of the output voltage is fed back to the input. The output capacitor C_{out} is selected on the basis of output reactance and frequency. The output capacitor prevents the load impedance from shorting the bias load resistor R_p to ground.

The circuit in Fig. 12-14B is used when the load resistor R_p is too large for the required bias voltage. The control grid is returned to a point on the load resistor R_p where the correct operating bias is obtained. The method used to obtain the bias voltage when the load resistor R_p is too small for the correct control-grid bias is shown in Fig. 12-41C. A resistor R_k is connected in series with the load resistor R_p and

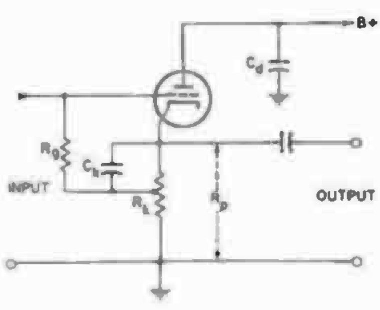

Fig. 12-41B. A cathode follower with a grid-bias tap on the load resistor.

bypassed in the usual manner. If the bias resistor is not bypassed, negative-current feedback will take place across all the resistance in the cathode circuit. In a properly designed cathode follower, the signal appears only in the cathode circuit. At times, it may be necessary to connect a large bypass capacitor from the plate to ground to prevent the possibility of the signal voltage getting

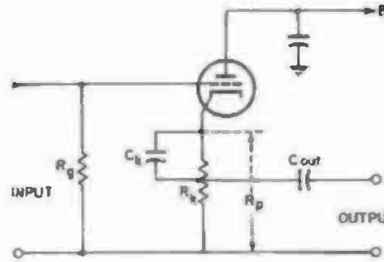

Fig. 12-41C. A cathode follower with bias resistor R_k.

into the power supply and causing common coupling to other parts of the amplifying system. Common coupling is discussed in Question 12.36.

12.42 How are tubes selected for cathode-follower circuits?—By first calculating the required transconductance using the formula:

$$g_m = \frac{10^6}{Z}$$

where,

Z is the output impedance desired in ohms,

g_m is the transconductance in micromhos.

12.43 What is the equation for calculating the load resistor R_p for a cathode follower?—For triodes the equation is:

$$R_p = \frac{Z \times r_p}{r_p - Z(1 + \mu)}$$

where,

R_p is the load resistor,

Z is the output impedance desired,

r_p is the plate resistance of the tube,

μ is the amplification factor of the tube.

For pentodes the equation is:

$$R_p = \frac{Z}{1 - (g_m \times Z)}$$

where,

R_p is the plate load resistor,

Z is the output impedance desired,

g_m is the transconductance of the tube in micromhos.

12.44 What is the equation for calculating the voltage gain of a cathode follower?—For triodes the equation is:

$$V_g = \frac{\mu \times R_p}{r_p + R_p\,(\mu + 1)}$$

where,

μ is the amplification factor of the tube,
R_p is the load resistor,
r_p is the plate resistance of the tube.

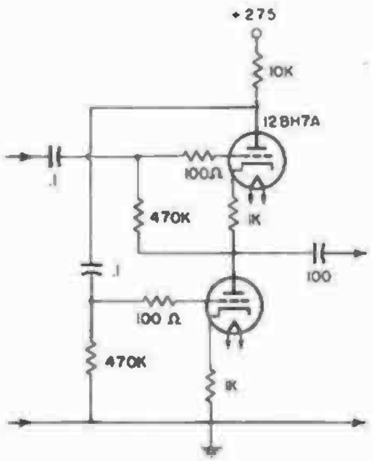
For pentodes the formula is:

$$V_g = \frac{g_m \times R_p}{1 + (g_m \times R_p)}$$

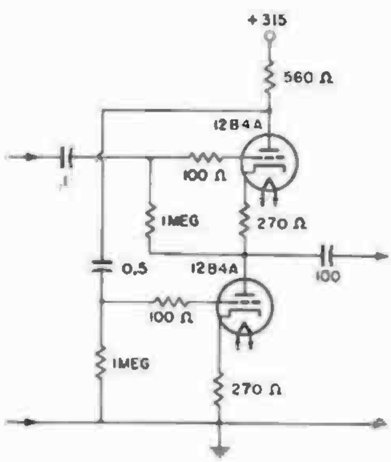
where,

R_p is the load resistor,
g_m is the transconductance in micromhos.

12.45 Describe a double cathode follower.—A double cathode follower, or as nicknamed "Totem Pole," is used in circuits where there is a large mismatch of load impedance, or a very low value of source impedance is required. The double cathode follower has about one-twentieth the output impedance of the conventional cathode follower. Typical circuits for a double cathode follower are shown in Fig. 12-45.



(a) Using a single 12BH7A tube.



(b) Using two 12B4A tubes.

Fig. 12-45. Double cathode-follower circuits.

12.46 Is it permissible to operate a cathode follower with a high load impedance?—Yes; this may be done if high output voltage is required. However, it will be necessary to use the circuit in Fig. 12-41B. The cathode capacitor C_1 must have a reactance that is negligible at the lowest frequency to be amplified. With a high resistance in the cathode circuit, the amplification factor approaches unity provided the plate voltage is increased above normal by the value of the grid bias voltage.

12.47 How far may the output circuit of a cathode follower be carried?—If the output impedance is in the order of 1000 ohms or less, 50 feet—more if coaxial cable is used. (See Question 25.212.)

12.48 Describe the procedure for plotting vacuum-tube load lines.—Load lines for vacuum tubes are made in the same manner as for a transistor described in Question 11.139, the principal difference being the names of the elements. In the transistor terminology the base corresponds to the control grid of a vacuum tube, the emitter to the cathode, and the collector to the plate element. In the instance of FET's, the gate corresponds to the control grid, the source to the cathode, and the drain to the plate.

12.49 What are the phase relationships in a cathode-follower circuit?—The input and output signals are in phase with each other.

12.50 What is a phase inverter?—Two tubes connected as shown in Fig. 12-50 and used for driving a push-pull amplifier stage. With proper design, two signals of equal amplitude and 180 degrees out of phase with respect to each other may be obtained. The incoming signal is applied to the control grid of tube V1, amplified, and then applied to the control grid of the upper tube of the push-pull stage V3. A portion of the signal at the grid of V3 is taken from the grid circuit by means of potentiometer P and applied to the control grid

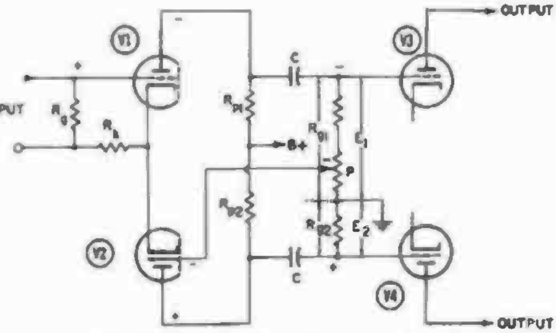


Fig. 12-50. A phase-inverter circuit.

of a phase-inverter tube V2. The signal, after inversion, is applied to the control grid of the lower push-pull tube V4. When the potentiometer P is properly adjusted, voltages of equal amplitude but 180 degrees out of phase are obtained at the control grids of tubes V3 and V4.

The term phase inverter is generally associated with a circuit employing two tubes, one as an amplifier and the other as an inverter, for the purpose of obtaining two voltages which are out of phase, although very frequently the terms phase inverter and phase splitter are used interchangeably.

12.51 What is a phase splitter?—A single-ended amplifier stage with the plate load divided between the cathode and plate circuits, as shown in Fig. 12-51. The incoming signal is applied to the control grid. Two signals of equal amplitude but 180 degrees out of phase are obtained from the plate and cathode circuits which may be used for driving a push-pull amplifier stage.

To assure that the two driving voltages will be exactly the same amplitude, the plate and cathode-load resistors must be matched to within one percent of their values. It is also equally important that the coupling capacitors C between the phase-splitter stage and the push-pull stage be of as nearly the same value as possible. If the values vary over too great a range, voltages developed at the control grids of the push-pull stage will not be of the same amplitude at frequencies below 50 Hz, because of the change in the reactance of each capacitor with frequency.

12.52 Can a transformer be used as a phase splitter?—Yes; a push-pull interstage transformer is, in reality, a phase splitter as shown in Fig. 12-52. The transformer delivers to the control grids of the output stage two voltages which are of equal amplitude and 180 degrees out of phase.

12.53 What is a floating paraphase inverter circuit?—Two vacuum tubes connected to produce two voltages 180 degrees out of phase as shown in Fig. 12-53A. The incoming signal voltage is fed to the control grid of tube V1, amplified, and applied to the control grid of V3. The signal voltage for V2 is taken from the junction of a voltage-divider network consisting of resistors R_{g1} and R_{g2}. Because of the phase reversal of the signal in passiug through V1, the signal is of the correct phase for V2. The signal is again reversed in passing through V2 and then applied to the control grid of V4. Resistor R_{g3} acts as a balancing resistor because the out-

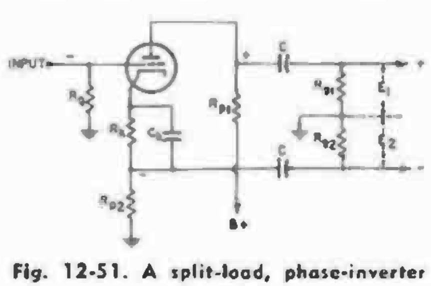

Fig. 12-51. A split-load, phase-inverter circuit.

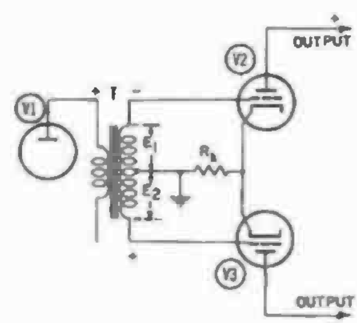

Fig. 12-52. A transformer phase splitter.

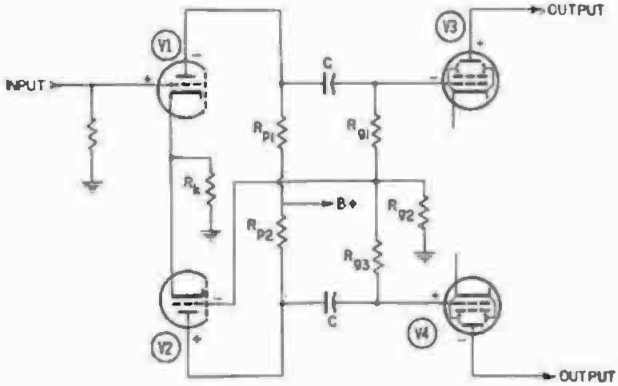

Fig. 12-53A. Floating paraphase inverter circuit.

put signals of both V1 and V2 are opposite in phase and flow through R_{g3} to ground, thus tending to cancel until a push-pull balance is achieved.

This circuit has good stability and low distortion. The common cathode resistor R_k is not bypassed. Without a signal at the input of V1, there is no feedback in the cathode circuit; however, for an unbalanced condition, feedback is generated.

A modified floating paraphase phase-inverter circuit designed to minimize out of balance conditions because of variations in tube characteristics is shown in Fig. 12-53B.

The plate currents for both halves of the tube pass through a common resistor R_{p3}. The grid swing for the second half of the tube requires only a fraction of the plate voltage swing to drive it; therefore, the control grid of the second tube is connected at the junction of the load resistors and the common resistor R_{p3}. With the proper values of resistors, the two halves of the circuit function with the same gain. If the plate currents of the two tubes were exactly the same, there would be no voltage variation across R_{p3}. The voltage variation at this point automatically adjusts itself so that the plate currents are slightly out of balance, sufficiently so to drive the second half of the tube.

12.54 What is a long-tailed phase inverter?—It is a phase inverter of a type similar to the floating paraphase and so called because of the long extension of the circuits from the plate. The inverter is essentially a cathode-coupled stage which will produce two voltages at the output having equal amplitudes and 180 degrees out of phase, as is shown in Fig. 12-54.

If a positive-going signal is applied to the grid of V1, plate current in this section will increase and a larger voltage will appear across R_1. The signal on the plate of V1 will be negative going. The increased voltage across R_1

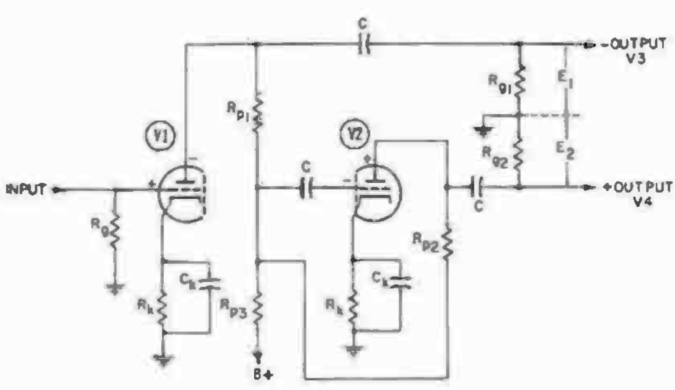

Fig. 12-53B. A floating paraphase inverter designed to minimize the variations in tube characteristics.

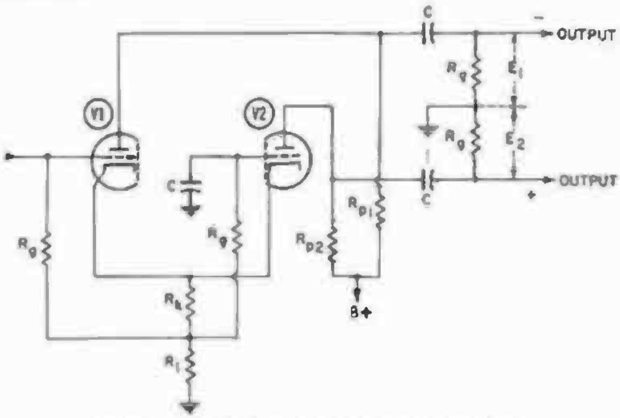

Fig. 12-54. A long-tailed phase inverter.

makes the cathode of V2 more positive than its grid. This, in effect, makes the grid of V2 more negative, the plate current in V2 decreases, and the plate voltage increases.

A common bias resistor R_k is employed together with suitable grid-leak resistors R_g. Capacitor C maintains the grid of V2 at ac ground. The size of this capacitor is important. If the capacitor is not large enough, phase unbalance will be introduced at the low frequencies, because then, in effect, the grid would not be returned to ground but to a tap on the voltage divider.

12.55 What is a fixed-bias, split-load phase splitter?—A tube connected as shown in Fig. 12-55A with two matched resistors, R_{p1} and R_{p2}, connected one in the cathode circuit and the other in the plate circuit. Signal voltages of equal amplitude, 180 degrees out of phase, are developed in the cathode and plate circuits and applied through coupling capacitors C to the control grids of a push-pull amplifier stage. Because of the high resistance in the cathode circuit of V1, the cathode is approximately 69 volts positive in respect to ground. The normal bias for a 6SJ7 tube is 9 volts. To obtain this bias voltage, a positive voltage is applied to the control grid through a 1-megohm resistor R_1 connected to the junction of the decoupling resistor R_d and the plate-load resistor R_{p1}. This places the grid 60 volts positive. With the cathode at 69 volts positive and the control grid at 60 volts positive, the control grid is 9 volts negative with respect to the cathode.

This circuit is quite stable and has good frequency characteristics with low distortion. The disadvantage of this circuit is that the gain is less than 1 for each half of the circuit. The voltage gain may be calculated:

$$V_g = \frac{2\mu R_p}{R_p(\mu + 2)r_p}$$

where,

R_p is the plate-load resistance,
r_p is the plate resistance of the tube,
μ is the amplification factor of the tube.

For best results, the load resistors R_p and the grid resistors R_g should be 1-percent resistors.

A split-load, phase-splitter circuit utilizing the diode-detector circuit of a radio receiver is shown in Fig. 12-55B. The two signals for driving the push-pull stage are taken from across the two 100,000-ohm resistors connected to the cathode of the diode rectifier. The capacitors C1 and C2 are small radio-frequency bypass capacitors and should be selected for a value that will not affect the high-frequency response.

12.56 What is an extended cathode-coupled phase inverter? — A self-balancing cathode-coupled phase inverter used for driving a single-ended push-pull amplifier such as that described in Question 12.126.

12.57 What is the equation for calculating the values of the coupling, screen-grid, and cathode capacitors for a resistance-coupled amplifier?

$$C = \frac{1}{2\pi f X_c}$$

where,

f is the lowest frequency to be amplified,
X_c is the reactance of the capacitor at the lowest frequency.

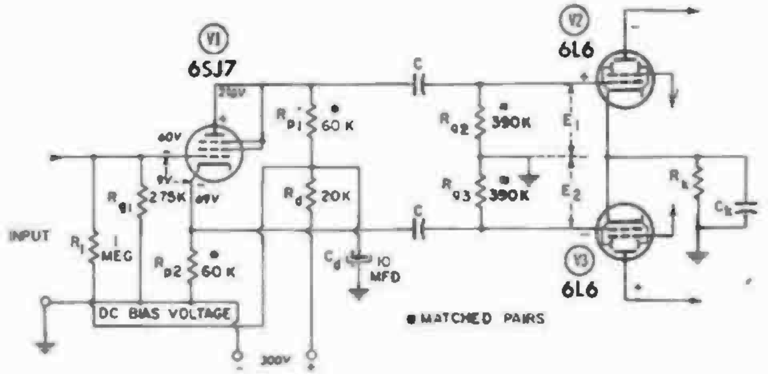

Fig. 12-55A. A split-load phase splitter with fixed bias on the control grid.

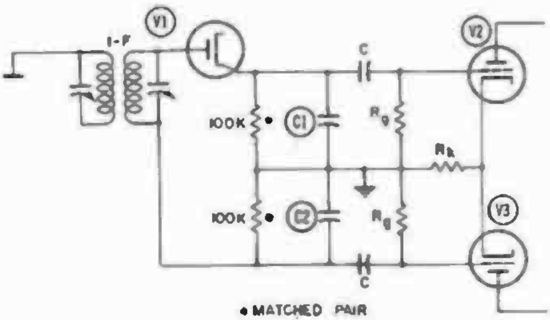

Fig. 12-55B. A phase-splitter circuit for a radio receiver using a diode rectifier.

The latter figure is based on a reactance of at least one-tenth the reactance of either the cathode resistor, screen-grid dropping resistor, or the grid resistor.

12.58 ***What is a single-ended amplifier?***—One having a single tube at the output.

12.59 ***What is a double-ended amplifier?***—It is an amplifier having two tubes at the output; a push-pull amplifier.

12.60 ***What is a parallel amplifier?***—One having two tubes of similar characteristics connected in parallel, such as two triodes with their control grids and plates connected in parallel, as shown in Fig. 12-60. This subject is further discussed in Question 12-111.

12.61 ***How are amplifiers classified?***—The classification depends primarily on the fraction of input cycle during which plate current is permitted to flow under full load conditions. The various classifications have been standardized characteristics and are known as: class-A, AB, B, and C. The dynamic operating of these amplifiers is explained in Questions 12.64 to 12.69 and 12.226 to 12.228.

12.62 ***What class amplifiers are employed for recording and broadcast purposes?***—For tube-type voltage amplifiers, class-A; for power amplifiers, class-A and class-AB. Solid-state voltage amplifiers are generally class-A, with power amplifiers operating class-B.

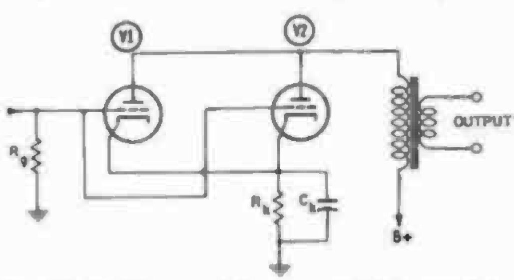

Fig. 12-60. Vacuum tubes connected in parallel.

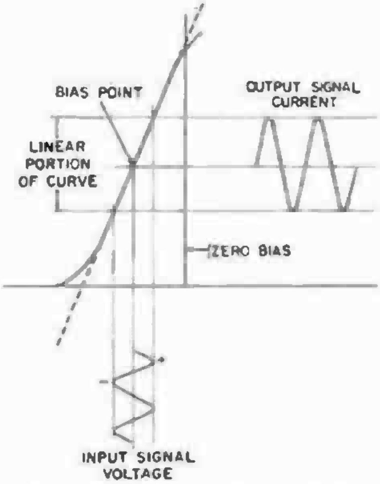

Fig. 12-63. Dynamic characteristics of a vacuum tube biased to operate class-A.

Power amplifiers of both types are always operated in push-pull.

12.63 What is a class-A amplifier? —An amplifier in which the grid-bias voltage is set to approximately one-half the cutoff voltage to obtain linear operation. (See Fig. 12-63.) The peak signal voltage at the control grid is limited to a value that will not exceed the dc grid-bias voltage. The control grid is never permitted to go positive and plate current flows at all times. Amplification is high and the harmonic distortion low. The efficiency is approximately 20 percent. Class-A amplifiers are used in high quality recording and reproducing systems. (See Question 12.226.)

12.64 What is a class-AB amplifier? —Class-A operation falls midway between class-A and class-B. Plate current flows for more than 180 degrees but less than 360 degrees of the signal at the control grid. Operating under these conditions, greater power may be obtained than with class-A and less distortion than with class-B. The efficiency is approximately 40 to 75 percent, depending on the bias voltage employed. (See Question 12.227.)

12.65 What is a class-AB$_1$ amplifier?—It is similar to the class-AB amplifier discussed in Question 12.64. The subscript indicates that grid current does not flow during any part of the cycle. The efficiency is approximately 40 percent. A typical characteristic is shown in Fig. 12-65.

12.66 What is a class-AB$_2$ amplifier?—It is a class-AB amplifier in which grid current is permitted to flow during some part of the input cycle. The efficiency is approximately 40 percent. A typical characteristic is shown in Fig. 12-66. Tubes biased for class-AB$_2$ are generally operated push-pull.

12.67 What is a class-B amplifier? —An amplifier that is biased at or near cutoff. Plate current flows during the positive half of the input grid signal and stops flowing during the negative half-cycle. The efficiency is from 40 to 60 percent. A typical characteristic is shown in Fig. 12-67. (See Question 12.228.) Tubes biased for class-B operation are operated push-pull.

12.68 Are any of the foregoing amplifiers operated as single-ended amplifiers?—Only the class-A and class-AB. Class-B amplifiers are always operated in push-pull.

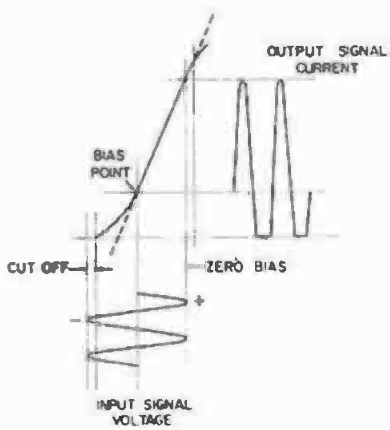

Fig. 12-65. Dynamic characteristics of a vacuum tube biased to operate class-AB.

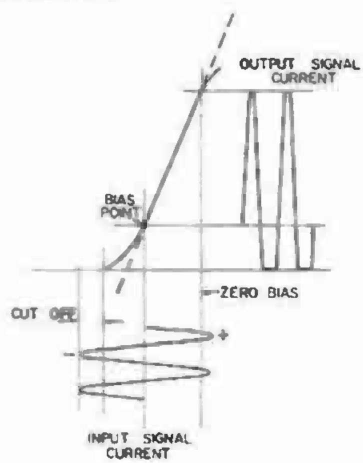

Fig. 12-66. Dynamic characteristics of a vacuum tube biased to operate class-AB$_2$.

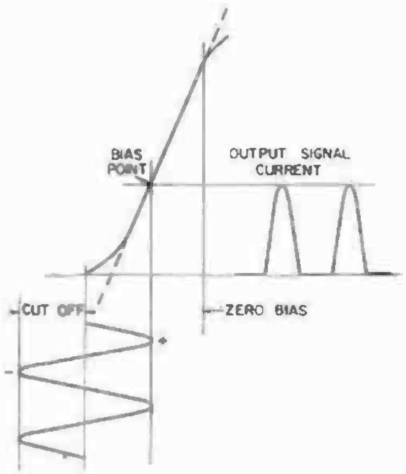

Fig. 12-67. Dynamic characteristics of a vacuum tube biased to operate class-B.

12.69 What is a class-C amplifier? —One whose operating point is located well beyond the plate-current cutoff point so that plate current flows for appreciably less than one-half cycle. (See Fig. 12-69.) Class-C amplifiers are used only for radio-frequency amplifiers where large power output and high efficiency are required. The efficiency of a class-C amplifier is in the order of 60 to 80 percent. The high distortion of a class-C amplifiers is overcome by the flywheel effect of the tuned circuits used.

12.70 What is a voltage amplifier? —An amplifier employed under conditions where voltage output is more important than power. Of course, all amplifiers produce power, although it may be rather small. Voltage amplifiers seldom produce more than one watt of power.

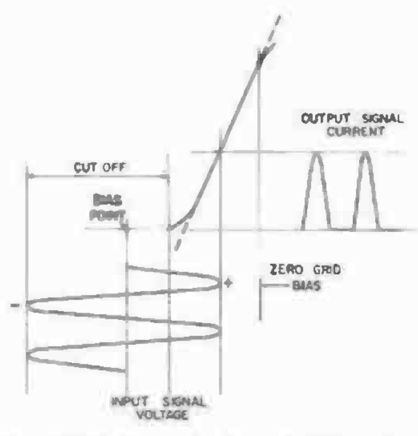

Fig. 12-69. Dynamic characteristics of a vacuum tube biased for class-C operation.

12.71 What is a power amplifier? —One which delivers a considerable amount of current to the load. The output impedance of a power amplifier is low, as a rule (16 ohms or less). However, many power amplifiers delivering a considerable amount of power have 600-ohm outputs for driving cutting heads and similar devices. Power amplifiers may be designed to deliver several hundred watts and are sometimes referred to as current amplifiers.

12.72 What is a preamplifier?—A small voltage amplifier used with photocells, pickups, and microphones, or any place where 30-50 dB of gain is required with a low-level output. Preamplifiers are designed to have extremely low noise and distortion, with or without equalization. A typical circuit for a microphone preamplifier suitable for recording purposes is shown in Fig. 12-72.

High-frequency equalization of up to 8 dB at 10,000 Hz may be introduced by varying the size of capacitor C1 and resistor R1 in the feedback loop in the cathode circuit of V1. The value of the capacitor C1 establishes the takeoff point of the equalization, and resistor R1 the magnitude of the equalization.

The amplifier shown has approximately 44 dB of gain and a frequency characteristic flat within 1 dB from 40 to 10,000 Hz in a nonequalized condition. The noise level is approximately 80 dBm. The distortion at plus 10 dBm is less than one percent. Preamplifiers are sometimes called preliminary amplifiers. The high-frequency response may also be varied by the value of capacitor C2 in the cathode circuit of V2. The 5-mH choke is used for eliminating rf interference.

12.73 What is a booster amplifier? —A small voltage amplifier similar to a preamplifier. It is used to compensate for the insertion loss of equalizers, or when a piece of equipment with a high insertion loss is inserted into a circuit. Also, it may be used in split-mixer circuits to compensate for the insertion loss of master and submaster gain controls. The frequency response is generally flat. High-power bridging amplifiers used with public address systems are sometimes referred to as booster amplifiers.

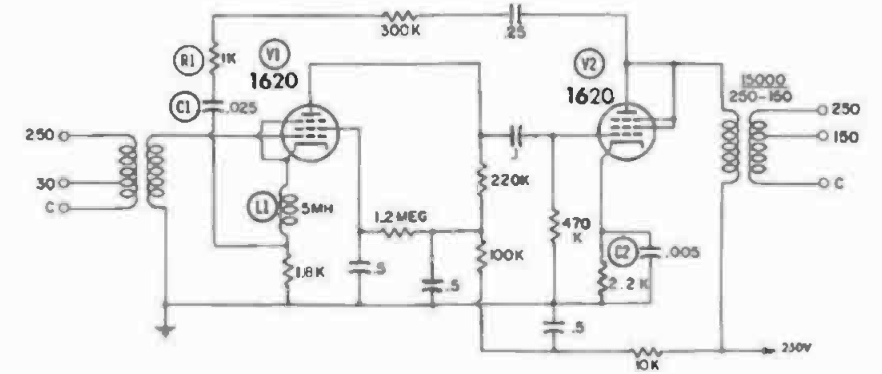

Fig. 12-72. A microphone preamplifier. Resistor R1 and capacitor C1 in the feedback loop control the high-frequency rise. The rf choke L1 is used to eliminate radio-frequency interference.

12.74 What is a line amplifier?—An amplifier following the output of a mixer network which, in turn, may feed a line or bridging bus. Line amplifiers generally are of medium gain, low distortion and noise with an output level of +20 dBm. In recording circuits they may be called recording amplifiers.

12.75 What is an isolation amplifier?—An amplifier of medium gain, with a variable gain control, consisting of several large and small steps so that the gain may be set for no-gain operation. It is used to isolate terminal equipment from a line, or to separate two devices to prevent interaction.

12.76 What is a monitor amplifier?—A high-quality amplifier used for listening to broadcast or recording circuits. Generally of medium gain with considerable power output, it must be of low distortion and noise. Input impedance may be matching or bridging.

12.77 What is a mixer-amplifier?—A portable amplifier used for remote broadcast purposes. It generally consists of three to four preamplifiers, mixer controls, line amplifier, volume indicator, and provision for monitoring the program. The schematic diagram for a typical portable broadcast mixer-amplifier is shown in Fig. 12-77. The amplifier is capable of producing a plus 22 dBm signal at the input of the line pad. Total gain is approximately 82 dBm. The frequency response is plus or minus 2 dB from 300 to 10,000 Hz with a slow rolloff below 300 Hz; at 100 Hz minus 4 dB and at 50 Hz minus 8 dB.

Center-tapped *balanced - to - ground* repeat coils are connected in each input circuit to isolate ground effects from external lines or equipment. (See Question 23.14.)

12.78 What is a direct-current amplifier?—Although a direct-current amplifier may be designed to amplify over a wide range of frequencies, its greatest use is in medical equipment where frequencies of 3 Hz or less and small pulses of direct current must be amplified.

Direct-current amplifiers are slow acting and rather unstable. Such amplifiers are not normally used in audio-frequency applications.

12.79 What is a compressor amplifier?—A special amplifier used for recording. Adjustments are available to adjust the characteristics for limiting the signal to a given output, or to compress the signal into a given volume range. Either characteristic may be used without excessive distortion.

When set for limiting, the amplifier acts as a ceiling control. When set for compressing, the output is held to a given maximum output level although the input signal increases in level.

When used for film recording, an additional circuit called a de-esser is switched in to remove or reduce the effect of sibilance in dialogue. Compressors are treated in detail in Questions 18.86 to 18.102.

12.80 What is an automatic level control compressor amplifier?—An automatic volume control amplifier designed to function both as an automatic level setting and compression amplifier. Such amplifiers are used with public address and background music systems. When used for background music application, it is set to maintain an *average level relative to the ambient noise level.* When the level has been established, it requires no further attention. The schematic diagram for an Altec-Lansing Model 436B compressor amplifier is shown in Fig. 12-80A, and its compression characteristics are given in Fig. 12-80B. Compressor amplifiers used for recording purposes are discussed in Questions 18.84 to 18.102.

12.81 *What is a side amplifier?*—The control amplifier used with a compressor-limiter or expander amplifier.

12.82 *Define the term off-set voltage or current.*—The term off-set is generally associated with dc or differential amplifier. It is the potential difference existing between the output with no signal at the input, and is caused by unbalance in the flow of current from two differential transistors or vacuum tubes to ground. Under these conditions, two voltages exist that are *unequal to zero.* Also, an off-set voltage is present if the two voltages are unequal to each other.

Assume two transistors are used in a differential amplifier; the off-set volt-

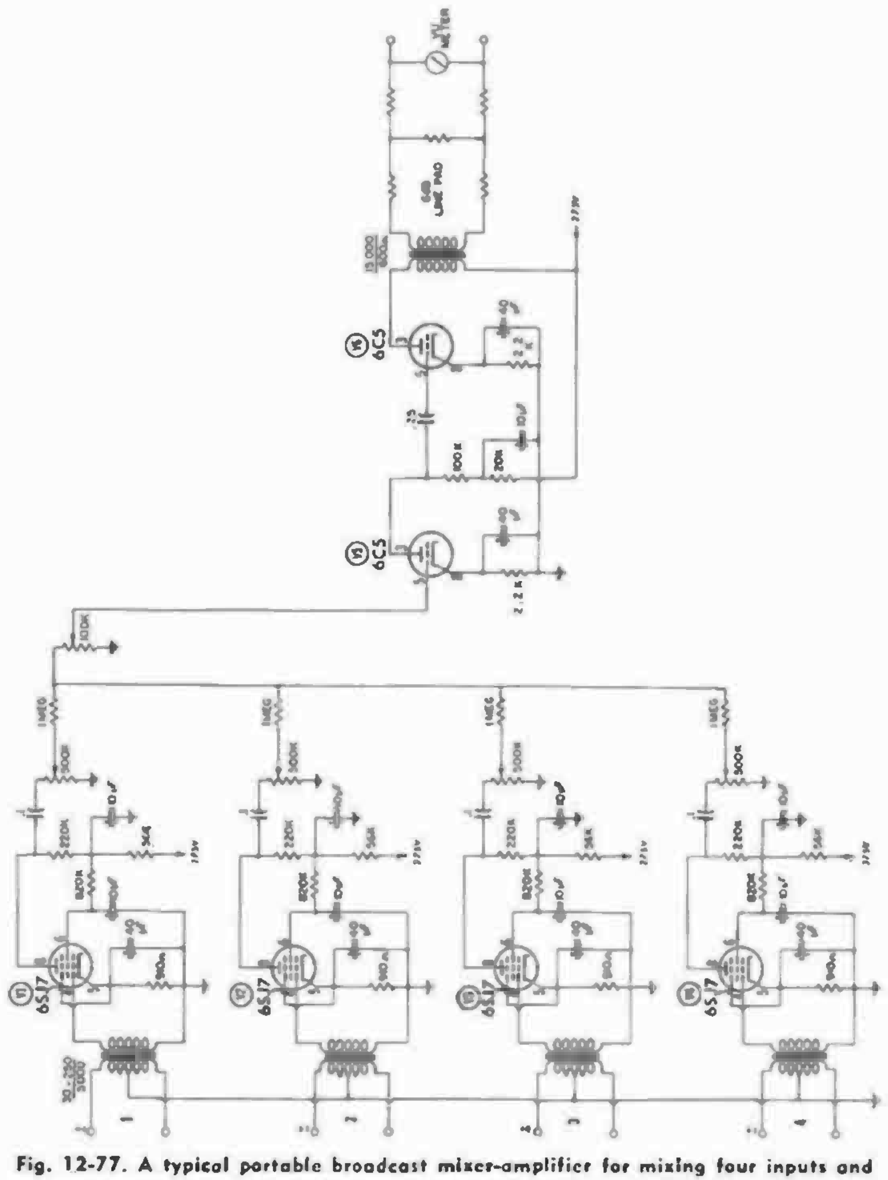

Fig. 12-77. A typical portable broadcast mixer-amplifier for mixing four inputs and feeding a 600-ohm line.

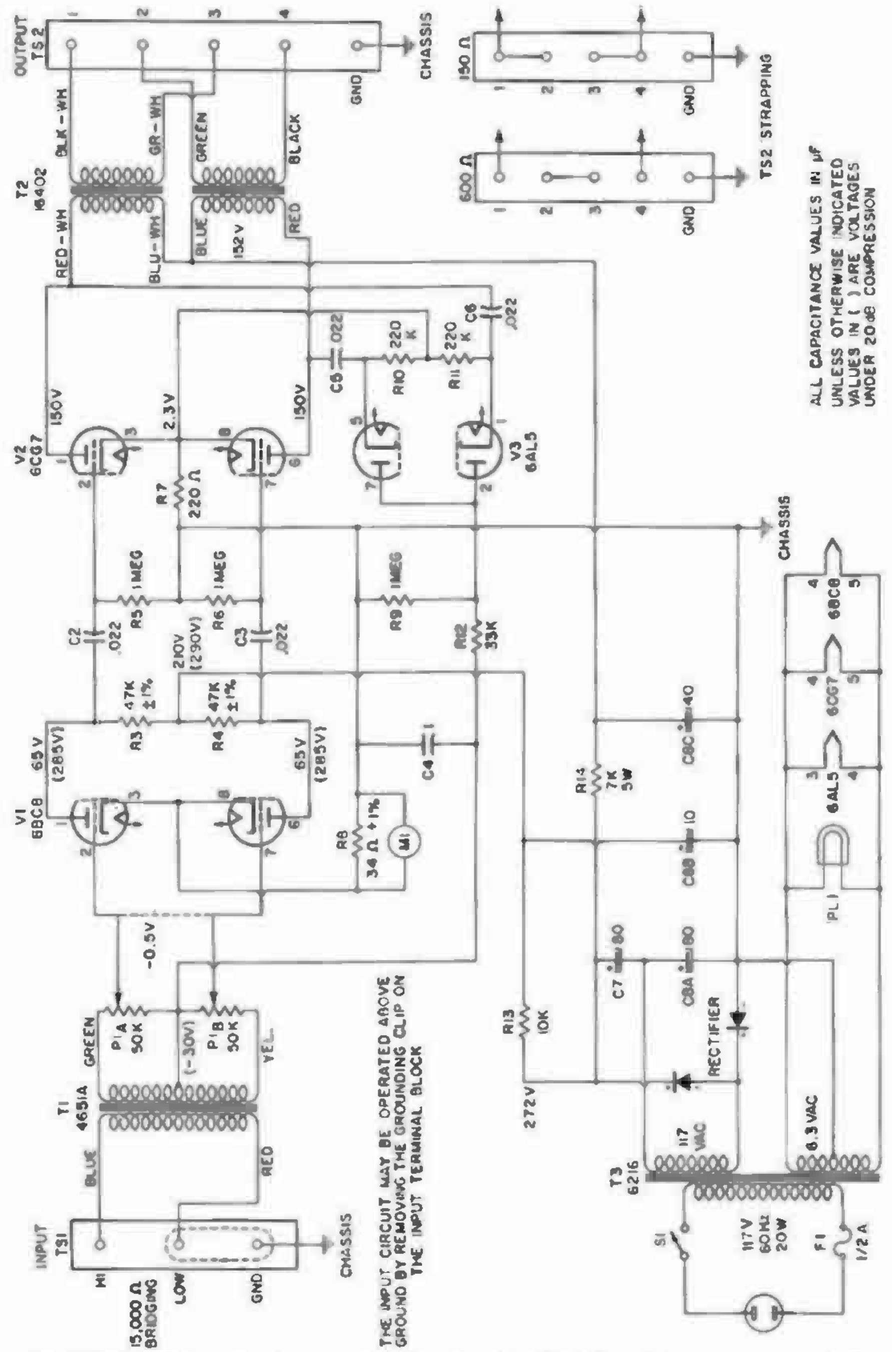

Fig. 12-80A. Schematic diagram for Altec-Lansing Model 436B compressor amplifier.

age, referred to the input, is simply the differential output off-set voltage divided by the double-ended voltage gain of the circuit. Using this method, a signal is applied to one input of the differential amplifier and varied until the differential output voltage is reduced to zero. The magnitude of the input voltage is then the off-set voltage *referred* to the input. Another method used is to reduce the base resistors to zero by shortcircuiting the input circuits to ground. Output off-set voltages measured in this manner are restricted in that unbalances caused by unequal base currents (beta) or by unequal base resistances are excluded. However, other unbalances are included in the measurement.

Unbalance is due to small variations in the geometry of the transistors, and also to differences in beta, internal resistance, thermal resistance, heat-flow paths, external resistances, and the leads within the transistor. (See Question 12.196.)

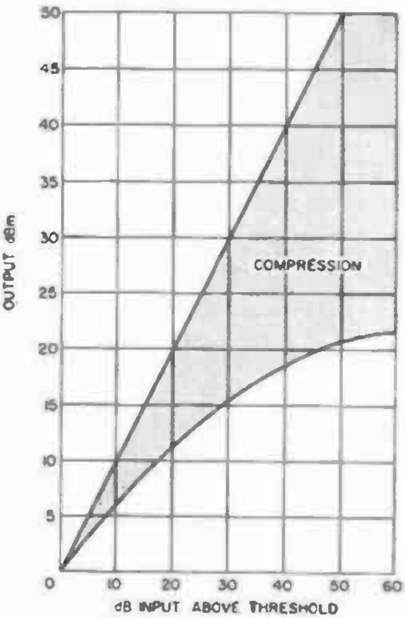

Fig. 12-80B. Compression characteristics for the Altec-Lansing Model 436B compressor amplifier.

12.83 What Is a noise-reduction (NRA) amplifier?—A special amplifier used for recording optical film to reduce the area of exposure on the film during periods of low or no modulation. It is also called a ground-noise reduction amplifier. (See Questions 18.55 to 18.76.)

12.84 Describe a program-leveling amplifier using electroluminescence control.—In broadcasting program material, some type of control system is required to prevent overmodulation of the transmitter. The control device is generally set for as near 100-percent modulation of the transmitter as possible, without overmodulation. To do this requires a control amplifier that limits the program peaks to a predetermined value so full advantage may be taken of the transmitter output. The use of conventional limiters or compressors in stereophonic broadcasting has posed problems such as unequal limiting between the left and right sides, causing an apparent loss of stereo balance. The Model LA-2A leveling amplifier (Fig. 12-84A) to be described is manufactured by Teletronix Engineering Co., and is designed especially for stereophonic and monophonic broadcasting and recording systems.

The description to follow is based on its monophonic use. The amplifier has essentially instantaneous gain reduction over a range of 40 dB, with no increase in harmonic distortion. The compression characteristics are shown in Fig.

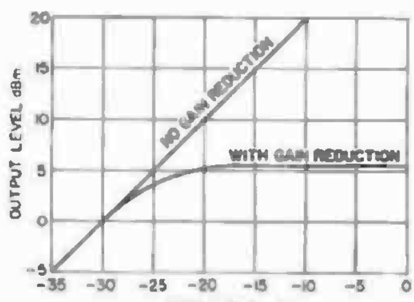

Fig. 12-84B. Gain-reduction characteristics of Teletronix Engineering Co. Model LA-2A leveling amplifier.

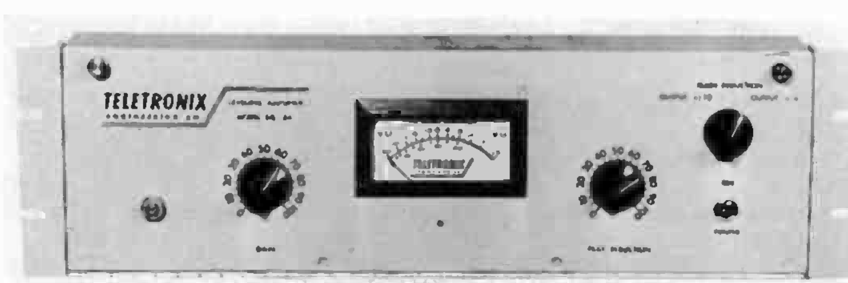

Fig. 12-84A. Teletronix Engineering Co. Model LA-2A leveling amplifier.

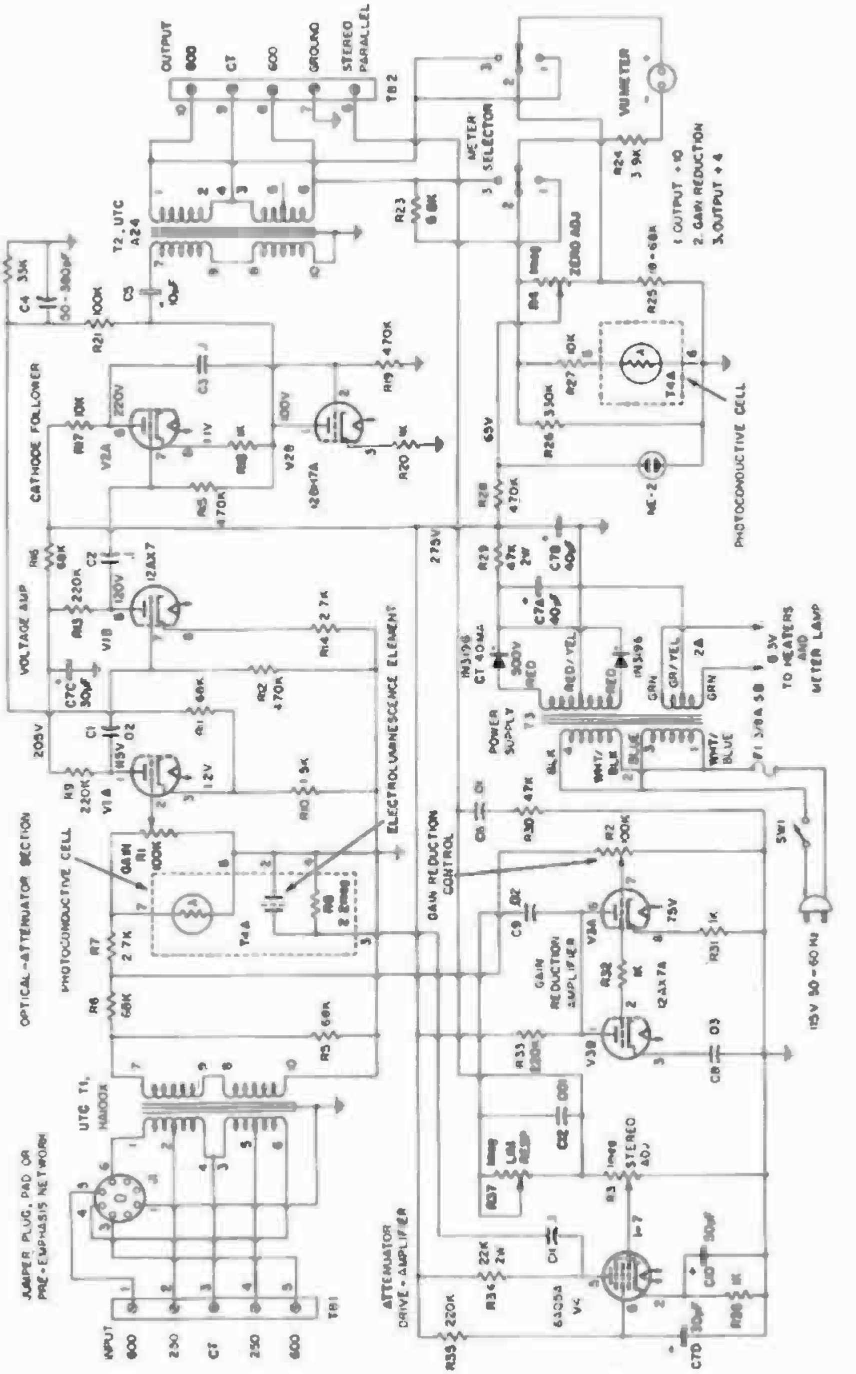

Fig. 12-84C. Schematic diagram for Teletronix Engineering Co. leveling amplifier Model LA-2A.

12-84B. Compression action starts at the breakaway point at minus 30-dB input and continues up to minus 20 dB, at which point the curve becomes horizontal or limiting in its action. When increasing the input signal another 20 dB, the output is held to within 1 dB. Thus, both compression and limiting are combined in its action. The heart of the leveling amplifier is an *electro-optical attenuator system* which is connected ahead of the voltage-amplifier stages.

The advantage of this type attenuation system is that the voltage-amplifier gain is fixed and not varied as in the conventional compressor-limiter. (See Question 18.84.)

The optical attenuator consists of a photoconductive cell which is optically coupled to an electroluminescence light source. This device provides a light intensity which is proportional to the audio voltage applied to its terminals. The gain or level-controlling element is a photoconductive cell. The internal resistance of the cell decreases with an increase of light intensity impinging on the luminous surface. Since light is produced by the audio-signal voltage, the response of the amplifier is instantaneous. Because no electrical filters are required in the control circuits, the speed of operation is limited only by the characteristics of the photoconductive cell. The cell will provide extremely fast attack and release times, the release time being about 60 milliseconds for 50-percent gain reduction, then a gradual release over a period of 1 to 15 seconds to a point of complete release. This device is further discussed in Question 5.97.

Referring to the schematic diagram of Fig. 12-84C, the input signal is applied directly to the optical attenuator from input transformer T1. At this juncture the signal is sent in two directions, to the input of voltage amplifier V1A through gain control R1 and through R2 at V3A from the junction of R6 and R7. The signal passes through V3A and V3B and is capacity-coupled through the limiting-response control R37 and stereo control R3 to the control grid of V4, the electroluminescence attenuator drive amplifier, and back to the lamp of the optical attenuator which controls the amount of attenuation and signal level to voltage amplifier V1A and V1B. The signal level to the voltage amplifier is also controlled by gain control R1. The voltage-amplifier stages have a net gain of 40 dB, with a feedback loop from the plate of V2A supplying 20 dB of negative-feedback voltage back to the cathode of V1A. The output stage consists of a single 12BH7A tube connected as a double cathode follower (see Question 12.45), providing a very low output impedance, and flat frequency response with low distortion.

For stereophonic broadcasting, an output signal is taken from the junction of limiting control R37 and stereo control R3 and brought out to terminal 6 on the right hand terminal strip. When two leveling amplifiers are used for stereo broadcasting, this terminal is connected to a similar terminal on the second amplifier; thus, the control voltage becomes common to both amplifiers. A gain-reduction control voltage generated at either amplifier will cause equal gain reduction in both amplifiers. The VU meter serves two functions; it indicates the output level and the gain reduction in dB.

During periods of no gain reduction, the meter reads zero. The scale is calibrated in terms of a standard VU meter. The VU meter circuitry consists of a zero-set control, and a second photoconductive cell connected across the balance circuit. The cell decreases its resistance in accordance with the intensity of the optical attenuator. Thus, the VU meter is made to follow the variations in gain reduction with the attenuation of the voltage amplifier. The NE-2 neon lamp acts as a voltage regulator to stabilize the 65 volts used for energizing the balance circuit.

The device is capable of 30-dB gain reduction or limiting, with less than 0.5-percent harmonic distortion. The gain reduction is a function of input level and is independent of frequency.

12.85 ***Describe a program-distribution amplifier?***—An amplifier or amplifier system for distributing a program signal to a number of feeds or services simultaneously. Figure 12-85A shows such an amplifier with a simple resistive combining network in its output for supplying six individual services. The combining network is of the conventional balanced type commonly used for sound mixers. The design of such networks is described in Questions 9.25 and 9.44. Disadvantage of the circuit shown is that little isolation between circuits is afforded, and if trouble should develop on any one feed circuit, the whole transmission may be lost.

Combining amplifiers have also been designed by making the output impedance of the amplifier very low, on the order of 1 to 2 ohms. The feed lines are then connected across this low output impedance using bridging impedances of 1000 ohms. If one of the feed circuits is shorted using this arrangement, little effect will be noted unless grounding troubles develop. This type circuit should be used only as a last resort.

The most desirable type program-distribution system is that shown in Fig. 12-85B, where each feed circuit has its own individual amplifier, affording complete isolation from the other circuits. Now if trouble develops, only the circuit concerned will be affected.

The system shown in Fig. 12-85B was developed for feeding radio and television networks, recording equipment, and public address systems simultaneously. The program signal is fed from the output of a mixer at a level of plus 4 dBm over a 600-ohm line to the bridging bus of the distribution amplifier system. Twenty-two plug-in amplifiers of the type shown in Fig. 12-85C are bridged across the bus. Normally, the amplifiers are designed to operate from a 600-ohm source; however, for this particular application a bridging resistor of 30,000 ohms is connected in series with one side of the 600-ohm input transformer. A 600-ohm resistor is connected internally in parallel with the 600-ohm input in the amplifier. These two resistors form a 30,000-ohm bridging input pad as shown in Fig. 12-85D. Installing the 600-ohm resistor in the amplifier and the 30,000-ohm series resistor at the bus will permit the replacement of any amplifier without resorting to the use of a soldering iron. Amplifiers 19 and 20 employ a 10,000-ohm bridging pad. This was done to obtain an output level of plus 8 dBm for feeding broadcast lines. All other outputs are zero dBm.

For feeds requiring a lower level, external pads are used. Connection of the pad at the input of the source being fed, rather than at the output of the program distribution amplifier (if the line is long), increases the signal-to-noise ratio as described in Question 23.133.

The method in which this amplifier was used on one remote installation to feed 22 different sources is shown in Fig. 12-85E. The circuit diagram of a Langevin Type 5116 plug-in amplifier is shown in Fig. 12-85F. Two views of the completed program-distribution amplifier appear in Figs. 12-85G and H. The microammeter in the rear view (Fig. 12-85H) is used for measuring the plate currents of the tubes and is actuated by small push buttons on each amplifier chassis.

Two power supplies may be seen on the lower shelf of Fig. 12-85G. The outputs of all amplifiers are terminated on binding posts to facilitate the connection to lines and the connection of attenuator networks. Three Cannon XL connectors are provided for the mixer output and two output circuits for feeding magnetic recorders.

The overall noise level of the amplifiers is minus 79 dBm. Distortion is 0.11 percent at 400 Hz. The frequency response is flat within plus or minus 1 dB from 30 to 16,000 Hz.

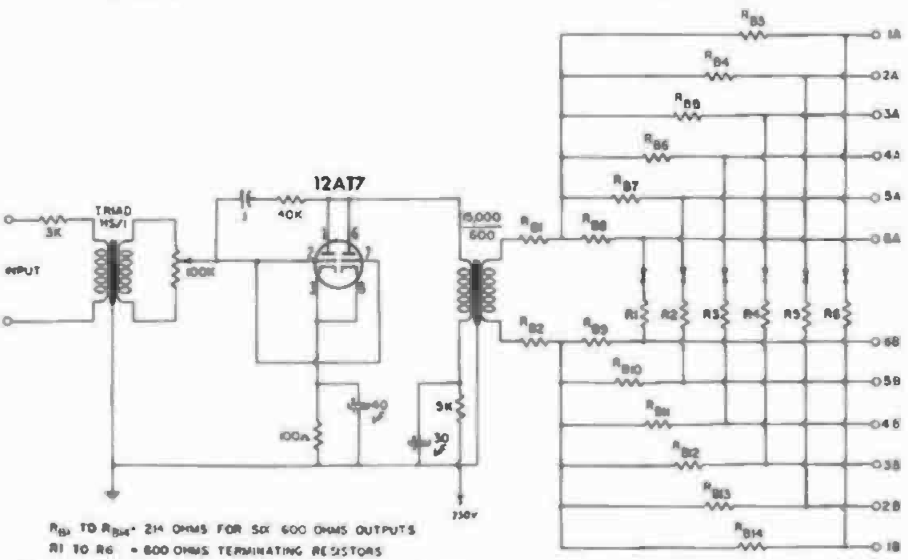

Fig. 12-85A. Program-distribution amplifier using a resistive network in the output.

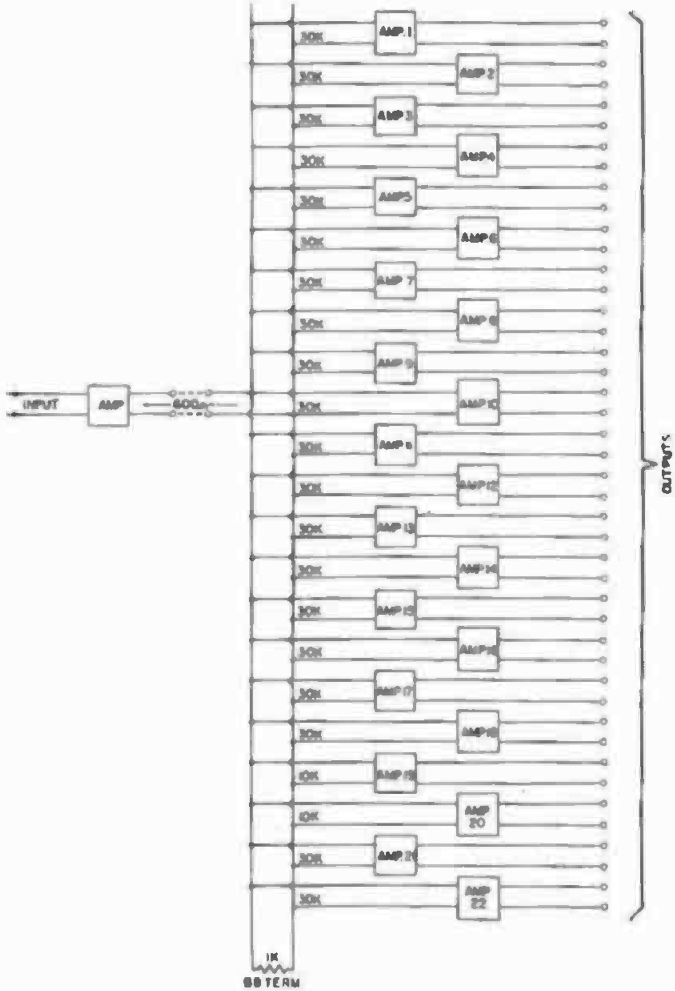

Fig. 12-85B. Program distributing amplifier system employing 22 separate amplifiers, one for each feed circuit. Amplifiers 19 and 20 employ 10,000-ohm bridging pads to raise the output level to plus 8 dBm.

Fig. 12-85C. Langevin type 5116 plug-in amplifier.

12.86 Describe a differential amplifier.—The term differential associated with an amplifier may be rather misleading; in reality, it is a difference amplifier. Such amplifiers are used in oscilloscopes for displaying a voltage difference that exists at every instant between the two signals applied to its inputs. When such an amplifier is used with an oscilloscope and two signals

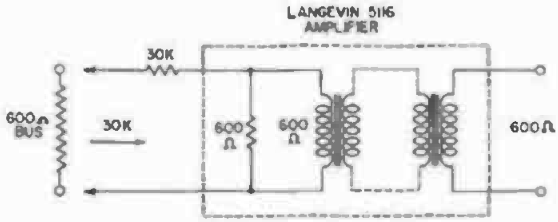

Fig. 12-85D. Bridging pad configuration.

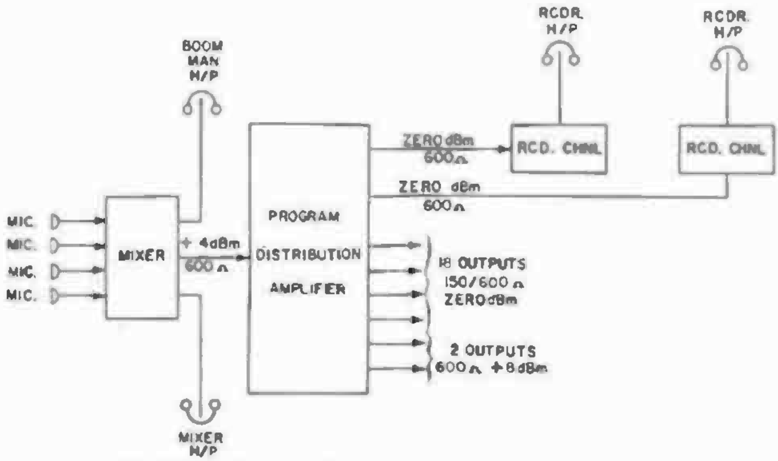

Fig. 12-85E. Block diagram for program-distribution amplifier system.

differing in both amplitude and coincidence are applied, the oscilloscope will display a complex waveform that represents the instantaneous difference between the two signals. On the other hand, when the two signals are identical in every respect, no display will appear on the oscilloscope cathode-ray screen.

The term differential implies a rejection of equal amplitude and coincident signals. However, the degree of rejection depends on the two amplifiers being identical. As this cannot be obtained in practice, the amount of rejection for a particular design is stated as a ratio between the two amplifiers, and is called the common-mode rejection ratio. Ratios of 20,000:1 are not uncommon. The design of such amplifiers is discussed in Question 22.72.

12.87 What is a bridging amplifier? —An amplifier having an input impedance of 10,000 ohms or greater and employing a special input transformer. Such amplifiers are designed to operate

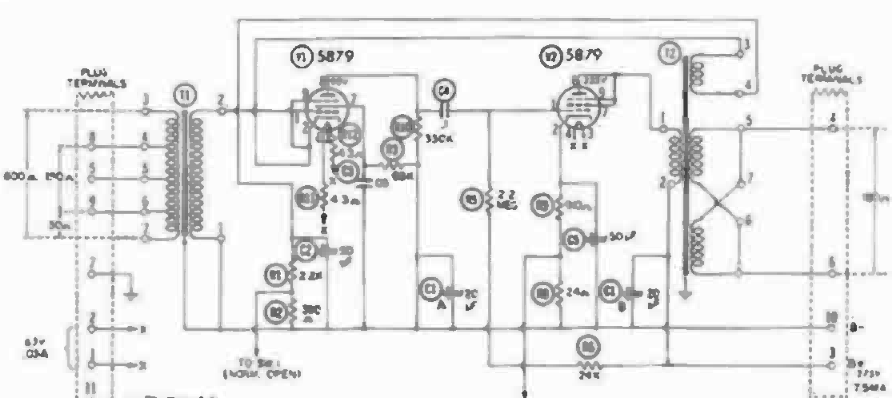

Fig. 12-85F. Circuit diagram of Langevin type 5116 plug-in amplifiers.

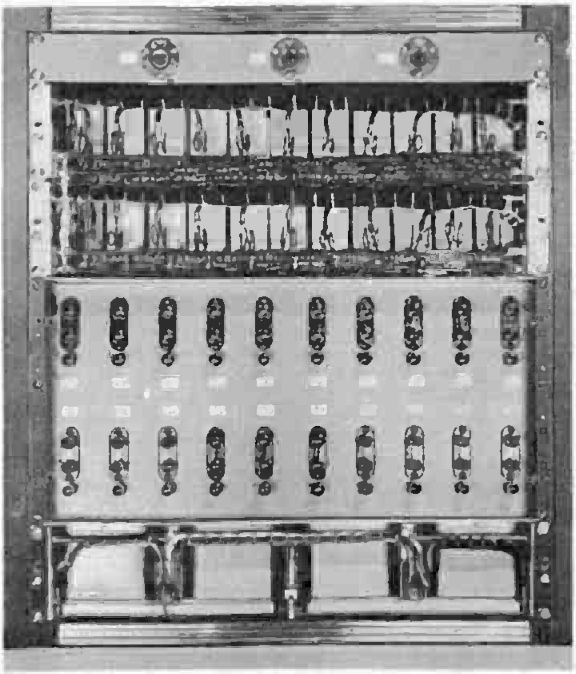

Fig. 12-85G. Front view of program-distribution amplifier showing the bridging bus and output terminals. (Courtesy, Lookout Mountain Air Force Station.)

from a low-impedance source, such as 600 ohms or less. Standard bridging impedance are: 10,000, 20,000, 25,000, and 30,000 ohms.

12.88 What is a cascoded amplifier?—An amplifier tube or tubes connected in such a manner that unusually low internal noise is obtained with high gain. A typical cascoded amplifier, as might be used in a piece of test equipment, is shown in Fig. 12-88A. The amplifiers consist of three tubes: a 12AT7,

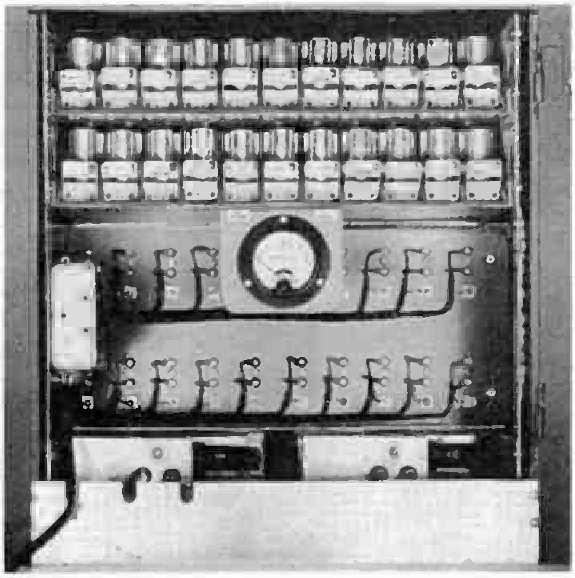

Fig. 12-85H. Rear view of program-distribution amplifier showing the 22 plug-in amplifiers. The power supplies are at the bottom of the case. (Courtesy, Lookout Mountain Air Force Station.)

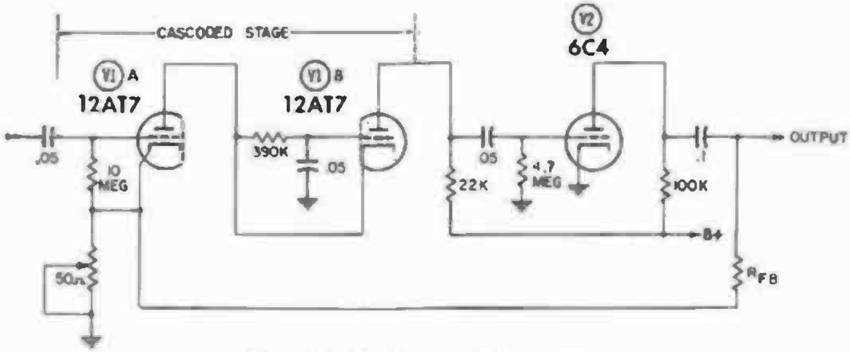

Fig. 12-88A. A cascoded amplifier.

V1A and V1B, an output tube V2, and a 6C4 medium-mu triode.

Tube V1A acts as a conventional voltage-amplifier stage. The plate load for this stage is supplied by the plate resistance of V1B and the 22,000-ohm resistor in the plate circuit of V1B. The signal voltage is amplified by V1A and direct-coupled to the cathode of V1B.

The gain in V1B is obtained by connecting its control grid through an 0.05-μF capacitor to ground and isolating the control grid from the cathode of V1B by means of a 390,000-ohm resistor. Thus, the control grid of V1B remains at a fixed potential while the cathode voltage is varied. This causes V1B to act as a grounded-grid amplifier.

Plate loading for V1B is supplied by a 22,000-ohm resistor in the plate circuit. The output signal voltage is coupled from the plate of V1B through an 0.05-μF capacitor and applied to the control grid of V2. The output signal is coupled through a 0.1-μF capacitor and returned to the cathode of V1A, creating a negative-feedback loop.

Current changes in the cathode circuit of V1A cause a change in the feedback voltage; consequently, the gain is changed. In this manner, gain stability is achieved. The variable resistor in the cathode circuit of V1A may be used to vary the gain over a limited range. A vacuum-tube voltmeter using a cascoded amplifier is described in Question 22.101.

A cascode preamplifier circuit developed by H. Wallman which has unusually low internal noise is shown in Fig. 12-88B.

12.89 What is an expander amplifier?—A reproducer amplifier with a nonlinear characteristic designed to increase its output level during loud passages of recorded music for the purpose of increasing the dynamic range. The amount of expansion is controlled by a rectifier in the side amplifier which utilizes the input signal to control the rate of expansion.

Volume-expansion amplifiers are, in reality, variable gain amplifiers that amplify the louder passages louder but have little effect on the low-level passages. Thus, an approach is made to the original volume range of the program material. Volume expansion is not used in professional recording and reproducing equipment because of the difficulty in maintaining the correct ratio between the recording compression and the reproducing expansion. Volume expansion has seen some use in home reproducing equipment; however, unless it is carefully controlled,

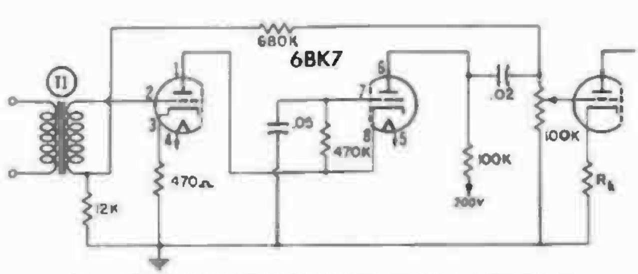

Fig. 12-88B. The Wallman cascode preamplifier.

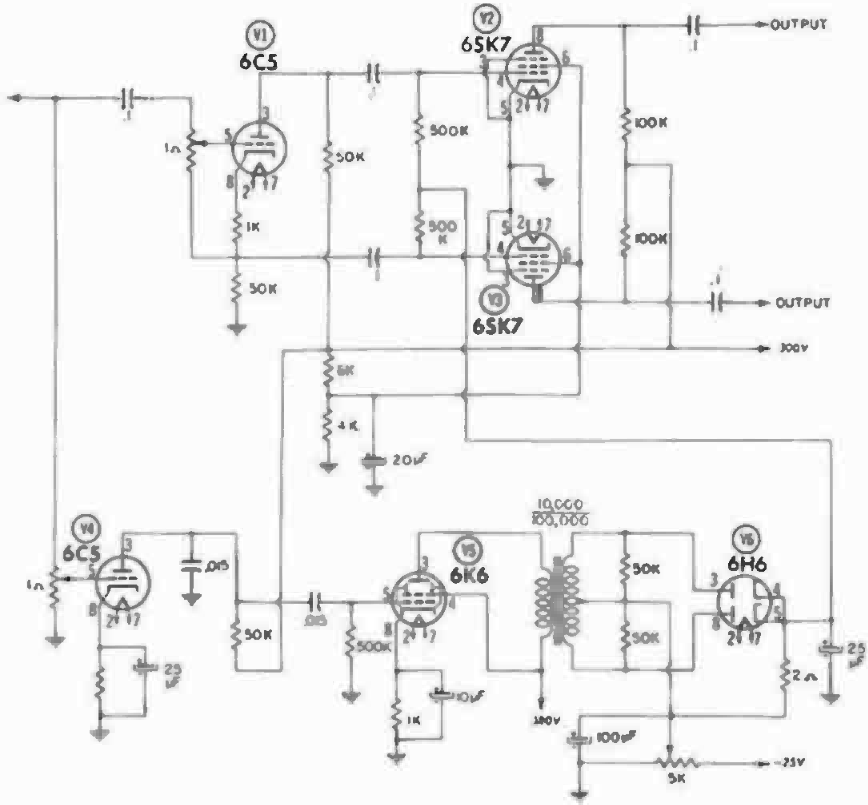

Fig. 12-89. A volume-expander amplifier.

volume expansion introduces distortion and will produce listening fatigue. Also, with the modern methods of recording, volume expansion is not required because of the wide dynamic range recorded in the original masters.

The circuit for a typical volume expander is shown in Fig. 12-89. The input signal is applied to the control grid of V1, a phase inverter, and then to the control grids of the push-pull stage, V2 and V3. Simultaneously, the input signal is applied to the control grid of a side amplifier V4 and then to V5 which is transformer-connected to a full-wave rectifier V6. The output from V5 is rectified and applied to the control grids of the 6SK7 variable-mu tubes in the output stage. An initial bias voltage is set by pot P1 in the rectifier circuit which establishes the amount of volume expansion. The changing value of the rectified dc signal at the output of V6 controls the amount of amplification of the variable-mu tubes V2 and V3. Thus, volume expansion controlled by the amplitude of the program signal is achieved.

12.90 What is a compander?—An amplifier similar to an expander, except for this important difference—the music in the original recording is compressed within a given range. When reproduced by the compander amplifier, the program material is expanded in the same ratio as recorded. Because of the difficulty in controlling the recording and reproducing characteristics, this system has not been used to any great extent.

12.91 What is a tuned amplifier?—An amplifier designed to pass only a given band of frequencies. It is used in audio test equipment and radio-frequency amplifiers.

12.92 What is a transformer-coupled amplifier?—An amplifier in which the stages are coupled by transformers, as shown in Fig. 12-92.

12.93 What is an impedance-coupled amplifier?—An amplifier coupled between stages by means of large choke coils in both the plate and grid circuits, as shown in Fig. 12-93.

The disadvantage of this type coupling is that the choke in the plate circuit must have a reactance at least

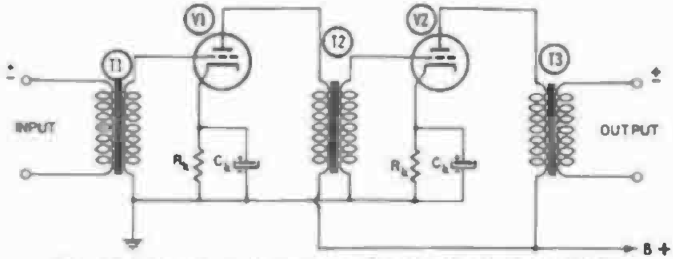

Fig. 12-92. A two-stage, transformer-coupled amplifier.

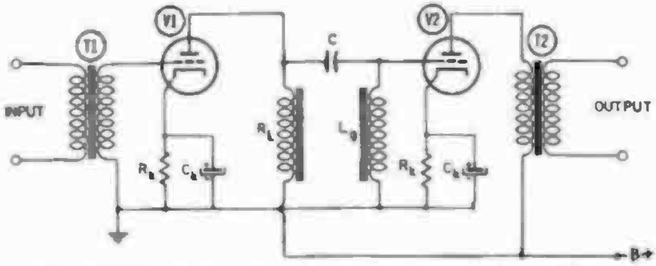

Fig. 12-93. A two-stage, impedance-coupled amplifier.

twice that of the plate resistance of the tube at the lowest frequency to be amplified. The choke in the grid circuit must also be of large proportions, which complicates the design, because the distributed capacity in the windings affects the high-frequency response.

12.94 What is a video amplifier?—A wideband, resistance-coupled amplifier with a frequency response from a few hertz up to several megahertz. They are used as picture amplifiers in television sets, radar equipment, oscilloscopes, and many similar types of equipment requiring extremely wide frequency characteristics.

12.95 What are in-phase amplifiers?—Amplifiers using cascode, grounded-grid, and inverted-input circuits. The input and output signals are in phase with each other.

12.96 What does the term rolloff mean?—The frequency response is slowly tapered off at either end of the frequency response curve for the particular device.

12.97 How many times does the phase of a signal reverse in an amplifier?—The number of phase reversals will depend on the number of tubes, transformers, etc. A typical two-stage amplifier is shown in Fig. 12-97 with the phase reversals shown by the instantaneous sines above the circuits. The total phase reversal for the amplifier shown is 720 electrical degrees.

For a single-stage *transistor* amplifier, the only configuration that will provide 180 degrees phase reversal between the input and output circuit is the grounded-emitter circuit. (See Question 11.60.)

12.98 What are considered good engineering practices in the design of audio amplifiers?—When practical, the power-output capabilities of an amplifier should be 6 to 10 dB higher than the working output level. The total rms

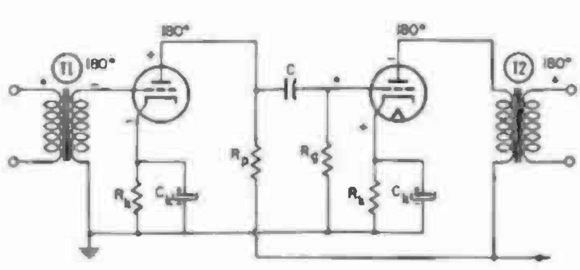

Fig. 12-97. Phase reversals in a two-stage, transformer resistance-coupled amplifier. Total phase reversals equal 720 electrical degrees.

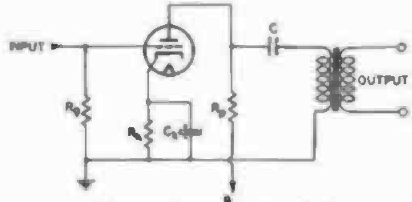
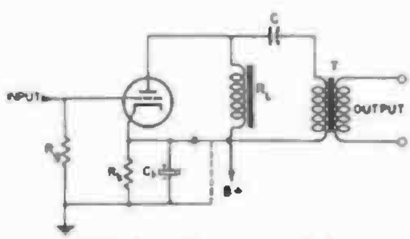
harmonic distortion should not exceed two percent at the maximum power output level, and one percent in the operating level. The internal noise should not be less than 40 dB below the maximum power output for monitor and sound reinforcement systems. For recording systems, it should be at least 60 dB.

12.99 Is it practical to couple a tetrode or pentode by means of a transformer?—No; the plate impedance is too high. Such tubes are generally resistance-coupled. This statement should not be applied to a beam-power tube which is a power-output tube and may be classed as a tetrode or a pentode, depending on its internal structure. (See Question 11.25.)

12.100 What is parallel-plate coupling a transformer?—Many times the manufacturer of a high quality transformer will specify that the transformer is to be operated with zero direct current in the primary winding to prevent saturation of the core. Referring to Fig. 12-100, the primary of the transformer is fed from the plate of the driver tube through a large coupling capacitor and the lower end of the transformer is returned either to the cathode of the driver tube or to ground. A resistor or an inductance is connected in the plate circuit of the tube to carry the plate current. Thus, only the ac signal current flows through the primary of the transformer. The coupling capacitor C must be of such a value that it does not



(a) *Resistance coupled.*



(b) *Impedance coupled.*

Fig. 12-100. Transformers parallel-coupled to the output of a triode.

resonate with the primary of the transformer at the low frequencies; otherwise, a severe resonant peak may result. For triode operation the value of the resistance (R_L) generally falls between 25,000 and 50,000 ohms. If an inductance is used, it must have an inductive reactance twice that of the plate resistance of the tube at the lowest frequency to be amplified.

12.101 If a dc milliammeter is connected in the plate circuit of a class-A amplifier, how does it react when a signal is applied?—If the tube is correctly biased, the meter will indicate a steady current, either with or without a signal at the input. As the signal amplitude is increased above the normal operating range, the plate current will start to fluctuate and, at the point of overload, will fluctuate quite rapidly over a wide range of current. If the tube is over-biased, the current will drop considerably and, if under-biased, the plate current swing will be the greatest in the positive direction.

Operating with the correct bias voltage and not overloaded but near the maximum signal voltage, the plate current will swing through a small arc of equal amounts of current, plus and minus the steady current (no signal).

12.102 What happens when the control grid of a class-A amplifier is driven into the positive region of grid voltage?—Grid current is caused to flow. The tube is driven into saturation causing it to draw excessive plate current generating harmonic distortion.

12.103 What is a zero-biased operated tube?—A circuit in which the control grid and cathode circuits of a tube are both returned to ground. Such circuits are discussed in Question 11.62.

12.104 What is a push-pull amplifier?—An amplifier circuit employing two tubes connected as shown in Fig. 12-104. The tubes may be operated either class-A, -AB, or -B (class-C is used for radio-frequency amplifiers only). Push-pull amplifiers afford greater output power with lower distortion and are used extensively in high-quality sound recording and reproducing systems. Referring to the diagram, it will be noted the upper half of the circuit is similar to the lower half; therefore, the tubes must be of the same type with the same static and dynamic characteristics. A common bias resistor may be used for both tubes. Transformer T2 supplies the load impedance to the plates of tubes V1 and V2 and couples them to the external load circuit. The primary of the output transformer is continuously wound and tapped in the exact impedance center of the winding and then connected to the plate supply voltage E_{bb}. The symbols for the various signal currents and voltages are indicated by the subscripts, which indicate which tube it is associated with.

It will be noted the control grid voltages E_{sig-1} and E_{sig-2} are of the same amplitude but 180 degrees out of phase with respect to each other. This same condition prevails for the signal output voltages E_{o1} and E_{o2} but, in addition, they are 180 degrees out of phase with the signal voltages on the control grids. The plate currents I_{p1} and I_{p2} are also of equal amplitude and 180 degrees out of phase. The instantaneous voltage across the entire primary winding of the output transformer is E_{prim}. The instantaneous current in the output winding is designated I_o and, without a signal at the control grids, is zero.

The dc path of tube V1 is from the cathode to the plate through the upper half of the output transformer T2 (points B to A) and back through the power supply to the cathode. For V2 the path is from the cathode to the plate through the lower half of T2 (point C to point A) and back through the power supply to the cathode. Points B and C are equally negative (no signal) with respect to point A, since the steady plate current is equal in both halves of the primary. Thus, total magnetizing force in the primary is zero and dc saturation of the core is avoided.

When sinusoidal signals E_{sig-1} and E_{sig-2} are applied to the control grids, sinusoidal plate currents I_{p1} and I_{p2} flow in the primary of transformer T. Current I_{p1} is 180 degrees out of phase with I_{p2} since the two control grid voltages are 180 degrees out of phase with each other. During positive swings of I_{p1}, point B on the primary becomes more negative with relation to point A. At the same time, the fall in I_{p2} causes point C to become less negative with respect to point A by an equal amount. Therefore, the voltage across the entire primary E_{prim} is twice the value of either E_{o1} or E_{o2}. A half-cycle later all polarities will be reversed.

Again the voltage E_{prim} across the primary is equal to E_{o1} plus E_{o2}. The relationship of E_{prim} in terms of E_{o1} and E_{o2} will hold true for all instantaneous values of plate current.

It is of importance that the signal voltages supplied to the control grids be of equal amplitude and exactly 180 degrees out of phase with respect to each other. These voltages may be obtained by means of a center-tapped transformer or a phase inverter similar to that described in Question 12.50. The dynamic characteristic of a class-A push-pull amplifier is described in Question 12.226. As a rule, for high power class-AB amplifiers, a self-bias resistor is not used but a fixed-bias voltage is employed as described in Question 12.229.

12.105 What are the advantages of operating tubes in push-pull?—Broadly speaking, a greater power output is possible with less harmonic distortion. More specifically, triode tubes which predominate in even harmonic distortion products can be operated at load values which will result in an increased power output and cancellation of the even harmonics. Under the proper load conditions, output powers up to 2.5

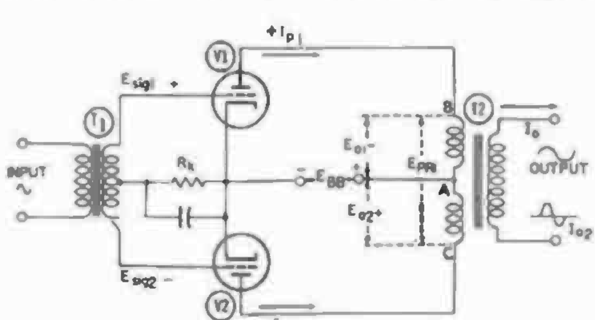


Fig. 12-104. Basic principles of a push-pull amplifier.

to 3 times that possible with a single tube may be obtained, with distortion components less than those of a single tube.

Because the odd harmonics predominate in a tetrode (four element tube) or a pentode (five element tube), they are not cancelled when operated in push-pull. However, if a pentode is operated into a higher than normal load impedance, the power output can be increased (with an attendant increase of second harmonic distortion). Operation of pentodes in push-pull will result in the cancellation of the second harmonic, leaving only odd harmonics. By the use of the proper load impedance and the addition of negative feedback, the push-pull connection may be used to lower odd harmonic distortion to negligible proportions.

Push-pull operation eliminates the dc magnetization of the transformer core material, preventing core saturation and distortion caused by the nonlinear magnetization of the core material. Power-supply ripple is cancelled by the fact that the plate currents in the amplifier are balanced; therefore, any ripple in the plate circuits caused by ripple voltage from the power supply will be cancelled. This reduces the amount of filtering in the power supply compared to that required for a single-ended amplifier. In certain types of push-pull amplifiers, the efficiency is quite high.

Beam-power tubes, although they may be considered to be pentodes, are treated differently; as a rule, the load impedance is roughly one-fifth that of the plate resistance. The value of the load impedance is determined by the class of operation and the type bias (self or fixed). Negative feedback is also recommended for operation with these tubes.

12.106 ***Why is it necessary to bypass the cathode resistor in a push-pull amplifier?***—Because it is next to impossible to maintain a perfect balance at all times between the two halves of the amplifier. If the tubes are perfectly balanced, the current flow through the cathode resistor for each tube is exactly the same. The odd harmonics cancel and only the even harmonics remain. This condition will cause the phase relationships to be such that the even harmonic components create a negative-current feedback, reducing the distortion by degeneration. When the tubes are not matched and the plate currents are out of balance, the phase relationships become such that odd harmonics are generated. This causes positive feedback with the odd harmonics predominating. Therefore, it is advis-

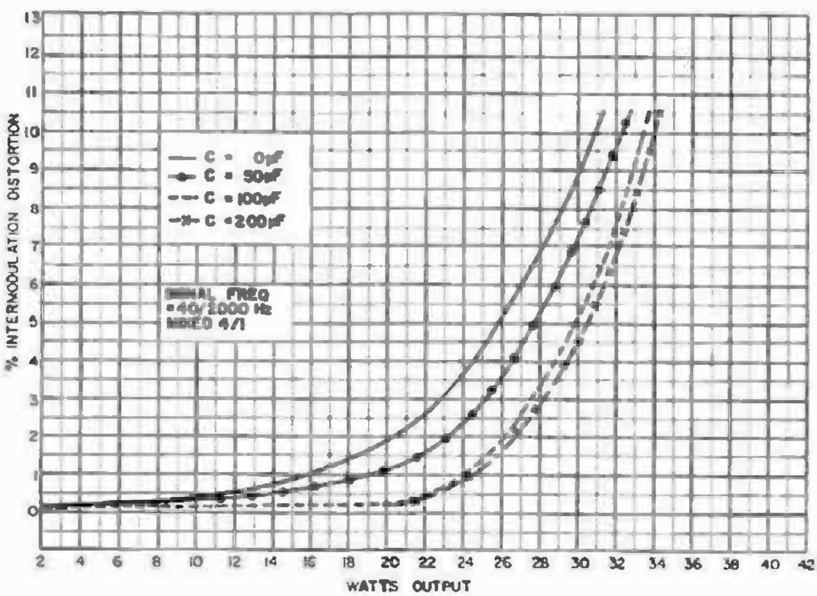

Fig. 12-106. Effect of cathode-bypass capacitor as intermodulation distortion in a Williamson ultralinear amplifier.

able to bypass the bias resistor with a large capacitor of 40 to 100 μF. However, one of 500 to 1000 μF is often used. As the voltage across a cathode resistor rarely exceeds 50 volts, these are not impractical values. The effects of a cathode-bypass capacitor relative to the intermodulation distortion in a Williamson amplifier using a pair of well-balanced tubes is shown graphically in Fig. 12-106. Using one-percent intermodulation as a reference distortion, it will be noted the power output for one percent distortion is 16 watts without a cathode-bypass capacitor. Connecting a capacitor of 50 μF across the bias resistor increases the power output to 19 watts for one-percent distortion. Increasing the capacitance to 100 μF, the power output is increased to 24 watts for the same distortion. Increasing the capacitance to 200 μF increases the output only one-half watt for the same distortion, because the amplifier has reached its maximum power output.

If the amplifier is designed for separate bias resistors, one in each cathode, each resistor is bypassed separately. If this is not done, the output plate impedance will be increased because of degeneration. Mitchell concludes, "In a class-A amplifier, the use of a bypass capacitor across the output cathode generally reduces intermodulation distortion although it may either decrease or increase the harmonic distortion."

12.107 How is the self-bias resistor calculated for a push-pull amplifier?—By the use of Ohms law:

$$R = \frac{E_c}{I_p}$$

where,

E_c is the desired bias voltage,
I_p is the plate current for the two tubes.

The bias voltage is that required for *one tube*. If the tubes are pentodes or beam-power tubes, the screen-grid current must be included in the total current flow through the bias resistor.

For calculating the value of a bias resistor for beam power, tetrode, and pentode tubes, the minimum plate and screen currents as stated by the manufacturer are used. For fixed-bias applications see Question 12.229.

12.108 If a phase-splitter is used for driving a push-pull stage, how critical are the grid resistors and coupling capacitors?—The grid resistors should be within one percent and the coupling capacitors as close to the required values as possible. If the two coupling capacitors vary in capacitance in opposite directions, at frequencies below 50 Hz the capacitive reactance variation with frequency will be considerable. Thus, the two voltages produced by the phase-splitting circuit will not be of the same amplitude at the lower frequencies, resulting in an unbalance and an increase in harmonic distortion. Capacitive reactance balance at higher frequencies is not important, as reactance of the capacitors is small; however, if excessive stray capacitance exists in the wiring, it may cause unbalance and subsequent distortion.

12.109 What are the impedance relations of a push-pull output transformer relative to the plate resistance of the tubes?—Because the tubes in a push-pull amplifier are effectively in series and parallel with the primary of the output transformer, the plate-to-plate impedance of the transformer must be twice that of the plate resistance of the tubes. (The above statement applies to triodes only.)

It appears that each tube in a push-pull amplifier sees only one-fourth its plate resistance on the basis of turns ratio. However, a push-pull transformer is a three-winding device and the reaction of one-half the primary winding to the other half is such as to cause each tube to see one-half the plate-to-plate impedance. Removing one tube from the circuit will result in the remaining tube seeing one-fourth the plate impedance.

12.110 What is the equation for calculating the plate-to-plate load impedance for a push-pull amplifier?—The two tubes in a push-pull amplifier may be considered to be two generators in series working into a load impedance of equal values. (See Fig. 12-110.) The

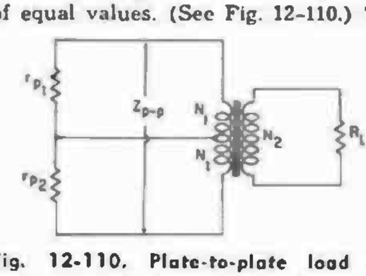

Fig. 12-110. Plate-to-plate load impedance equivalent circuit of a push-pull amplifier stage.

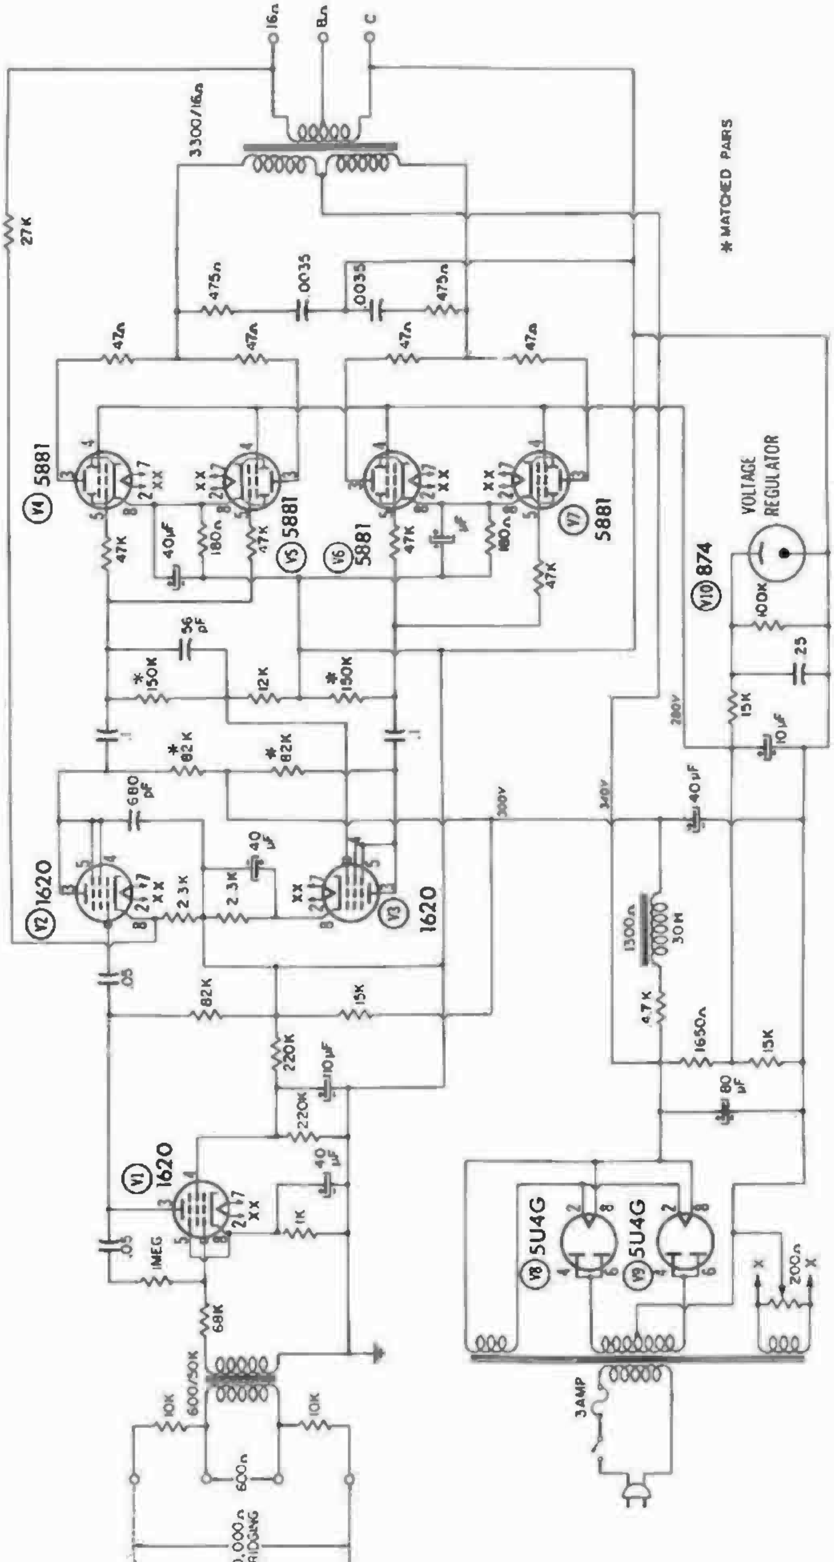

Fig. 12-111. Schematic diagram of an amplifier using push-pull parallel output.

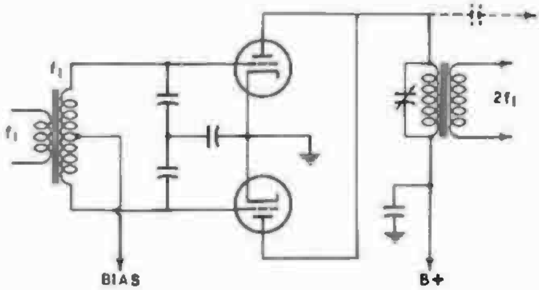

Fig. 12-112. A push-push frequency-doubling circuit. The plate circuit is resonated to the second harmonic of the fundamental frequency.

plate-to-plate impedance is equal to the reflected secondary load impedance. The primary winding is continuous and tapped at its exact electrical center. The plate-to-plate impedance may be calculated:

$$Z_{p/p} = \left(\frac{2N_1}{N_2}\right)^2 R_L$$

or

$$\left(\frac{N_1}{N_2}\right)^2 R_L = \frac{r_p}{2}$$

where,

$Z_{p/p}$ is the reflected load impedance seen by the plates of the tubes,
R_L is the external load impedance,
N_1 is the number of turns in one-half the primary winding,
N_2 is the number of turns in the secondary winding,
r_p is the plate resistance of each tube.

12.111 What is a push-pull parallel amplifier?—A push-pull amplifier in which two tubes are connected in parallel in each side of the circuit as shown in Fig. 12-111. For this type operation, the impedance of the output transformer primary, plate-to-plate, is one-half that normally used for two tubes. The power output is increased approximately six times that of a single tube.

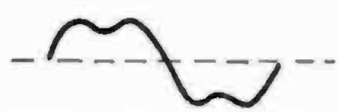
To prevent parasitic oscillation, a 47-ohm resistor is connected in the plate circuit of each tube and a 47,000-ohm resistor is placed in series with each control grid. The plate currents of each tube should be approximately the same to secure the lowest distortion. The amplifier shown will produce 30 watts of power with approximately 0.75 percent rms distortion.

12.112 What is a push-push amplifier?—An amplifier with an input circuit similar to a push-pull amplifier. The control grids are operated 180 degrees out of phase. The plates are connected in parallel. It is used for frequency doubling.

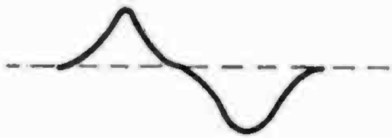
The amplifier is operated class-C. The plate circuit is tuned to the second harmonic of the frequency applied to the control grids. The bias is adjusted for a maximum output. (See Fig. 12-112.)

12.113 What are the phase shift characteristics of an amplifier?—Phase shift is a problem that exists in almost any equipment that must pass complex waveforms, and amplifiers are no exception. In modern wide-range high-quality amplifiers, phase shift is a very important characteristic. Phase shift as discussed here should not be confused with phase reversal discussed in Question 12.97 and Question 11.60.

If one frequency component of a complex waveform takes longer to pass through an amplifier than another, a time delay or displacement occurs and the output waveform is not an identical reproduction of the input waveform. This is phase distortion. In general, phase distortion causes a loss of articulation and a decrease in the intelligibility of speech.



(a) *Fundamental and third harmonic.*



(b) *Distorted waveform.*

Fig. 12-113A. The appearance of a fundamental frequency and its third harmonic after being distorted by passing through an amplifier with phase shift.

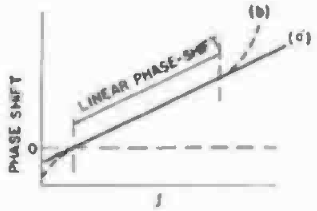


Fig. 12-113B. Phase-shift characteristics of an amplifier. (a) Constant phase shift (ideal). (b) With phase shift.

A signal consisting of a fundamental frequency and its third harmonic is shown at part (a) in Fig. 12-113A. Although the amplitudes of both components are increased in identical ratios as they pass through the amplifier, the resultant waveform at the output, shown at (b) is considerably different from that of the input, because the phase of the third harmonic has been shifted with respect to the fundamental frequency. Phase distortion is introduced in amplifiers because of the reactance in the circuits, and the type coupling used between the stages. A typical phase-shift characteristic is shown in Fig. 12-113B.

In an amplifier using negative feedback, unwanted phase shift may be caused by the components in the feedback loop or the output transformer. The measurement of phase shift is discussed in Question 23.111.

12.114 What are the effects of nonlinearity in an amplifier?—Nonlinearity in an amplifier is generally the result of operating the amplifier tubes in the nonlinear portion of the characteristic curve (Fig. 12-114A). Operating vacuum tubes in the nonlinear portion of the characteristic curve causes generation of unwanted harmonic distortion and intermodulation products, and as the harmonics are not a part of original program material, they cause distortion of the output signal waveform.

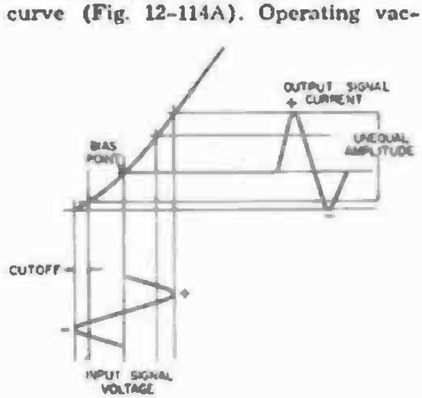

Fig. 12-114A. Dynamic characteristics of a vacuum tube incorrectly biased and operating on the nonlinear portion of its dynamic transfer characteristic.

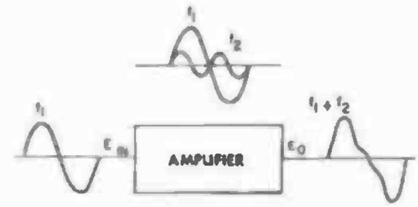

Fig. 12-114B. An amplifier with a fundemental frequency f_1 applied to the input, and a second harmonic f_2 generated within the amplifier because of internal distortion. The output waveform is distorted because it contains both the frequencies f_1 and f_2.

As an example: If a fundamental frequency f_1 (Fig. 12-114B) is applied to the input of an amplifier, and because of its nonlinearity characteristic it generates a strong second harmonic f_2 and the output waveform will be distorted. This is caused by the combining of the generated second harmonic with the fundamental frequency.

Fig. 12-114C is a plot showing the characteristics of a linear and nonlinear amplifier. It will be noted for the linear plot (a) the output voltage rises directly in proportion to the amplitude of the input signal, resulting in a straight line between input and output voltages.

Plotting the input signal amplitude versus the output voltage for a nonlinear amplifier results in a characteristic as shown by the dashed line (b). As may be seen, the output voltage does

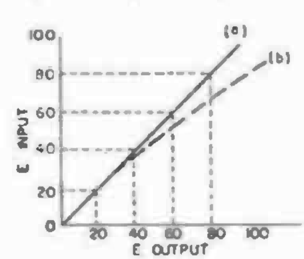

Fig. 12-114C. Input and output characteristics of an amplifier with a linear response (a) and one with a nonlinear response (b).

not rise in the same proportion as the input signal. Although the nonlinear characteristic is shown as a straight line, it will generally bend near the upper limits.

The measurement of nonlinearity in amplifiers is discussed in Question 23.94.

12.115 ***What is frequency distortion in an amplifier?***—If the gain frequency characteristics of an amplifier are not uniform, certain frequencies will be amplified to a greater or lesser degree causing the ratio between frequencies to be changed from the original waveform ratios. Thus, when frequencies passed through an amplifier are not amplified with their original amplitude ratios, this is called frequency distortion. If the high frequencies are amplified excessively, the harmonic distortion will be increased. (The foregoing statement does not apply to an equalized amplifier.)

12.116 ***Define the term intermodulation distortion.***—In amplifiers and other electrical devices designed to pass a multiple frequencies, sum and difference frequencies may be generated inducing intermodulation distortion. Intermodulation distortion may be defined as the production in a nonlinear circuit element of frequencies corresponding to the sum and differences of the fundamentals and harmonics of two or more frequencies which are transmitted through that element.

Designating two fundamental frequencies f_1 and f_2, the intermodulation products will consist of second and third order terms. In general none of these terms is harmonically related to either of the fundamental frequencies.

Intermodulation distortion will manifest itself as a harsh or rough unpleasant reproduction, or by a buzz at the higher frequencies. This type of distortion is not directly related to harmonic distortion and cannot be measured using a conventional harmonic analyzer or meter. Therefore, special intermodulation analyzers have been developed for this express purpose. (See Questions 22.129 and 23.117.) To date, no significant psychological tests have been made to determine just how much intermodulation distortion can be tolerated by the human ear. (See Question 1.118.) However, it is sufficient to say that amplifier systems having a low order of intermodulation distortion sound much cleaner than an amplifier of comparable harmonic distortion. It is generally agreed that sound recording and reproducing systems must have less than 1-percent intermodulation distortion.

Other forms of distortion aside from that just mentioned are harmonic, phase-shift, frequency, and noise. Distortion may also be caused by magnetic fields from power transformers and chokes, and the overloading of the output transformer which causes saturation of the core material.

12.117 ***What is random noise?***—Spurious frequency signals which are amplified with the program material. Random noise is caused by thermal agitation produced by the movement of electrons in a material. This movement of electrons causes minute pulses which are intermixed with the signal voltage and amplified. Random noise covers the entire frequency band and is the limiting factor in the design of a low-level, high-gain amplifier.

12.118 ***What is the shot effect?***—Noise in a vacuum tube caused by the movement of electrons between the cathode and plate elements. This effect causes unsteadiness in the plate current and is amplified with the signal voltage.

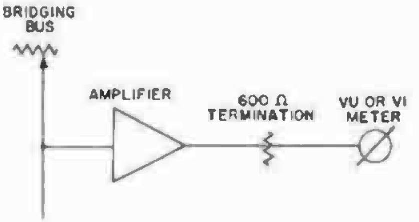

Fig. 12-119. VU or VI meter with an amplifier connected ahead of the meter to increase the voltage level.

12.119 ***Describe the use of a VU or VI meter amplifier.***—When the voltage level of a sound circuit is too low for the use of a standard VU meter, an amplifier may be connected ahead of the meter, and the signal amplified before it is applied to the meter (Fig. 12-119).

The disadvantage of this method is *gain variations* in the amplifier caused by tube variations and operating voltages. However this may be overcome to a great extent by the use of a semiconductor amplifier highly stabilized by the use of a generous amount of negative feedback and regulated operating voltages. Even then, the calibration should be frequently checked if the meter is connected in a critical part of the system. Whenever possible, the meter (without amplifier) should be connected across a circuit impedance of 600 ohms and of the correct voltage level. The frequency response of the amplifier must be uniform across the frequency band of interest. (See Question 12.196.)

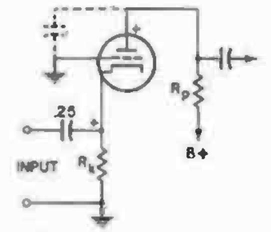
To calibrate the meter with the amplifier, a plus 4-dBm signal is applied to the amplifier input and the amplifier gain adjusted for a 100-percent reading on the meter (100 percent on a standard meter is plus 4 dBm), with the meter attenuator set to plus 4 dBm. (See Questions 10.17 and 10.24.)

12.120 ***What is a buffer amplifier?***—A stage of amplification between an oscillator or other device to isolate it from succeeding stages.

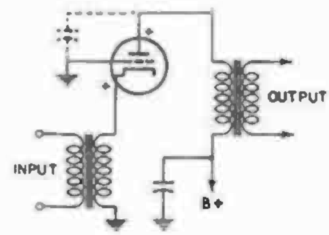
12.121 ***What is a frequency-doubler stage?***—An amplifier stage having a resonant circuit in its plate circuit tuned to a harmonic of the fundamental frequency at the input. They are used in radio transmitting equipment and in test equipment. A push-push amplifier is a frequency doubler. (See Fig. 12-112.)

12.122 ***What is a grounded-grid amplifier?***—A vacuum tube connected as shown in Fig. 12-122. The incoming signal is applied to the cathode across a low resistance while the output signal is taken across a high-resistance load in the plate circuit. The control grid is tied directly to ground. The input and output signals are in phase.

Grounded-grid amplifiers are often used to couple a low-impedance source to a high-impedance load, thus providing gain as well as an impedance match.



(a) *Resistance-coupled.*



(b) *Transformer-coupled.*

Fig. 12-122. Grounded-grid amplifiers.

The theoretical gain of a grounded-grid amplifier may be computed:

$$V_g = (1 + \mu)\frac{Z_2}{r_p + Z_2}$$

where,

r_p is the plate resistance,
Z_2 is the load impedance including the capacity between the grid and plate, neglecting the capacity between plate and cathode.
μ is the amplification factor of the tube.

In some respects it may be said a grounded-grid is the reverse of a cathode-follower amplifier.

12.123 ***What is a grounded-plate amplifier?***—This is another name of a cathode-follower amplifier as described in Question 12-41.

12.124 ***What is a gas-tube coupled amplifier?***—An amplifier using a gas-filled tube as a coupling medium be-

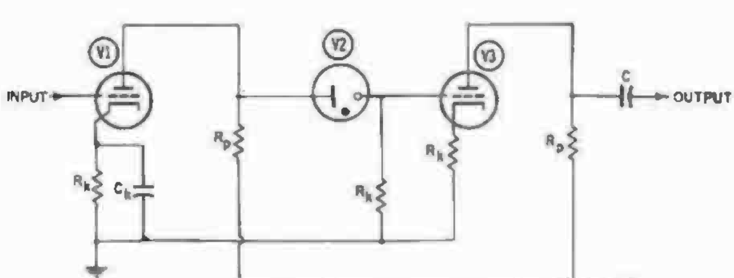


Fig. 12-124. A two-stage, RC amplifier using a gas-filled tube in place of the usual coupling capacitor.

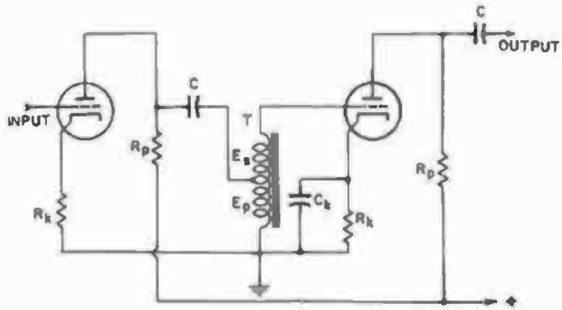

Fig. 12-125. A two-stage, autotransformer-coupled amplifier.

tween stages. A typical circuit is shown in Fig. 12-124. The first stage is a conventional amplifier with a resistive plate load. Instead of the usual coupling capacitor, the control grid of the second stage is fed from the plate of the first tube through a small neon tube. Voltage-regulator tubes, as a rule, are not satisfactory because of their high operating potentials. The purpose of such coupled amplifiers is to reduce the phase shift generally associated with resistance-coupled amplifiers at the extremely low frequencies. Gas coupling is only practical at fairly high signal levels because of the high internal noise level of a gas tube. The frequency response and stability may be improved by the use of negative feedback by eliminating the usual cathode-bypass capacitors.

12.125 What is an autotransformer-coupled amplifier?—An amplifier as shown in Fig. 12-125 which uses an autotransformer rather than the conventional two-winding coil to step up the voltage between stages. The autotransformer is parallel-coupled to the plate of the first tube to eliminate the flow of direct current through the winding. There is no particular advantage to autocoupling, therefore it is seldom used.

12.126 What is a series or single-ended push-pull amplifier?—An output stage in which two tubes are connected in series across the direct-current plate-voltage supply, as shown in Fig. 12-126. The output tubes are driven from a phase-inverter stage which produces two voltages of equal amplitude but 180 degrees out of phase.

The unique feature of this phase-inverter circuit is that it drives each tube from its own control grid to its own cathode circuit, driving the tubes in a balanced fashion.

The advantages of this circuit are that it has a single-ended output and is capable of driving a two-terminal load such as a loudspeaker voice coil, and requires no output transformer. The advantages of eliminating the output transformer are manifold; also, large amounts of negative feedback may be applied with a high degree of stability, enabling very low distortion characteristics to be obtained. With modifications this circuit is used extensively in transistor output stages.

12.127 What is a cathamplifier?—A push-pull amplifier circuit in which

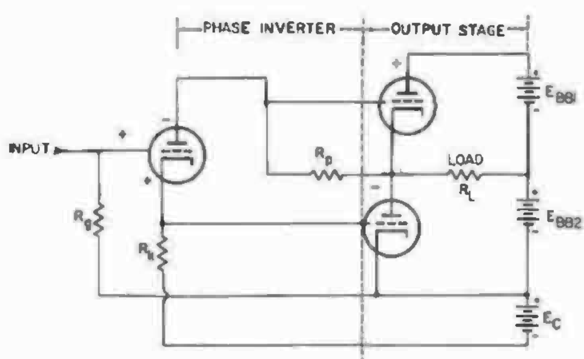

Fig. 12-126. Basic circuit of a single-ended push-pull amplifier.

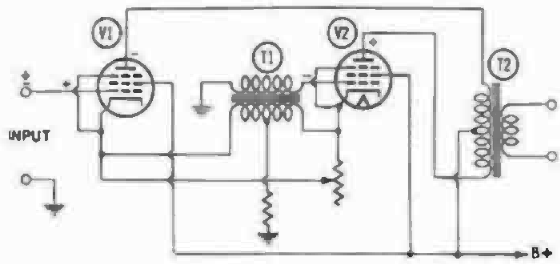

Fig. 12-127. A push-pull cathamplifier.

the push-pull input transformer is connected to the cathodes, as shown in Fig. 12-127. The input signal is applied directly to the control grid of tube V1 and to the secondary of transformer T1. Transformer T2 is a conventional push-pull output transformer.

12.128 What is an ultralinear amplifier?—An amplifier circuit designed for high quality sound reproduction which was developed by Hafler and Keroes and employs a special output transformer. (See Fig. 12-128A.)

When a pentode tube is operated with the screen grid and the plate elements at the same positive potential, pentode operation is obtained. If the screen grid is connected to the plate element and fed from the same end of the output transformer, triode operation is obtained.

In the ultralinear method of operation, the screen-grid element is returned to a tap on the primary of the output transformer at a point about 18.5 percent of the primary impedance (measured from the center tap of the primary winding). This provides an intermediate operating point between a pentode and a triode, with the power output of a pentode and the low internal output impedance of a triode. Under the above operating conditions, the tube functions as a pentode with negative feedback applied to the screen grid, resulting in lower distortion products at the higher levels of operation. When the

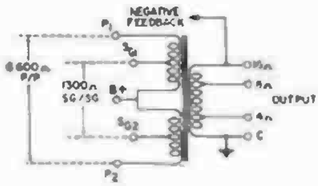

Fig. 12-128A. An ultralinear output transformer designed for use with 5881 or 6L6 beam-power tubes.

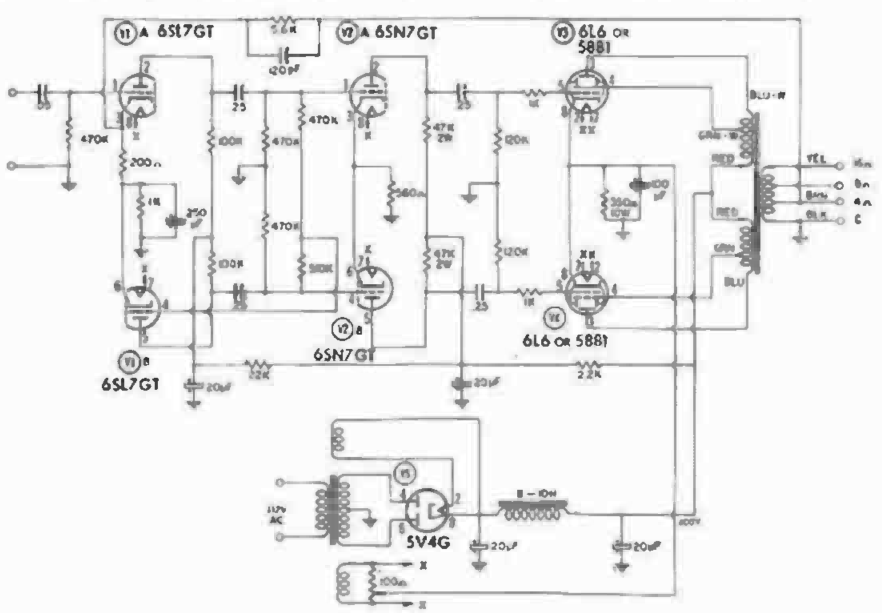

Fig. 12-128B. An ultralinear amplifier using 6L6 or 5881 tubes.

ultralinear circuit is used in conjunction with the well-known Williamson amplifier circuit (Fig. 12-232A), a power output of over 20 watts is possible from a pair of 5881 tubes, with less than one percent intermodulation distortion.

The impedance of the output transformer for ultralinear operation is shown in Fig. 12-128A. The impedance from plate-to-plate is 6600 ohms and from screen grid to screen grid is approximately 1300 ohms.

Referring to Fig. 12-128B, negative-feedback voltage is taken from the secondary winding of the output transformer and carried back to the cathode circuit of the first tube, through a 5600-ohm resistor shunted by a 120 pF capacitor. The capacitor assists in maintaining a smooth frequency response above 100 kHz and also helps maintain a constant 180-degree phase shift at the higher frequencies. The total feedback is 20 dB. The frequency response has been extended to more than two octaves above the usual 20 to 20,000 Hz. This wide frequency response is necessary to maintain a constant phase shift and improve transient response.

The weakness of the amplifier lies in the fact that its *negative feedback becomes a positive feedback at ultrasonic and subsonic frequencies*, leading to a considerable amount of distortion at the lower frequencies, unless it is very carefully designed. The amount of negative feedback applied to the first stage should not exceed 20 dB.

Tests for oscillation at inaudible frequencies may be made by the application of a square wave to the input while observing the output waveform on an oscilloscope.

In some circuit designs of the Williamson amplifier using the ultralinear output stage, high-frequency oscillation will occur when a capacitive load such as an electrostatic loudspeaker is connected across the output, or the leads of the loudspeaker have considerable distributed capacity. The measurement of capacitive load effects is discussed in Question 23.125.

12.129 What is a Circlotron amplifier?—An amplifier circuit developed by Wiggins, and manufactured by Electro-Voice Inc., using a specially designed output stage employing two 6V6 beam power tubes which develop an unusually large amount of power with low distortion. One of the fundamental requirements of a high-quality amplifier is that it have an output transformer with negligible leakage reactance. This leakage reactance must be low to avoid the transient distortion resulting from collapsing currents such as those encountered in class-AB or -B push-pull amplifiers when the tubes are driven beyond cutoff. Transient distortion appears as a parasitic oscillation in the waveform at the instant of cutoff. A high value of leakage reactance will also cause the output transformer of a conventional amplifier to lose efficiency at the high frequencies; therefore, the distributed capacitance of the output transformer should be very low, in order to minimize high-frequency attenuation and phase shift. It is claimed for the circuit of Fig. 12-129A, a Wiggins Circlotron amplifier, that this objectionable feature of the conventional amplifier is overcome.

Fig. 12-129B is a simplified version of the above amplifier. Two power supplies are indicated as batteries. Each power supply is connected from the plate of one tube to the cathode of the other. The plate current of each tube circulates through both power supplies without traversing the windings of the output transformer. Because any pair of opposite points in this configuration is equipotential, the circuit is a balanced bridge under no-signal conditions.

The total primary impedance of the output transformer presents a load to each of the two output tubes. One-half of this load is in the cathode circuit and the other half is in the plate circuit. The plate load of one tube is the cathode load of the other. Because each tube looks into the same load as the other, the result is unity coupling between the tubes. Despite the residual leakage reactance in the transformer, no switching transients can occur during the operation of the amplifier, for both halves of the transformer primary winding have the same signal current flowing in them; thus, switching transients are eliminated

The impedance of the primary winding is one-fourth that of the conventional amplifier; therefore, the distributed capacitance is less. Also, the leakage reactance makes a wide frequency range more easily attained. The quiescent current being low results in higher efficiency and produces more power without exceeding the dissipation rating of the tubes.

The gain of the Circlotron output stage is approximately unity; thus, it requires a high signal driving voltage. This higher signal voltage is obtained by means of a technique called "bootstrapping." By this method, the B-plus supply voltage to the driver stage is dynamically changed as the signal volt-

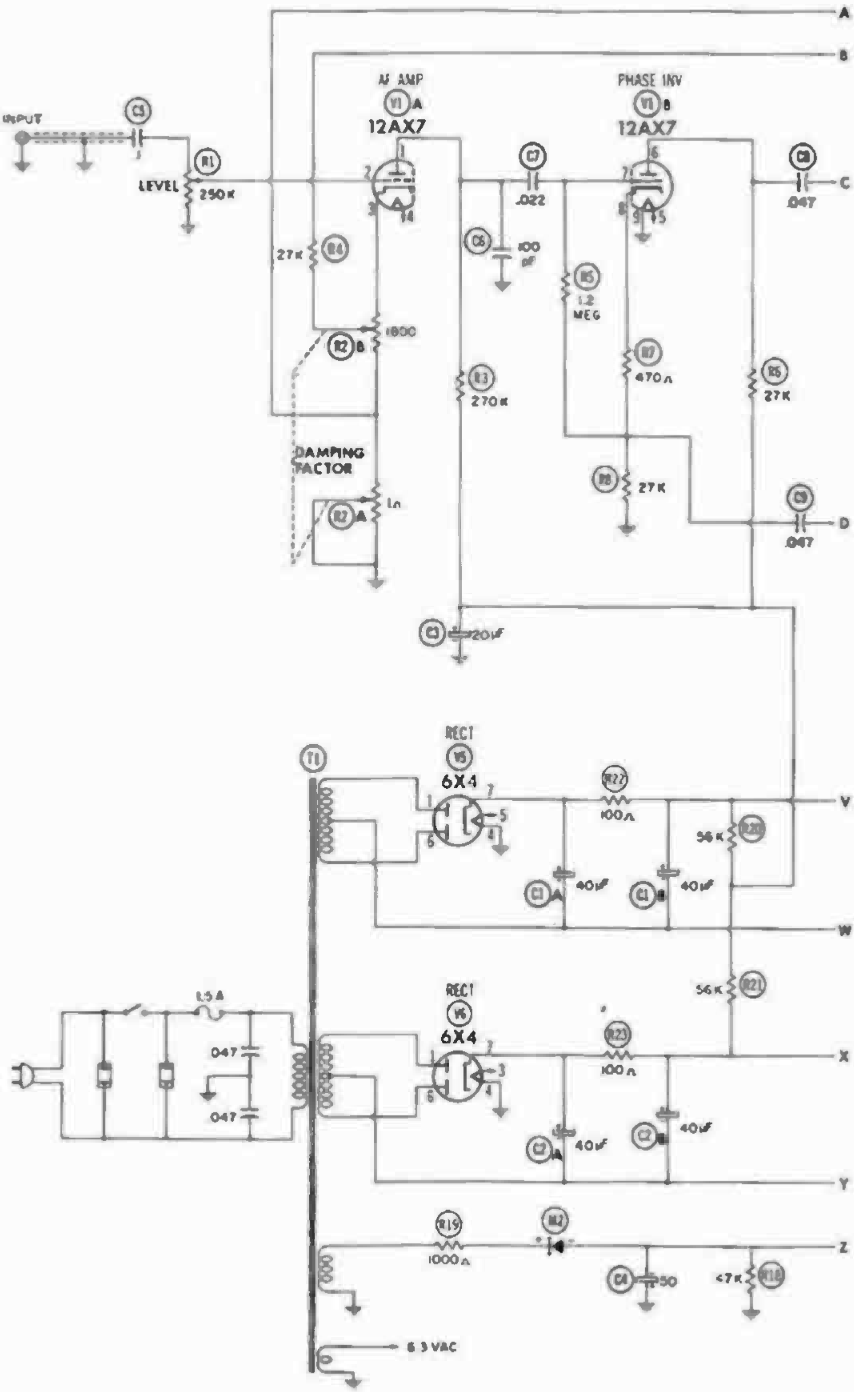

Fig. 12-129A. Wiggins Circlotron

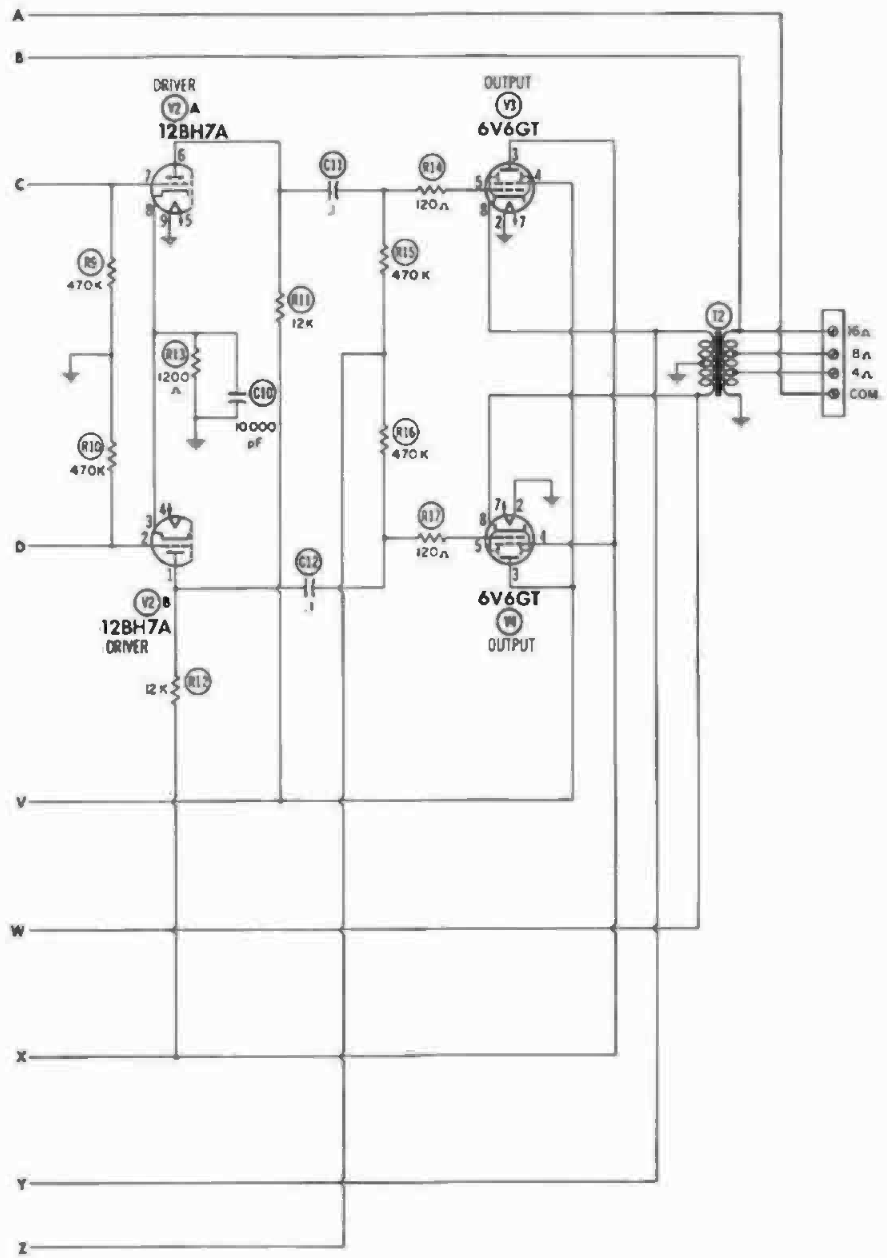
age changes. This permits linear operation over a wide range.

Variable damping is also provided in the output to present a means of matching the impedance characteristics of the loudspeaker system to the amplifier at the lower frequencies. The values of the critical damping resistance vary widely with different type speakers and are dependent upon the flux density, type of enclosure in which the speaker is mounted, the length of the conductor



20-watt power amplifier.

in the air gap, and, to some extent, the position of the speaker enclosure in the room.

The variable-damping control circuit is so designed that varying amounts of reactive voltage and current feedback are combined to match the effective impedance while maintaining the total feedback at a constant value. (Variable damping is discussed in Question 12.242.) The maximum power output available is independent of the damping factor and remains constant for all settings of the damping control. Referring to Fig. 12-129A, the incoming signal is applied to the control grid of V1A which is coupled to a split-load phase splitter V1B which, in turn, drives a push-pull driver stage V2A and V2B. The output stage V3 and V4 is cathode coupled to the external load circuit by means of transformer T2. The primary of the output transformer is connected to the cathodes of the output tubes and center tapped to ground. A fixed bias voltage is applied to the control grid of the output tubes. This is supplied by a half-wave rectifier M2. (Fixed bias circuits are discussed in Question 12.229.) Negative-feedback voltage is obtained by taking voltage from the 16-ohm tap of the output winding and returning it to the potentiometer R2A in the cathode circuit of V1A. Negative-current feedback is obtained by connecting the ground side of the output winding to the junction of R2A and R2B in the cathode circuit of V1A. These two controls are mechanically connected and operate as a unit.

The power output is rated at 20 watts (40 watts on peaks), at less than 0.5-percent harmonic distortion, or less than one-percent intermodulation. Hum and noise are rated 85 dB below 20 watts or minus 42 dBm. The feedback is 19 dB in the output circuit, 16 dB in the feedback loop, and 2 dB positive feedback in the driver circuits, making a total of 33 dB total negative feedback. The frequency response is plus or minus 1 dB from 20 to 60,000 Hz at 20 watts output. The damping factor is adjustable from 0.1 to 15. The input impedance is 250,000 ohms with a 0.1-μF isolation capacitor in the input.

12.130 What is an extended class-A amplifier?—A push-pull amplifier employing a triode and a beam-power tube in parallel on each side of a push-pull circuit. (See Fig. 12-130.) At low levels the amplifier operates as a triode amplifier with the beam-power tubes at cutoff. At the higher levels, the output is almost entirely from the beam-power tubes. The plate dissipation is about one-third that of a normal class-A amplifier for the same power output.

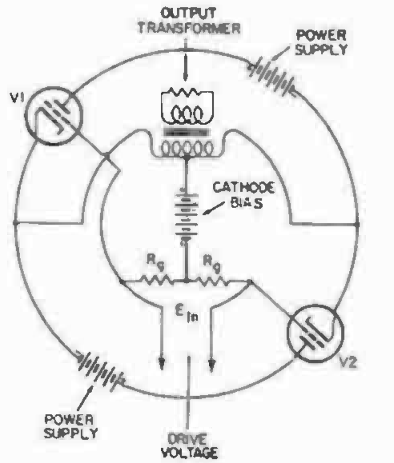


Fig. 12-129B. Basic circuit for Wiggins Circlotron power amplifier.

In the circuit shown, a power output of 47 watts may be obtained with low distortion. The input signal may be supplied from either a transformer or a phase splitter.

12.131 Are the frequency characteristics of a power amplifier the same at all power levels?—Unless the output transformer is of unusually good design, frequency response will show a loss at both the high and low ends at higher output levels. Typical power curves are shown in Fig. 12-131.

12.132 Describe an output transformerless amplifier (OTA).—It is an amplifier that does not use an output transformer. The external load circuit is generally connected to the cathode of the output tubes, through a 100- to 1000-μF capacitor, to the external load circuit, such as a voice coil of a loudspeaker. The capacitor is only required if the external load circuit will cause a current flow between the output point and ground. A typical OTL circuit is shown in Fig. 12-132.

12.133 What is a preliminary amplifier?—This is another name for a preamplifier. (See Question 12.72.)

12.134 What is a dielectric amplifier?—An amplifier requiring no vac-

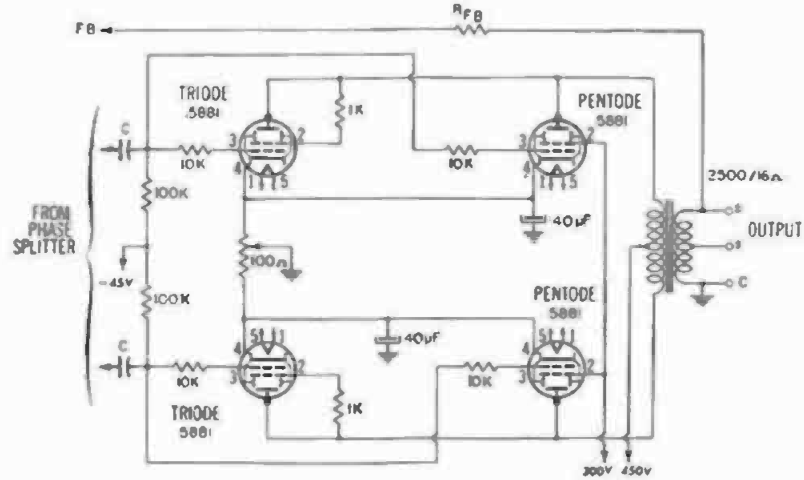

Fig. 12-130. A push-pull parallel, extended class-A amplifier using a combination triode and pentode connection.

uum tubes but employing a device similar to a capacitor using polycrystalline dielectric which exhibits a ferromagnetic effect. Ceramics using barium titanate, barium zirconate, strontium titanate, and lead zirconate are among the materials used. The device has a frequency range running into the megahertz. Its characteristics are nonlinear. It is caused to operate on the linear portion of its characteristic curve by the use of a dc bias voltage in conjunction with a high-frequency power supply. This type amplifier is used in computers and similar devices.

12.135 What is a program amplifier?—An amplifier connected in the main program channel of a broadcast station speech-input system. It must be capable of developing an output level of at least plus 18 dBm. It is also called a line amplifier.

12.136 What is a negative-feedback or degenerative amplifier?—An amplifier in which a portion of the output signal voltage is fed back 180 degrees out of phase to the input. Two types of negative feedback are in common use—voltage and current.

12.137 Describe a nyquist curve.—It is a graphical method, devised by H. Nyquist of the Bell Telephone Laboratories, for plotting the relationship between amplification and feedback in an amplifier employing either negative or positive feedback. Such curves are generally plotted in polar form and are used as a criteria for determining the stability of an amplifier to which feed-

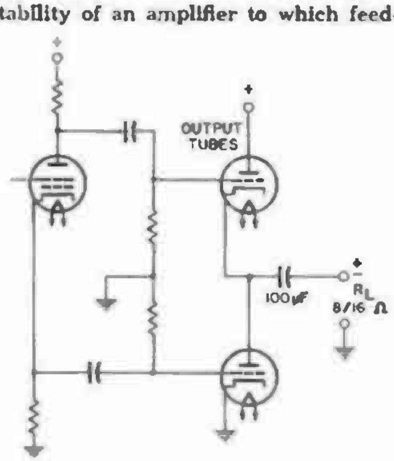

Fig. 12-132. Output stage for transformerless (OTL) amplifier.

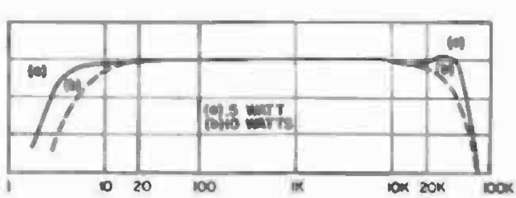

Fig. 12-131. Frequency response of a wide range high-quality audio amplifier at 0.5 and 10 watts output.

back is applied. Nyquist curves can also be used for plotting oscillators and other circuit data critical to stability. A typical Nyquist plot is shown in Fig. 12-137. The reader is referred to the references at the end of this section.

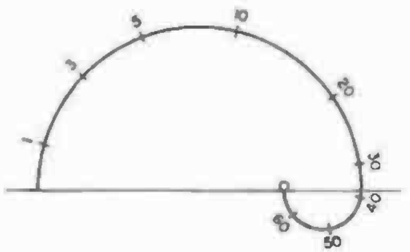

Fig. 12-137. Typical Nyquist plot used for determining the stability of an amplifier or other device.

12.138 What are the advantages of using negative feedback in an amplifier? —Negative feedback lowers the harmonic and intermodulation distortion components(assuming the amplifier does not have excessive distortion before the negative feedback is added); the frequency response may be made quite uniform over a very wide range; the stability may be increased and is less subject to variation in tubes and operating voltages; lower hum and internal noise; constant gain for a given response; lower internal output impedance providing a high factor of internal output damping; and less phase shift.

12.139 Explain how a negative-feedback amplifier functions.—In the conventional audio amplifier, the internal resistance of the output tube shunts the external load impedance. When the plate resistance is less than the load impedance, variations in the load impedance have very little effect on the output voltage, because the load-impedance variations are shunted by the low resistance of the output tube. This indicates that a tube of low plate resistance is desirable in the output stage.

When the plate resistance is high (as is the case of a pentode or beam-power tube), the effect of a variable load impedance is to increase the distortion components, producing strong peaks, and thus impairing the quality of reproduction. Amplifiers employing pentodes or beam-power tubes in the output stage may make use of a resistance-capacitance network in the plate circuit as described in Question 12.169 to compensate for the effects of the variable load impedance. However, using this method, some loss of power is to be expected, particularly at the higher frequencies.

Amplifiers employing pentodes or beam-power tubes may be designed to have the characteristics of a low plate resistance tube, yet have the advantages of the increased power sensitivity afforded by the pentode. This advantage is obtained by the use of negative feedback in the output stage. The addition of uegative feedback is accomplished at the expense of sacrificing a portion of the amplifier gain. However, the benefits gained by the use of negative feedback offset the loss of gain in the improved performance of the amplifier. The loss of gain may be compensated for by increasing the gain in the voltage-amplifier section. A typical two-stage RC amplifier employing negative feedback is shown in Fig. 12-139A. The feedback voltage is obtained by feeding back to the input of the amplifier a portion of the output voltage in such a

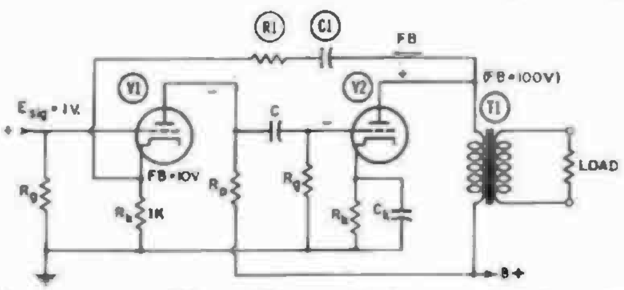

Fig. 12-139A. A two-stage RC amplifier employing negative-voltage feedback. In this circuit the characteristics of the output transformer are not included. To include the output transformer, the feedback voltage is taken from the top of the transformer secondary. The lower end is returned to ground (feedback voltage must be of the correct polarity.)

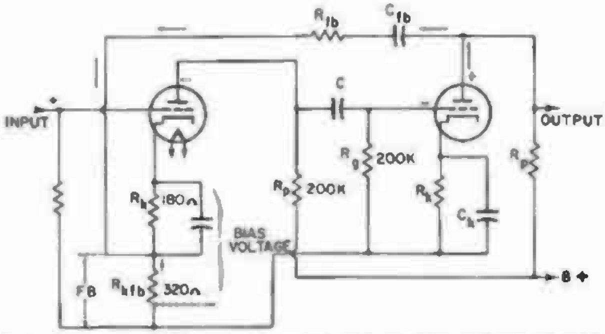

Fig. 12-139B. A two-stage RC amplifier using negative-voltage feedback from the plate of the output tube to a portion of the cathode resistance of the first stage.

phase relationship as to oppose the input signal. Assume an instantaneous positive pulse of 1 volt is applied to the control grid of tube V1. At the plate will appear a negative pulse because of the 180-degree phase reversal within the tube as described in Question 11.60. This negative pulse is transferred to the control grid of V2 through the coupling capacitor C, causing a decrease of plate current in V2. The signal is again amplified, reversed 180 degrees, and appears as a positive pulse at the plate of V2. This pulse is transmitted through capacitor C1 and resistor R1 in the negative-feedback loop to the upper end of the cathode resistor R_k of V1, applying a positive pulse to the cathode. This effect is the same as biasing the control grid more negatively. When the feedback voltage increases, the gain of V1 is decreased. As an example: with 100,000 ohms in the feedback loop and 1000 ohms in the cathode circuit of V1, a voltage divider is formed with the cathode of V1 at the junction of the two resistors (for this illustration it will be assumed the reactance of capacitor C1 in the negative-feedback loop is negligible).

With a signal voltage of 100 volts at the plate of V2, 10 volts will be fed back to the cathode of V1. Now to obtain 100 volts of signal at the plate of V2 will require the signal voltage at the input of V1 be increased to 11 volts. In other words, the signal voltage must be increased the amount of the feedback voltage in the cathode circuit plus the original signal voltage at the control grid of V1. By definition, the foregoing illustration is called 10-percent negative feedback.

Negative feedback may also be applied as shown in Fig. 12-139B. Here the feedback voltage taken from the plate of V2 is applied to only a portion of the cathode resistor R_{KFB} of V1. Under these conditions the dc bias voltage for the tube is the voltage drop across R_K and R_{KFB}, while the negative-feedback voltage is formed across only the lower portion of the resistor. As the feedback voltage is confined to the lower portion of the cathode resistor, the upper portion is used only for bias voltage and may be bypassed to prevent current feedback, thus increasing the actual gain of the stage. This system of applying negative feedback permits the correct value of feedback voltage to be applied to the tube, while maintaining the correct value of resistance for the cathode circuit.

Gain controls cannot be connected in the area encompassed by the feedback loop, but must be removed to a position outside the feedback loop, as shown in Fig. 12-217B. Negative feedback may be utilized to increase the output impedance (negative-current feedback) or to reduce the impedance by the use of negative-voltage feedback. This subject is discussed in Questions 12.142 and 12.154.

12.140 How is harmonic distortion reduced by means of negative feedback? —All amplifiers, regardless of design, have some distortion and will have some component in the output signal that was not present in the input signal. The feedback voltage taken from the output of the amplifier contains both the original signal and the distortion component added by the amplifier. That part of the feedback voltage consisting only of the original signal will be cancelled at the input by the applied signal voltage. However, any distortion originating within the amplifier, when fed

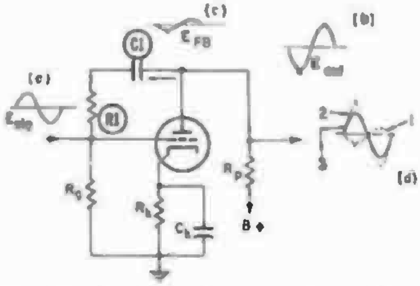

Fig. 12-140. Waveforms indicating how negative feedback tends to cancel distortion generated within an amplifier.

back will not be cancelled by anything present in the input, since the distortion is not present in the input but is developed within the amplifier. Therefore, the distortion voltage is passed through the amplifier from the input and arrives at the output with a polarity opposite to the distortion produced within the amplifier. The result is that the total distortion is reduced because it cancels itself. To better understand how the distortion is reduced by the application of negative feedback, Fig. 12-140 shows a single-stage, resistance-coupled amplifier with negative feedback, with the various voltage waveforms as they appear at different points in the circuit. At point (a) is shown the signal voltage which is of sine-wave character. It will be assumed that the signal in passing through the tube is distorted and this distortion appears as a small pip on the negative half of the output signal waveform as shown at point (b). A portion of this voltage (c) is fed back to the grid circuit. This voltage is 180 degrees out of phase with the grid voltage and has the same wave shape as the voltage at (b) but at a fraction of the output amplitude. Applied to the control grid, it acts to cancel the original distortion. At the output (d) is shown the relationship of the various waveforms. Curve (1) of waveform (d) is the plate-current component due to the feedback voltage applied to the control grid. Curve (2) of (d) is the plate-current component developed by the signal voltage at the control grid. Curve (3) of (d) is the algebraic sum of curves (1) and (2) and is the resultant plate current, clearly indicating a considerable reduction in the original distortion shown at point (b). The same principles apply to any amplifier in which negative feedback is used, including push-pull amplifiers class-A, class-B, and class-AB_1.

As a rule, negative feedback is not used with the power-output triodes such as the 2A3, because of its low plate impedance (800 ohms) and the fact that it is not too greatly affected by changes in the load impedance, such as might be encountered with a loudspeaker. However, negative feedback is highly desirable with pentodes and beam-power tubes.

12.141 How is noise reduced by negative feedback?—Any noise induced by the amplifier is fed back to the input and appears at the output with reversed polarity, effecting an overall reduction of noise. (See Fig. 12-140.)

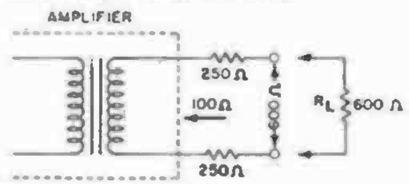

Fig. 12-142. Building-out resistors in the output of a negative-feedback amplifier, with a 100-ohm internal output impedance. The resistors build-out the impedance to 600 ohms.

12.142 Describe the effect of negative feedback on the internal impedances of an amplifier, and the use of building-out resistors.—As a majority of present day amplifiers employ a considerable amount of negative feedback to reduce distortion and noise, this lowers the internal output impedance. The effect on input impedance is not determined by the type of feedback (voltage or current), but by the method it is applied. If it is applied in series with the input-signal voltage, the input impedance is increased. Applied in shunt with the input voltage, the input resistance is decreased. *Negative-voltage* feedback reduces the internal output impedance, while *negative-current* feedback increases the internal output impedance. (See Question 12.139.)

Although the amplifier may be rated to operate with a given load impedance, the internal output impedance of the amplifier may be on the order of 100 ohms or less. This lower impedance can seriously affect the operating characteristics of equipment following the amplifier, particularly if it is a filter or an equalizer. A typical example would be the case where an amplifier is rated to operate with a 600-ohm load impedance, but has an internal output impedance of 100 ohms (in some instances it could be as low as 4 ohms). To effect a proper impedance match, series resistors are connected in each side of the output circuit (Fig. 12-142). The value of the resistors are such that they supply a match between the amplifier and the load impedance, which in the instance of a 100-ohm internal output impedance, wonld be 500 ohms divided equally between the two sides. It should be remembered, the insertion of the resistors decreases the output in the ratio of the internal output impedance to load impedance. Using the example of the 100-ohm internal output impedance terminated in 600 ohms, the ratio is 6:1. Building-out resistors are used extensively in preamplifier circuits when used in sound mixers. Referring to the graph of Fig. 5-50, the incurred loss is 3dB; therefore, if the amplifier is capable of producing plus 26 dBm for a given amount of distortion, the maximum output level for the same value of distortion, using one 250-ohm resistor in each side of the output, would be reduced to 23 dBm.

12.143 ***How does negative feedback affect the frequency characteristics of an amplifier?***—Negative feedback tends to maintain a uniform output resembling a constant-voltage generator. When the output voltage increases, the feedback voltage is increased, which has the effect of reducing the output. If the output level is reduced, the reverse takes place; thus, the output is held constant. Therefore, for a constant input of any frequency within the frequency range of the amplifier, output voltage will be constant.

12.144 ***What does the term open-loop gain mean?***—It is the gain characteristics of an amplifier before the application of negative feedback. Thus, an amplifier using 20-dB feedback could have a closed loop gain of 40 dB, but with the loop open, a 60-dB gain.

12.145 ***What are the advantages of a low internal output impedance?***—If an amplifier is used to drive an electromechanical transducer, a reduction in the internal output impedance is desirable, because a mechanical vibratory system continues to vibrate even after the exciting force is removed. In a loudspeaker, cutting head, or light modulator, this is an undesirable condition as it causes hangover effects, resulting in a fuzziness and lack of definition.

If the internal output impedance is lower than the load impedance, a damping effect is obtained and the unwanted vibrations are damped out. It is not uncommon for an amplifier having a 600-ohm output impedance to have an internal output impedance of 100 ohms or less, and for one rated 16 ohms, less than 1 ohm. In the case of a voltage amplifier (preamplifier) driving a filter or equalizer, building-out resistors, discussed in Question 9.24, may be required. (See Questions 12.142 and 20.103.)

12.146 ***What is the gain-reduction factor of a negative-feedback amplifier?***—A factor used in the design of negative-feedback amplifiers. This factor may be calculated:

$$dB = 20 \operatorname{Log}_{10} (1 - A\beta)$$

where,

A is the gain without feedback,
Beta (β) is the fraction of the output voltage fed back to the input.

Because of the gain reduction, the input-signal level must be increased by the amount of the feedback voltage to obtain the same level signal at the output obtained without feedback. (See Question 12.139.)

12.147 ***Does negative feedback affect the power output of an amplifier?***—No. However, the power sensitivity is reduced and a greater input signal is required to drive the amplifier to produce the same amount of power for a given input signal without feedback. As a rule, greater power is obtained for a given amplifier when using negative feedback because the distortion is reduced; therefore, more useful power is available.

12.148 ***What does the term decibels of feedback mean?***—It designates the amount of negative feedback induced in an amplifier, and is equivalent to the gain reduction caused by the application of the feedback. (See Question 12.139.)

12.149 ***Show an equivalent circuit for a simple negative-feedback amplifier.***—A simple resistance-coupled amplifier employing negative feedback is

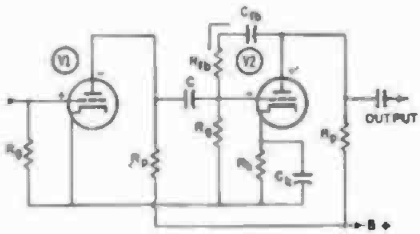

Fig. 12-149A. A two-stage RC coupled amplifier with negative feedback applied to the output stage only.

shown in Fig. 12-149A. In this circuit negative feedback is used only in the second tube; however, certain factors of the first tube enter the configuration of the equivalent circuit. Examining the equivalent circuit in Fig. 12-149B, it will be noted the grid resistor R_g is paralleled by the plate-load resistor R_p of tube V1. This, in turn, is paralleled by the plate resistance r_p of V1. The total impedance seen by the control grid of V2 is these three impedances in parallel and is designated R_{eq} (equivalent resistance).

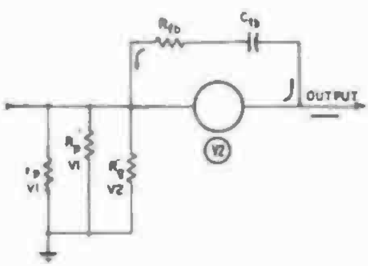

Fig. 12-149B. Equivalent circuit for the plate load of the negative-feedback amplifier shown in Fig. 12-149A.

12.150 Is it practical to include several amplifier stages in the feedback loop?—Yes, because negative feedback reduces the distortion only within the feedback loop; therefore, it is desirable to include as many stages as can be operated with good stability. If the amplifier contains several stages and has a tendency to become unstable, individual feedback loops may be used covering a single or several stages.

If the amplifier stages include coupling transformers, the proper polarities must be observed or positive feedback may be the result. If several feedback loops are used, the total feedback is the sum of the feedback in each individual loop.

12.151 How are the polarities determined for an amplifier in which the feedback loop encompasses several stages?—For an odd number of stages, the feedback loop is connected from the plate of the output tube to the control grid of the first stage. If taken from an output transformer secondary, the feedback loop is connected to the cathode of the first stage. For an even number of stages, the feedback loop is connected from the plate of the last tube to the cathode of the first stage.

12.152 Are special output transformers required for use with negative-feedback amplifiers?—No. Standard high-quality transformers may be used; however, they must have the correct impedance ratios as specified for a particular circuit operation. Output transformers should have a high degree of coupling between output winding and primary winding to reduce the effects of leakage reactance and insertion loss.

12.153 Does the method used for interstage coupling in an amplifier affect the phase-shift characteristics?—Yes, the interstage coupling has a pronounced effect on the phase-shift characteristics. This is particularly true of resistance-coupled amplifiers at very low frequencies.

12.154 What is negative-current feedback? — Negative-current feedback is obtained by connecting a resistor in series with the output load of the amplifier, as shown in Fig. 12-154. The feedback voltage is taken from across this resistor and returned to an earlier part of the circuit. Negative feedback is proportional to the output current and may be likened to a constant-current generator with infinite internal impedance, because it delivers a constant current regardless of the load impedance. If the output current increases, the feedback voltage is increased, tending to reduce the output current to its

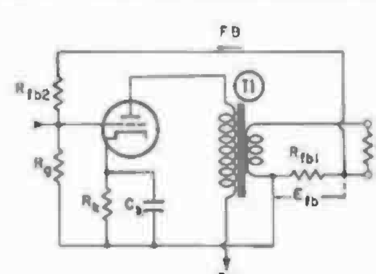

Fig. 12-154. Negative-current feedback.

former value. Negative-current feedback is not generally used in audio amplifiers except in the case where variable damping is used.

Negative-current feedback can also be obtained by omitting the cathode-bypass capacitor C_k across the cathode resistor R_k. This method decreases the gain and the distortion, but increases the internal output impedance. Consequently the output voltage rises, and if a loudspeaker is being driven, the resonant frequency of the speaker system and hangover effects are accentuated. Current feedback increases the internal output impedance, while negative-feedback voltage decreases the internal output impedance.

12.155 What is the procedure for designing an amplifier using negative feedback?—Referring to the amplifier schematic in Fig. 12-155, assume the gain of each stage is 20 or a total voltage gain of 400 (20×20). To determine the amount of negative feedback that will be required, assume the overall harmonic distortion of the two stages is 10 percent, and that it is desired to reduce this distortion to a value of 2 percent. This is a gain reduction of five, therefore:

$$(1 - A\beta) = 5$$
$$-A\beta = 4$$
$$-\beta = \frac{4.0}{A}$$

where,

A is the voltage gain of two stages before the application of negative feedback.

Substituting the voltage gain:

$$-\beta = \frac{4.0}{400}$$
$$= 0.01$$

To obtain the value of the feedback resistor R_{fb}, beta is used as a positive number.

$$\beta = \frac{R_k}{R_{fb} + R_k}$$

All values are known except R_{fb}; therefore, solving for R_{fb}:

$$R_{fb} = \frac{R_k}{\beta} - R_k$$
$$= \frac{500}{0.01} - 500$$
$$= 49{,}500 \text{ ohms.}$$

The feedback capacitor C_{fb} is selected for a value that will have a reactance equal to one-tenth of 49,500 ohms or 4950 ohms at the lowest frequency to be amplified. The capacitor may be calculated:

$$C = \frac{1}{2\pi f X_c}$$

where,

f is the lowest frequency to be amplified,

X_c is its reactance at the lowest frequency.

To express the feedback voltage in decibels use the formula:

$$dB = 20 \text{ Log}_{10} (1 - A\beta)$$
$$= 20 \text{ Log}_{10} 5$$
$$= 14 \text{ dB.}$$

The foregoing does not include the current feedback applied to the first stage because of the unbypassed cathode resistor. To determine beta for the current feedback use the formula:

$$\beta = \frac{R_k}{R_{eq}}$$

where,

R_k is the cathode resistor,

R_{eq} is the load impedance of the tube. (The load impedance is the parallel combination of R_p and the following grid resistor R_g.)

Therefore:

$$\beta = \frac{500}{100 \times 10^{-3}}$$
$$= 5 \times 10^{-3}$$
$$= 0.005$$

To express the current feedback in decibels, use the formula:

$$dB = 20 \text{ Log}_{10} (1 - A\beta)$$

where,

A is the gain of the stage to which current feedback is applied (for this example, 20).

$$dB = 20 \text{ Log}_{10} 1 - (20)\ (-0.005)$$
$$= 20 \text{ Log}_{10} 1 - (-0.1)$$
$$= 20 \text{ Log}_{10} 1.1$$
$$= 0.84 \text{ dB.}$$

In performing calculations involving beta for negative-feedback amplifiers, beta is always negative. However, when calculating the feedback resistor R_{fb}, it is used as a positive number.

12.156 What is the effect of reducing the size of the feedback-loop capacitor C_{fb}?—Less feedback is obtained at

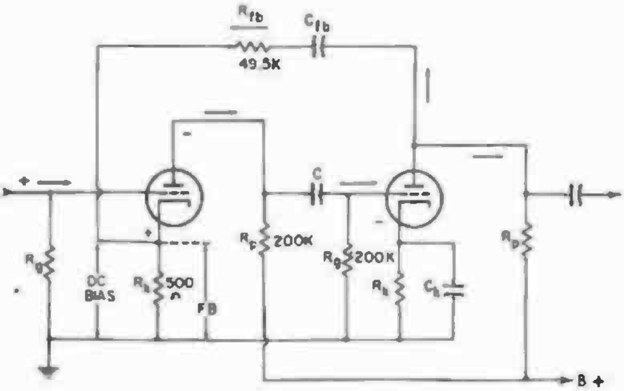

Fig. 12-155. A two-stage RC negative-feedback amplifier for design problems.

the lower frequencies, resulting in more gain at the lower frequencies. This results in a rising frequency characteristic and is sometimes used to increase the low-frequency response in preamplifiers.

12.157 Can the feedback-loop circuit be used for equalization?—Yes, if precautions are taken to prevent excessive phase shift and the amplifier is not overloaded at the maximum frequency of equalization. Fig. 12-157 shows how the equalization (equalizer components) may be connected in a feedback loop to secure a particular frequency response. Resonant circuits may be inserted in the feedback loop; however, the coils should be of fairly high Q to permit the shunting of resistors across them, and thus control the shape of the resonant curve. Resistors may be connected in series or shunt with the capacitors to obtain a particular shape of the resonant curve. For the initial adjustment, the coils are resonated to their midfrequency; then resistors are adjusted in value for desired response.

The use of tuned circuits in a feedback loop is rather risky, as oscillation may be induced because of phase shift. After final adjustment, the amplifier should be tested for oscillation by connecting an oscilloscope across the output and applying short pulses or tone bursts to the input. Also, the frequency response should be limited to about 8000 Hz. If bridged-T equalizer configurations are used in the feedback loop, it is less likely to develop oscillation. (See Question 6.96.)

12.158 Is it permissible to equalize an amplifier stage within the feedback loop?—No. Equalization is always connected in the stages outside the feedback loop because the feedback attempts to flatten out the frequency response of the stages within the feedback loop. Fig. 6-96 shows the various positions where equalization may be induced in an amplifier circuit.

12.159 What are the disadvantages of taking the feedback voltage from the primary or top of the output transformer?—Although phase shift is re-

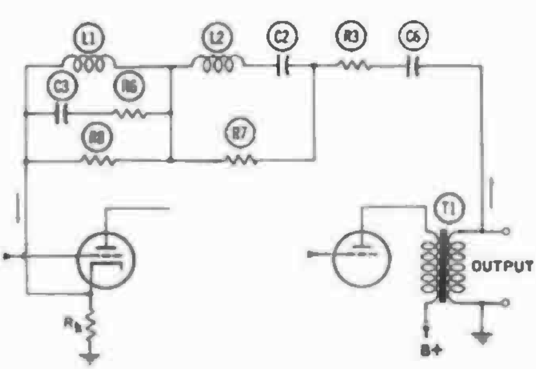

Fig. 12-157. Equalizer components in a negative-feedback loop. A parallel-resonant circuit is formed by L1 and C3. A series-resonant circuit is formed by L2 and C2.

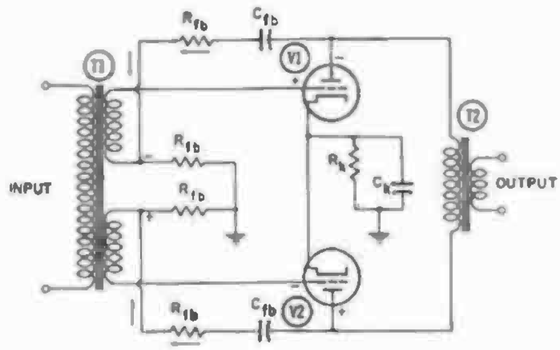

Fig. 12-161. A push-pull amplifier with negative feedback.

duced to a minimum, some loss of high frequencies may result due to the shunting effect of the feedback loop. Also, the characteristics of the output transformer are not included in the feedback loop.

12.160 What are the advantages of taking the feedback voltage from the output winding of an output transformer?—The characteristics of the output transformer are included in the feedback loop.

12.161 Is it practical to use feedback in both sides of a push-pull amplifier?—Yes; it may be done as shown in Fig. 12-161. However, the feedback loops must be carefully balanced to secure exactly the same amount of feedback in each side of the circuit. The transformer characteristics are not included in the feedback loop.

12.162 Describe a tertiary winding and its use.—It is the practice of some manufacturers to use a tertiary winding (third-winding) in the negative-feedback loop of an amplifier to eliminate the ground connection required to complete the feedback loop circuit when the characteristics of the output transformer are to be included in the feedback loop. Fig. 12-162 is a typical example of such design.

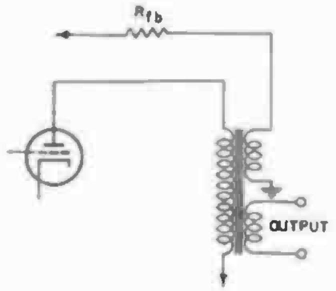

Fig. 12-162. Negative feedback using a tertiary or third coil on the output transformer.

Tertiary windings are also used on interstage transformers for driving auxiliary equipment and on output transformers for the same purposes. In designing such transformers, specified loads are given for each winding to prevent upsetting the impedance relationship of the windings relative to other portions of the circuitry.

12.163 How can a negative-feedback amplifier be used with 20 dB of feedback if it becomes unstable with 18 dB of feedback?—By introducing phase-shift networks or by staggering the time constants in the feedback loop. The time constants must also take into consideration the output transformer. Because of manufacturing variations, the output transformer is often the cause of instability and the duplication of a given circuit may be difficult.

The time constant of the output transformer will also vary with the dc balance of the tubes, core material, windings, and the excitation level of the output stage. All these factors will cause instability, particularly at the low-frequency end of the spectrum.

In a well designed negative-feedback amplifier, it should be possible to increase the feedback at least 6 dB before the amplifier becomes unstable over a frequency range one octave below the lowest frequency, and two octaves above the highest frequency.

12.164 What type amplifier is recommended for driving a cutting head, loudspeaker, light modulator, and similar devices?—One using negative feedback in the output stage, because of the damping offered by its use. (See Question 12.145.) The internal output impedance of the amplifier should be approximately one-tenth that of the load impedance. This would be a damping factor of 10:1. Damping factors below 1.0 are generally hard to obtain, because of the dc resistance of the output winding. The measurement of internal output impedance is discussed in Question 23.138.

12.165 Show several methods of connecting the negative-feedback loop

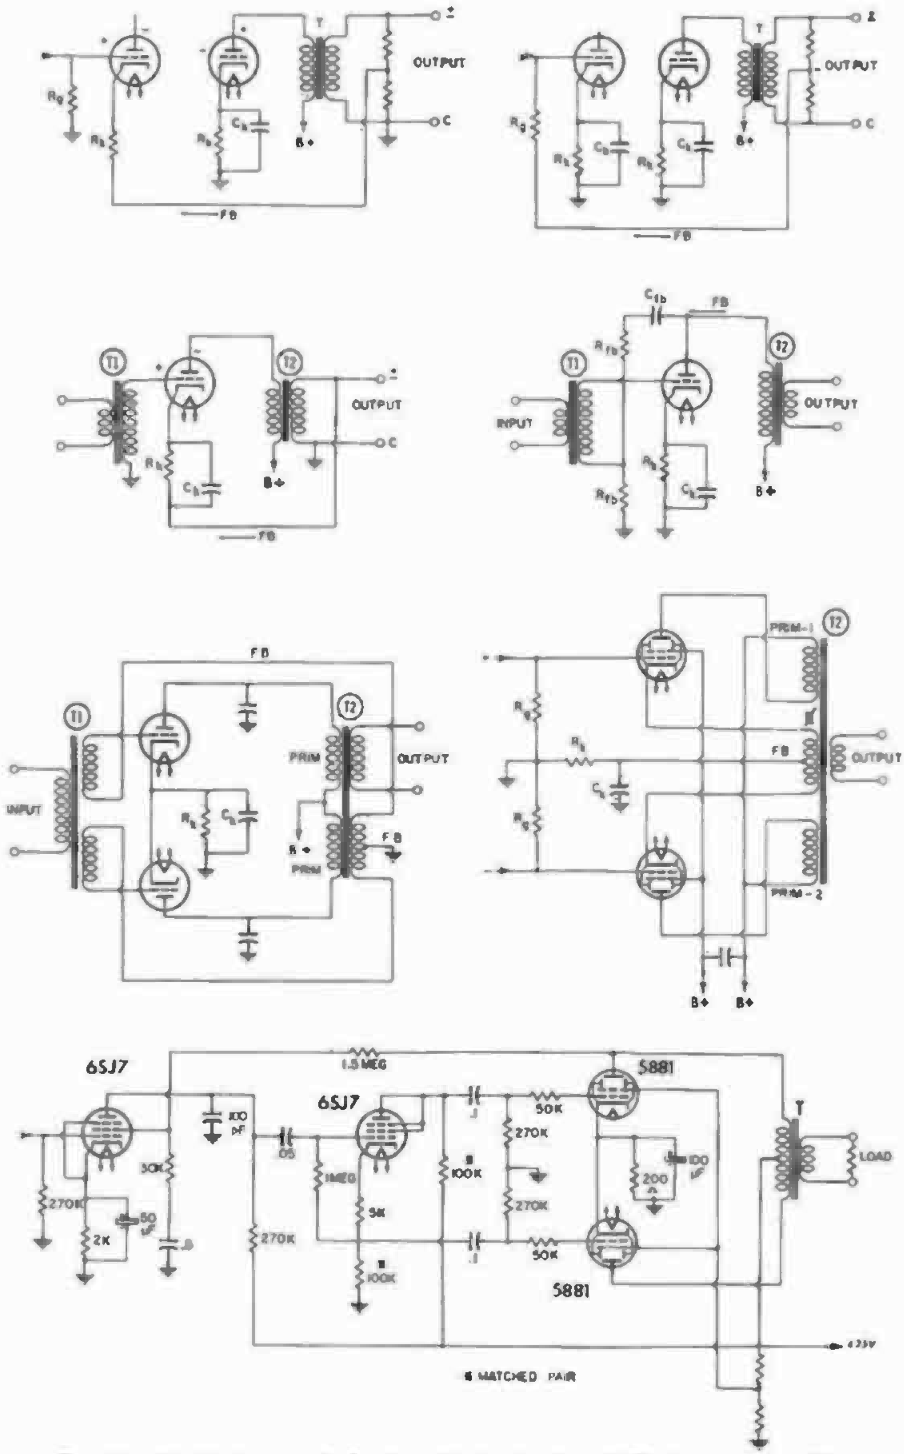

Fig. 12-165. Various methods of applying negative feedback to an amplifier.

in an amplifier.—Various methods used for applying negative feedback to an amplifier are shown in Fig. 12-165. In so doing, care must be taken that the voltage fed back from the output to the input is always 180 degrees out of phase with the voltage at the input circuit where the feedback loop is connected. The simplest way to determine the polarity of the voltage is to assume an instantaneous positive voltage at the input and then follow the phase reversals through the amplifier to the point from which the negative-feedback voltage is to be taken.

12.166 What is a balanced negative-feedback amplifier? — An amplifier employing both negative and positive feedback as shown in Fig. 12-166. The advantage of such circuitry is the wide frequency range possible without the loss of gain suffered with the conventional negative-feedback circuits. The amplifier is first designed for use with conventional negative feedback and then the positive feedback loop is added to bring the gain back to its original value before the negative-feedback loop was added. Although this type amplifier is called a balanced amplifier it is not necessary that the two feedback loops balance each other. The disadvantage of this circuit is that if the negative loop should open, the amplifier will go into violent oscillation.

12.167 How may a negative-feedback amplifier be tested for stability?— By connecting a capacitor across the output winding in parallel with a resistive load and observing with an oscilloscope the effect on a square wave applied to the input, as described in Question 23.125.

Negative-feedback amplifiers are generally thought of as being quite stable and little attention is given to the idea that they may oscillate at an inaudible frequency when a signal is applied to the input. Although the stability of an amplifier may appear to be satisfactory using a resistive termination, when a reactive load is substituted for the resistive termination the story may be quite different. This is particularly true of some types of amplifiers when a capacitive load, such as an electrostatic loudspeaker, is connected across the output. Such devices reflect a high capacitive reactance to the plates of the output tubes, equivalent to several microfarads; the exact amount will depend on the impedance ratio of the output transformer and the internal capacitance of the loudspeaker. The transformation of capacitance is discussed in Question 8.34.

As an example, assume an electrostatic loudspeaker with an internal capacitance of 0.0025 μF is connected across the output of a push-pull transformer with a ratio of 6600/16 ohms. This is an impedance ratio of 412:1. The equivalent reflected capacitance to the plates of the output tubes will be in the order of 1.03 μF. Unless the amplifier is of very stable design, it will oscillate violently. In some instances, if the capacity of the cable connecting the loudspeaker is high, it may reflect enough capacitive reactance to cause the amplifier to oscillate. When making tests for stability, capacitors ranging from 0.0025 to 1.0 μF should be connected in parallel with a resistive termination across the output and the effect observed as described in the foregoing.

Negative-feedback amplifiers in which the feedback voltage is taken from the top of the output transformer

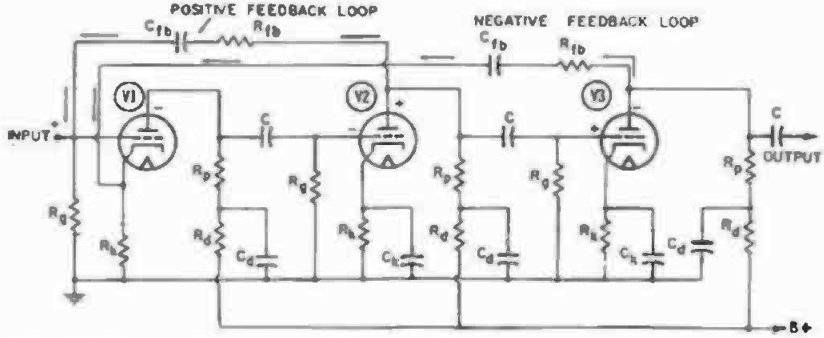

Fig. 12-166. A balanced amplifier using both negative and positive feedback.

primary are, as a rule, quite stable. Those supplying the feedback voltage from an output winding are more prone to oscillation at inaudible frequencies, because of the phase shift induced by the output windings at the high frequencies.

The stability of a negative-feedback amplifier may be increased by staggering the cutoff frequency of the various stages to vary the time constant between stages. The calculation of time constants is discussed in Question 25.106.

To assure the maximum stability in an amplifier, the design should be such that the feedback voltage can be increased at least 6 dB and preferably 10 dB over that normally used in the circuit over a frequency range of two to three octaves above and below the normal operating frequency range. This means that for an amplifier of 20 to 20,000 Hz, the frequency response must be extended from 10 to 60,000 Hz.

When an amplifier is oscillating at an inaudible frequency, the high frequencies become hard and rasping and will quickly cause listener fatigue. If the amplifier is near the point of oscillation and is shock-excited by the input signal, it will break into oscillation at subharmonic frequencies, causing the low frequencies to be distorted and have a lack of definition.

12.168 What are the phase-shift characteristics of a high-quality negative-feedback amplifier?—To obtain a flat frequency response in an amplifier from 20 to 20,000 Hz, with low distortion characteristics and phase-shift, requires that the bandwidth be 7 to 10 times the usable frequency response. Phase shift becomes apparent and measurable at values of one-seventh to one-tenth the frequency where the response falls off 2 dB, with respect to the reference frequency. Small changes in the frequency response of only 0.1 dB can cause phase shift up to 10 degrees, and a change of 3 dB can cause a shift of 45 degrees. Therefore, the negative feedback is reduced in proportion to the cosine of the phase-shift angles. This indicates the necessity for such a wide bandwidth. The phase-shift characteristics for an amplifier having a frequency response of plus or minus 1 dB, at 20 Hz to 100,000 Hz, are shown in Fig. 12-168.

12.169 What is the purpose of connecting a resistor and capacitor from plate to plate in a push-pull amplifier employing beam-power tubes in the output?—To improve the output impedance characteristics and frequency response when the tubes are terminated in a load such as a loudspeaker, cutting head, light modulator, or similar device in which the reflected impedance is not constant.

A network connected in the plate circuits of a push-pull amplifier using beam-power tubes without negative feedback is shown at part (a) in Fig. 12-169. It will be noted the network consisting of resistor R and capacitor C is connected in parallel with the reflected impedance to the tubes.

The equivalent circuit for the network shown at part (a) is given at part (b). When the reactance of the transformer primary Z_{pri}, and the resistor, R, are equal, the combined impedance seen by the plates of the tnbes will equal R. As the frequency is increased, the reactance of capacitor C decreases; thus, at the higher frequencies, only the resistor R is left in the circuit. At the lower frequencies, the reactance of C is quite high which is equivalent to removing resistor R from the circuit.

A network more suitable for push-pull amplifier operation is shown at part (c) in Fig. 12-169. Resistors R1 and R2 are about 1.3 times the recommended plate-to-plate impedance and are connected in series with capacitors C1 and C2 to ground. The capacitor is selected for a value that will result in the same voltage gain at 3000 Hz as that at 400 Hz. Generally, a capacitor of 0.03 to 0.06 μF will suffice for the average amplifier. If the components of the above networks are selected properly, a fairly uniform impedance is reflected to the plates of the output tubes resulting in

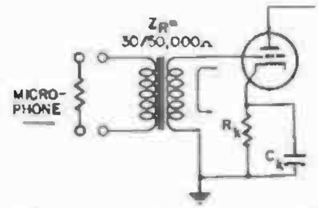
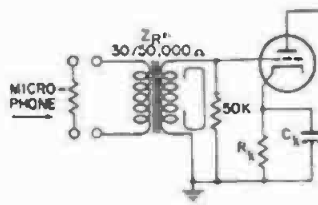
a considerable improvement in performance.

The same type of network may also be used in a single-ended amplifier as shown at part (d) in Fig. 12-169. In this instance, the resistance is also 1.3 times the recommended plate-load impedance. As a rule, the foregoing networks are not used in amplifiers employing negative feedback, although they have been used to some extent in the past.

12.170 Is it advisable to terminate the secondary of an input transformer in a microphone preamplifier?—No, because of the reduced signal voltage at the control grid. In the circuits of Fig. 12-170 are shown an unterminated input, also called an open-circuit input in part (a) and a terminated input in part (b).



(a) *Unterminated input (maximum voltage).*



(b) *Terminated input (signal voltage 50% lower).*

Fig. 12-170. Preamplifier input circuits.

To illustrate the difference between the two circuits, assume the input transformer has an impedance ratio of 30 to 50,000 ohms (1666/1). Using the unterminated circuit in part (a), the primary does not terminate the output of the microphone because the secondary winding is unloaded. In this instance, it may be said the transformer is terminated by the microphone on the primary side. Therefore, the secondary presents to the control grid of the tube a 50,000-ohm impedance and the maximum signal voltage of the secondary is applied to the control grid. (Actually, the input impedance of the tube terminates the secondary of the transformer; however, unless the input capacitance is considerable and the secondary very high, the effect of the tube capacitance may be neglected.) For the terminated secondary in part (b), only half the signal voltage is applied to the control grid. This is a 6-dB reduction of signal voltage, which also reduces the signal-to-noise ratio by 6 dB. This may be explained as follows: Connecting a 50,000-ohm resistor across the secondary of the input transformer is the same as having a 50,000-ohm generator working into a 50,000-ohm load. Therefore, the voltage at the secondary of the transformer is divided, with one-half across the internal impedance of the generator (50,000-ohm secondary) and the other half across the load (50,000-ohm resistor). Because the control grid is connected to the top of the secondary and the other end of the secondary is grounded, the control grid sees only one-half of the signal voltage—that across the 50,000-ohm resistance.

As a rule, microphone input transformers are designed to be operated open circuit (unterminated) and, because the grid circuit of a vacuum tube may be considered to be an open circuit, the secondary is said to be unterminated or working into an open circuit.

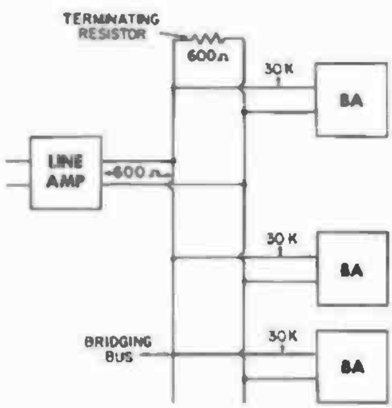


Fig. 12-171. Line amplifier with a 600-ohm output bridged by three 30,000-ohm inputs.

12.171 What is a bridging input?—A device with a high input impedance, designed for connection across an impedance of low value. Bridging inputs are used with amplifiers, volume indicator meters, and similar devices that may be required to bridge another circuit without drawing appreciable power from the circuit bridged. Standard bridging impedances used in the broadcasting and recording industries are: 7500, 10,000, 25,000, and 30,000 ohms. A 600-ohm circuit being bridged by three 30,000-ohm inputs is shown in Fig. 12-171. Bridging transformers are discussed in Question 8.62.

12.172 How can a low-impedance input transformer be used as a bridging coil?—This problem is discussed in Question 8.63.

12.173 How is the loss for a low-impedance transformer computed when it is used as a bridging transformer?

$$\text{dB loss} = 10 \operatorname{Log}_{10} \frac{B_r}{R}$$

where,

B_r is the impedance of the bridging transformer,

R is the impedance of the circuit bridged.

This equation should not be used for an impedance ratio less than 10.

12.174 What is the purpose of connecting a resistor in series with each plate of a push-pull parallel amplifier?—To balance the plate currents and to prevent parasitic oscillation. The value of these resistors is generally on the order of 47 ohms.

12.175 What is the purpose of connecting a resistor in series with each control grid of a push-pull amplifier?—The resistor serves two purposes: (1) if a sudden overload occurs, grid current will be caused to flow and the series resistor tends to reduce distortion by causing the bias on the control grid to be increased by the flow of grid current through it, and (2) the resistor also tends to prevent parasitic oscillation by acting as a damper in the grid circuit.

The use of grid-limiting resistors is not entirely confined to use in push-pull amplifiers but they are used in many vacuum-tube circuits. Generally, the value of such resistors will vary between 100 and 10,000 ohms. There are no set rules as to the exact value; however, a rule of thumb indicates that tubes with high values of G_m will have a tendency to become unstable, particularly tubes such as 6L6, 1614, 5881, 6146, 6550 and similar type tubes, unless grid-stopping resistors are employed. This instability is due to wiring and socket capacitance, causing the tubes to oscillate at very high frequencies. Stopping resistors of 500 ohms are used in screen-grid circuits, and sometimes a 47-ohm resistor is connected in the plate circuit, which helps to balance the plate currents. The resistor must be connected at the socket terminal to be effective. The use of stopping resistors is illustrated in Fig. 12-130.

12.176 What does the term plate-to-plate mean?—It is the total impedance seen by the plates of the two sides of a push-pull amplifier. (See Question 12.110.)

12.177 How is the damping factor of an amplifier calculated?—By the use of the equation given below:

$$D_f = \frac{Z_L}{Z_{out} + R_{vc}}$$

where,

Z_L is the rated load impedance,
Z_{out} the internal output impedance of the amplifier,
R_{vc} the dc resistance of the voice coil as measured by an ohmmeter.

The subject of damping is discussed in detail in Questions 12.183, 20.103, and 23.138.

12.178 What is a driver stage?—The amplifier stage preceding the output—the power-amplifier stage.

12.179 What does the term "looking into" mean?—An expression used to designate the point from which a circuit is to be considered. Example: The impedance seen when looking into the output of an amplifier.

12.180 What is source impedance?—The impedance of a device or line that is the source of a signal voltage.

12.181 What is input impedance?—The rated input impedance of a device.

12.182 What is internal input impedance?—The actual impedance seen when looking into the input terminals of a device. The actual internal impedance may be different from that specified for the source impedance. As an example, an amplifier with a bridging input impedance of 10,000 ohms may be specified to work from a 600-ohm source. Or, an amplifier designed to work from a 250-ohm source may have an actual input impedance of 1000 ohms.

12.183 What is internal output impedance?—The actual impedance seen when looking into the output terminals of a device. The internal impedance may be only a fraction of the specified load impedance. This is particularly true of negative-feedback amplifiers. A typical case is an amplifier using negative feedback which is specified to work into a 16-ohm load, although the internal outpnt impedance may only be 1.6 ohms. (See Question 12.145.)

12.184 What is load impedance?—The specified load impedance a device is designed to work into. Many times the load impedance is higher than the internal output impedance. (See Question 12.183.)

12.185 What is nominal impedance?—The impedance specified hy the manufacturer which will produce a given set of results. Amplifiers may be designed to operate from several different values of source impedance; thus, the overall gain will vary with different values of source impedance. It is customary for the manufacturer to specify the gain and other characteristics for a given source and load impedance.

12.186 What is the maximum undistorted power output of an amplifier?—The maximum power output obtainable with the lowest possible harmonic distortion.

12.187 Under what conditions is the maximum power transmitted from a generator to an external load?—When the external load is equal to the internal impedance of the generator. This is shown graphically in Fig. 12-187.

As the load impedance is increased from a low value the transmitted power is increased until a point is reached where the internal impedance of the generator and the external impedances are the same. At this point, a maximum transfer of power is effected. The voltage across the load and the generator will be equal. If the load impedance is increased to a value greater than the generator impedance, the power will drop off as shown by the right-hand portion of the curve.

Although maximum power is transmitted when the load is equal to the generator, this does not always hold true for amplifier design. It is not uncommon to find the internal output impedance (generator) of an amplifier considerably different from that of the specified load impedance.

12.188 What should the load impedance be to obtain the maximum undistorted power output from a vacuum tube?—For triodes, the plate-load impedance should be twice the plate resistance of the tube at the lowest fre-

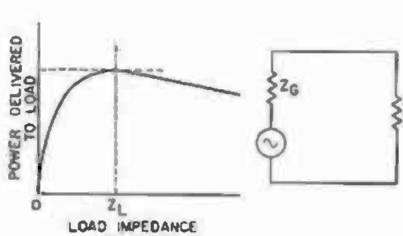

Fig. 12-187. Variation in power transfer for different values of load resistance.

quency to be amplified. For pentodes and beam-power tubes, the plate-load impedance is generally in the order of one-fifth to one-tenth the plate resistance. Under these conditions, the maximum power is obtained with the lowest harmonic distortion. In the latter instance, the manufacturer generally states the load and distortion for a given set of conditions in the tube data sheet.

12.198 What type tubes are generally selected for a voltage amplifier?—Tubes having a high transconductance with low internal noise.

12.190 What type tubes are used in power amplifiers?—Tubes which will deliver a high signal current rather than voltage. Typical power tubes are the 2A3, 6V6, 6L6, 5881, and the KT-66. All of the above, except the 2A3 are of the beam-type construction.

12.191 What is the Miller effect?—It is the effect on the high-frequency response of a vacuum tube caused by the internal capacitance existing between the various elements used in its construction.

Input capacitance exists in all vacuum tubes between the control grid and the plate, screen grid, and cathode elements. The value of this capacitance will vary with the internal construction and the amplification factor. This effect is known as the "Miller effect" and was named for its discoverer.

An interesting fact regarding the control grid-to-plate capacitance is that its apparent value is controlled by the amplification factor of the tube. When an input signal changes the voltage at the control grid, the cathode potential remains stationary and the internal capacity is charged to a given value. However, the capacitance existing between the control grid and the plate elements is not only charged by the control grid signal but also by the plate variation in voltage which is opposite in direction to the control grid change and larger by the voltage gain of the tube involved. These considerations lead to an equation for the input capacitance:

$$C_{in} = C_{cg-k} + C_{cg-p} + (A + 1)$$

where,

A is the voltage gain of the tube.
C is the capacitance between the tube elements.

The static values of interelectrode capacitance may be obtained from the tube manufacturer's data sheets. If the plate load consists entirely of resistance, the input impedance of the tube appears as a capacitance. If the plate load consists of a reactance, such as an inductance, the input of the tube appears as a resistance.

A capacitive input tends to reduce the high-frequency responses of the stage. Pentodes which have smaller input and output capacitance show considerably less Miller effect and are preferred where the frequency response must cover a wide range. (See Question 11.63.)

12.192 At what points are the signal voltages in a vacuum tube measured?—The input voltage is measured between the control grid and ground, and the output signal between the plate and ground. This statement will only hold true for conventional tube circuits, as there are instances where the signal is measured between other points and elements.

12.193 What does the term motorboating mean and what is its cause?—Motorboating is a low-frequency oscillation in an amplifier caused by common coupling between the stages of a multistage amplifier. The result is a low-frequency sound similar to the putt-putt of a motorboat; hence, its name.

Generally, this type of oscillation is caused by the lack of adequate decoupling between the amplifier stages, unwanted coupling being provided by the internal impedance of the power supply. In equipment which has been known to be functioning properly, motorboating may be caused by an open, or a changing in value of a bypass capacitor or grid resistor. Decoupling circuits are discussed in Question 12.36.

12.194 What is the purpose of supplying direct current to the heater circuit in a preamplifier?—Because a preamplifier is generally operated in a low-level circuit such as at the output of a microphone, photocell, or pickup, it is subject to hum pickup created by the ac operation of heater circuits. The use of direct current will eliminate this difficulty.

As a rule, most professional magnetic recorders use dc on the heaters of the record and playback amplifiers. The dc voltage may be obtained from small silicon or selenium rectifiers. This subject is discussed further in Question 21.64.

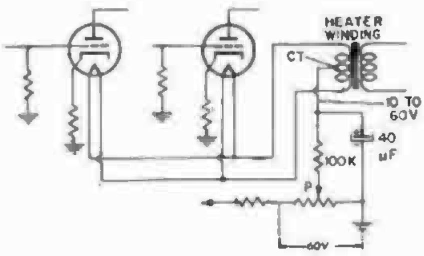

Fig. 12-195. Cathode-leakage reduction by the use of a dc bias connected to the center tap of the heater winding.

12.195 What is the purpose of connecting the center tap of an ac heater winding to a source of dc potential?—To reduce the difference of potential between the cathode and heater circuits. In this manner, leakage between these elements is eliminated resulting in a much lower noise level. A typical circuit for this use is shown in Fig. 12-195.

The dc potential is adjustable and is made positive by the same amount or a slightly higher amount than the cathode bias. Potentiometer P is adjusted while observing the noise level at the output of the amplifier, on a vacuum-tube voltmeter.

12.196 Describe an operational amplifier, its circuitry, and use.—Functionally speaking, an operational amplifier is a device which by means of negative feedback (and other elements), is capable of processing a signal voltage with a high degree of accuracy, limited only by the tolerances of the passive elements used in the amplifier and feedback networks. Electronically, it is a simple high-gain amplifier of high stability with large amounts of negative feedback connected between the input and output circuits. The external feedback elements may be resistive, reactive, nonlinear, or linear.

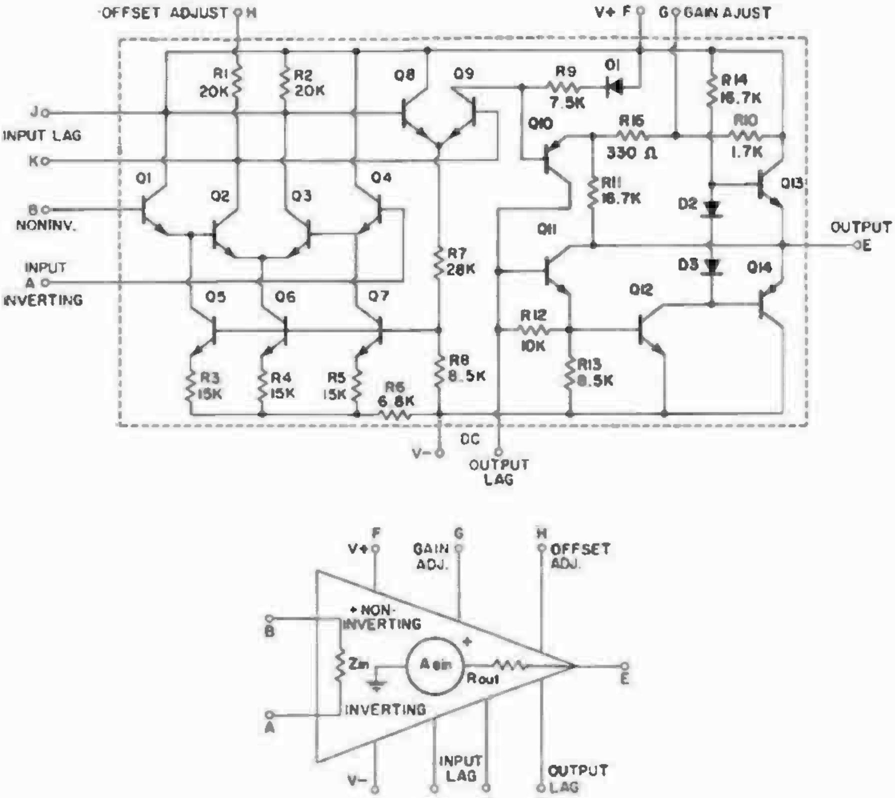

Fig. 12-196A. Circuitry for a monolithic operational amplifier, and its equivalent. (Courtesy, Motorola Semiconductor Products, Inc.)

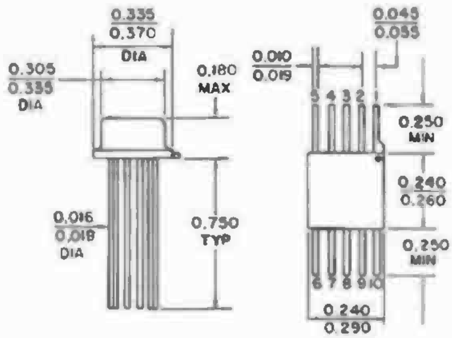

Fig. 12-196B. Physical dimensions of module. (Courtesy, Motorola Semiconductor Products, Inc.)

Operational amplifiers are of such design that an open-loop gain of several million may be reduced to one-tenth the gain by the application of negative feedback. This would be impossible using conventional amplifier circuitry. To achieve these results, the internal amplifier circuits are direct-coupled, the gain rolled-off before unity gain occurs, and before phase shift can cause oscillation. Its frequency characteristics are determined entirely by the external feedback loop and other elements. As a rule, most operational amplifiers are constructed using integrated circuit solid-state devices, although they may consist of vacuum tubes; however, tube amplifiers are not as versatile for this purpose as those employing transistors. (See Question 12.144.)

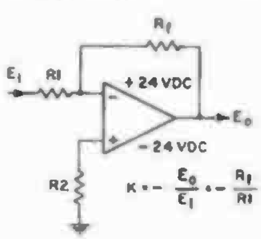
Although originally developed for use in computers, operational amplifiers find many uses in the electronic field, and are generally purchased for a particular application. They are available as booster amplifiers, phase inverters, noninverters, voltage regulators, oscillators, nonlinear amplifiers, and many other types.

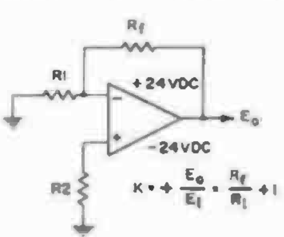
Design requirements for operational amplifiers are: high-gain, low output impedance, zero ground potential (with respect to dc), direct-coupling low dc drift, with the high-frequency response rolled-off before phase shift reaches 180 degrees.

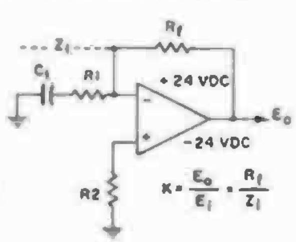
The circuitry for a monolithic-type operational amplifier is given in Fig. 12-196A, with its physical dimensions given in Fig. 12-196B. This particular circuit is designed to be used as a summing amplifier, integrator, or its operating characteristics as a function of the external feedback components. The open-loop gain is on the order of 60,000 (75.5 dB) with an output voltage of 13 volts, using a 15 Vdc power source. The internal output impedance is approximately 100 ohms.

In Figs. 12-196C to R, are given the design considerations for differential operational amplifiers, developed by B. J. Losmandy of Opamps Laboratories, and will be of considerable interest to the audio engineer, as they are similar to the design of solid-state devices used in sound-mixing consoles.

Operational amplifiers may be powered from a conventional single-voltage power supply, or from a bipolar type







—NOTE— ALL AMPLIFIER CIRCUITS ARE OPERATED FROM −24 VDC AND +24 VDC

(Fig. 12-196R). As a rule, a regulated supply is not required since the ripple voltage is a disturbance within the negative-feedback loop, and is reduced by a factor equal to the open-loop gain divided by the closed-loop gain. Thus, if the amplifier has an open-loop gain of 500, and the gain is reduced to ten, the ripple voltage is reduced by a factor of 50.

Referring to Fig. 12-196C, a differential dc gain-inverting amplifier, the closed-loop gain (K) for this circuit is equal to minus feedback resistor R_f value, divided by the value of input resistor R1. Resistor R2 is used to balance the input current to the positive input. Its value is the parallel combination of R1 and R_f. The frequency response for this circuit ranges from dc to the upper limit of the particular amplifier employed. Input voltage E_i is equal to the difference of the positive input voltage and the negative input voltage, times the open-loop voltage gain of the amplifier.

A noninverting-gain amplifier is given in Fig. 12-196D. Here the closed-loop gain (K) is equal to resistor R_f divided by R1 plus one. The additional value of one is required because of certain mathematical relations in the differential-amplifier circuitry. The dc path for the positive input is through ground; thus, bias current is supplied to the positive base of the transistor.

The amplifier of Fig. 12-196E is a typical ac amplifier. At very low frequencies, capacitor C1 approaches infinity at unity gain. Increasing the input frequency reduces the reactance of C1 until a point is reached where R1 equals $1/\pi C1$. At this point (breakaway frequency) the gain is reduced to a value of two, then increases with frequency to full gain (R_f/R1) and is then maintained over the balance of the passband. The low-frequency breakaway point $f_1 = 1/2\pi R1C1$. Capacitor C1 in the input circuit prevents the input off-set voltage from being multiplied by the gain of the amplifier (see Question 12.82) since the gain at dc is unity. This is an advantage, as each stage of a system connected in this manner will always have a minimum of dc off-set voltage in the output. Furthermore, this configuration has no phase reversal of the input signal. Therefore, when used in sound mixing circuits, the signals are not out-of-phase with respect to each other. (See Question 12.82.)

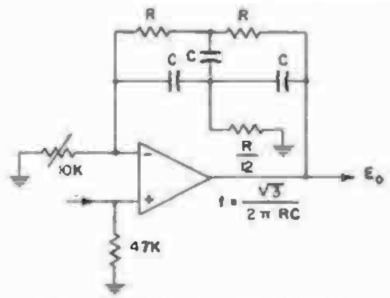

Fig. 12-196K. Bandpass amplifier.

Illustrated in Fig. 12-196F, is a microphone preamplifier with approximately 60-dB (1000) gain, capable of developing plus 22 dBm into 600 ohms. A transformer is used in the input between the output of the microphone and the input of the positive amplifier to step-up the voltage and match impedances. The overall noise is reduced since the total noise is equal to the internal noise of the transformer, plus the noise of the amplifier divided by the step-up ratio of the transformer. With the closed loop adjusted for a gain of 50, the overall gain is 60 dB. For this particular configuration, this is accomplished by adjusting feedback resistor R_f to 47,000 ohms, and the series input resistor R1 to 1000 ohms. The low-frequency minus 3-dB point is set by the combination of the 15-μF capacitor and the 1000-ohm resistor in the input, resulting in a low-frequency cutoff point of approximately 10 Hz. This circuit may also be employed as a playback amplifier for a variable reluctance pickup, by connecting the pickup between the positive input and ground.

For use as a magnetic playback amplifier, the configuration of Fig. 12-196G is employed. Here, the magnetic head is connected between the positive input and ground, with an RC network consisting of a 100-ohm resistor and a 0.005-μF capacitor in parallel to prevent self-oscillation. The network will not affect the frequency response of the head. It will be observed, the input series resistor R1 has been omitted; thus, a full open-loop gain of 54 dB (500) is realized.

An amplifier equalized for phonograph reproduction (RIAA) is given in Fig. 12-196H. The low-frequency breakaway point is set by the 40-μF capacitor and 220-ohm resistor connected in series with the negative input. For frequencies below 20 Hz, the slope is 6 dB per octave downward. The feedback resistor network has a breakaway point of 50 Hz, dropping 6 dB per octave up to 2000 Hz, then continuing out to about 30,000 Hz, then again dropping off at the rate of 6 dB per octave. The gain at 30 Hz is 60 dB, and 22 dB at 10,000 Hz. (See Question 13.95.) This same configuration also may be used for NAB tape equalization (playback) by changing

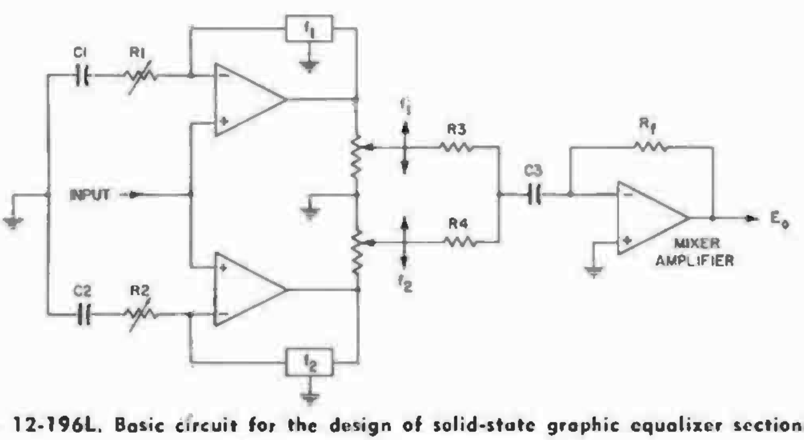

Fig. 12-196L. Basic circuit for the design of solid-state graphic equalizer sections. Only two inputs are shown here.

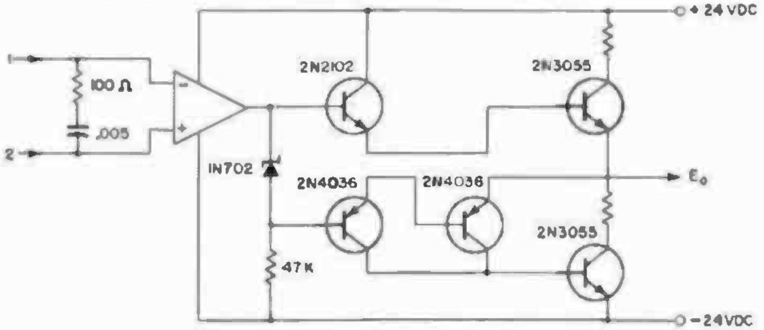

Fig. 12-196M. A 50-watt operational power amplifier.

the component values in the feedback loop given in the same diagram. For this configuration, the low-frequency breakaway point is 20 Hz, and the first high frequency is 50 Hz, then dropping 6 dB per octave to 500 Hz. From this point on, the response remains flat out to 2000 Hz, then again decreasing at a rate of 6 dB per octave. The gain at 30 Hz is 60 dB. (See Question 17.173.)

A line amplifier (Fig. 12-196I) differs from the foregoing circuits, as it makes use of both an input and output transformer. The configuration shown has a gain of 40 dB (100), with a maximum output level of plus 22 dBm. Decreasing the primary impedance of the output transformer from 600 ohms to 150 ohms will increase the output level to plus 30 dBm. The overall frequency response is limited by the frequency response of the transformers.

Compressor amplifiers are an absolute necessity in sound recording. (See Questions 18.84 to 18.101.) A simple configuration is given in Fig. 12-196J. This amplifier has adjustable attack and release-time controls with a maximum compression of 20 dB. The circuit makes use of a p-channel junction field-effect transistor (FET) connected across resistor R1. With the output level set to minus 20 dBm, the FET in the on condition, it presents an equivalent source-to-drain resistance of about 1000 ohms. Therefore, the overall gain is high. Increasing the output level and rectifying the signal through diode IN4001, it appears as a positive voltage at the gate of the FET (see Question 11.145). When the output level reaches about 0.8 V, the FET is then fully off, and the gain drops to a value of two. At low levels, the gain is about 10, resulting in a dynamic range of 10:1 (20 dB). Resistor R4 controls the charging rate of capacitor C2, thus the *attack time*. Variable resistor R2 determines the discharge time of C2, thus the *release time*. It will be noted the FET is connected inside the negative-feedback loop and automatically adjusts the gain of the amplifier as a function of output level.

Quite often a bandpass amplifier is required. Referring to Fig. 12-196K, this may be accomplished by the use of a notch filter connected in the feedback loop. The gain is controlled by the 10,000-ohm variable resistor in the input also serving as a "Q" control for the circuit, permitting the bandwidth of the filter circuit to be varied over a limited range (see Question 7.12).

The basic configuration for developing graphic equalizers is given in Fig. 12-196L. Here, each input (up to 20,

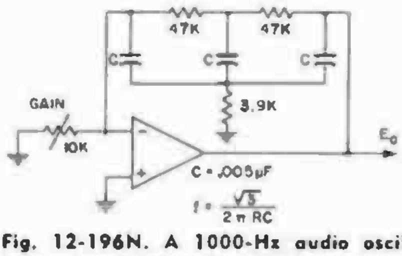

Fig. 12-196N. A 1000-Hz audio oscillator. Amplitude of oscillation is controlled by the variable resistor in the input circuit.

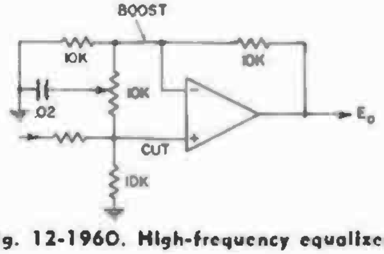

Fig. 12-196O. High-frequency equalizer.

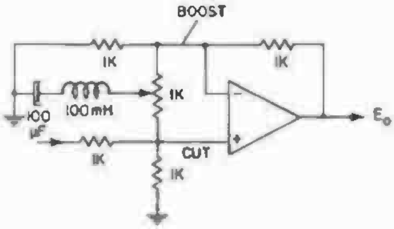

Fig. 12-196P. Low-frequency equalizer.

although only two are shown) has for its feedback elements reactive-tank circuits f_1 and f_2, or a notch filter. Each input is resonated at a selected frequency. Potentiometers R3 and R4 are connected in the output circuits of each channel and set to their midpoints. Controls R1 and R2 are adjusted to result in a broad, flat frequency response after being *summed* into the mixer-amplifier stage. To accentuate or attenuate either one of the selected frequencies (f_1 or f_2) potentiometers R3 and R4 are adjusted for the desired response in a particular stage. With high-Q LC resonant circuits, about 20-dB boost and 20-dB attenuation may be expected. The operation of graphic equalizers is discussed in Questions 6.108 to 6.128.

Configuratiou in Fig. 12-196M is an operational 50-watt amplifier, consisting of two silicon 2N3055 transistors. The upper output transistor is driven from a 2N2102 transistor connected as an emitter follower, resulting in a Darlington circuit. The lower transistor is a combination Darlington quasi-complementary configuration. The four base-to-emitter junctions of the drivers and power stages are forward-biased for class-AB operation by zener diode 1N702. Negative pull-down current is supplied by the 47,000-ohm resistor. The power stages are fed from an operational amplifier, given in Fig. 12-196E. Stability is assured by rolling-off the positive and negative input response at 320 kHz, using a 100-ohm resistor and a 0.005-μF capacitor across the two inputs. (See Questions 12.251 to 12.253.)

Power amplifiers as shown are generally operated with a closed-loop gain ranging between 2 and 20. If necessary, the power output may be increased by paralleling additional 2N3055 transistors across the output stages. In this latter instance, 0.5-ohm resistors are connected in each emitter element of the 2N3055 transistors.

Fixed frequency oscillators may be designed using the configuration of Fig. 12-196N, consisting of a 1000-Hz notch filter (or any other frequency) conuected in the feedback loop. The amplitude of oscillation is controlled by means of a 10,000-ohm variable resistor in the input circuit, and operates similar to the bandpass filter of Fig. 12-196K. Configurations for high- and low-frequency equalization are given in Figs. 12-196O and 12-196P. The high-frequency configuration employs a capacitor connected to a potentiometer across the negative and positive input circuits. The gain of the positive amplifier is only two (feedback loop adjusted for a gain of one). The positive input employs a voltage divider to reduce the gain to unity. A potentiometer is connected across the positive and negative inputs, with a capacitor between the swinger and ground. Moving the swinger from one side to the other provides an adjustable bypass from either one of the input circuits. The range of attenuation or equalization is 20 dB each, at 10,000 Hz.

Setting the potentiometer to the negative input, the upper 10,000-ohm series resistor to ground is completely bypassed and the gain is maximum. When the swinger is placed at the positive in-

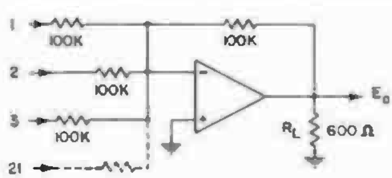

Fig. 12-196Q. Mixer-amplifier (active combining network).

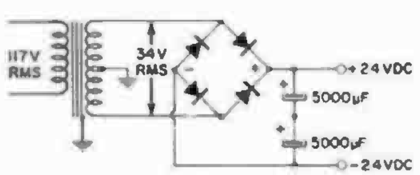

Fig. 12-196R. Bipolar power supply for operational amplifiers.

put, the input signal is also bypassed to ground. Increasing the frequency passes less signal to the amplifier input, thus the signal is attenuated. The parallel combination of the 0.02-μF capacitor and the values of resistance employed determines the frequency of turn-over. For the values given, the turn-over freqnency is 800 Hz.

For control of low frequencies, the configuration in Fig. 12-169P may be used. Here the circuit is much the same, except an LC rather than an RC circuit is used. With the potentiometer at the negative input, the inductance would short-circuit this point through the dc resistance to ground, thus driving the amplifier into saturation. This is avoided by the connection of a 100-μF capacitor in series with the inductor. The LC circuit should be resonated at the low-frequency end of the system in which it is employed. Fnr the values given, the resonant frequency is 50 Hz. The operation of this circuit is similar to the high-frequency configuration. The turnover frequency is 1600 Hz.

A mixing circuit, capable of handling up to 20 inputs, presenting no insertion loss, is given in Fig. 12-196Q. Since this circuit has uniform frequency characteristics, it may be operated as an amplifier with gain, depending on the ratio of R_f to series resistor R1. For minimum cross-talk conditions, the lowest source impedance, highest input series resistor, and highest gain amplifier shonld be used. Cross talk for the values given is on the order of 80 dB, when operating from a source and load impedance of 600 ohms. The gain equals one, with an output level of plus 22 dBm. Such circuits are often referred to as active combining networks. (See Question 5.99.)

Shown in Fig. 12-196S is the internal circuitry for a Motorola Model MC-1533 integrated circuit operational amplifier. The input stage consists of Darlington differential amplifiers Q1, Q2, Q3 and Q4 which provide a high input resistance of 1 megohm. Separate sources of current are used for Q1 and Q2 rather than a single source for the whole stage. Thus, a constant collector current is provided, making the Darlington amplifier characteristics independent of beta. Temperature compensation is provided by the feedback circuit from the second stage Q8 and Q9, through a 28,000-ohm resistor.

Q10 is a pnp low-gain transistor, driving emitter follower Q11. Transistors Q10 and Q11 shift the quiescent dc level applied to driver Q12 to almost zero. Negative feedback taken from the

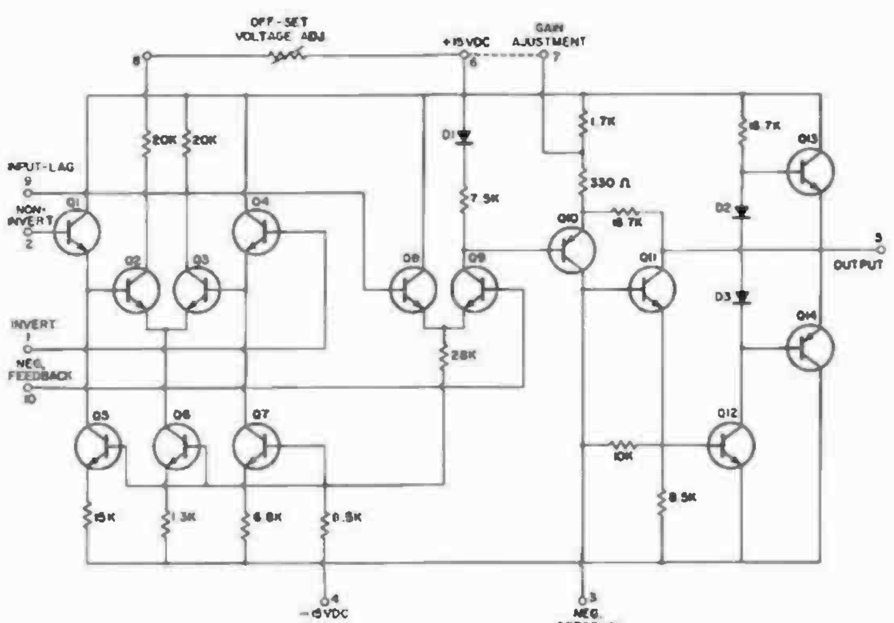

Fig. 12-196S. Internal circuitry of Motorola Model MC1533 IC operational amplifier. Negative feedback is applied between terminals 3 and 9.

output is applied to these stages to reduce the effects of crossover distortion. Output transistors Q13 and Q14 are connected complementary-symmetry biased for class-AB operation, and driven by transistor Q12. Bias voltage is supplied by the voltage drop across diodes D2 and D3, providing a small quiescent forward current to Q13 and Q14. Temperature compensation is provided by diode D1.

This circuit will provide an open-loop gain of 60,000 (75.5 dB). Maximum gain is attained when pin 7 is tied to pin 6. With pin 7 open, the gain is reduced approximately 6 dB because of degeneration in the emitter circuit of Q10. The input offset current is adjusted to zero by adjusting the voltage between pin 8 and 6. With a 15-volt supply, the output signal is 13 volts. Output impedance is 100 ohms. Common-mode rejection is 100 dB.

12.197 How may radio-signal pickup be avoided in a preamplifier stage?—By connecting a 5-millihenry radio-frequency choke coil in the upper end of the cathode in the first stage as shown in Fig. 12-197. The choke coil must *not* be bypassed. As the dc resistance of such choke coils is generally quite low, the bias voltage is not greatly affected; however, if the dc resistance does affect the bias voltage the value of the bias resistor may be decreased to compensate for the dc resistance of the choke. (See Question 24.71.)

12.198 What is a cross-coupled amplifier?—A two-stage, push-pull amplifier as shown in Fig. 12-198 used for driving a push-pull output stage. A balanced signal is applied to the control grids of tubes V1 and V2. The output signal is taken from the plates of V3 and V4. The advantages of the above circuit are low distortion and balanced output voltages.

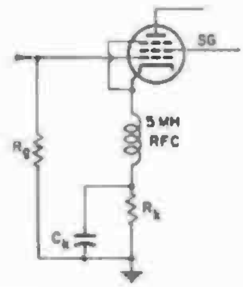

Fig. 12-197. An rf choke connected in the cathode circuit of a preamplifier stage to prevent radio interference.

12.199 If two amplifiers are connected in tandem, what is the overall frequency response?—It is the algebraic sum of the individual frequency-response characteristics of the two amplifiers. This is true regardless of the type of coupling or whether the amplifiers are individual units, as might be found in a recording system.

12.200 If two amplifiers of 20-dB gain each are connected in tandem, what is the overall gain?—Assuming all impedance matches are satisfied, the overall gain is the sum of the individual amplifiers, or 40 dB.

12.201 If two amplifiers of the same power output are connected in parallel, what is the total power output?—Assuming the amplifiers are similar in design and the output impedances are the same, the power output will be double that of a single amplifier, pro-

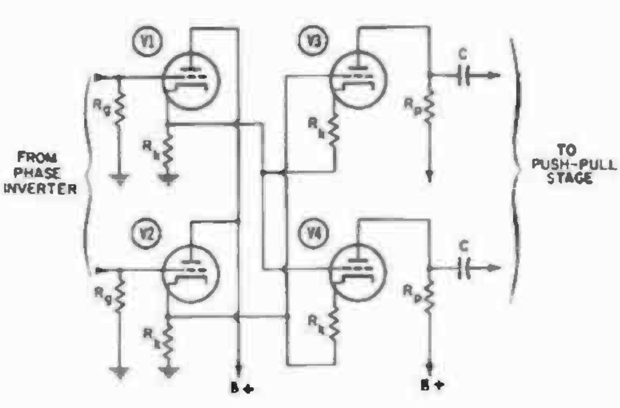

Fig. 12-198. A cross-coupled amplifier designed to take a balanced signal and supply a balanced output for driving a push-pull power amplifier.

vided the outputs are connected in phase. The output impedance will be halved.

12.202 How are the output circuits of parallel-connected amplifiers phased? —Each amplifier is adjusted for the same gain by sending a constant-level signal through both amplifier inputs simultaneously. The output circuits are then connected in parallel. If the output circuits are in phase, the output voltage will be maximum; if they are out of phase, the voltage will drop to a low value. These tests should be conducted at a low power output in an unterminated circuit. When the two output circuits are in phase, the output impedance is one-half of the normal output impedance of one amplifier.

12.203 If two amplifiers of the same power output are connected in parallel, how much is the output level increased?—Three dB and may be computed:

$$10 \operatorname{Log}_{10} 2 = 10 \times 0.301 = 3.01 \text{ dB}.$$

where,

the output impedances are the same, the outputs are in phase.

12.204 What does the term optimum plate load mean?—The ideal plate-load impedance for a given tube and set of operating conditions.

12.205 What type resistors are recommended for high-gain, low-level amplifier construction? — Noninductive wirewound types, as they have extremely low internal noise levels. Wirewound resistors are recommended for grid, plate, screen, and cathode use. Amplifiers using such resistors generally have a much lower internal noise level. The resistors must be noninductive if the amplifier is to cover a very wide band of frequencies. (See Question 5.16.)

12.206 How should the power-output rating of an amplifier be stated?— The power output should be stated for a power at which the harmonic or intermodulation distortion is not objectionable. A typical example would be: Maximum continuous power output 30 watts; total rms harmonic distortion 0.30 percent at 400 Hz, intermodulation distortion 0.5 percent for peaks less than 60 watts, using 40 and 7000 Hz mixed four to one; high frequency 12 dB lower in amplitude than low frequency.

When power amplifiers are rated in *music power output*, they are tested and rated in accordance with the Institute of High Fidelity (IHF) Standard A-201-1966, as discussed in Question 23.208.

12.207 How should the internal noise and hum of an amplifier be stated? —It should be stated in two ways: (1) with reference to the maximum power output, and (2) with reference to a 1-milliwatt reference level.

The mere statement that the noise level is so many dB below the maximum power output is often misleading unless correctly interpreted. If the noise level is stated to be 90 dB below 20 watts output, the actual noise level is, with reference to 1 milliwatt, a minus 47 dBm. This figure is obtained by subtracting the power output level, 20 watts (plus 43 dBm), from the stated noise level of 90 dB.

This interpretation is important because the amplifier is not always operated at its maximum power output. If the internal noise and hum are high, in a small room they can become quite objectionable. For high-quality reproduction, the internal noise of an amplifier should be at least 40 dB below a reference level of 1 milliwatt.

12.208 What causes the internal noise in an amplifier?—The components which make up the amplifier such as the resistors, tubes, capacitors, transformers, gain controls, and ripple voltage from the power supply. Magnetic coupling through the metal chassis also can be a cause of hum. (See Question 23.59.)

12.209 What is a class-D amplifier? —The term class-D applied to an amplifier was proposed by Crowhurst to classify a pulsed-type transistor audio amplifier. The theory behind its design being that the transistors can be operated close to 100-percent efficiency by switching at an ultrasonic frequency. The effects of switching are filtered out of the program signal.

12.210 What is magnetic coupling in an amplifier?—It is hum and noise induced in the low-level stages caused by the close proximity of the power transformer or filter chokes mounted on the same chassis. Hum and noise may also be induced by the wiring and ground loops. The subject of magnetic coupling is discussed further in Question 23.59.

12.211 What precautions should be taken when connecting equalization networks in an amplifier stage?—Measurements should be made to determine that the stage in which the equalization has been connected is not being overloaded when the maximum equalization is used. It should be remembered that an equalizer induces a loss. The amplifier must be capable of developing sufficient output to overcome the loss of the equalizer. If this precaution is not observed, serious distortion will be the result. (See Question 23.13.)

12.212 What is the purpose of extending the frequency range of an audio amplifier into the inaudible frequency range?—To obtain a frequency response covering a range of 20 to 20,000 Hz, with low distortion, flat frequency response, and low phase shift, requires a very wide frequency band for the following reasons: Phase shift becomes apparent and measurable at values of one-seventh to one-tenth the frequency where the amplifier response is down 2 dB with respect to the reference frequency.

To obtain the foregoing frequency response with less than 1-percent total harmonic distortion, the bandwidth must be 7 to 10 times the usable frequency range. This means that for an amplifier to reproduce 20 to 20,000 Hz, the frequency range of the amplifier must extend from 2 to 200,000 Hz. This frequency range is not unusual for modern high-quality amplifiers. (See Question 12.231.) This wide frequency range also permits high frequency sum and difference frequencies generated by the instruments in the original program material to be reproduced in their normal frequency bands.

A wide frequency range must exist without any trace of oscillation either in a static or dynamic condition, as oscillation at the subaudible and inaudible frequencies adds distortion to the reproduction. Oscillation at the extreme ends of the frequency response may be checked by means of a square wave generator and an oscilloscope as described in Question 23.49.

12.213 If an amplifier is oscillating at an inaudible frequency, what is the effect on the reproduction?—Harshness of the high frequencies and a rasping type distortion which induces listening fatigue.

12.214 Is the efficiency of an amplifier output stage important?—No, the efficiency of an output stage is of little importance compared to the overall current consumed by the amplifier. The greatest portion of the power consumed by an amplifier is used to heat the filaments or heaters of the tubes.

The efficiency of an amplifier stage may be calculated:

$$E_{ff} = \frac{P}{E_{av}\, I_{av}}$$

where,

P is the developed power,
E_{av} is the average voltage at the plate,
I_{av} is the average plate current.

However, this is not true of transistor amplifier output stages, as efficiency is important particularly if the amplifier is battery operated.

12.215 What is a starvation amplifier?—An amplifier employing pentode tubes with the screen voltage set 10 percent below the plate voltage and the plate-load resistance increased 10 times that normally used for a particular tube. In this manner the amplification factor is greatly increased, although the transconductance is decreased. A stage gain of 2000 or more is possible with a circuit of this kind.

12.216 How should the gain of a bridging amplifier be stated?—The actual gain when the amplifier is bridging a given impedance. As an example; assume a bridging amplifier is being fed from a 600-ohm bridging bus. The input impedance of the amplifier is 30,000 ohms. The bus level is a plus 4 dBm and the output level of the amplifier is a plus 22 dBm, what is the gain of the amplifier?

The gain is obtained by subtracting the bus level (plus 4 dBm) from the output level (plus 22 dBm) or 18 dB. There is a bridging loss of 17 dB between the input of the amplifier and the bridging bus which is the ratio of 600/30,000 and may be calculated:

$$\frac{30{,}000}{600} = 50$$

$$10 \operatorname{Log}_{10} 50 = 10 \times 1.699$$
$$= 17 \text{ dB.}$$

The actual gain of the amplifier when fed from a 30,000-ohm source is 35 dB.

The gain is stated as being 18 dB when operating from a 600-ohm source impedance. (See Question 8.62.)

12.217 Describe the procedure for designing a small single-ended amplifier with negative feedback.—Assume it is desired to design a small single-ended power amplifier which is capable of producing 6.5 watts with a maximum of 3 percent total rms harmonic distortion. The input and output impedances are to be 600 ohms. The maximum signal-input level is plus 4 dBm.

The first step is to block diagram the amplifier as shown in Fig. 12-217A. The various factors of design will be entered in these blocks as the design progresses.

For an amplifier of the foregoing proportions, a single beam-power tube such as a 6L6 will be satisfactory. Referring to the operational data for this tube, operating class-A, 6.5 watts may be obtained under the following operating conditions:

Plate voltage	250 volts
Screen grid	250 volts
Grid bias	14.5 volts
Cathode resistance	170 ohms
Peak audio-frequency voltage	14.0 volts
Maximum plate-signal current	78 mils
Maximum screen-signal current	7.5 mils
Load resistance	2500 ohms
Total rms harmonic distortion at 6.5 watts output	10 percent
Maximum power output	6.5 watts

It will be noted the distortion is stated to be 10 percent; this is without negative feedback. By the use of feedback, the distortion is to be reduced to a maximum of 3 percent.

The amplifier is first designed without feedback, and then feedback is added as explained later in the procedure. If the distortion is 10 percent without feedback and the final distortion is to be 3 percent, the distortion reduction factor is 3.33. Allowing a margin of safety, a factor of 4 will be used; thus, the gain factor is also 4. With a signal of 14 volts without feedback, 56 volts will be necessary with feedback since to maintain the same signal-to-power output, the signal at the control grid of the 6L6 must be increased by a factor of 4. This value is entered at the input of the output stage on the block diagram. The next step is to determine the gain required to drive the output stage from an input signal level of plus 4 dBm. The power at the input in watts is:

$$P = \text{Antilog}\,\frac{\text{dB}}{10} \times \text{ref. level}$$

where,

dB is the input level of plus 4 dBm,
the reference level is 0.001 watt (1 milliwatt).

The input power may now be calculated:

$$\text{Antilog } 0.4 \times 0.001 = 2.51 \times 0.001$$
$$= 0.00251 \text{ watt}$$

To find the voltage required at the input:

$$E = \sqrt{WZ}$$
$$= \sqrt{0.00251 \times 600}$$
$$= \sqrt{1.51}$$
$$= 1.23 \text{ volts rms}$$

where,

W is the watts as determined from the foregoing,
Z is the input impedance of the input transformer (600 ohms).

It is desirable at this time to convert the above voltage to peak volts, since the signal voltage at the input of the power stage is in peak volts.

$$\text{Peak volts} = 1.23 \times 1.414$$
$$= 1.74 \text{ volts}$$

The required voltage gain between the input of the voltage amplifier and the control grid of the power stage is:

$$VG = \frac{56}{1.74}$$
$$= 32.2$$

The next step is to select an impedance ratio for the input transformer.

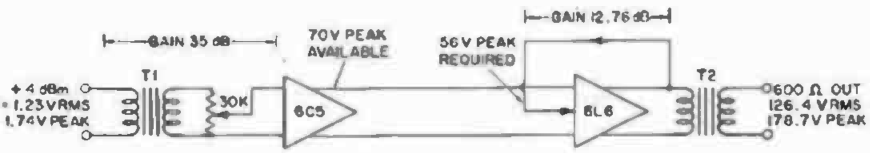

Fig. 12-217A. Block diagram for amplifier design problem.

For this problem, an impedance ratio of 600/30,000 ohms will be used, although a ratio of 50,000 to 100,000 ohms is common. The turns ratio for an impedance ratio of 600/30,000 ohms is:

$$\text{Turns ratio} = \sqrt{Z_r} = \sqrt{50} = 7.07$$

where,
Z_r is the impedance ratio.

This means that the signal voltage at the primary of the input transformer will be increased by a factor of 7.07.

As this amplifier is to present a 600-ohm impedance to the source, the secondary is terminated in a 30,000-ohm gain control. This reduces the signal voltage at the secondary to one-half the voltage obtained without the termination. Thus, the increase in signal voltage is one-half of 7.07 or 3.5. (See Question 12.170.) From the previous calculation, it was determined that 32 dB of gain was required in the first stage. To permit a small margin of safety, the gain will be taken as 35 dB.

Gain is achieved by the amplification of the first tube and the step-up ratio of the input transformer. The tube for the first stage is now selected for a voltage gain of ten or more, that will produce a peak signal voltage of 56 or greater at its plate. A medium-mu triode, such as the 6C5, resistance-coupled will produce about 70 volts rms at its plate. Therefore this tube will be used for the first stage. Referring to a resistance-coupled data chart for the 6C5, 70 volts rms signal voltage may be obtained under the following conditions:

Plate supply voltage	300 volts
Plate load resistance	50,000 ohms
Following grid resistance	100,000 ohms
Cathode resistor	2600 ohms
Coupling capacitor	0.04 μF
Voltage gain	11
Peak output volts	70 volts
Cathode bypass capacitor	2.3 μF

Both the cathode and coupling capacitors will be multiplied by a factor of 4 to extend the low-frequency response as explained in Questions 12.19 to 12.21. The next portion of the problem will be devoted to the design of the negative-feedback loop. Negative feedback will be taken from the plate of the 6L6 to its control grid through resistor R_{fb} and capacitor C_{fb} (Fig. 12-217B).

To calculate the feedback circuit, the gain of the power stage must be determined. As the stage develops 6.5 watts into a load impedance of 2500 ohms, the signal voltage at the plate is:

$$E = \sqrt{WZ} = \sqrt{6.5 \times 2500} = \sqrt{16{,}250} = 126.4 \text{ rms}$$

where,
E is the signal voltage developed at the plate,
W is the power developed by the tube,
Z is the load impedance.

To convert the rms plate voltage to peak voltage it is multiplied by 1.414, resulting in a peak voltage of 178.7 volts. The voltage gain is the peak output voltage divided by the peak input voltage (14) which is 12.76. Beta may now by calculated:

$$(1 - A\beta) = 4.00$$
$$-A\beta = 3.00$$
$$-\beta = \frac{3.00}{12.76} = 0.235$$

The equivalent resistance from the control grid of the 6L6 to ground is the resistance across which the feedback voltage is delivered and consists of the grid resistor R_g, the plate-load resistor

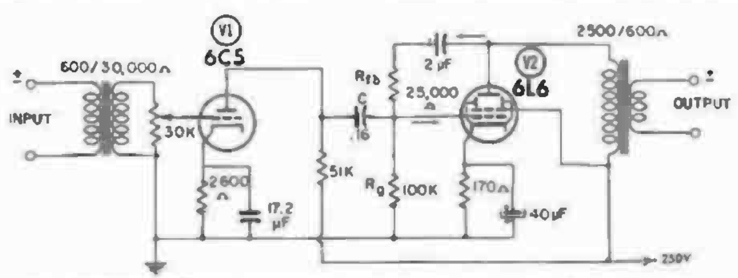

Fig. 12-217B. Power amplifier and driver stage for design problem.

R_g, and the plate resistance r_p of the preceding tube, all in parallel. The values of these components are:

R_g 100,000 ohms
R_g 50,000 ohms
r_p 10,000 ohms

The equivalent resistance R_{eq} of the above is 7700 ohms.

The feedback resistor R_{fb} may be calculated:

$$\beta = \frac{R_{eq}}{R_{fb} + R_{eq}}$$

$$R_{fb} = \frac{R_{eq}}{\beta} - R_{eq}$$

$$= \frac{7700}{0.235} - 7700$$

$$= 32{,}750 - 7700$$

$$= 25{,}050$$

where,
R_{eq} is the equivalent resistance,
R_{fb} is the feedback resistance.

The feedback loop extends from the plate to the control grid of the output tube. The resistor R_{fb} establishes the correct feedback voltage at the control grid. The capacitor C_{fb} is included to isolate the plate voltage from the grid circuit. This capacitor must have a reactance at least one-tenth the value of the total resistance in the feedback loop at the lowest frequency to be amplified.

The total resistance R_{eq} is 7700 ohms and R_{fb} 25,050 ohms making a total of 32,750 ohms. Therefore, the reactance of C_{fb} should be approximately 3300 ohms at the lowest operating frequency which, for this problem, is assumed to be 40 Hz. This will result in a capacitance of 2.0 μF.

The cathode resistor is 170 ohms and bypassed with a 40- to 50-μF electrolytic capacitor. The total plate current drawn by the amplifier will be the maximum plate and screen currents of the output tube, plus the current drawn by the first stage.

12.218 If the size of the capacitor in the feedback loop in the previous question is altered, what effect will it have on the frequency response?—Normally, the reactive element in a feedback loop is of such value it has little or no effect on the frequency response of the amplifier. This is accomplished by using a value of capacitance which has negligible reactance at the lowest frequency to be passed by the amplifier. However, if desired, the value of the capacitor in the feedback loop may be changed to obtain a rising characteristic at the lower frequencies.

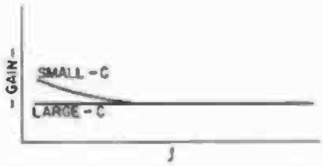

Fig. 12-218. The effect of decreasing the value of the feedback capacitor in a negative-feedback amplifier.

Assuming the value of the capacitance in the original design was selected for a flat frequency response, reducing the value of the capacitor results in less feedback at the lower frequencies; therefore, the gain of the amplifier at the lower frequencies is greater, resulting in a rising low-frequency characteristic. The effect of varying the value of capacitance in a feedback loop for a given set of conditions is shown in Fig. 12-218.

12.219 What is the purpose of connecting small capacitors from the grid or plate circuit to ground in a push-pull amplifier stage?—To prevent the generation of parasitic oscillations. If the amplifier stage employs a push-pull driver transformer, small capacitors may be connected across each half of the secondary, or from the control grid to ground. Both of these methods will affect the high-frequency response. However, if the amplifier is used only for paging or other services not requiring a wide frequency response, either method will be satisfactory. In either case, only enough capacity is used to prevent oscillation.

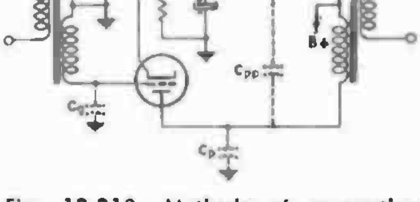

Fig. 12-219. Methods of connecting small capacitors in a push-pull amplifier to prevent parasitic oscillations.

Capacitors connected in the plate circuits may be somewhat larger in value than those used in the control-grid circuit because of the lower impedance of the circuit. At times, only a single capacitor connected from plate-to-plate will be necessary to prevent oscillation.

Parasitic oscillation is often caused by unbalances in the output transformer windings due to a greater amount of capacity existing between windings in one-half of the primary to ground. The connection of a single capacitor from one of the plates to ground to compensate for transformer unbalance will prevent oscillation. The proper plate must be found by trial.

A well-designed amplifier should not require compensation to prevent parasitic oscillation; however, because of manufacturing tolerances, this may be necessary at times. Typical methods of installing capacitors for the prevention of parasitic oscillations are shown in Fig. 12-219.

The values for the grid circuit vary from .00001 to .0005 μF. The value used, for the plate circuit is generally about .001 μF. Usually a .001 μF-capacitor is used if a single capacitor is connected from plate-to-plate. For a single capacitor from one plate to ground, use only as large a value as needed to prevent oscillation. The voltage ratings for the plate capacitors must be such they will stand the full dc plate voltage, and the peak signal voltage. Generally, 1000-volt mica capacitors are used for this purpose.

12.220 How should beam-power tubes be operated for the lowest harmonic distortion without negative feedback?—Beam-power tubes without negative feedback generally have from 7 to 13 percent total rms harmonic distortion, the greater part of the distortion being third harmonic. If the output load varies, as would be the condition when terminated by a loudspeaker, a capacitor and series resistor may be connected from plate to ground as described in Question 12.169, to help maintain a more constant load to the tubes.

A further reduction of harmonic distortion is obtained by operating the tube into a plate impedance one-fifth, or less, the plate resistance of the tube.

12.221 Why is the harmonic distortion increased when using high-frequency equalization?—Because the harmonic frequencies are accentuated and even small percentages of distortion may become objectionable. This type distortion is independent of any distortion induced by the equalized stage.

If the high frequencies are attenuated, the distortion is reduced. A good rule to remember is if the frequency response is to be extended, distortion must be reduced to a negligible amount.

12.222 How does the efficiency of an output transformer affect the power output of an amplifier?—At low-output powers the efficiency of the output transformer can be ignored; however, at powers of 10 watts and greater, the insertion loss of the transformer may become the limiting factor in the design of an amplifier. As an example, assume an output transformer of conventional design induces a power loss of 0.25 dB. For 20 watts of output power, the power loss between the primary and secondary amounts to approximately 1 watt.

If this same insertion loss occurred in an amplifier developing 100 watts of power, the loss between the primary and secondary would amount to about 5 watts of power. Therefore, it is extremely important that an output transformer used in an amplifier developing any amount of power have a low insertion loss or an efficiency as high as possible. This means that the transformer must have low leakage reactance.

Interstage transformers, as a rule, have about 1-dB insertion loss but, as these transformers are used in low-level circuits, it is of no particular consequence and the loss may be overcome by increasing the gain in the voltage amplifier stages 1 dB. The efficiency of an output transformer may be calculated:

$$E_{ff} = \frac{P_{sec}}{P_{pri}} \times 100$$

where,

P_{pri} is the power at the primary,
P_{sec} is the power at the secondary, operating with its normal load impedance.

Several new designs in output transformers have appeared in the last few years, in which the power loss is quite low. One of these designs is the McIntosh described in Question 12.231. The measurement of transformer loss is discussed in Question 23.71.

12.223 How is the insertion loss of a transformer calculated?—It may be calculated in two different ways—power or decibels. For the loss of power in watts, the equation is:

$$\text{Watts} = \frac{P_{pri}}{P_{sec}}.$$

For the loss in decibels:

$$\text{dB} = 10 \text{ Log}_{10} \frac{P_1}{P_2}$$

where,

P_1 is the power at the primary,
P_2 is the power at the secondary, when operating into its normal load impedance.

12.224 Can the frequency response of an amplifier be judged by its response to a square wave?—Yes. It may be said that if a square wave is applied to the input of an amplifier and not distorted by passage through the amplifier, the frequency response is uniform from f/10 to 10 f, where f is the fundamental frequency.

The square-wave generator is set to different fundamental frequencies and the shape of the square wave observed on an oscilloscope connected across the output of the amplifier. The frequency response of the oscilloscope must be such that it does not distort the square wave.

This can be checked by comparing the image at the output of the amplifier with that at the output of the square-wave generator. Square-wave testing is discussed in Question 23.154.

12.225 How are wideband vacuum-tube amplifiers compensated for frequency response?—As a rule, audio equipment requires a frequency response between 20 and 20,000 Hz. However, many devices used for testing audio-frequency equipment such as an oscilloscope, distortion-measuring sets, and vacuum-tube voltmeters require an extremely wide frequency response, ranging from 10 hertz to 1 megahertz in width. The conventional resistance-coupled amplifier will not amplify all frequencies equally over this wide band without special frequency compensating circuits.

The loss of low frequencies is due principally to the impedance of the bypass capacitor C_k in the cathode circuit rising as the frequency is decreased. This may be overcome to some extent by making the capacitor quite large, say 150 to 1000 μF.

Low-frequency response is also affected by the value of the coupling capacitor and the grid resistor used to couple the following stage or located at the input of the wideband stage. The time constant of this combination is also of importance. If the time constant is made long to pass very low frequencies, serious phase shift is caused which results in distortion of the lower frequencies. Phase shift at the lower frequencies may be avoided by using a direct-coupled circuit as described in Question 12.39.

The bypassing of the screen dropping resistor is also quite important, as it also affects the low-frequency response. To assure that the power supply impedance is low, a large capacitor should be connected across the dc output. As some of these capacitors would become rather impractical because of the large value required, it is more satisfactory to compensate the amplifier at the low frequencies.

High-frequency loss is due to the Miller effect, internal capacities of the tube, and the distributed capacities of the circuit which are difficult to overcome; therefore, compensation is also used for extending the high-frequency response. (See Question 12.191.)

Whenever compensation circuits are used, a loss of gain takes place, which may be compensated for by the use of tubes of high transconductance, such as the 6AC7.

An RC coupled stage with both a low-frequency and a high-frequency compensating circuit is shown in Fig. 12-225. Compensation is obtained by designing the time constants of the low-frequency compensating circuit to equal the time constant of the cathode circuit elements R_k and C_k. The compensating circuit consists of capacitor C_c and resistor R_c which increases the plate loading at the low frequencies and compensates for the phase shift which is caused by coupling capacitor C and grid resistor R_g.

To properly compensate the circuit, resistor R_c must have a value greater than the cathode resistor R_k by an amount equal to the voltage gain of the amplifier stage. Capacitor C_k in the cathode circuit must also be greater than C_c by the same amount, to obtain equal time constants in two parts of the circuit. Therefore:

$$R_c \times C_c = R_k \times C_k$$

where,

R_c is greater than R_k by the voltage gain of the stage.

To illustrate the design procedure, assume the amplifier stage has a gain of 18 at the midfrequencies, the cathode resistor is 150 ohms, bypassed by a 250-μF capacitor. The value of R_c is then:

$$18 \times 150 = 2700 \text{ ohms}$$

$$C_c = \frac{250}{18}$$

$$= 13.9\ \mu\text{F}.$$

At the low frequencies, the plate load consists of the plate-load resistor R_p and R_c in series, and at the higher frequencies principally R_p. At frequencies of 50 to 10 Hz, the compensating capacitor C_c will have a reactance of approximately 230 and 1200 ohms, respectively. In practice, the compensating resistor R_c is adjusted by applying a square wave signal to the input while observing the output waveform on an oscilloscope.

The high-frequency compensating circuit consists of a 70 to 250 millihenry slug-tuned peaking coil connected in the plate circuit. The frequency response at the high frequencies is adjusted in a similar manner to that used for the low-frequency circuit. When both circuits are properly adjusted, the waveform at the output of the amplifier should be the same as the waveform at the input. The compensating circuits, because of their design, are independent of each other.

12.226 Describe the dynamic characteristics of a class-A push-pull amplifier.—The dynamic characteristics of two tubes connected to operate in class-A push-pull are shown in Fig. 12-226. The characteristic curve has been constructed from the individual dynamic characteristics of each tube. The characteristics of the individual tubes may be identified as V1 and V2.

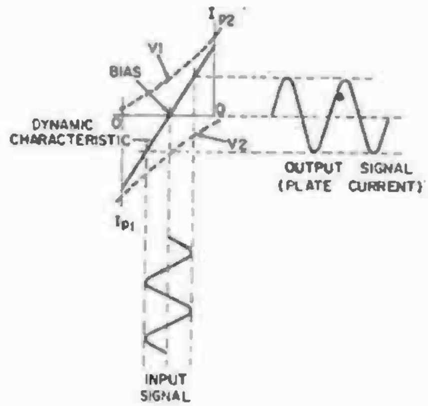

Fig. 12-226. Dynamic characteristics of two tubes operating class-A, push-pull.

The plot of the two tubes is the same because they are caused to operate 180 degrees out of phase. When operating as a single tube, class-A, little distortion exists because the grid signal operates in the most linear portion of the dynamic characteristic. In push-pull operation, the distortion is even less because of the increased linearity.

By projecting the signal at the control grid to the push-pull characteristic, the output waveform is obtained. As a rule, a greater grid voltage swing is possible in push-pull because the dynamic characteristics are linear over a greater voltage range. Thus, more power output is obtained.

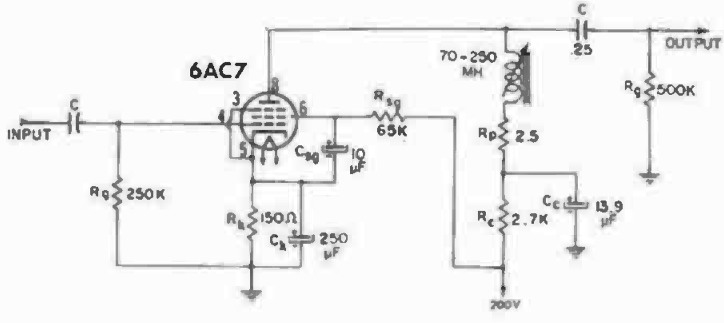

Fig. 12-225. A wideband RC amplifier compensated to cover a frequency band from 10 Hz to 1 MHz.

Efficiencies up to 30 percent are common with push-pull amplifiers where, with one tube only, 20 percent is average. Operating two tubes in class-AB can result in efficiencies up to 55 percent.

12.227 What are the dynamic characteristics of a class-AB$_1$ and -AB$_2$ push-pull amplifiers?—The dynamic characteristics are similar in appearance to that of the class-B$_1$ (Fig. 12-228A). The actual characteristic is a function of the bias voltage. As a rule, the output stage of a transistor amplifier is operated class-AB$_2$, class-B, or class-B$_1$.

12.228 Describe the dynamic characteristics of a class-B push-pull amplifier.—Although vacuum-tube amplifiers operating class-B and its subscripts are not as a rule used for driving recording equipment, extensive use is made of transistors operating in this mode. However, precautions must be taken to reduce crossover or notch distortion to a negligible amount. Amplifiers operating class-B are always designed for push-pull operation, as discussed in Question 12.67.

Two types of class-B amplifiers are in general usage, class-B$_1$ and class-B$_2$. In the class-B$_1$, grid current is not permitted to flow, while in the class-B$_2$ grid current is permitted to flow for a fraction of the input signal cycle; therefore, the harmonic distortion is higher than for the class-B$_1$ amplifier.

The dynamic characteristics of a typical class-B$_1$ push-pull amplifier are shown in Fig. 12-228A. A higher value of bias voltage is used than for the class-AB$_1$. It will be noted the dynamic curve for the class-B$_2$ amplifier (Fig. 12-228B) has a bend at the crossover point which induces harmonic distortion. Class-B amplifiers require very stable power supplies with good voltage regulation because the tubes in their quiescent state draw very little current; however, when a signal voltage is applied to the control grids, the plate current rises quite rapidly to a rather large value.

It is again emphasized that in the use of class-B amplifiers, crossover or notch distortion must be reduced to a negligible value for high quality recording and reprodnction.

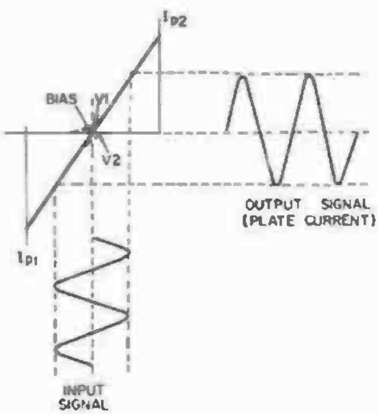

Fig. 12-228A. Dynamic characteristics of a push-pull amplifier operating class-B$_1$

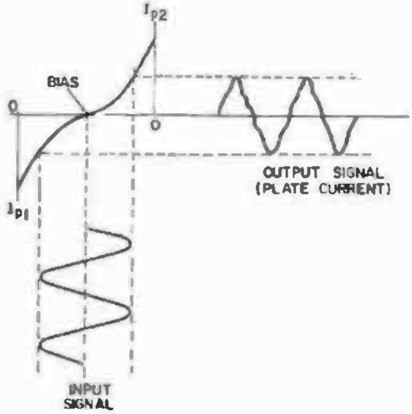

Fig. 12-228B. Dynamic characteristics of a push-pull amplifier operating class-B$_2$. Tubes are biased to plate-current cutoff.

12.229 How is fixed bias obtained?—Fig. 12-229A shows a fixed-bias circuit using a resistor R1 in the common negative return of a full-wave rectifier circuit normally used for supplying plate current. Because the total plate current drawn by the amplifier flows through resistor R1, a voltage drop is created which is used for a bias voltage. Only a small amount of filtering is required which may be obtained with a 100,000-ohm resistor (R2) and a 10-μF electrolytic capacitor. The fixed-bias may also be obtained by means of a rectifier connected to one-half of the high-voltage winding of the power transformer in Fig. 12-229B. Filtering is obtained by means of resistor (R) and a 20-μF capacitor C. The circuit in Fig. 12-229C is similar, except the ac voltage is obtained from a separate winding on the power transformer.

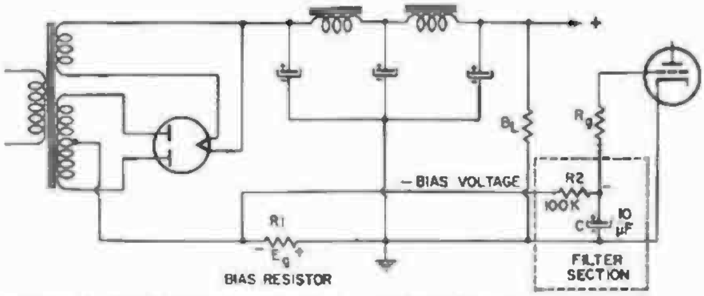

Fig. 12-229A. A fixed-bias circuit using a resistor in the negative return of a full-wave rectifier circuit.

12.230 Define the terms crossover and notch distortion.—When operating vacuum-tube amplifiers class-B or any of its subscripts, the bias voltage is adjusted for a condition of near plate-current cutoff. This type of operation is the cause of considerable distortion termed *crossover or notch distortion*, and occurs each time the signal passes through the zero plate-current point. This distortion is aggravated also by the imperfect coupling existing between the primary and secondary windings of the output transformer.

Crossover distortion can be corrected to a great extent by the application of a small amount of bias voltage applied in the cathode circuit of the individual tubes. For a 6L6 tube, this amounts to about 0.6 to 1.5 volts, and can be obtained by the use of a resistor of 5 to 10 ohms in each cathode circuit. After reducing the distortion in this manner, the remaining distortion can be further reduced by the use of a generous amount of negative feedback. As a rule, special class-B interstage transformers are employed to drive the output stage, with a low-impedance secondary because of grid-curreut flow.

Values of 1-percent or less THD are not difficult to obtain in a transistor amplifier for power outputs of 50 to 100 watts. What is important is the distortion at power output levels of 1 watt or less. Distortion at these levels can be up to five times greater than at full power output because of crossover or notch distortion. Distortion at the lower levels is usually generated in the output stage because of class-B operation. Therefore, it is highly important that several measurements be made at low power output to check for this type of distortion. The making of such measurements is discussed in Question 23.208.

Since an output transformer is seldom used with transistors, its contribution to the overall distortion is eliminated, and only the notch distortion has to be considered. The efficiency of a class-B push-pull stage ranges from 60 to 70 percent. (See Questions 11.143 and 23.210.)

12.231 Describe the McIntosh amplifier circuit.—The McIntosh circuit is a highly efficient beam-power tube push-pull amplifier circuit, using a special output transformer, developed and patented by Frank H. McIntosh. The

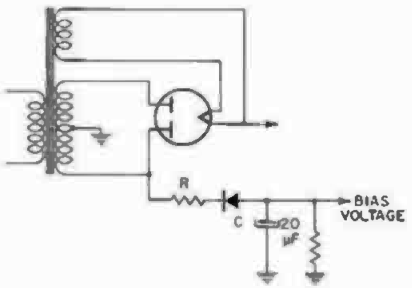

Fig. 12-229B. A fixed-bias circuit using a half-wave rectifier.

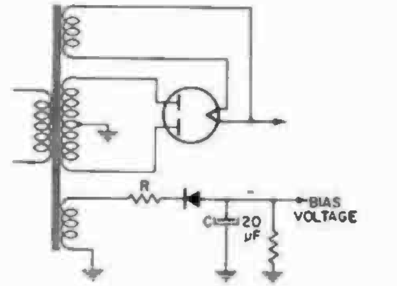

Fig. 12-229C. A fixed-bias circuit using a half-wave rectifier with a separate winding on the power transformer.

output stage attains its high efficiency through a combination of the output transformer and working approximately class-AB_2.

The transformer has four sets of windings, one connected in the cathode, one in the plate circuit, and two output windings, one of which is used for supplying a negative feedback voltage. A schematic diagram of the McIntosh MC-40 power amplifier is shown in Fig. 12-231A.

The output transformer of Fig. 12-231B provides two load impedances, one for the cathode and one for the plate. The primary and cathode windings are *bifilar* wound; that is to say, the two windings are made by winding the wires side-by-side, providing for all practical purposes unity coupling; thus, the leakage is greater than 80,000:1, which reduces the leakage inductance (lack of coupling) to a negligible amount. After the coils are wound,

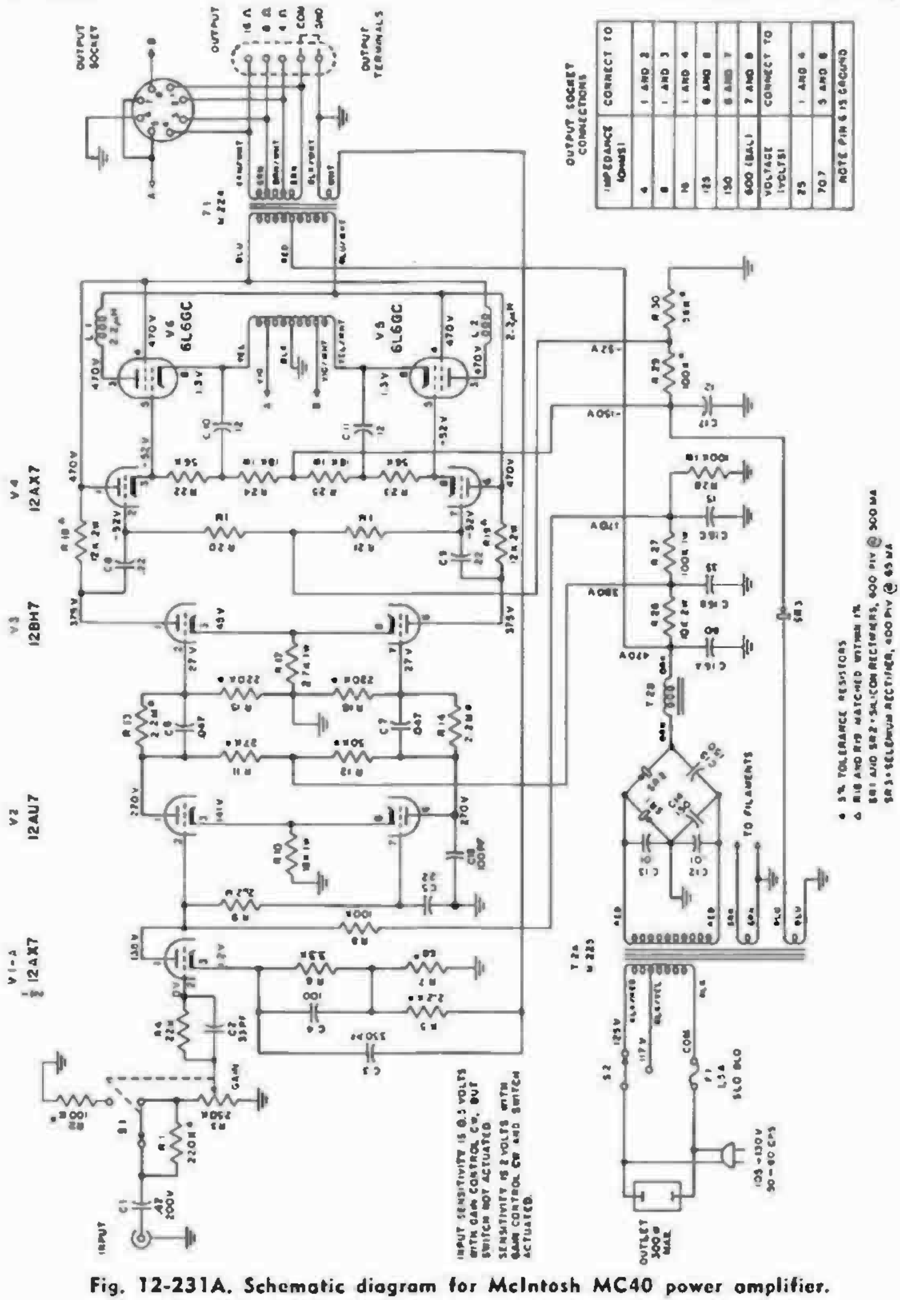

Fig. 12-231A. Schematic diagram for McIntosh MC40 power amplifier.

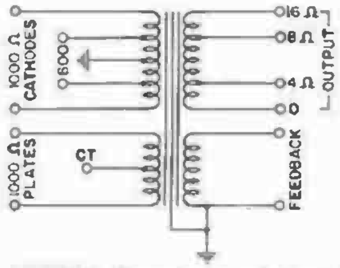

Fig. 12-231B. Impedance relations for McIntosh unity-coupled bifilar-wound output transformer.

grain-oriented steel "C" type cores are inserted in the coils, resulting in a shell-type construction as seen in Fig. 12-231C. (See Fig. 8-105.) The two cores weigh approximately five and one-half pounds each. The power bandwidth is thus increased to over 100,000 Hz.

In operating tubes push-pull class-A, class-B_2, and class-B distortion is generated, termed notch or crossover distortion. (See Question 12.230.) This distortion is particularly bad in the class-B modes. Notch distortion is generated at the instant the current is cut off during the idle period, and again when current starts to flow. This is caused by the imperfect coupling in the conventionally wound transformer. The use of a bifilar winding provides an extremely tight coupling between windings, removing a condition which aggravates notch distortion. Furthermore, the tubes are connected as partial cathode followers, half of the circuit being in the cathode and half in the plate circuit of each tube. This provides a local feedback loop which reduces distortion and generator impedance, and eliminates the need for balancing the circuits. The primary and secondary windings of the coils are interleaved no less than five times, to improve the coupling. Interleaving is accomplished by winding groups of primary layers, then secondary layers, until the whole transformer is completed.

Referring again to Fig. 12-231B, the small 5-ohm winding supplies a negative-feedback voltage, while the fourth winding is employed for coupling to the external-load circuit. Taps are provided at 4, 8, and 16 ohms. A 600-ohm output is also provided by the winding in the cathode circuit. Because of a small amount of dc current flow between the cathode and the center-tap gronnd connection, this winding cannot be used with grounded circuits. Only a symmetrical or balanced-to-ground circuit may be used. (See Question 8.25.) The small voltage drop across this winding has the effect of reducing the notch or crossover distortion mentioned earlier.

It will be observed in Fig. 2-231A that the screen grids are connected to the top end of each half of the primary winding, but the plate of a given tube is fed from the opposite end of the primary winding. Thus, the signal voltage at the cathode and the screen grid for a given tube is the same. Connected as shown, the screen grids are bypassed to the cathode providing ideal conditions for beam-power tube operation. The impedance relationship existing between the several windings is shown in Fig. 12-231B. It will be noted the impedance of the primary from plate-to-plate is 1000 ohms, which is quite low compared to the conventional push-pull amplifier where the plate-to-plate impedance may range from 4000 to 10,000 ohms. The impedance from cathode-to-cathode is also 1000 ohms. Because the signal voltage at the cathodes is quite high, the circuit requires tubes in the output stage that will withstand a high

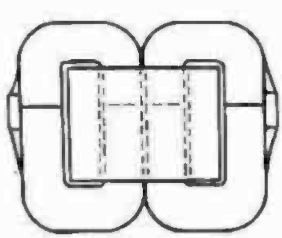

Fig. 12-231C. Interior construction of McIntosh output transformer. The coils are wound on grain-oriented steel "C" cores.

Fig. 12-231D. McIntosh MC40 power amplifier.

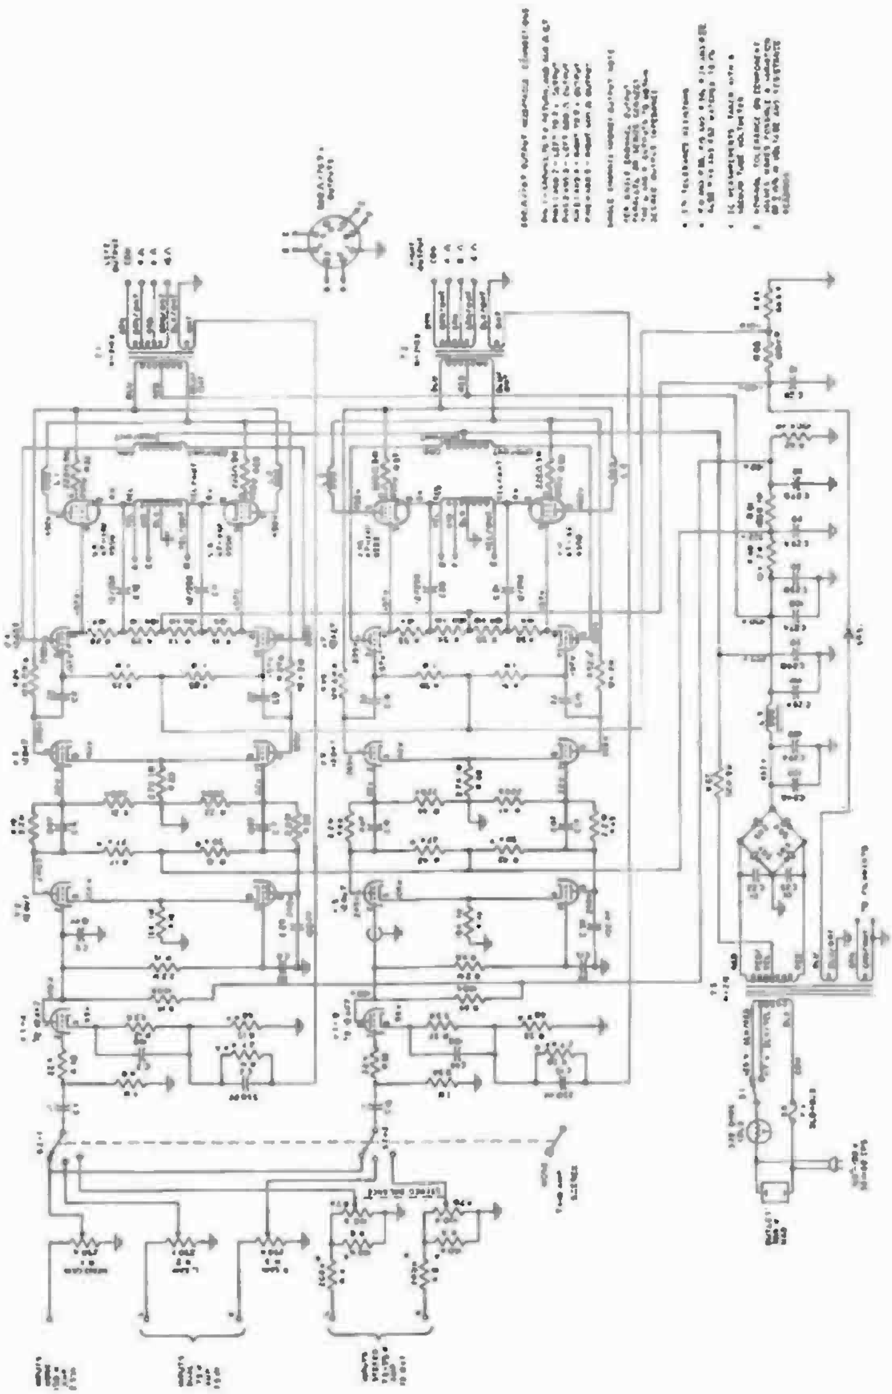

Fig. 12-231E. Schematic diagram for McIntosh MC275 stereophonic amplifiers.

heater-to-cathode potential. The 6L6G beam-power tube meets these requirements.

Referring again to Fig. 12-231A and tube V1A the input signal is applied to a single-ended amplifier stage, consisting of one-half of a 12AX7 tube, followed by a "long-tailed" phase inverter comprised of a 12AU7 tube. This stage is followed by a second push-pull stage, 12BH7 tube which drives a third push-pull stage, a 12AX7 tube connected as a cathode follower. The cathodes of this stage are direct-coupled to the control grids of the 6L6G beam-power tubes in the output stage.

Negative-feedback voltage is taken from a 5-ohm winding and carried back to the cathode circuit of the first stage. The 6L6G tubes in the output stage are operated with fixed bias supplied by a series half-bridge employing two silicon diode rectifiers, and two capacitors. (See Question 21.98.) Small radio-frequency chokes of approximately 2 microheuries are connected in the plate of each output tube to prevent parasitic oscillation. An input control and attenuator complete the circuit. The rated continuous power output is 40 watts, with less than 0.5-percent harmonic distortion at 20 to 20,000 Hz, and in the midfrequencies a 0.10-percent distortion. Intermodulation distortion is less than 0.5 percent for any combination of frequencies between 20 and 20,000 Hz, if the instantaneous peak power is less than 80 watts. Hum and noise is 90 dB below the output of 40 watts (plus 46 dBm). The internal output impedance is less than 10 percent of the load impedance. If the amplifier is to be used with a 70.7-volt distribution system, the load is taken from taps A and B on the 600-ohm winding in the cathode circuit of the output tubes. Phase shift is less than 8 degrees at 20 to 20,000 Hz. The completed amplifier appears in Fig. 12-231D.

To provide large amounts of power with good frequency response requires that an amplifier have a wide frequency range. To provide low distortion with a large amount of power requires a uniform frequency response with small amounts of phase shift. This design assures that the feedback voltage at fundamental high frequencies will maintain the proper phase relationship with the higher harmonics, thus permitting the maximum use of the feedback voltage loop to cancel distortion and improve the linearity. Small changes in the frequency response such as 0.10 dB will cause a phase shift of 10 degrees, and a change of 3 dB will cause a phase shift of 45 degrees. Therefore, the effect of the feedback is reduced in proportion to the cosine of the phase shift angles. As a rule, phase shift becomes apparent and measurable at one-seventh to one-teuth the frequency where a 2-dB change in the frequency response takes place. This indicates quite clearly that a bandwidth 7 to 10 times the highest frequency to be reproduced is necessary.

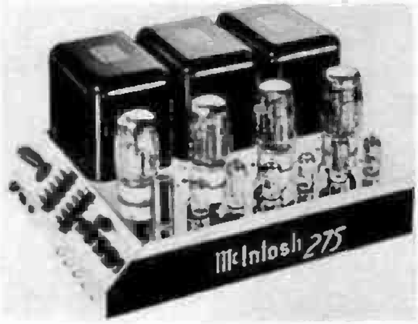

Fig. 12-231F. McIntosh MC275 stereophonic power amplifiers. Each channel develops 75 watts of power.

The schematic diagram for a dual 75-watt version, the McIntosh MC275, is shown in Fig. 12-231E. Except for the values of certain components, and the output tubes being changed to KT-88 or 6550 tubes, the theory and operation of the circuit is the same as for the MC40. An additional winding appears on the output transformer, which is fed from the plates of the driver stage V4, and is *trifilar* wound, improving the power

Fig. 12-231G. McIntosh Model C24 solid-state stereophonic preamplifier.

bandwidth. The output power rating for this amplifier is 75 watts continuously for each channel, or 150 watts monophonic. The frequency response, harmonic and intermodulation distortion, and phase-shift are the same as for the MC40. The complete amplifier is pictured in Fig. 12-231F. Either of the described amplifiers are designed to operate with any type preamplifier or stereo center.

In Fig. 12-231G is shown a solid-state preamplifier (stereo center) Model C24, especially designed to operate with the previously described amplifiers. In the schematic diagram of Fig. 12-231H, the preamplifier employs a total of 18 silicon planar transistors, eight in each side, with one in a third L + R channel (for driving an additional amplifier and loudspeaker) and one in the voltage regulator circuit in the power supply. The preamplifier section of the phono pickup and magnetic tape head employs three of the eight transistors. Standard RIAA or LP equalization may be selected by a slide switch. This is followed by a mode-selector switch, loudness control, channel balance, the first section of the volume control, and an emitter-follower transistor driving a Baxandall-type tone-control circuit. (See Question 6.86.) This is followed by two more amplifier stages, rumble and noise filter, and an output stage using two transistors. The second section of the volume control is next, followed by a voltage divider network feeding the L + R third channel.

The power supply consists of two silicon diodes in a full-wave rectifier circuit. The output voltage is regulated to 75 volts and further regulated by a zener diode to 10 volts. A second zener diode is connected in the emitter of the voltage-regulating transistor. An unusual feature of this unit is that the output circuits of the power amplifiers are returned to this unit before going to the loudspeaker voice coils. This permits the user to reverse the phasing of one speaker if required, and feed a pair of stereo headphones from a network connected between the left and right channels. The frequency response of the complete unit in the flat position is within 0.5 dB, from 20 to 20,000 Hz. The output is rated 2.5 volts for less than 0.10-percent distortion, with a slight increase to 0.30 percent at 10-volts output. The hum and noise is 78 dB below 2.5-volts output.

12.232 Describe a Williamson circuit using ultralinear operation.—In Fig. 12-232A is shown a schematic diagram for the well-known Williamson power amplifier using ultralinear operation. Starting at the left, the signal from a preamplifier is applied to the input control grid of tube V1, through a network consisting of a 15,000-ohm resistor, 0.10-μF capacitor, grid resistor, and a 15,000-ohm grid-limiting resistor. The 15,000-ohm series resistor in the input increases the input impedance of the amplifier. The 0.10-μF capacitor prevents any dc component in the signal from the preamplifier from affecting the control-grid circuit of the power amplifier, as would be the case if the preamplifier did not include a dc isolating capacitor. The 15,000-ohm grid-limiting resistor in the control grid prevents overloading of input stage if too great an input signal voltage is applied from the preamplifier (as would be the case if the signal were taken from the plate circuit of the output tube in a preamplifier).

The output of V1 is direct-coupled to the control grid of V2, a phase splitter employing equal values of load resistance in both the plate and cathode circuits. Because of the large value of resistance in the cathode circuit of V2, an 88-volt positive potential is developed at the cathode. The control grid of this tube, being connected to the plate of V1, is also 88 volts positive. This means the control grid is operating at a zero potential. By direct-coupling to the input of the phase-inverter tube V2, phase shift at the lower frequencies due to the presence of a coupling capacitor is avoided.

The signal at the cathode of V2 is in phase with the signal at the control grid, while the plate signal swings in the opposite direction. These two signals are of equal amplitude but 180 degrees out of phase. This balanced signal is applied to the control grids of the driver stage V3 and V4, through coupling capacitors of 0.10 μF each. Two signals of equal amplitude and 180 degrees out of phase are again available at the output of V3 and V4 and are applied to the control grids of the 5881 or 6L6G push-pull output tubes through

1.0-μF coupling capacitors. The use of large coupling capacitors increases the low-frequency response, besides providing a 10:1 ratio of time constants between the two amplifier stages and thus reducing the tendency to oscillate at the low frequencies. The signal is finally amplified by the output tubes

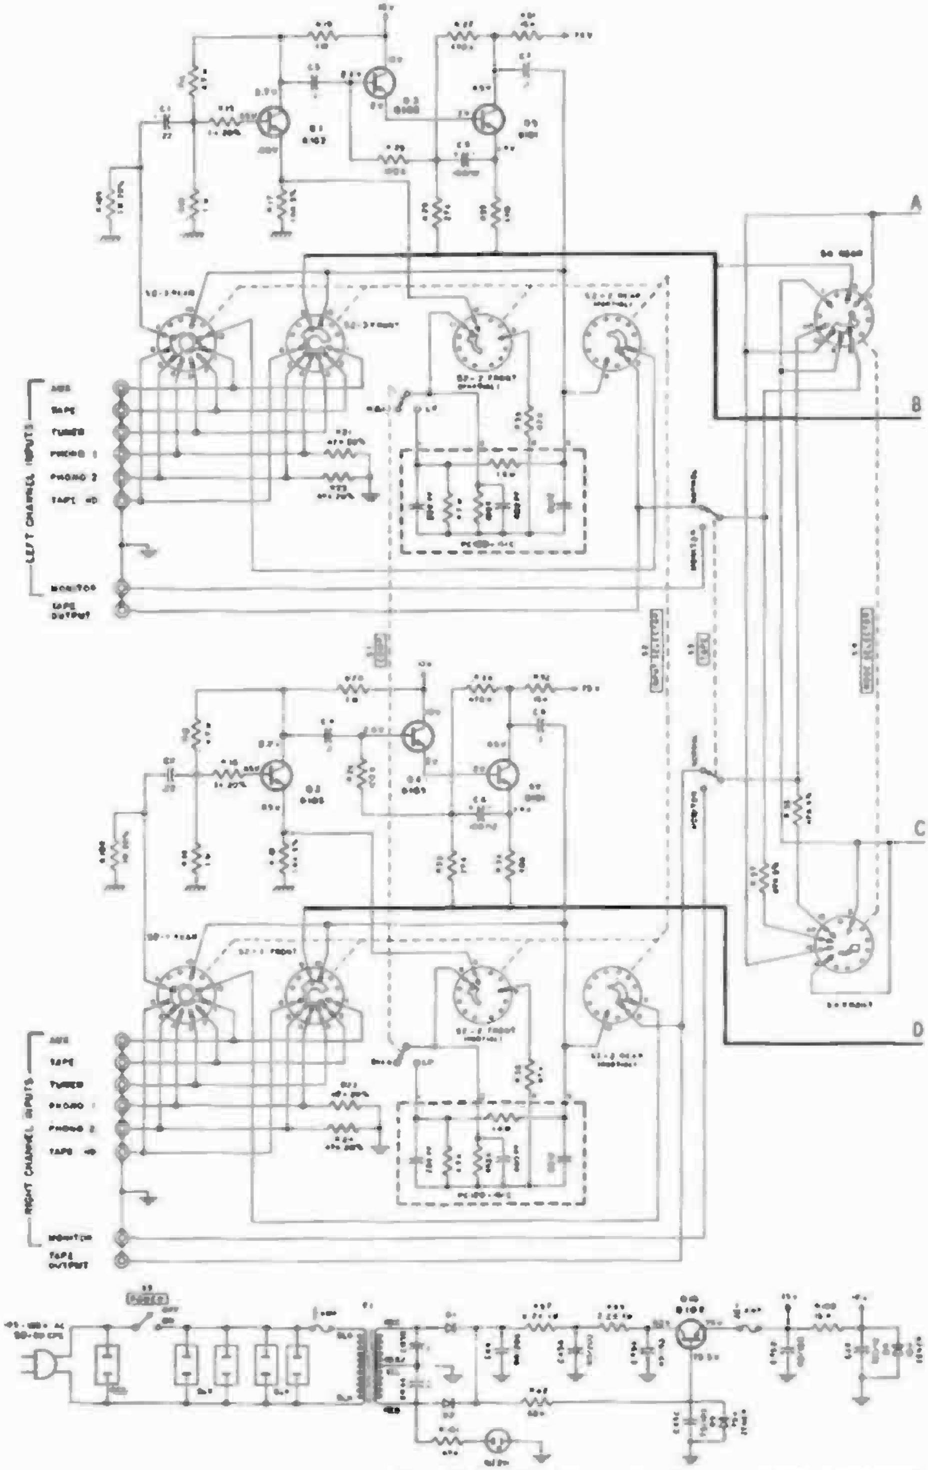

Fig. 12-231H. Schematic diagram of the McIntosh

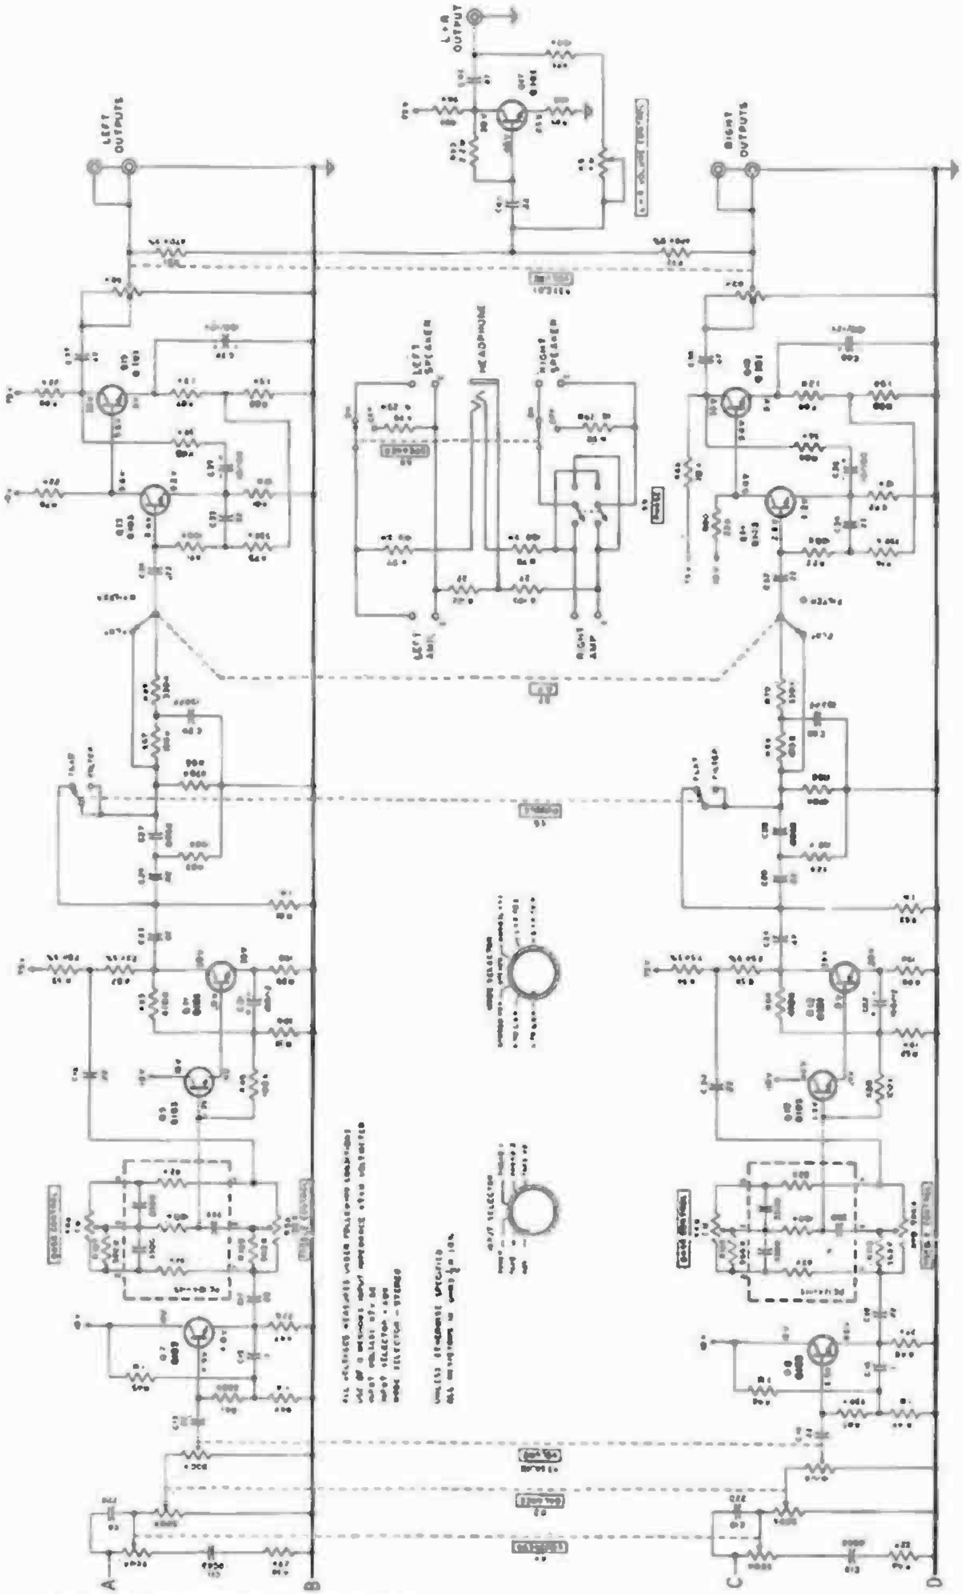

Model C24 stereophonic preamplifier.

and applied to the output load by means of the output transformer T1.

Negative-feedback voltage is taken from the output winding of T1 and carried back to the cathode of the first stage V1A, through a 4700-ohm series resistor shunted by a 240-pF capacitor, which increases the high-frequency response above 50,000 Hz and assures a 180-degree phase shift at the higher frequencies around 100,000 Hz.

To obtain the lowest distortion with this circuit, the plate currents of the output tubes must be balanced as closely as possible. To achieve this balance, a network consisting of potentiometer P1 and several fixed resistors is connected in the control-grid return circuit of the push-pull input circuit. A pin jack is connected to the upper end of each cathode element. To balance the plate currents, a dc voltmeter is connected across the pin jacks and the potentiometer P1 adjusted for a minimum or zero indication on the voltmeter. The accuracy of the volt-

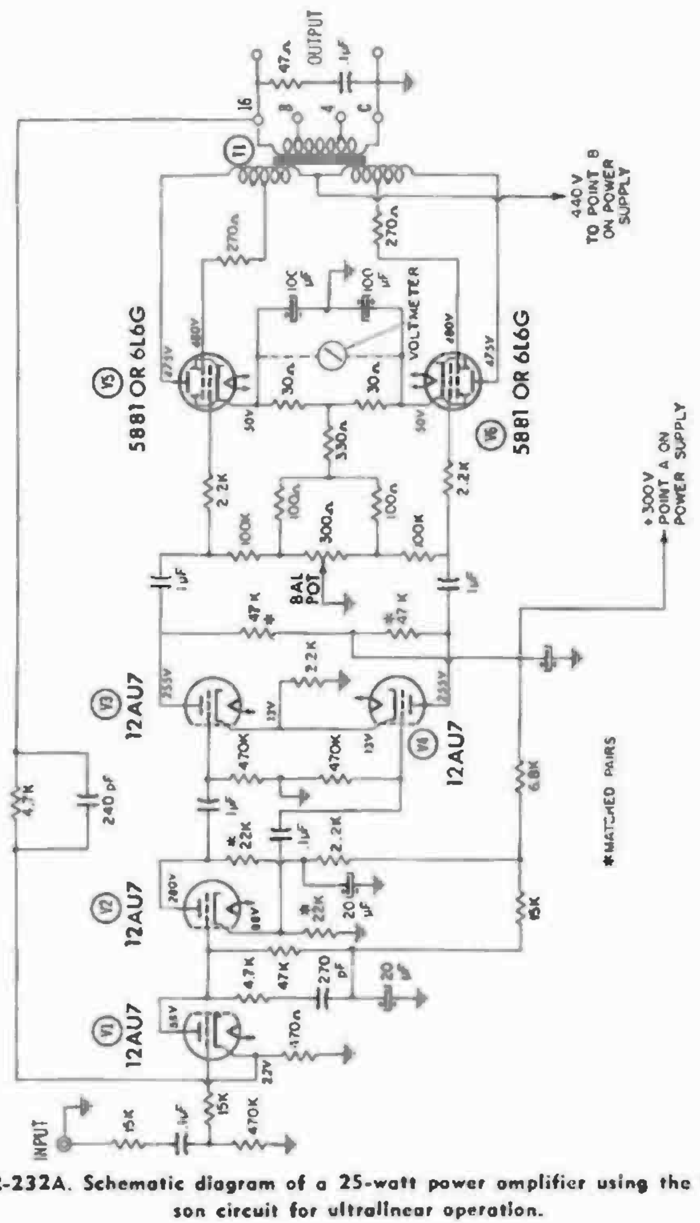

Fig. 12-232A. Schematic diagram of a 25-watt power amplifier using the Williamson circuit for ultralinear operation.

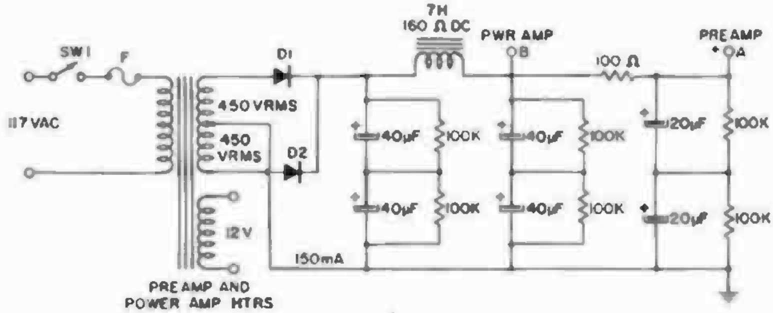

Fig. 12-232B. Schematic diagram for Williamson 25-watt ultralinear amplifier power supply.

meter does not enter into the adjustment, as it is used only as a null indicator. When a balance is achieved, the voltage drop across each cathode resistor is the same; therefore, the plate current in each tube is the same. The potentiometer P1 minimizes the unbalanced dc in the primary of the output transformer, reducing the core saturation. Thus, the low-frequency response is increased and the distortion below 50 Hz reduced. (See Question 23.45.)

A limiting circuit, consisting of a resistor and capacitor connected in series and in parallel with the secondary of the output transformer T1, prevents damage to high-frequency speaker units caused by transient disturbances. The values of resistance and capacitance will not affect the frequency response in the normal frequency spectrum.

Although the power supply for the above combination is shown in a separate diagram, Fig. 12-232B is actually a part of the power amplifier assembly, and consists of a power transformer, two diode rectifiers, and an LC and RC filter section. The high voltage for the output tubes is taken at point B and for the preamplifier at point A. To obtain a high value of filter capacitance in the filter circuits and still have a large margin of safety relative to the operating voltage, electrolytic capacitors of 40 μF are connected in series at the input and output of the filter choke, with resistors of 100,000 ohms connected across each capacitor, to assure an even voltage distribution across each capacitor. The 8-pin plug at the right of the diagram is for providing power to the preamplifier.

Fig. 12-232C is a plot of power output versus intermodulation distortion. The frequency response for 5 and 25 watts is given in Fig. 12-232D, with the phase-shift characteristics given in Fig. 12-232E. Hum and noise is 99 dB below the output level of 25 watts (plus 44 dBm), or 45 dB with reference to 1-milliwatt.

12.233 How is the bandwidth of an amplifier designated?—It is stated as the difference between the half-power point at the upper and lower frequencies, or the frequency of 3 dB loss with respect to the flat portion of the passband as shown in Fig. 12-233.

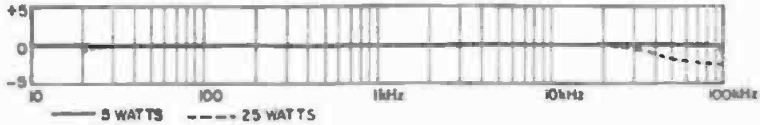

Fig. 12-232D. Frequency response of the power amplifier in Fig. 12-232A.

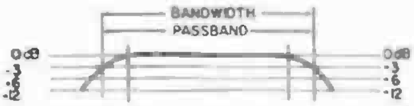

Fig. 12-233. Bandwidth of a transformer.

12.234 What is the purpose of connecting a small capacitor in parallel with the resistor in a negative-feedback loop. —It is employed as a phase-shifting device to assure the signal being 180 degrees out of phase at the midrange frequencies. Phase shift at the high frequencies is maintained by the stray capacitance due to components and internal wiring.

12.235 What precautions should be observed when mounting coupling capacitors in a wide-range amplifier?—They should be mounted up and away from the metal chassis to prevent the distributed capacity from affecting the high frequencies. Metal bathtub type capacitors should be avoided for interstage coupling.

12.236 What is the purpose of paralleling an electrolytic capacitor with a paper or mica capacitor?—To nullify the inductive effect of electrolytic capacitors, thus providing better bypassing at the higher frequencies. Generally, about 0.10 to 0.025 μF will suffice for frequencies up to 50,000 Hz.

12.237 How does a hum potentiometer across a heater winding reduce the hum frequencies in the output?—When the pot is in balance, equal voltages but opposite in sine are fed to the control grid by induction from the heater circuit cancelling out the induced hum frequencies.

12.238 What is the principal cause of distortion in an output transformer? —When the maximum operating flux is reached, the core material cannot produce any more lines of force because of saturation. Under these conditions strong harmonics are produced, the order being dependent on the amplifier design.

12.239 How is the input level of an amplifier calculated to drive it to full output?—Assume an amplifier is stated to have 64 dB gain and to be capable of developing a plus 43 dBm at the output, what level at the input is required to drive it to plus 43 dBm?

$$\begin{aligned} dB_{in} &= (dB_{gain} - dB_{out}) \\ &= (64 - 43) \\ &= 21 \text{ or } -21\ dBm_{in}. \end{aligned}$$

Thus a signal level of minus 21 dBm at the input will drive the amplifier to a plus 43 dBm.

12.240 What is the equation for calculating the voltage gain in decibels when an ideal transformer of a given impedance ratio is inserted between a generator and the load?—The gain in decibels may be computed:

$$dB = 20 \operatorname{Log}_{10} \sqrt{Z_r},$$

or $$= 20 \operatorname{Log}_{10} T_r,$$

or $$= 10 \operatorname{Log}_{10} Z_r,$$

where,

Z_r is the impedance ratio of the transformer,

T_r is the turns ratio of the transformer.

12.241 If the output stage of a voltage amplifier employs a screen-grid tube and must be transformer-coupled at the output, what type transformer is recommended?—If the tube is a 6J7 or similar type, an output transformer with a 30,000-ohm impedance primary

Fig. 12-242. Variable damping circuits.

may be used, with a secondary impedance to suit the requirements. The load supplies the terminating impedance.

12.242 What is variable damping and how is it used?—Variable damping is used in the output circuit of an amplifier for the purpose of matching the loudspeaker impedance to that of the amplifier. The damping factor of the amplifier is varied by means of a control which permits the use of either negative voltage or current feedback. Three typical variable damping control circuits are shown in Fig. 12-242. It is claimed by the designers of these circuits that the various effects noted in loudspeakers because of impedance variations are eliminated by the use of variable damping. Also, that when properly adjusted, the amplifiers will present the correct impedance match to the loudspeaker voice coil at all times. Variable damping circuits have been the subject of much discussion but have not yet been accepted as the remedy for the mismatch between the amplifier output and the loudspeaker. Measurements of amplifiers using variable damping are discussed in Question 23.139.

12.243 Show the circuit for a class-AB push-pull amplifier using fixed bias.—Such a circuit is shown in Fig. 12-243 for an amplifier capable of producing 30 watts of audio frequency power. The output stage is driven from a cathode-coupled phase inverter. It will be noted the negative bias is obtained from a small half-wave rectifier and is applied to the cathode return of the inverter stage. The amplifier, although it has considerable harmonic distortion, is quite suitable for public address work.

12.244 How are harmonics generated in a nonlinear amplifier?—Harmonic distortion in an audio amplifier may be caused by several factors, such as the tubes not operating on the straight portion of their characteristic curve, operating in an overloaded condition caused by applying too great a value of signal voltage to the input resulting in a flow of grid current, improper operating voltages, or poor regulation in the power supply.

Amplitude distortion is caused by the nonlinear action of the tubes. If a pure

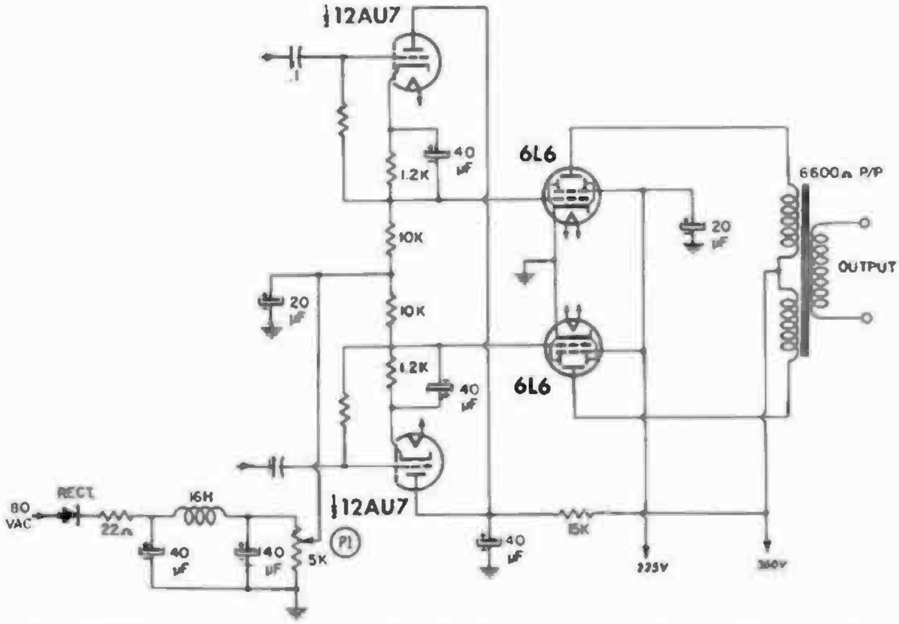

Fig. 12-243. A cathode-follower phase-inverter and push-pull amplifier operating class-AB_2 using fixed bias.

sine wave (a single frequency which contains no harmonics) is applied to the input of a vacuum tube which is supplied with the correct operating voltages and the amplitude of the sine wave is such that it does not overload the input, a pure sine wave may be expected at the output or plate circuit. The only departure from the original waveform at the input will be the increase of amplitude and a phase reversal of 180 degrees.

To illustrate the cause of nonlinear distortion, the plot of the grid-voltage plate-current characteristics of a general purpose triode biased for class-A operation is shown in Fig. 12-244A. The tube selected for this illustration requires a normal bias voltage of minus 6 volts. This point is indicated on the plate curve as the normal operating point.

Operating under the foregoing conditions, if a sine wave is applied to the control grid, a sine wave is reproduced in the plate circuit. However, this will

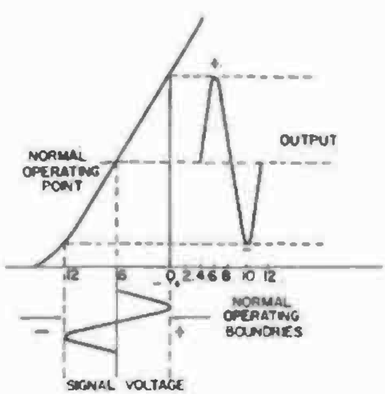

Fig. 12-244A. Plate current for a medium triode that is biased for class-A operation.

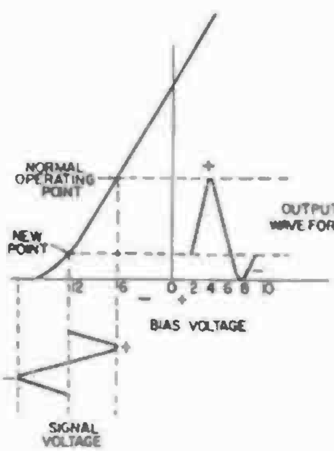

Fig. 12-224B. Output waveform distortion caused by overbiasing.

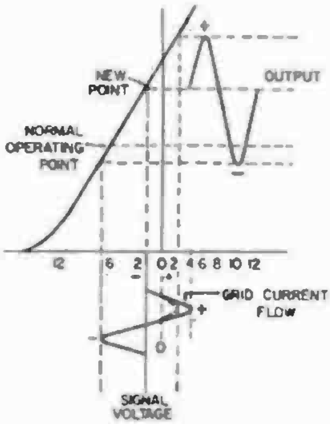

Fig. 12-244C. Output waveform distortion caused by underbiasing.

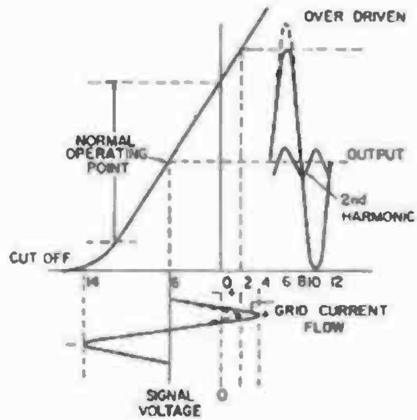

Fig. 12-244D. Distortion in a correctly biased tube caused by the application of too large a signal voltage at the control grid.

only hold true if the applied signal voltage does not exceed the normal operating boundaries. These boundaries are the points on the straight portion of the curve starting at minus 12 volts bias and continuing up to the zero bias point. If the signal voltage does not exceed these limits, a sine wave will be reproduced in the plate circuit; hence, no distortion of the input signal will occur.

Now consider an amplifier in which the bias voltage is incorrect, or too large, as shown in Fig. 12-244B. Here the negative bias voltage has been increased until the operating point (value of plate current) has been shifted downward towards the toe or bend in the plate current curve, or to the minus 12-volt point. Under these conditions, if a sine wave is applied to the control grid there will be a greater flow of plate current for the positive half of the grid swing than for the negative half, resulting in an unsymmetrical output waveform in the plate circuit.

If the bias voltage is reduced to a value of minus 2 volts, as shown in Fig. 12-244C, the operating point will be shifted upward. Now when the control grid swings positive, the amplitude of the positive half of the plate-current waveform will be less than the negative half because of being driven into the saturation region of the plate-current characteristic. When the control grid is driven above the zero point, it will draw grid current because the grid is now positive with respect to the cathode. This flow of grid current causes a voltage drop across the load in the grid circuit, and as this voltage is in opposition to the signal voltage, the amplitude of the positive peak of the signal voltage is reduced. This region is indicated by the dotted line in the positive half of the signal voltage at the control grid. Conditions as described in the foregoing cause strong second harmonics to be generated within the tube, distorting the output waveform in the plate circuit. Thus it is apparent the control-grid bias voltage and the amplitude of the applied signal play an important part in controlling the distortion in a vacuum tube.

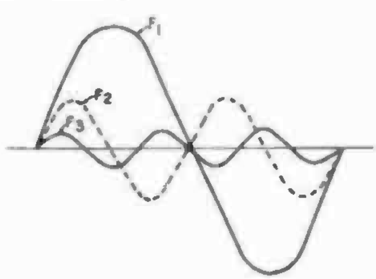

Fig. 12-244E. A fundamental frequency F_1, and its second and third harmonics F_2 and F_3.

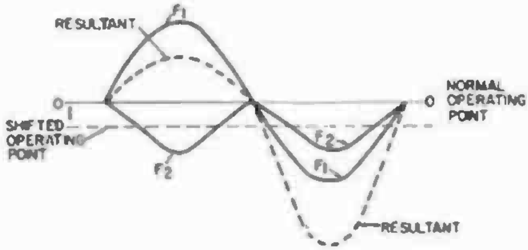

Fig. 12-244F. Adding the fundamental frequency F_1 and the second harmonic F_2 of Fig. 12-244E produces a new frequency-designated resultant.

The effect of overdriving the control grid by applying too great a signal voltage is shown in Fig. 12-244D. In this illustration the tube is again biased to operate at its normal operating point using a minus 6 volts at the control grid.

For the sake of illustration, the signal voltage has been increased to a point where it drives the control grid into the positive region or saturation and cutoff, the negative toe of the plate current curve. Driving the grid so far negative practically cuts off the plate current on the negative swings of the control grid. This action flattens off the negative peak, while the positive peak is driven into saturation and flattened off. (Saturation is a point where the plate current is increased to such proportions that no further output is obtained.) The slightest flattening or distortion of either the negative or positive peak will cause distortion of the output waveform producing both even and odd order harmonics.

Harmonics generated in a vacuum tube because of overloading is the result of inherent characteristics of the tube. First the plate resistance is not always uniform and secondly, the so-called straight portion of the plate current curve is not really straight, but has some curvature. The most objectionable harmonics are the second, third, fifth, and seventh because they are generally of higher amplitude and fall in the audible band.

To further illustrate the generation of harmonics within an amplifier, in Fig. 12-244E are shown three superimposed sine waves. F_1 is a fundamental frequency, F_2 the second harmonic, and F_3 the third harmonic. Adding the second harmonic and fundamental frequency algebraically (Fig. 12-244F) results in a new frequency indicated as the resultant. This new frequency is the same as the fundamental except the amplitude of the negative peak has been increased, while the amplitude of the positive peak has been reduced. Under these conditions the second harmonic will predominate, and is similar to a condition where the bias is too low.

The fundamental frequency and the second harmonic in a different phase relationship are shown in Fig. 12-244G. For this condition, the positive or resultant peak has a greater amplitude than that of Fig. 12-244F. It is of interest to note that for the condition in Fig. 12-244G the second harmonic is generated as if too great a grid bias voltage has been used, and is similar to the conditions in Fig. 12-244B.

In Figs. 12-244F and G a horizontal line has been added to indicate the shifted operating point. This line represents a dc component caused by self-rectification within the tube. Self-recti-

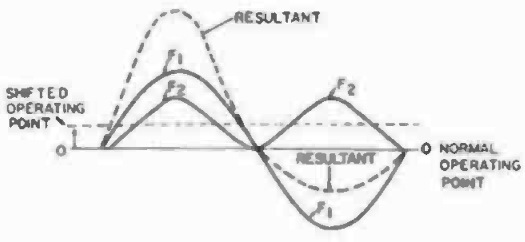

Fig. 12-244G. Resultant waveform when the operating point has been shifted due to self-rectification.

fication shifts the operating point on the plate curve of the tube, moving either upward or downward depending on the conditions to which the tube is being subjected at the moment.

The operating point has shifted upward due to the increase of the positive half-cycles and the decrease of the negative half-cycles in Fig. 12-244G, causing the introduction of second harmonics. When large values of second harmonics are present, there is an increase in plate current for an increase of signal voltage. In Fig. 12-244F the reverse has taken place.

When the distortion consists of a flattening of only one peak in the output waveform, the principal distortion is second harmonic. This is accompanied with a change in the average plate current and is called self-rectification.

Whenever both peaks are flattened, third harmonics predominate and if the distortion is considerable, a fourth harmonic will be generated, particularly if the control grid is driven positive.

When the control grid is driven positive, grid current will flow and a voltage drop is caused by the flow of current through the input load impedance, which may be a transformer or resistor in the grid circuit. This voltage drop flattens off the peaks of the input signal which is in turn reflected in the output waveform, along with the distortion caused by driving the tube into saturation.

When the voltage drop caused by the flow of grid current is 20 percent of the peak signal voltage, a second harmonic of 5 percent will be generated. As a rule when second harmonics are generated, third harmonic distortion is also generated at an amplitude approximately the same as second harmonic.

It is important in the design of class-B amplifiers (in which grid current flows an appreciable part of the input cycle), that the input load resistance be small and that the voltage drop caused by the load impedance in the grid circuit be small, as the voltage drop caused by the flow of grid current increases the bias voltage at the control grid, making it more negative than normal. This is why an input transformer designed to drive a class-B stage always has a low resistance secondary.

When a triode is overloaded, second-order harmonics are generated, while pentodes generate third-order harmonics. Even-order harmonics may be eliminated or reduced to a negligible value by the use of push-pull circuits. Odd-order harmonics generated by pentodes may be reduced by the use of push-pull circuits and the selection of the proper load impedance.

The addition of negative feedback will reduce the odd harmonics to a negligible value. As a rule a pentode is operated into a load impedance ⅕th to ⅛th the plate resistance of the tube. As the value of the load impedance is rather critical for a given harmonic distortion, the manufacturer's recommendations relative to load impedance and operating voltages should be closely adhered to.

12.245 What are the basic reasons for the difference in sound reproduction between transistor and vacuum-tube amplifiers?—The difference in sound reproduction of a transistor amplifier and a vacuum-tube amplifier of comparable power and frequency characteristics has long been a subject of contention between advocates of the two types of amplifiers.

As most transistor power amplifiers employ class-B operation in a push-pull power-output stage, the greater part of the distortion is generated within this stage. The disadvantage of using class-A output stages with transistors (single-ended or push-pull) is that collector current flows continuously. As a result, transistor dissipation is *highest* when no signal is present. Dissipation can be greatly reduced by the use of class-B push-pull operation. When two transistors are connected class-B push-pull, one transistor amplifies half of the signal and the other transistor amplifies the other half. These half-signals are combined in the output circuit to restore the original waveform.

Ideally, transistors used in class-B operation should be biased to collector cutoff so that no power is dissipated under zero-signal conditions. At low signal inputs, however, the resulting signal would be distorted, because of the low forward-current transfer ratio of the transistor at very low currents. This distortion is termed crossover or notch distortion, as discussed in Question 12.230.

In early designs of transistor amplifiers this type distortion was overlooked because the amplifiers were tested at their maximum power output, similar to vacuum-tube amplifiers; thus, crossover distortion was missed. Crossover distortion has a faculty of generating high-order odd harmonics, which are more annoying than second or third harmonics. Such reproduction leads to listening fatigue.

Another very important point is that transistors change their characteristics with temperature (contrary to the general belief); therefore, temperature-compensating circuits may have to be included and means taken to keep the amplifier at a reasonable operating temperature. Amplifiers are also affected by line voltage changes as discussed in Question 23.210. Several other factors also enter, such as the time-constant of the coupling circuits, and the bandwidth of the transistors which has a very definite effect on the feedback loop and can also induce distortion. Many other factors enter into the design, which are more or less in common with vacuum-tube amplifiers.

One of the features of a transistor amplifier is that it will deliver more power into a *reactive* load than appears, using a *resistive* termination, because it is a *current amplifier*. Therefore, the harder it is driven, the more current it delivers (assuming the load impedance is of low impedance). This is one of the reasons wby transistors in the output stage can be easily damaged.

Transistors adapt themselves easily to direct coupling, thus eliminating components and phase shift. By the use of opposite type transistors (pnp and npn), phase inverters are eliminated. Also, because of the low impedance of transistors, stray capacitance is reduced and therefore phase shift at the higher frequencies is reduced. These helpful factors permit the use of more negative feedback, increasing the stability and lowering the distortion and noise. To summarize, the difference in transistor sound has in the past been principally because of certain types of distortion being overlooked, and other design problems. Transistor amplifiers, although basically similar to vacuum-tube amplifiers, require special treatment in design concept and in testing procedures.

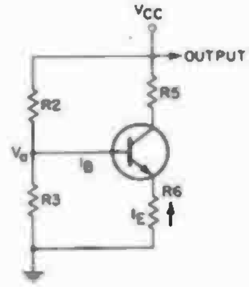

Fig. 12-246. Bias-voltage network for design problem.

12.246 Describe the procedure for designing a transistor bias network.— Assume a bias voltage network for a transistor is to be designed, using the network configuration in Fig. 12-246, for a low-level application operating at near-room temperature. The collector-to-emitter voltage V_{ce}, collector supply voltage V_{cc}, and emitter current I_e are selected by the designer, using values taken from the manufacturer's data sheet for small-signal parameters. The base current I_b equals $I_e/h_{fe} + I_{co}$; the voltage at point V_b then equals $(I_e \times R6) + V_{be}$ (dc). The base to emitter voltage V_{be} is approximately 0.2 volt for germanium and 0.7 volt for silicon. The voltage drop across R6 should be at least five times greater than V_{be}. The current through R3 is chosen to be at least five times I_b. Resistor R3 is then V_b/I_b, and R3 may be computed:

$$R3 = \frac{V_{cc} - V_b}{I_{R3} + I_b}$$

The load resistance R_L may be computed:

$$\frac{V_{cc} - I_E R6 - V_{CE}}{I_E} \text{ or } \frac{V_{cc} - V_{CE}}{I_E} - R6$$

Several other methods for developing bias voltage for transistors are discussed in Question 11.133. Voltage stabilization using thermistors is discussed in Question 11.157.

12.247 What effect does negative feedback have on transistor circuitry?— Negative feedback is discussed in some length in this section, as applied to vacuum-tube circuitry. Negative feedback may also be used with transistors for equalization and to reduce distortion and noise. The feedback voltage can be made proportional to the output current or voltage, and may be applied to either the input voltage or current. If the feedback voltage is proportional to the *output current*, the output impedauce will be *increased*. If the feedback voltage is proportional to the *output voltage*, the output impedance will be *decreased*. A negative-feedback signal applied to the input current decreases the input impedance, while a negative voltage applied to the input voltage increases the input impedance. If the feedback voltage is positive, opposite effects take place. As a rule, most of the information relative to negative feedback for vacuum tubes is applicable to transistor circuitry, when care is taken to observe the proper signal polarities.

12.248 Describe a solid-state plug-in microphone preamplifier.—The Model AT240 microphone solid-state preamplifier, manufactured by McCurdy Radio Industries, Ltd. (Canada) is typical of high-quality amplifiers designed for recording and broadcast use. The amplifier employs silicon transistors, and because of its low noise characteristics and wide input dynamic range, it will permit input levels of minus 60 dBm to minus 20 dBm to be used with very low distortion. The input impedance is quite high to prevent loading the microphone circuit, and its output impedance is low to provide maximum isolation against cross talk, when it is used in a mixer console or similar complex system. The mechanical assembly consists of glass-epoxy card design, using gold-plated printed circuitry. Because of its small physical size, 12 amplifiers may be plugged into a mounting tray of standard rack dimensions. Its outward appearance is shown in Fig. 12-248A.

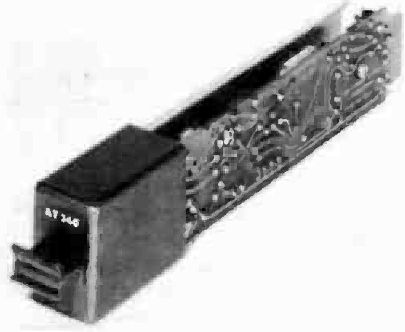

Fig. 12-248A. Model AT240 solid-state plug-in preamplifier manufactured by McCurdy Radio Industries (Canada).

Referring to the schematic diagram in Fig. 12-248B, the input is coupled through matching transformer T1 to the base of the common-emitter amplifier Q1. This transistor provides a large portion of the amplifier gain, while presenting a sufficiently high input impedance to avoid loading the source impedance. The output of Q1 is direct-coupled to Q2, which operates in

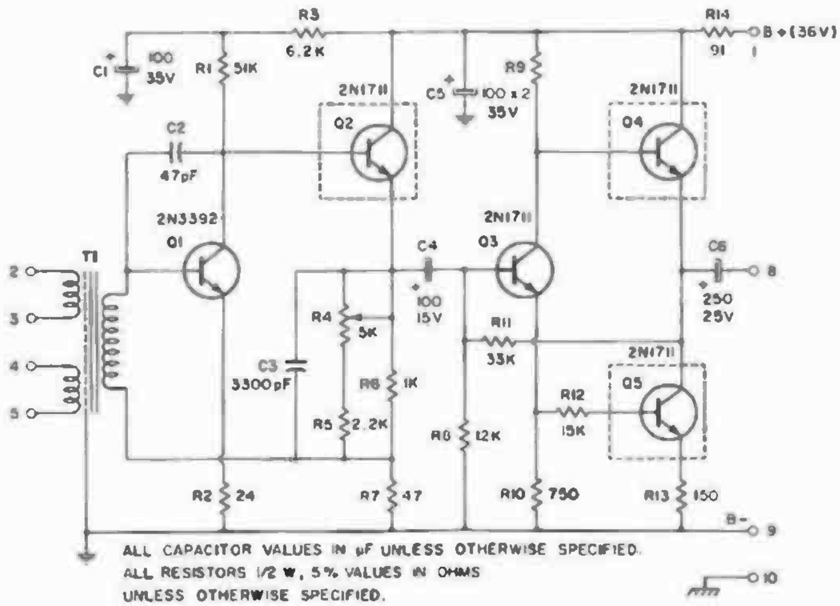

Fig. 12-248B. Schematic diagram for McCurdy Radio Industries Ltd. (Canada) Model AT240 plug-in solid-state microphone preamplifier.

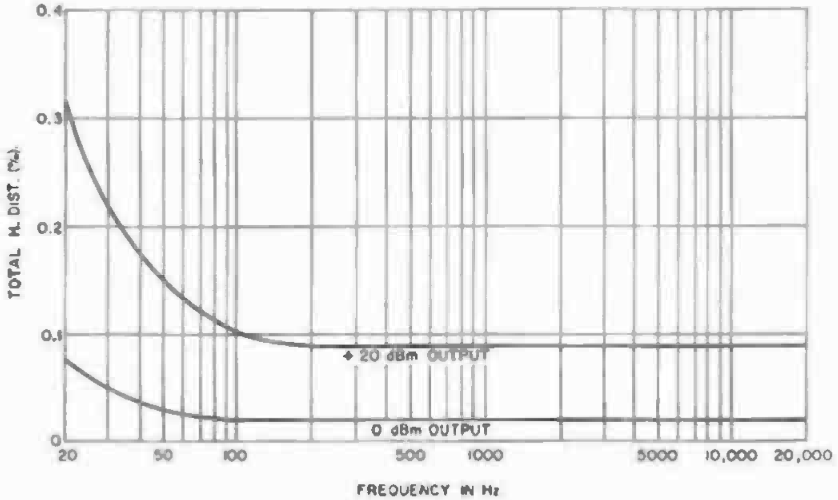

Fig. 12-248C. Distortion characteristics for McCurdy Radio Industries Ltd (Canada) AT240 solid-state microphone preamplifier.

an emitter-follower configuration and feeds the output amplifier. The gain-control circuit comprising potentiometer R4 provides a limited gain adjustment of approximately plus or minus 1 dB, by varying the negative feedback to the base of Q1 via T1. The signal developed at Q2 emitter is coupled through C4 to the base of Q3. Transistor Q3 functions as a phase splitter, since signals of opposite polarities appear at its collector and emitter. The outputs of Q3 are direct-coupled to the base of Q4 and Q5 respectively. Transistors Q4 and Q5 form a single-ended push-pull output stage, with the signal at the emitter of Q4 in phase with that appearing at the collector of Q5. These signals are added in the common output circuit and the resultant signal is coupled to the load resistance through C6. Transistors Q3, Q4, and Q5 operate class-A, with the dc operating point set by resistors R11 and R8. Resistor R11 also provides negative feedback from the output to the base of Q3 to reduce distortion and stabilize the gain. Additional feedback is provided by the unbypassed emitter resistors R2, R7, R10, and R13. Transistors requiring heat sinks are shown in dotted lines.

Specifications are: Gain is 40 dB plus-minus 1 dB; with frequency response from 20 to 20,000 Hz, plus-minus 0.5 dB. Input noise unweighted 10 to 100,000 Hz, minus 124 dBm, or minus 127 dBm, 10 to 20,000 Hz (bandwidth specified at the minus 3-dB point). Maximum output is plus 20 dBm. Source impedance is 37.5 and 150 ohms. Input impedance is greater than ten times the source impedance. Internal output impedance is 25 ohms. The distortion characteristics are given in Fig. 12-248C.

12.249 Describe a solid-state mixer (booster) plug-in amplifier.—In Fig. 12-249A is shown the schematic diagram for the Model AT241 McCurdy

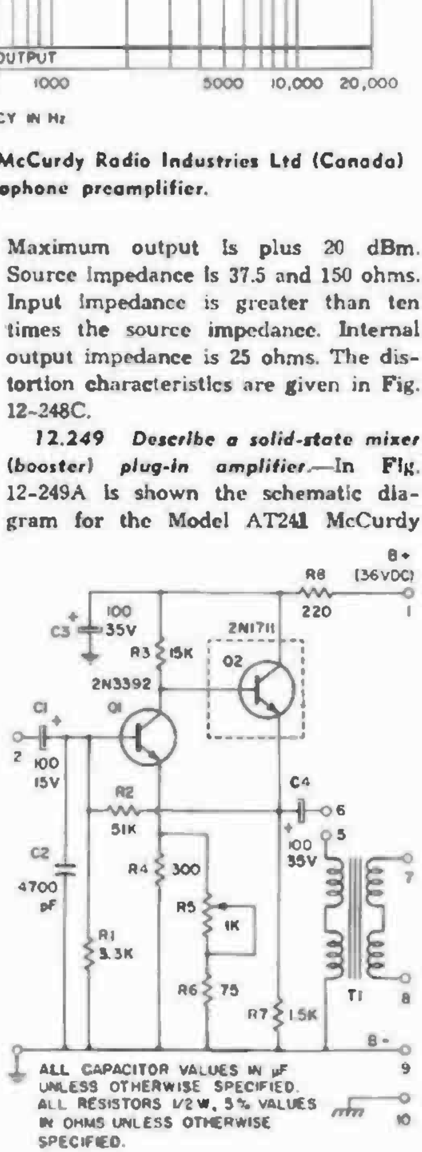

Fig. 12-249A. Schematic diagram for McCurdy Radio Industries Ltd. (Canada) Model AT241 plug-in solid-state mixer amplifier.

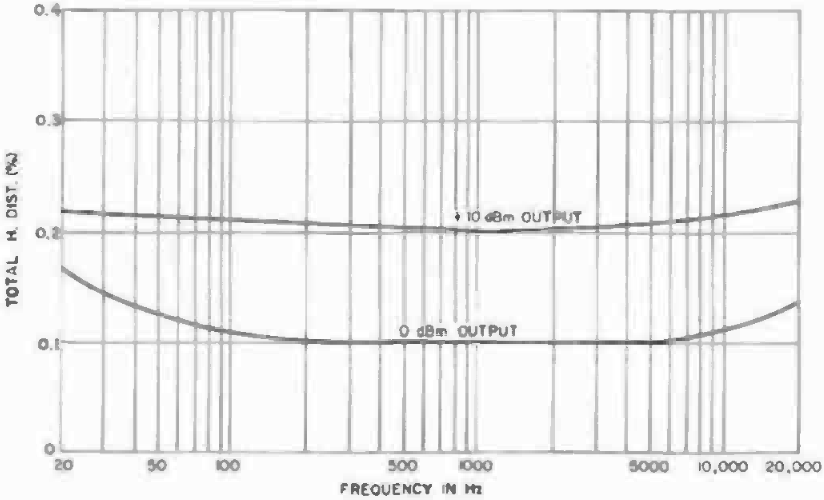

Fig. 12-249B. Distortion characteristics for McCurdy Radio Industries Ltd (Canada) AT241 solid-state mixer or booster amplifier.

Industries Ltd. (Canada) silicon transistor mixer or booster amplifier. Normally a mixer or booster amplifier is used after the mixer network to compensate for network-insertion loss. The amplifier is similar in mechanical construction to the AT240 amplifier, described in Question 12-248.

Referring to the schematic diagram, transistors Q1 and Q2 form a direct-coupled pair, with Q1 operating as a common-emitter amplifier, and Q2 operating as an emitter-follower. The input signal is coupled through C1 to the base of Q1, where it is amplified and direct-coupled to the base of Q2. Transistor Q2 provides the necessary power gain and its low output impedance provides optimum isolation when working into a 600-ohm load.

Resistors R1 and R2 supply voltage feedback to the base of Q1 to set the impedance of this stage at 600 ohms. Unbypassed emitter resistors R4 and R6 at Q1 supply negative feedback to reduce distortion and stabilize the gain, with R5 providing for a small gain adjustment. Transformer T1 is normally connected in the output; however, its position may be reversed and used as an input transformer by re-strapping.

Specifications are: Gain 35 dB, plus-minus 1 dB. Frequency response 20 to 20,000 Hz, plus-minus 0.25 dB. Input noise unweighted, minus 120 dBm to 100,000 Hz (bandwidth specified at minus 3-dB points). Harmonic distortion is less than 0.2 percent at zero dBm, output 20 to 20,000 Hz. Maximum output is plus 10 dBm. Source impedance is 600 ohms. Internal input impedance is plus-minus 10 percent of source impedance. Internal output impedance is 50 ohms; with transformer connected for 600-ohm load, it is 150 ohms. Load impedance is 600 ohms. Distortion characteristics appear in Fig. 12-249B.

12.250 Describe a transistor monitor amplifier operating class-A.—Many times a small monitor amplifier is required, having an output between 1 and 10 watts. A monitor amplifier operating within this range, using transistors and operating class-A, is shown in Fig. 12-250A. This amplifier manufactured by Langevin, may be used as either a program or monitor amplifier. Provision is made for reducing the power output to 1 watt, by removing a single strap connection. The Model AM17, to be described, is unusual in its design as most transistor amplifiers are operated as class-AB or class-B.

Starting at the input, the secondary of the input transformer is split and a balancing control R10 is inserted for adjusting the balance of the output stage, which is measured by connecting a voltmeter between the emitters of transistors Q9 and Q10. Transistors Q1 to Q6 are voltage amplifiers, with the outputs of Q5 and Q6 coupled to Q7 and Q8, through diodes D1 and D2. The purpose of these diodes is to prevent the output stage from drawing excessive current. With the output stage balanced, there is no appreciable current change in Q9 and Q10 with a change of signal level, which is normal for a proper class-A amplifier stage. (See Question 12.226.) Choke L1 and capacitor C7 comprise an interference filter which attenuates any rf interference that may be picked up on the incoming dc power-supply connections. It will also remove video vertical-sync pulses when used around video equipment.

With the amplifier strapped for 1-watt operation, plus 30 dBm, the current demand is about 1 ampere, and for 8 watts (plus 39 dBm), it is 2 amperes. The lower power connection is used when it is operated as a program amplifier. All transistors are silicon. The fre-

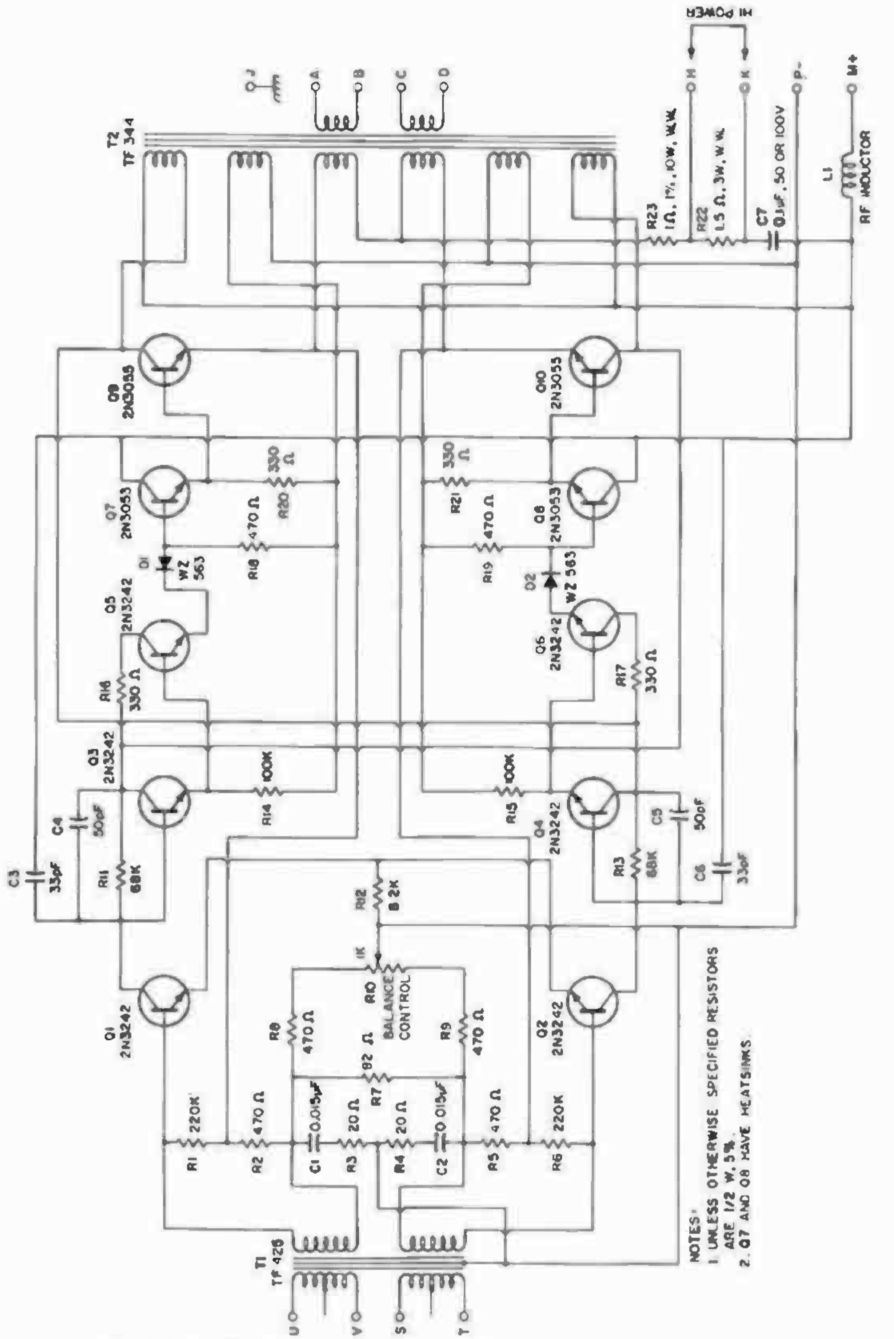

Fig. 12-250A. Langevin Model AM17 transistor power amplifier.

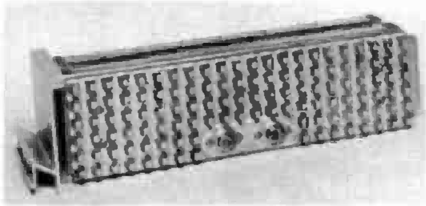

Fig. 12-250B. Langevin Model AM17 transistor class-A power amplifier.

quency response is plus-minus 0.5 dB, 20 to 20,000 Hz, with a gain of 57 dB. Harmonic distortion is 1 percent at plus 24-dBm output. Equivalent noise is minus 115 dBm. The appearance of the complete device is pictured in Fig. 12-250B. A separate power supply is required. Four of the units shown may be plugged into a supporting tray.

12.251 ***Describe the basic principles of a transistor complementary-symmetry amplifier operating class-B.***—Due to the nature of the pnp and npn transistors, they may be connected to have all the benefits of the conventional push-pull amplifier circuit, without the need of a phase-inverter stage, driving transformer, or output transformer. The basic circuit for this type amplifier is shown in Fig. 12-251A. Input-coupling capacitor C charges through one transistor during the positive half-cycle of the input signal, and discharges through the other transistor during the negative half-cycle of the input signal. This action eliminates the need for discharge diodes with capacitance coupling, as required in conventional transistor class-B push-pull amplifiers.

The circuit of Fig. 12-251A shows two transistors connected in a complementary-symmetry circuit. Transistor Q1 is an npn type and Q2 is a pnp type. If a negative-going input signal is ap-

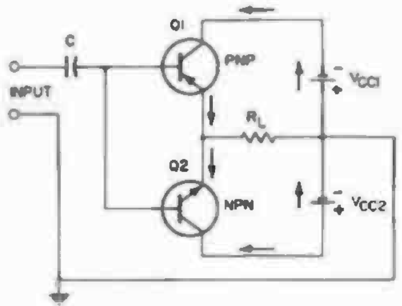

Fig. 12-251A. Basic circuit for a complementary-symmetry transistor amplifier operating with zero bias.

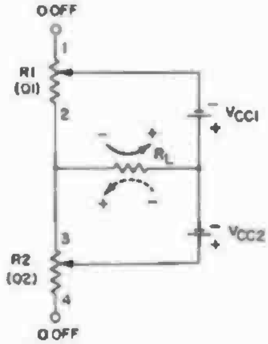

Fig. 12-251B. Simplified circuit of a transistor complementary-symmetry amplifier.

plied to capacitor C, transistor Q1 is forward biased and it conducts. With a positive-going signal, Q2 is caused to conduct. As one transistor is conducting, the other is nonconducting. The resulting action in the output circuit may be better understood by referring to Fig. 12-251B. The external emitter-collector circuit of transistor Q1 is represented by variable resistor R1 and that of Q2 by resistor R2.

With no input signal and the amplifier biased for class-B operation (zero emitter-base bias), the variable arms of the resistors can be considered to be in the off position. As the arm of R2 moves toward point 3, current passes through the series circuit consisting of battery V_{CC2}, resistors R_L and R2. The amount of current flow depends on the magnitude of the incoming signal, the variable arm moving towards point 3 for increasing forward bias, and toward point 4 for decreasing the bias. Current flowing in the direction of the arrows produces voltages with the indicated polarities.

When the input signal goes negative Q1 couducts and Q2 becomes nonconductive. The same action is repeated as for resistor R1. Current flows through V_{CC1}, resistor R1, and load resistor R_L in the direction shown by the solid line arrow and produces a voltage across R_L with the indicated polarities.

12.252 ***Describe a complementary-symmetry transistor amplifier operating class-A.***—To operate a complementary-symmetry amplifier class-A, a forward bias voltage is applied to both transistors, so the collector current is not cut off at any time. Referring to Fig. 12-251B, under class-A operation the variable resistors will not be in the off position at any time. The dc bias current in the output flows out of the negative battery terminal V_{cc2}, into the positive terminal of battery V_{cc1} through resistors R1 and R2, and into the positive terminal of battery V_{cc2}. No current flows through the load resistor R_L. Under these conditions the output circuit may be considered to be that of a balanced bridge, consisting of resistors R1, R2 and batteries V_{cc1} and V_{cc2}. With a positive-going input signal, transistor Q2 conducts more, and Q1 conducts less.

In the simplified circuit of Fig. 12-251B the arm of resistor R1 moves toward point 1, and that of resistor R2 moves toward point 3. This results in an unbalanced bridge condition and electrons flow through resistor R_L, in the direction of the dashed-line arrows, producing the indicated polarities. With a negative-going input signal, transistor Q1 conducts more and Q2 conducts less. The variable arm of R1 moves to point 2, and that of R2 moves toward point 4. Again the bridge is unbalanced, and electrons flow through R_L in the direction of the solid-line arrows, producing voltage with the indicated polarities. For either class-A or -B operation there is no direct current flow through load resistor R_L; therefore, a loudspeaker voice-coil winding may be directly connected in place of load resistor R_L.

12.253 Describe a direct-coupled complementary-symmetry amplifier.—A common-emitter complementary symmetry circuit is shown in Fig. 12-253A. In this circuit, transistors Q3 and Q4 are driven directly by another common-emitter complementary-symmetry stage, Q1 and Q2. The signal for Q1 and Q2 is taken from a single-ended stage. When the input goes positive, Q1 conducts and Q2 is nonconductive because of the 180-degree phase reversal in the common-emitter configuration, the collector of Q1 goes negative which causes Q3 to conduct, and Q3 collector goes positive. With a negative input signal, Q2 conducts and its collector goes positive, which causes Q4 to conduct and its collector to go negative. Transistors Q1 and Q3 are nonconductive during this period. Battery V_{EE1} supplies the required biasing for Q1 and Q3, and battery V_{EE2} biases Q2 and Q4. The emitter-base junction of Q3 is in series with the collector-emitter circuit of Q1 and battery V_{EE1}. As a result the emitter of Q3 is positive with respect to its base (forward bias) and the collector of Q1 is positive with respect to its emitter as is required for electron flow. A similar arrangement exists for Q2, Q4, and battery V_{EE2}.

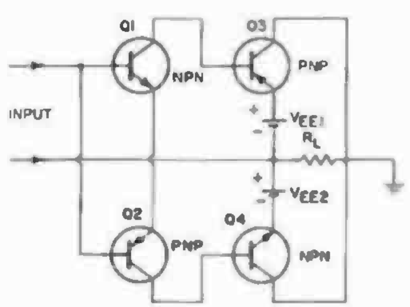

Fig. 12-253A. Common-emitter direct-coupled complementary-symmetry amplifier.

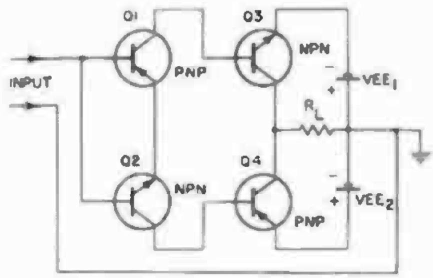

Fig. 12-253B. Common-collector direct-coupled complementary-symmetry amplifier.

A common-collector configuration is shown in Fig. 12-253B. As for a single transistor, maximum voltage, current, and power gain are obtained with the common-emitter connection; however, its input resistance is low. The common-collector configuration will provide higher input resistance with less current, voltage, and power gain.

12.254 What is a compound-connected transistor amplifier?—By the use of a compound configuration, the drop-off of collector current or the reduction in audio feedback at higher emitter currents can be made negligible. Fig. 12-254A shows a variation of collector currents versus emitter current for a single transistor, and two transistors in a compound configuration. Compound-connected transistors can be single-ended, push-pull, or in a complementary-symmetry configuration; the latter circuit appears in Fig. 12-254B. This

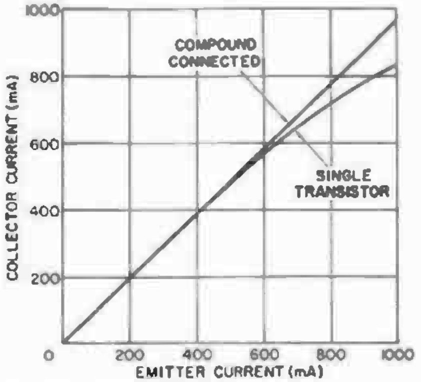

Fig. 12-254A. Variation of collector current with emitter current for a single transistor and for compound-connected transistors.

circuit is somewhat similar to that of Fig. 12-253A. Transistor Q1 is replaced by the compound connection of Q1A and Q1B. The gain for such a configuration is greater than that of the complementary-symmetry configuration. Such circuits are used in power-amplifier output stages.

12.255 ***Describe an 80-watt transistor power amplifier, using a half-bridge output stage.***—The basic design for a half-bridge push-pull power amplifier given in (a) of Fig. 12-255 is capable of developing 80 watts of audio power, with less than 2.0-percent total harmonic distortion (THD) up to full output. The general form is that of a two-stage transformer-coupled half-bridge push-pull output circuit, direct-coupled to an 8-ohm load. This arrangement allows considerable design latitude in achieving high sensitivity and high values of negative feedback, with the least number of active components, as compared to the symmetry approach. In addition, the circuit is thermally stable relative to the bias for the output transistors. The use of a driver transformer presents no particular problems, as the design is quite simple.

The output circuit is of standard half-bridge configuration, which drives the load directly from a balanced plus-minus power supply. Because of the balanced power supply, there is only a negligible dc component across the load, caused by bias-voltage tolerances. This dc component and the ac ripple accompanying it are easily nulled out by small bias pots, if desired. The bias network itself is a stable voltage divider which presents a fixed voltage to the base of each power transistor to allow an idling current determined by the inherent transconductance characteristics of the device. The 0.47-ohm emitter resistor provides a small amount of degeneration, enhances the stiff bias voltage to present a thermally stable circuit, and offers a small amount of local ac feedback. The output circuit employs the driver-transformer secondary dc resistance as a part of the bias network, since it can be held to tighter tolerance than a separate resistor. This arrangement minimizes the total drive voltage required from the transformer secondary so that the emitter diode of the power transistor is avalanched only a minute amount.

Shunt-bias networks are only practicable when the output transistors are driven from the low-impedance source (as reflected through the transformer) to minimize the effects of the shunt negative-voltage feedback loop, which degrades the input impedance and increases the required driving power. Extensive tests have indicated this type voltage drive optimizes the basic linearity throughout the whole bandwidth and extends the frequency range of the output circuit. The low source impedance provides a constant voltage to the output transistors, as their input impedance changes with load and frequency. This permits a low distortion gain through the exceptionally linear transconductance characteristic.

The driver section consists of two common-emitter stages, direct-coupled and feedback-biased for maximum sta-

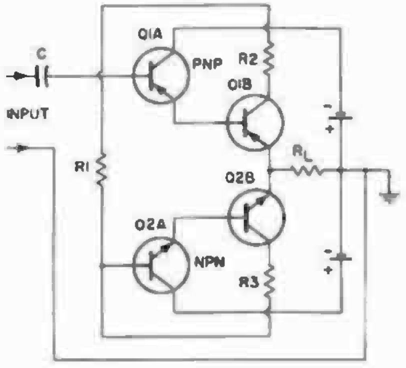

Fig. 12-254B. Compound-connected transistors in a complementary-symmetry configuration.

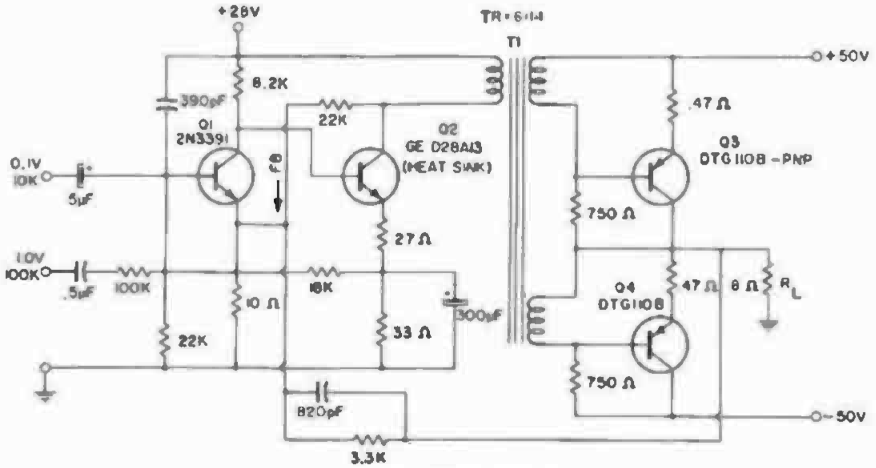
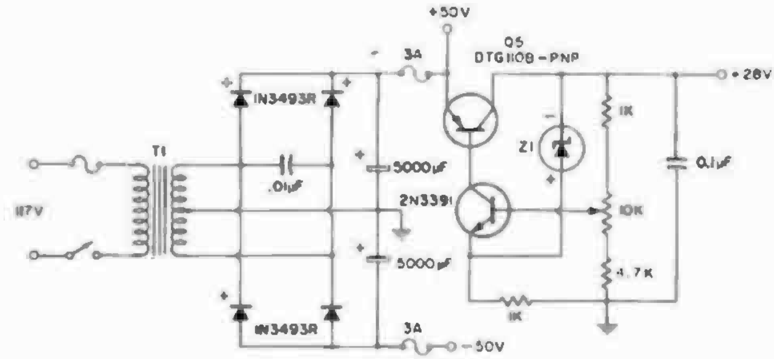


(a) *Amplifier circuit.*



(b) *Power-supply circuit.*

Fig. 12-255. Schematic circuits for 100-watt half-bridge transistor power amplifier. (Courtesy, Delco Radio Division.)

bility. The dc feedback bias is derived from the emitter of Q2 and applied back to the input of Q1. This provides good thermal stability and compensates for dc parameter variations between the two transistors. About 16 dB of ac negative feedback is derived from the collector of Q2 to reduce the output impedance of the driver stage, thereby providing a low-impedance (voltage) source to drive the output stage.

The driver transformer is of split-primary design, using grain-oriented steel core material. The split-primary is bifilar wound and permits a high degree of coefficiency between the primary and secondary, resulting in a flat frequency response throughout the audio spectrum, and rolling-off in a frequency range most beneficial to the total gain-phase behavior of the composite amplifier. This favors maximum driver efficiency. (See Question 8.109.)

A 6:1 turns ratio was chosen, for the driver transformer (Goslin Corp. TAD 3257) so that a large drive voltage swing from a low current signal device would drive the DTG 110A's (Delco) output transistors to full output. The GED28A13 transistor is quite satisfactory for this purpose when mounted on a 1" × 1" × 1/16" aluminum plate insulated from the chassis. The circuit shown provides exceptional sensitivity for the rated output of 80 watts, with 34 dB of total negative feedback. This is achieved by staggering the frequency-response characteristics of the silicon planar transistors Q1 and Q2, the low impedance of the driver transformer, and the DTG 110A output transistors.

The power supply is capacitor filtered, which provides sufficient regulation for full continuous output of two 80-watt amplifiers. A simple feedback regulator Q5 and Q6 provides the driver bias supply with very low ripple content for optimum noise and power-supply feedback rejection.

The amplifier will deliver up to 80 watts to an 8-ohm load from an input signal of 0.10 volt from an input impedance of 10,000 ohms, or driven from a 1-volt source with a 100,000-ohm input impedance. Bandwidth is plus or minus 1 dB, 20 to 20,000 Hz at 1 to 20 watts output. Total harmonic distortion is less than 2 percent at 1 kHz up to full output. Intermodulation distortion is less than 2 percent up to full output, using 60 and 6000 Hz in a 4:1 ratio. Signal-to-noise ratio (thermal) is 80 dB below rated output. Internal output impedance is 0.5 ohm and rise time is 10 microseconds to full output.

The output transistors must be mounted on heat sinks with at least 165 square inches of surface, with mica washers using silicon oil, or mounted directly on the heat sinks, then insulating the heat sink from the chassis for greater dissipation of heat. When making square-wave tests, the waveform at the output can be improved (if necessary) by trimming the 390- and 820-pF capacitors. The output may be reduced to 50 watts by reducing the operating voltage to 35 volts, rather than the 50 volts called for. This will require changing the values of the 750-ohm resistors in the output stage to 550 ohms each.

12.256 Describe a 200-watt stereophonic transistor amplifier, using the Sharma circuit.—The attainment of high power output in transistor amplifiers is rather difficult and has been the subject of much research. An interesting circuit has been developed by Madan M. Sharma, of Mattes Electronics Inc., using a double class-B or totem-pole output-stage configuration (Fig. 12-256A). It has been found that the presence of bias voltage in the output stage does not entirely eliminate notch distortion common to class-B amplifiers, and imposes limitations on the driver stage. Therefore, the power-output stage of the Sharma circuit does not use bias voltage. Referring to Fig. 12-256B, the basic circuit, the output stage employs simulated negative-impedance characteristics driven by a low-power, low-distortion driver amplifier, which is basic in design.

The low output of the driver stage stabilizes the power stage and provides the drive signal. Near the zero crossing, when the power transistors are below the threshold of conduction, the output load is driven entirely by the driver stage. When the signal rises, the parallel combination of the load impedance and the negative output impedance of the power stage appears across the output of the driver as a very high impedance. The driver stage drives the load when the signal is low, but drives a high impedance when the signal level is high. In either condition, the driver stage is required to supply only a small amount of power.

To achieve maximum power output, this circuit was modified (Fig. 12-256C) to use two latching diodes, D1 and D2, and resistors R1 and R2. The combination is called a latching circuit and disconnects the power stage from the output of the driver stage when the instantaneous voltage across the output terminals is greater in magnitude than the driver power-supply voltage. This action isolates the two amplifiers when isolation is required, yet permits the system to operate as a basic circuit during the balance of the time. At low levels, the drive is connected to the output terminals through latching diodes D1 and D2, permitting dc feedback to stabilize the dc output at the output terminals. High-level signals are transformer-coupled, offering the best impedance match between the driver and the output transistors. Using separate power supplies, the power stage may be operated at any voltage.

The driver stage also supplies power. The proportion of power delivered by the two amplifier stages depends on the signal level. The two amplifiers continue to drive the load collectively until a signal level is reached when the power amplifier supplies the power. At this point, the driver stage supplies no power but acts as a control signal. At the higher levels, when the power transistors are supplying all the output power, they tend to drive themselves through the driver transformer. Since the driver stage presents a low output impedance (lower than the impedance of the power stage), the excess current which would have caused oscillation returns to ground through the driver stage. When the output is larger than

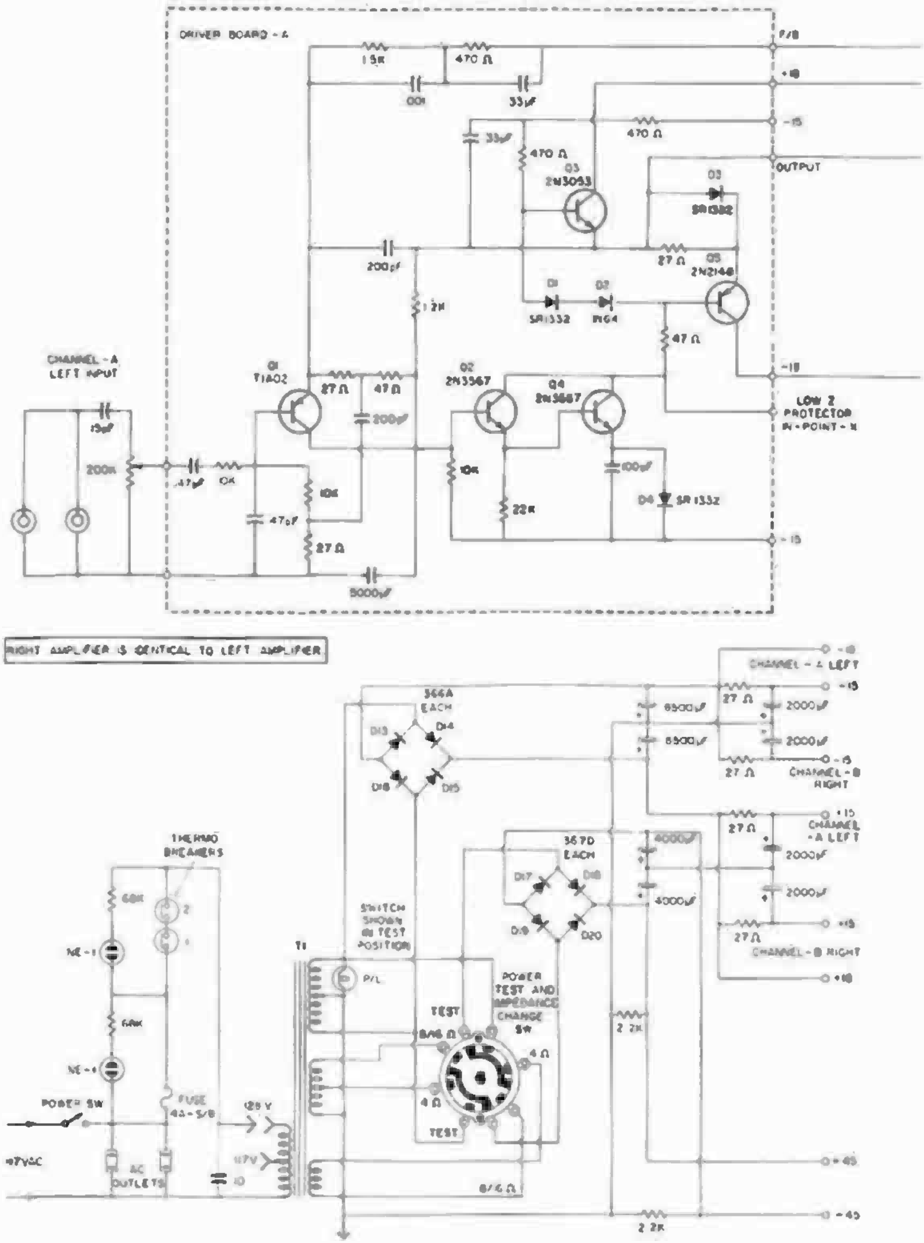


Fig. 12-256A. Schematic diagram for Mattes Electronics, Inc.

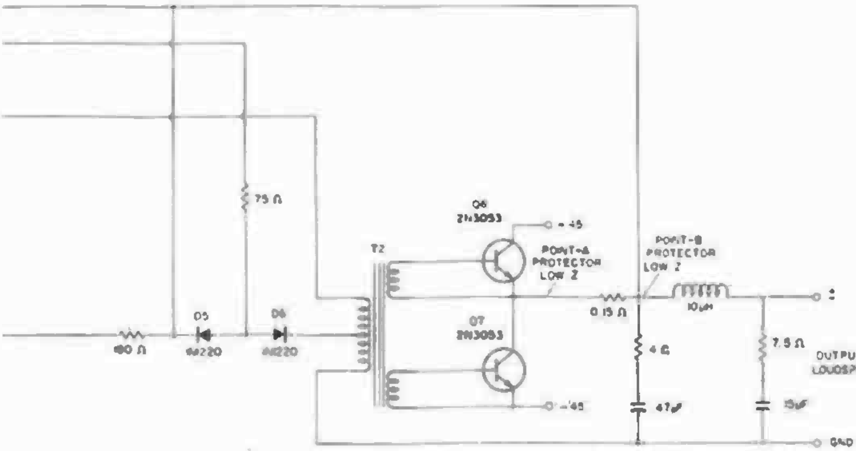
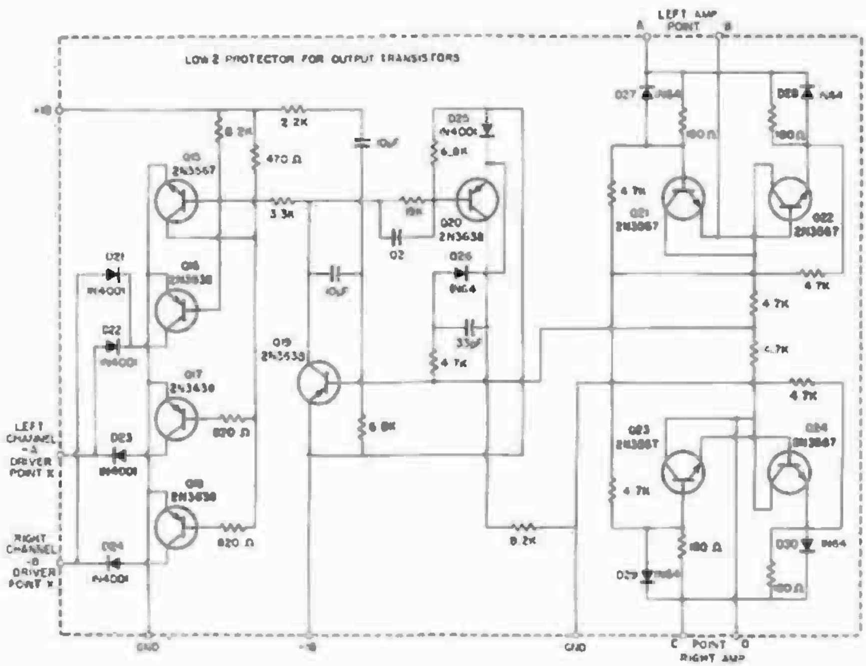
the supply voltage of the driver, the latching diode stops conduction. This isolates the two amplifiers. Now the signal flow is maintained through the driver transformer only, and the amplifier operates like any transformer-coupled amplifier. Because of the negative feedback, transients between the different modes are smoothed out and linearity established throughout.

The complete circuit with its voltage amplifier stages is shown in the overall schematic diagram in Fig. 12-256A. It will be observed a driver amplifier limiter has also been included. The two amplifiers are each capable of developing 100 watts of continuous power into a load of either 4 or 8 ohms. For a load of 16 ohms, the maximum power output drops to 60 watts per channel. The intermodulation distortion, working into 4 or 8 ohms is 0.07 percent, using the





200-watt stereophonic transistor amplifier using the Sharma circuit.

SMPTE test method as set forth in Section 23. The harmonic distortion is 0.5 percent maximum at 100 watts. Frequency response is plus-minus 0.5 dB, 15 to 30,000 Hz. Damping factor is 250, with an effective internal output impedance of 0.04 ohm. Hum and noise are 90 dB below the rated output, or 1 millivolt. One of the important features of the Sharma circuit is that the output terminals may be operated with a direct short circuit without damaging the output transistors. Also, because of the design capacitive loads of 0.5 microfarad may be driven; however, maximum power output cannot be achieved.

To summarize, at very low signal levels, the power transistors are below the threshold of conduction, the driving power being supplied by the driver stage. As the signal level is increased, the power transistors begin to conduct and supply power to the external load circuit.

The output stage has an efficiency of 78 percent, the theoretical maximum for a class-B amplifier. The driver transformer has a turns ratio of 3:1, using *pentafilar* windings of low dc resistance. The output transistors are rated 15 amperes collector current. If a lower rating is used, it is possible for them to be damaged, if the output terminals should become short-circuited. Balanced component values are not necessary, standard 10-percent resistors are quite satisfactory.

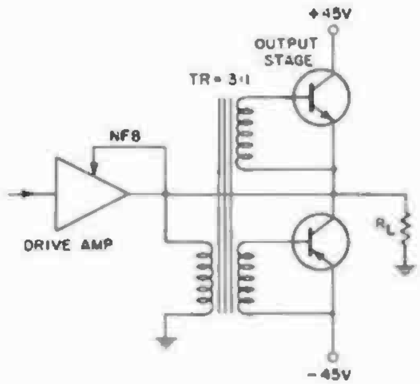


Fig. 12-256B. Basic circuit of Sharma circuit used in the Mattes Electronics, Inc. stereophonic solid-state amplifier.

Because of the 100-watt output capabilities of the amplifier, a test switch has been incorporated to decrease the power output to about 12 watts when setting up for testing. The 10-microhenry chokes and the capacitors in the output circuit constitute a low-pass filter which removes very high frequency components from the signal, that are not entirely eliminated by the feedback circuit due to transient-time effects present in all power transistors. The cutoff frequency is high enough to not affect the response of the amplifier as a whole. Suggested specifications for the driver transformer are given in Question 8.109.

Connected across the output of each power transistor stage is a protective circuit consistiug of 5 transistors and 5 diodes. It is a fact, but not generalized, that the internal input impedance of a loudspeaker system at the very low frequencies may present a *dead short* circuit to the output power transistors. If they are not adequately protected instaut failure is the result.

With the protective circuitry shown at the lower right of Fig. 12-256A, the output transistors of each channel are protected against changes in phase angle (caused by the speaker characteristics), and against a short circuit across the output. If the built-in limits set by the manufacturer are exceeded even by a partial short circuit, the amplifier will cease operating instantly, then sample the load impedance every second for a few milliseconds duration to determine if the amplifier load impedance has returned to normal.

It will be noted that the actuating signal is taken from across a 0.15-ohm resistor connected in series with the output line, at points A and B in the left channel and C and D in the right channel. The outputs of the protective circuits are returned to the driver stage at points X and Y. Thus for a malfunction in the output circuit, the driver circuits instantly become inoperative,

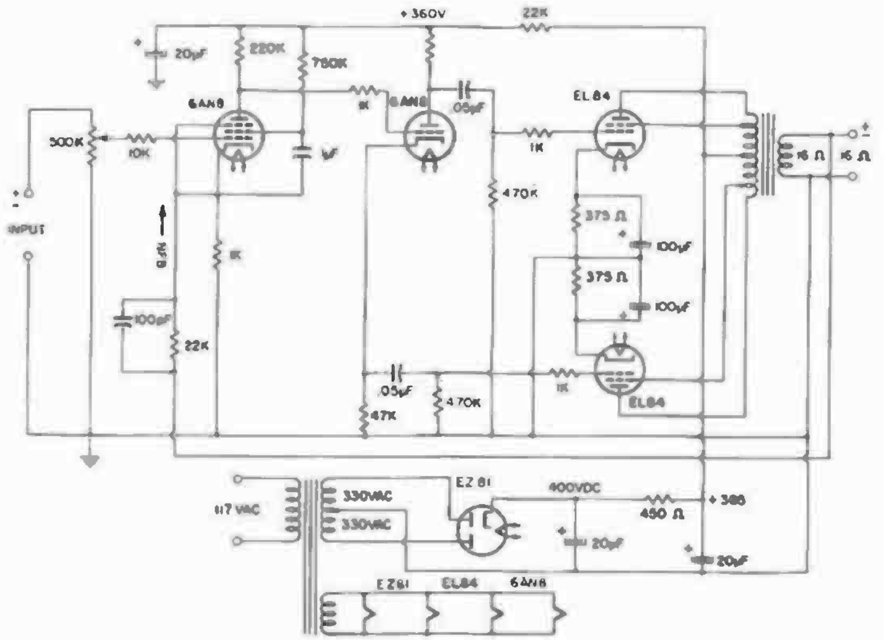

Fig. 12-257A. 15-watt Williamson ultralinear amplifier used in FET conversion.

and damage to the output transistors is prevented. The operation of the sensing control circuit produces a characteristic sound in the speaker system, warning the listener of difficulties in the output circuit. When trouble has been cleared, the amplifier returns to normal operation. (See Question 20.138.)

12.257 Can a field-effect transistor (FET) be directly substituted for vacuum tubes in an amplifier?—Yes, under certain conditions and if they are used only for *voltage-amplifier stages.* Considerable work in this direction has been done by Rheinfelder. All tubes, except the power output stage were replaced, and only a slight modification to the power supply circuitry was made to reduce the voltage. The output stage of a typical 15-watt Williamson ultralinear amplifier is shown in Fig. 12-257A, with its conversion in the voltage stages to FET's shown in Fig. 12-257B. After conversion, measure-

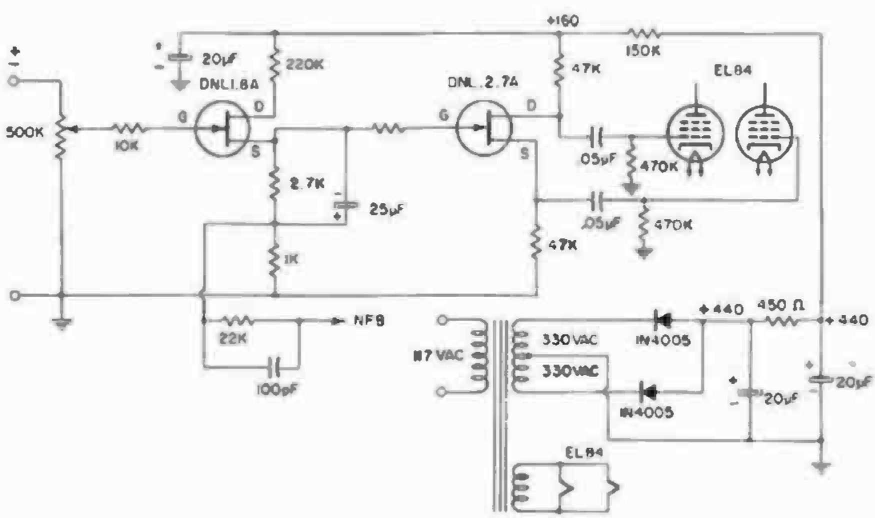

Fig. 12-257B. 15-watt Williamson ultralinear amplifier voltage stage and phase-splitter after conversion to FET's.

ments indicated the same overall gain, improved frequency response, lower hum and noise for over a 10-percent increase in power output for 1-percent distortion. The rectifier tube in the power supply was replaced with two diode rectifiers, and the voltage was dropped by the use of a 150,000-ohm resistor in the high-voltage lead to the voltage amplifier stages, rather than the 22,000-ohm resistor in the original circuit. The FET's were soldered directly to the tube sockets. The original values of the components in the negative-feedback loop were retained. (See Questions 12.128 and 12.232.)

12.258 Describe a source follower, using a field-effect transistor (FET).— A source follower is quite similar in nature to the cathode-follower circuit used with vacuum tubes. In the circuit of Fig. 12-258A, the output voltage is taken from the source element and follows the input (gate) due to the action of the negative series-voltage feedback, because the output voltage is applied in series with the input signal voltage. Therefore, the gain is:

$$A' = \frac{A}{(1 + A)}$$

where,

A is the gain before feedback,
A' is the gain with feedback.

The input impedance (R'_{in}) with feedback is derived:

$$R'_{in} = \frac{R_{in}}{1 - A'}$$

where,

R_{in} is the input impedance without feedback,
A' is the voltage gain of the source follower.

The output impedance may be approximated:

$$R_o = \frac{1}{G_m}$$

where,

G_m equals the effective circuit transconductance.

A typical example: A gain of (A) equal to 70 results in a net gain of 0.985, with feedback, and an impedance multiplying factor of 666 (666 megohms with a gate impedance of 10 megohms). Under these conditions, the output impedance is 1000 ohms, depending on the type FET employed. The output capabilities for a source follower are identi-

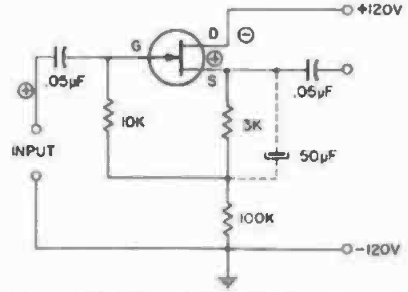

Fig. 12-258A. Field-effect transistor (FET) source follower. Signal polarities are given to indicate the phase reversals between input and output signals.

cal to a conventional source amplifier stage; however, the distortion below overload is considerably better because of the negative feedback. The source follower finds its greatest use where an extremely high input impedance is required, with a low output impedance. It should be operated into a load impedance of 100,000 ohms minimum, and from a source impedance higher than the input resistance, before the feedback was applied (10 megohms).

Optimum performance is obtained with the source element set to 65 percent of the voltage applied to the drain, which may be obtained for the circuit shown, using the specified FET, with a 3000-ohm resistor in the source circuit. This resistor may be left bypassed as little effect is noted with it unbypassed. The frequency response of the follower circuit shown is down 3 dB at 290 kHz, using a source resistance of 100,000 ohms, and with a total capacitance of 5.3 pF at the input, including the socket.

The optimum gate voltage for a source follower is close to one-half the supply voltage, the same as for the conventional source amplifier. A direct-

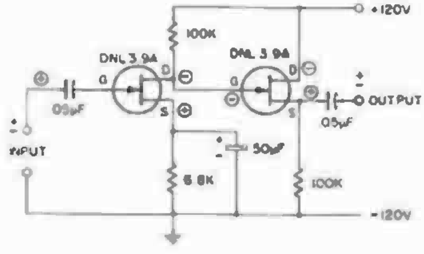

Fig. 12-258B. Direct-coupled field-effect transistors (FET) signal polarities are given to show the phase reversals between the input and output signals.

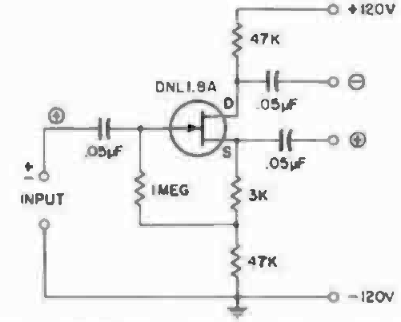

Fig. 12-259A. Phase-splitter circuit using a single FET (after Rheinfelder).

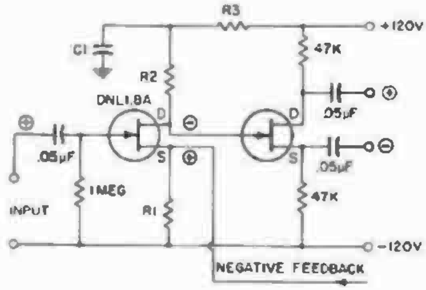

Fig. 12-259B. Direct-coupled phase splitter using two FET's (after Rheinfelder).

coupled source follower is shown in Fig. 12-258B. The characteristics for several different values and source resistance are given below.

Drain resistance	*Source resistance*	*Gain*	*3-dB bandwidth*
100K	6.8K	35.6 dB	30 kHz
220K	15K	39.0 dB	23 kHz
470K	39K	41.2 dB	15 kHz

The above values are for a Dickson DNL 3.9A FET. (See Question 11.145.)

12.259 ***Describe a phase-splitter circuit using a field-effect transistor (FET).*** —The FET phase splitter performs the same function as its vacuum-tube counterpart. The circuit shown in Fig. 12-259A is an adaptation of the source follower shown in Fig. 12-258A. Resistors of 47K in both the drain and the source were found to be quite satisfactory, regardless of the supply voltage. As the signal is split at the output, only half the input voltage is available at each output; however, the feedback is nearly as effective in reducing distortion as in the source follower. Greater output may be obtained by increasing the supply voltage until the breakdown is reached. In this manner, sufficient signal-output voltage may be obtained to drive a pair of EL 34 tubes in push-pull to 100-watts output, with only 23.4 volts for each grid. An FET operating with 160 volts can easily supply this voltage with less than 1-percent distortion.

A direct-coupled phase splitter is shown in Fig. 12-259B, and a source-coupled phase inverter is shown in Fig. 12-259C. Signal polarities have been indicated to show how phase-splitting and inversion is obtained. Referring to Fig. 12-259B, in this circuit the biasing is adjusted in favor of the phase splitter. As a rule, optimum performance is achieved with the drain-to-source voltage at 45 percent of the supply voltage; the gate voltage should run about plus 33 volts dc. The optimum drain voltage

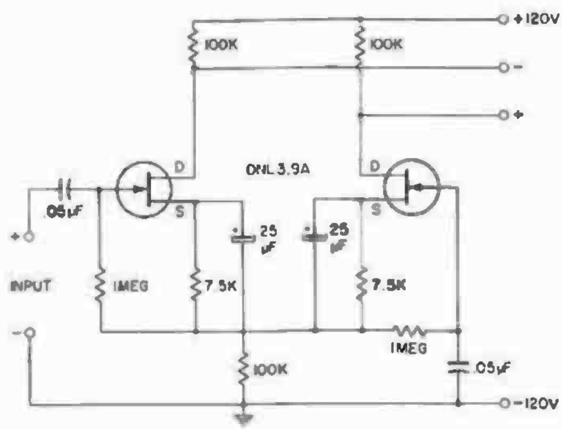

Fig. 12-259C. Source phase inverter using two FET's (after Rheinfelder).

for the first stage is plus 55 volts dc. Therefore, improved performance may be obtained by lowering the supply voltage at the first stage by the insertion of resistor R3 and capacitor C1. These components also aid in decoupling the two stages. Lowest distortion is obtained when resistor R1 equals 2100 ohms unbypassed, and R2 is 100,000 ohms. The distortion for these values is 0.97 percent, with an output signal voltage of 15 volts each side, and a gain of 20 dB. It should be realized that the distortion figures for this and other circuits are those *without* the benefit of negative feedback, which would be normally used in a high-quality amplifier. Changing the value of R1 to 7500 ohms, R2 to 220,000 ohms, and with R3 at zero ohms, and the supply voltage at 200 volts, the signal voltage on each side for 1-percent distortion is 23 volts. Increasing the input sufficiently to obtain 30 volts at the output results in a distortion of 3.4 percent, with a gain of 43 dB. If negative-feedback is used, it is applied to the top of R1, which is not bypassed. (See Question 11.145.)

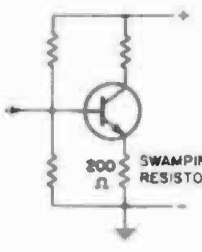

Fig. 12-260. Configuration of a swamping resistor connected in the emitter circuit of a transistor.

12.260 Describe a swamping resistor.—This term is used with resistors employed for several different purposes. One of the most common uses of such resistors is its connection in the emitter circuit of a transistor (Fig. 12-260). The base-emitter junction generally has a negative temperature coefficient; that is, the resistance decreases with the increase of temperature, permitting leakage currents to increase. Typically, the V_{e-b} will rise about 2.5 millivolts per degree centigrade, forward biasing the transistor, with the possibility of causing thermal runaway. If the swamping resistor is large in comparison to the emitter-base junction resistance, it will effectively swamp out the negative-resistance effect. This resistor is generally referred to as an emitter resistance, and for the average small transistor equals about 200 ohms.

12.261 Describe the construction of an integrated circuit element.—Integrated circuitry is a technology developed over the past decade by several companies whereby a *single* tiny module can contain several transistors, diodes, and passive elements on a single substrate. The most striking property is their microscopic size. A single module may contain up to 10 to 20 transistors and 40 to 60 resistors on a single piece of silicon 1/10 to 1/20-inch square. Arrays of resistors and capacitors are created in the form of *thin-films*.

The fundamental requirement of an integrated circuit is that its components be processed simultaneously. By the use of sophisticated thin-film techniques, *active* as well as *passive* components are formed. However, most integrated circuits are not based on thin-film techniques. Silicon planar techniques similar to the manufacture of transistors are used.

A typical integrated circuit is shown in Fig. 12-261A. The circuit for a typical element is given in Fig. 12-261B. Employing conventional construction methods, this circuitry would require very many external connections. As shown here, the external connections are reduced to 10. In addition to the tremendous reduction in size, the operating characteristics are greatly improved.

The basic procedure for the manufacture of an integrated circuit is given in Figs. 12-261C to I. The process is started by diffusing two n-type crystals in a single uniform crystal of p-type characteristics (Fig. 12-261C) from a uniform p-type crystal (Fig. 12-261D), using the masking properties of silicon and photochemical techniques with the control of time and temperature. In this manner *isolated nodes* are achieved. Diodes are thus formed by the p-type substrate and n-type nodes. Transistors are formed by the addition of p-type and n-type regions (Fig. 12-261E). The silicon wafer is then coated with an insulating oxide layer, and the oxide opened to permit the metalization and interconnections (Fig. 12-261F).

Resistors are formed by omitting the n-type emitter diffusion and two con-

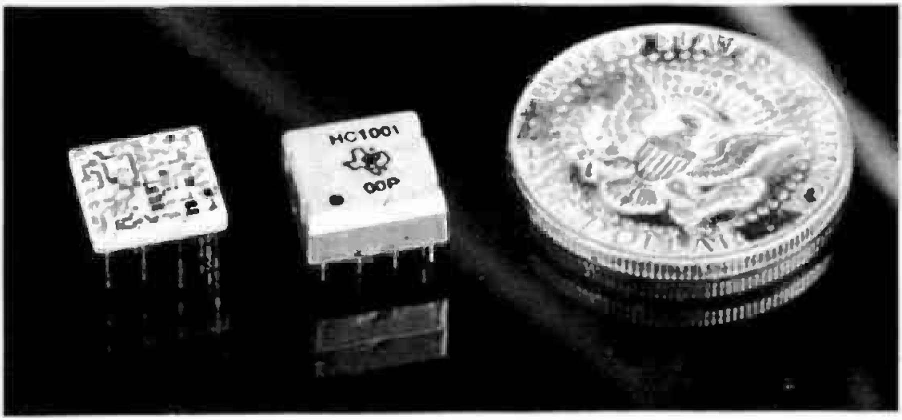

Fig. 12-261A. A typical hybrid IC circuit, used as an fm sound system module. (Courtesy, Texas Instruments, Inc.)

tacts are made to a p-type region (Fig. 12-261G). For capacitors, the oxide is used for the dielectric (Fig. 12-261H). A typical combination of three different elements is shown on a single wafer (Fig. 12-261I).

By employing the above mentioned techniques for the formation of an integrated circuit, the circuit elements thus formed are similar to discrete elements. However, integrated resistors are quite different from those of discrete design, as these are normally manufactured to a standard form factor, with the value of resistance obtained by a variation in the resistive material. In the design of integrated circuits the value of the semiconductor resistor depends on its geometry. Large values of resistance are long and narrow whereas small values are short and squat.

The value of a capacitor is equal to the product of its area, the ratio of the dielectric constant of the diffused material, and the thickness of the oxide. In practice, the area is kept constant and the capacitance varied directly with the area.

An important factor in the design of semiconductor resistors is operating temperature, making it rather difficult to achieve a close tolerance. Therefore, the ratios of the photolithographic masks

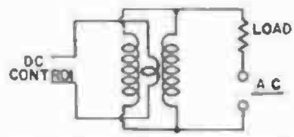
used in the manufacture are closely controlled.

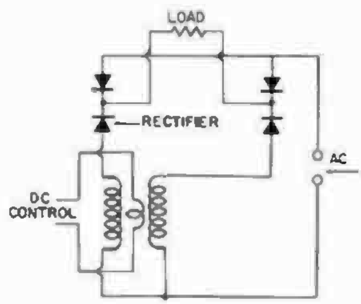
Where several transistors are included on the same chip, they have a number of operating advantages over that of the discrete unit design. Because of their proximity, they receive almost identical processing, are closely matched and because of the close spacing, suffer from minimum temperature differences. Thus a close match is possible over a wide range of operating temperatures. In addition, many more transistors can be included in a given area with their circuit elements than could be with the discrete element design.

12.262 ***Describe a magnetic amplifier and its purpose.***—Magnetic amplifiers are used in servomechanisms for the control of electromechanical devices. They are also known as direct-current transformers, current transformers, saturable reactors, and amplistats. Such amplifiers consist of one or more saturable reactors, the controlling voltage being from a dc source. Magnetic amplifiers can be designed to deliver almost any amount of power in the 60 to 400 Hz range.

Magnetic amplifiers can also be designed to operate at radio frequencies; however, their frequency range is limited by the transformers and rectifier elements.



(a) Ac output, dc control voltage.



(b) Rectified ac output controlled by dc.

Fig. 12-262. Magnetic amplifiers.

Time-constants play a large part in the design of magnetic amplifiers. To reduce the time-constant to a minimum, large amounts of both negative and positive feedback are employed. To increase the gain several stages may be cascaded, the total gain being that of the individual stages. In such systems a gain of one million is not uncommon; however, a low time-constant can only

be achieved with low gain. Typical circuits are shown in Fig. 12-262.

12.263 Describe a three-terminal amplifier.—It is a European expression to denote a stereophonic amplifier where two amplifiers are combined on a common chassis. As there are two plus-minus terminals and the ground common to both, it is termed a three-terminal amplifier (Fig. 12-263).

12.264 What is a fluid amplifier?—Fluidic amplifier systems are composed of devices employing aerodynamic and mechanical principles, and are designed to operate similar to an electronic amplifier. Such devices may be constructed to produce the action of a gate, resistor, flip-flop, binary counter, and many other devices similar to their electronic counterparts. They require no moving parts, and have very low wear factor, and are not affected by nuclear radiation.

The fluid use for their operation is air maintained at a constant pressure. The amplifier devices consist of channels and passages. The advantages of such devices are they are free from vibration and have been operated up to 15,000 G's with few adverse effects.

12.265 Give a block diagram for a typical stereophonic control center.—Stereophonic control centers consist of a group of control circuits and preamplifiers for the reproduction of phonograph records, microphones, magnetic-tape reproducers, radio, and any other source of electrical pickup. Stereo centers do not contain power amplifiers for driving loudspeakers; these are separate units. Stereophonic-amplifier assemblies containing power amplifiers are called integrated stereo amplifier systems. In some instances the center

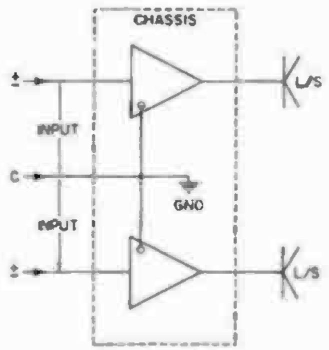

Fig. 12-263. Three-terminal amplifier.

may include an additional output circuit for driving a center or remote speaker derived from the left and right channels.

Referring to the block diagram in Fig. 12-265A, the signal will be traced for the left channel. The right channel is the same in all respects, except for one slight modification. Assume the signal is from pickup unit A, which is fed to selector switch B. This switch selects the desired input signal and equalization (magnetic or ceramic pickup, response flat for microphone and radio) and applies it to preamplifier C, then to switch D. This switch permits the user to select the proper circuitry for balancing the left and right channels, reproduction for either stereo or monophonic records, and the reversing of the right and left sides.

The signal is next applied to a rumble filter E for reducing turntable rumble (or rumble recorded in the record), then to high- and low-frequency equalizers F and G (tone controls). This signal then passes to a scratch filter H for reducing surface noise. This is followed by an overall gain control I (volume control), in combination with a switch for converting the volume control to a *loudness* control. In this latter position, the frequency response is equalized to compensate for the human ear characteristic, when reproducing at low levels (see Question 5.65). The signal is now sent through amplifier J and on to the output terminals, an external power amplifier, and loudspeaker.

The right channel is the same except for the additional amplifier stage L. This stage operates in combination with switch K, a phase-reversal switch, for reversing the phase of the signal fed to the right power amplifier. This may be necessary when reproducing stereophonic records that were recorded before the phasing standard for recording stereo records was initiated.

Connected across the left and right output circuits is potentiometer O and amplifier stage N for deriving a center or remote-amplifier signal. Potentiometer G is for achieving a balance between the two sides for the best stereophonic reproduction, and is adjusted using a monophonic or special balancing record.

It will be observed that switches B and D are two-section ganged switches with identical circuitry in both channels. The overall gain control I is also a two-gang component. The two sections of the control must track within 1 dB over their entire range to assure that the balance between the two sides is maintained as the volume control is adjusted. Also, precautions must be taken that initially the left and right power amplifiers and loudspeakers are in phase. This latter subject is discussed in Section 20.

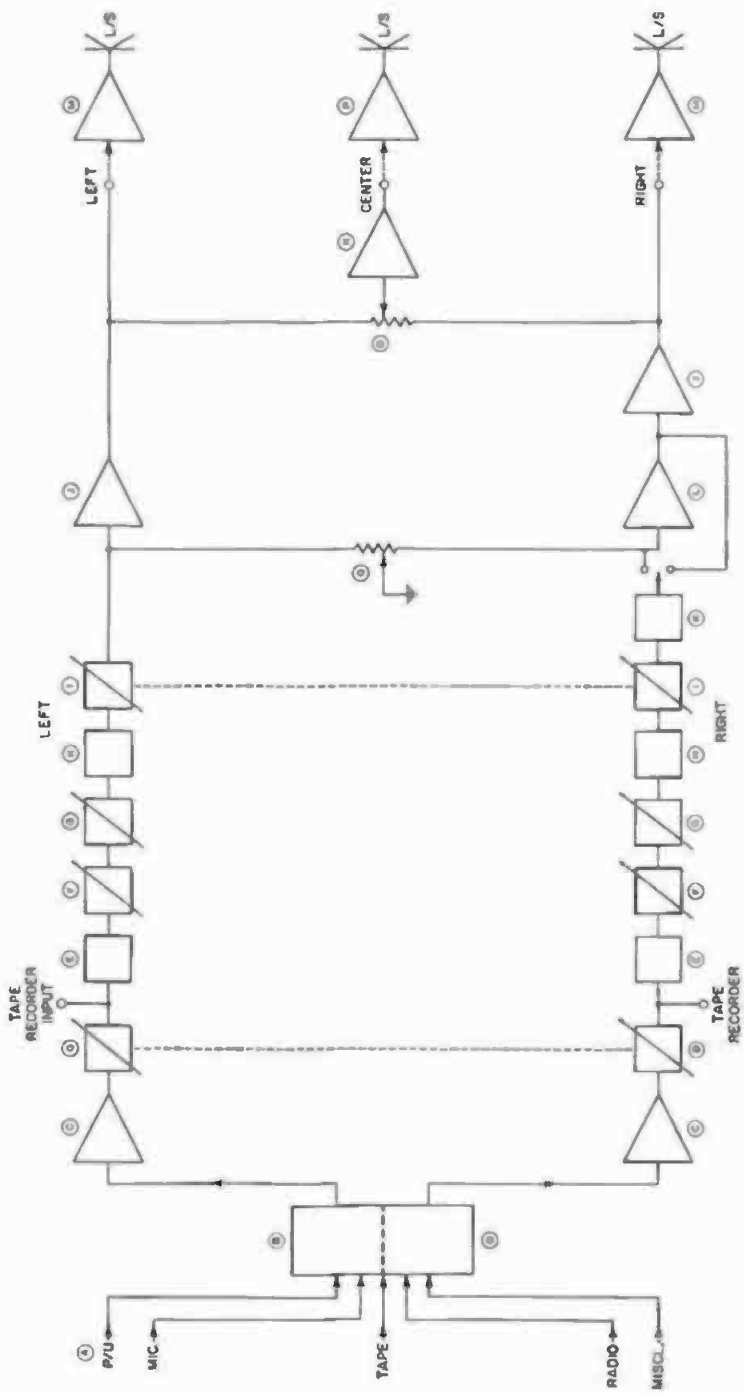

Fig. 12-265A. Block diagram for a typical stereophonic control center.

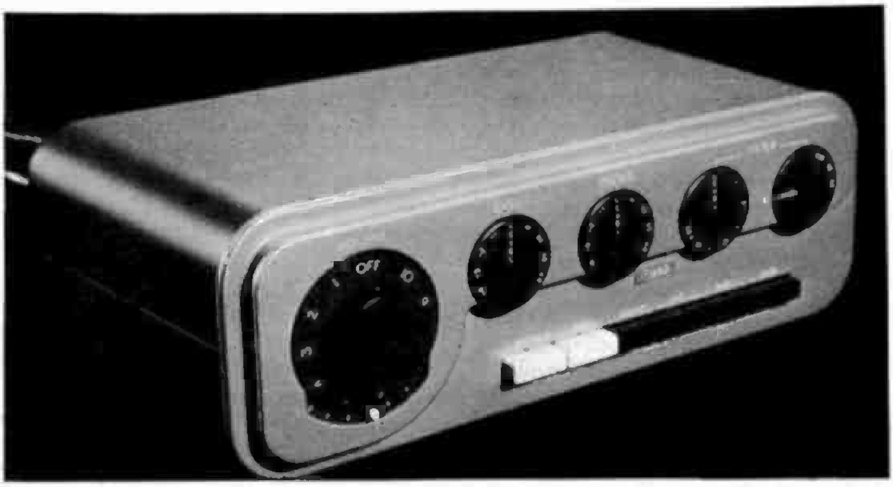

Fig. 12-265B. Stereophonic control center Quad 22, manufactured by Acoustical Manufacturing Co., Ltd. (England)

The block diagram does not represent any particular manufactured unit. The circuits shown are only to illustrate the controls and components found in an average stereo center and may vary considerably from that shown. In addition, a circuit is generally provided for driving a magnetic tape recorder, and for monitoring the program material being recorded.

Pictured in Fig. 12-265B is a stereophonic control center manufactured by Acoustical Mfg. Co. (England). At the left is the master volume control, with a stereo balance control in the slot below the knob. Along the bottom is a group of push-button switches for selecting the type of reproduction with the desired input and the correct equalization. Above the push buttons are four knobs. The first two are the conventional treble and bass controls. The remaining two are controls not found on all stereo centers. The right control of this pair is an m-derived low-pass filter with cutoff frequencies of 5, 7, and 10,000 Hz, which may be switched in half-octave steps. This permits the high end to be adjnsted for surface noise of the best reproduction within the scope of the program material. The remaining knob is for adjusting the effectiveness of the filter. There is a choice of four playback characteristics, obtained by pressing a combination of buttons in accordance with a chart supplied by the manufacturer.

At the rear are provided facilities for connecting the sources of signal inputs, tape recording, and outputs for power amplifiers and miscellaneous facilities. The overall frequency response of the unit is 20 to 20,000 Hz; distortion is 0.10 percent at 1.4 volts output; noise is minns 70 dB below 1.4 volts; crosstalk is 40 dB, 20 to 20,000 Hz.

Shown in Fig. 12-265C is an integrated solid-state stereophonic amplifier assembly, manufactured by Sherwood Electronic Laboratories, Inc. In

Fig. 12-265C. Integrated stereophonic amplifier assembly Model S-9000A manufactured by Sherwood Electronic Laboratories, Inc.

this assembly are included two solid-state power amplifiers capable of developing 120 watts of continuous sine wave power, and 160 watts of music power, both at 8-ohms output impedance. The front panel controls include an input selector switch, stereo-monophonic switch, bass and treble controls, and loudness and balance controls. In this unit, the base and treble controls are common to both channels, which is quite satisfactory if the speakers are matched. At the lower portion of the panel are a group of switches for monitoring, high- and low-pass filters, loudness control, and speaker on-off switch. Also included is a headphone jack which cuts off the speakers when it is used.

The specifications for this unit are: harmonic distortion at sine-wave rated output 0.25 percent, below 10 watts 0.05 percent; intermodulation distortion at rated output 0.25 percent, below 10 watts, 0.10 percent; damping factor is 40; hum and noise is 70 dB below rated output, using a weighted response curve. Power bandwidth for 0.5-percent THD is 12 to 25,000 Hz.

The solid-state components consist of 23 silicon transistors and 4 silicon diodes. (See Question 12.231 and Fig. 12-231H.)

12.266 Describe the basic design principles of a Darlington circuit pair.—The Darlington circuit (Fig. 12-266A) is a direct-coupled transistor pair, whereby an emitter-follower Q1 is used as the load for a previous emitter-follower. The gain of this circuit is approximately *unity*, with a current gain equal to the product of the beta's of the transistors involved. The two transistors may be viewed as a single unit. The resistor in the emitter of Q1 is also across the emitter-base circuit of Q2. The voltage drop across R1 is equal to its own voltage drop, plus that of R2 in the emitter of Q2.

A second version of a Darlington pair is given in Fig. 12-266B. Here a diode D1 having the same voltage characteristics as the base-emitter junction of Q2 is connected. Assuming that the voltage across the diode and resistor R2 are the same, the currents through both resistors are the same. Such circuits are often used in integrated circuitry (IC), where a *high* input resistance is required. The input resistance is the input resistance of Q2 multiplied by the beta of Q1. In some instances, resistor R1 (Fig. 12-266A) is omitted.

A Darlington pair (General Electric D16P4 I/C) connected for use with a

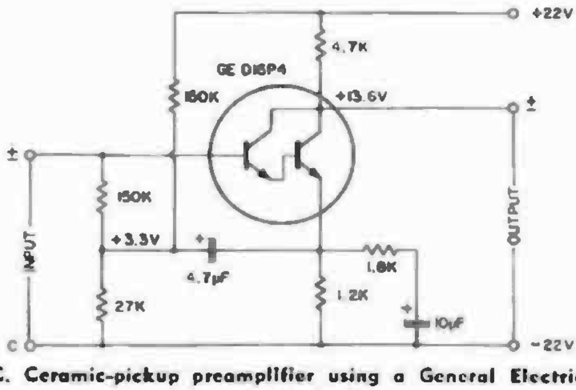

Fig. 12-266C. Ceramic-pickup preamplifier using a General Electric D16P4 integrated circuit.

ceramic phonograph pickup is given in Fig. 12-266C. In this circuit, the input resistance is on the order of 2.7 megohms at 50 Hz. The frequency response is 40 to 12,000 Hz within ±2 dB, with a THD of 0.2 percent, 1 to 15kHz. Intermodulation distortion is approximately 1.5 percent, using 60 and 6000 Hz in a 4:1 ratio for a 1.9-volt output. This level is 10 dB *below clipping*. The unweighted noise level is 80 dB, referred to 1.9 volts. An input signal level of 250 millivolts is required to produce an output of 1.9 volts.

Section 13

Disc Recording

The invention of the cylindrical phonograph and record by Thomas A. Edison in 1877 resulted in a method of recording sound using a constant groove-velocity vertical sound track, without tangent error. However, because of the nature of the record, each had to be a master; therefore, large production became rather a problem.

Emil Berliner, with his invention of the laterally recorded flat disc record, sacrificed the feature of constant groove-velocity recording; thus, tangent error and a loss of high-frequency response resulted as the smaller diameters were approached. However, the disc record was more practical and economical and could be easily reproduced in great quantities by stamping from a metal master. Because of these features, the disc record became the standard for the phonograph industry. Eldridge Johnson, a machinist with Berliner, contributed many improvements to the original reproducing machine of Berliner.

Since the introduction of electrical recording in 1927, the search has been endless for a better recording media, mechanical drives, speed stability, less tangent error, recording heads, pickups, reproducing machines, and materials for pressing the final disc.

Although Blumlein, in 1931, first proposed the 45/45-degree stereophonic method of recording, it has only been in recent years confirmed as standard by the recording industry.

Stereophonic and microgroove recording demonstrate the mutability of the overall disc record industry, all the way from foil to vinyl. Coarse pitch to microgroove, pickup arms weighing from pounds to grams, and frequency ranges extending beyond audibility are all part of the progress of the industry.

Various types of disc recording and the techniques are discussed in this section, with descriptions of recording lathes and their associated equipment.

13.1 What is an electrical transcription?—A disc recording used in radio broadcasting for the transmission of program material, recorded on 10- or 12-inch discs, using microgroove techniques. Before the advent of microgroove recording, transcriptions were recorded in 16-inch disc records, using either lateral or vertical recording at 96 to 150 lines per inch. Many of the transcriptions heard today are actually magnetic tape.

13.2 Describe a disc recording lathe.—A commercial recording lathe, manufactured by Neumann of West Germany, is pictured in Fig. 13-2A, with its principal components indicated. Basically the recorder consists of a heavy steel base, mounted on shock mounts supported by a steel cabinet A. Turntable B weighs 65 pounds, with three stroboscopic rings on its outer rim for three speeds which are illuminated by a neon light. The turntable is isolated from the drive system below by means of an oil-filled coupling, thus preventing rumble and flutter being transmitted from the drive to the turntable. The turntable is driven by a film of oil between two concentric cylinders at C. The lathe bed D is of the slide type, with two ball-bearings riding on top the bed to relieve strain placed on the sled E by the weight of the cutter suspension and cutting head F.

Directly below the lathe bed is a calibrated scale on which are mounted the starting cams and end-groove stop.

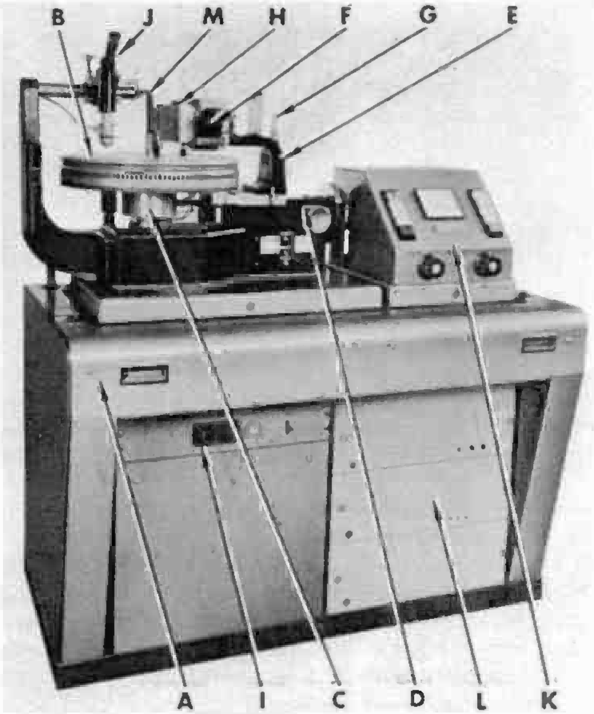

Fig. 13-2A. Neumann master disc recording lathe Model AM-32b with automatic pitch and depth control. (Courtesy, Gotham Audio Corp.)

Three cams for 7-inch, 10-inch, and 12-inch discs are provided. An adjustable end-groove stop for the three standard RIAA groove diameters cause the cutting head either to lift immediately (with eccentric grooves) or with an adjustable delay to provide for a locked groove. A lead screw engaging lever G is interlocked in such a way that the cutter will lift at any time it is not being driven by the lead screw, with a braking assembly to prevent the lead screw from coasting when the end is reached. A vacuum system provides a means of holding down blank discs from 10- to 17¾-inches in diameter on the turntable, with a disabling valve to shut off the vacuum holes when they are not in use.

Cutting-head connections are brought to the rectangular box H on the transport sled E by means of a plug to permit the exchange of cutting heads without disturbing the alignment. The connector plugs (for stereo) consist of 6 pins which carry the audio signal, feedback loop, and dc for the stylus heating coil. A release solenoid lifts the

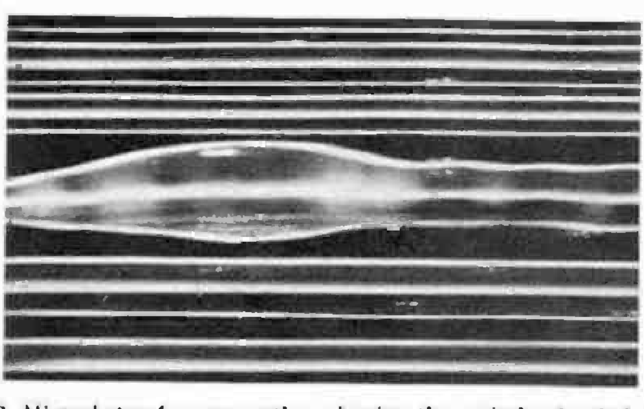

Fig. 13-2B. Microphoto of groove action, showing the variation in pitch and depth.

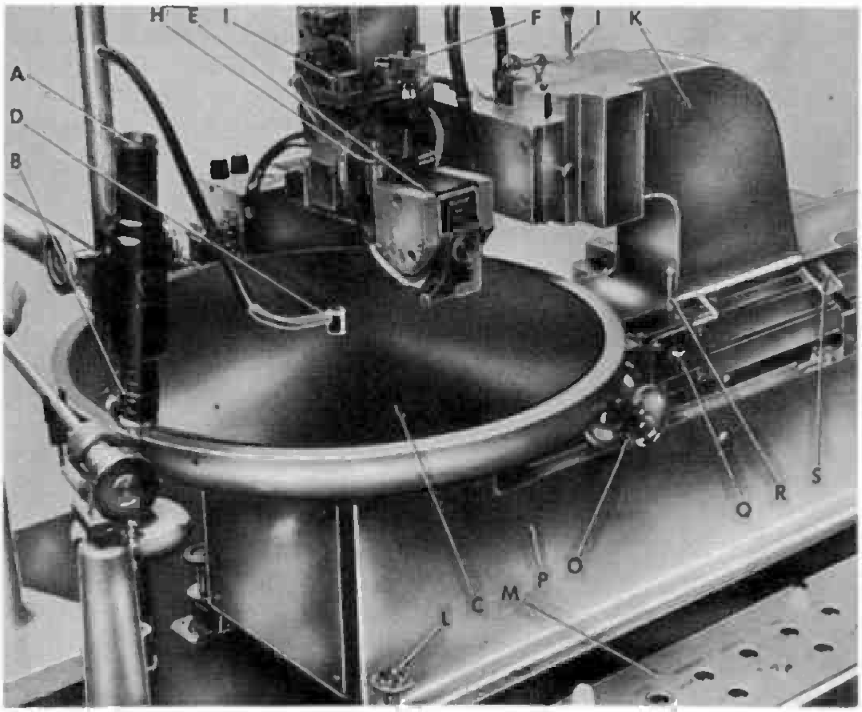

Fig. 13-2C. Scully Recording Instruments Corp. master disc recording lathe with automatic pitch and depth control.

cutting head whenever the stop button I is depressed, when the sled hits the end groove-stop, or when the lead screw is disengaged. A dash pot on the front of the cutting-head suspension mechanism is equipped with a perforated piston, with an adjustable shield over the perforations, to allow a wide latitude of adjustment. A tilting mechanism is connected to a moving-coil system which, together with the depth-of-cut control, provides electronic-depth variation, thus eliminating the advance ball generally used.

The depth-of-cut control supplies direct current to a moving-coil system in the cutting-head suspension mechanism, thus relieving the cutting-head pressure on the disc. This operation is controlled by a potentiometer, which is adjusted while observing the cut through a microscope J. A second control presets the increased depth used with the lead-in, lead-out, and spiraling grooves. The variable-pitch control K is a separate piece of equipment situated at the right end of the lathe. The pitch-control mechanism is self-driven and coupled to the lead screw by a four-way shock-isolated coupling. The variable-pitch motor is connected by means of a belt, and through an oil-filled flexible coupling to the lead screw. A copper disc on the shaft of this motor runs over the pole of an electromagnet, in which a direct current flows, producing a braking action, which stabilizes motor revolutions. A second motor, identical to the belt-connected motor, connected to an overdrive in the gear train, serves for the speed-up of pitch for lead-in and lead-out spiraling.

The turntable motor is of the synchronous type. The motor consists of a gearlike armature about 10 inches in diameter, rotating inside a similar inside gear. By means of a winding, a rotating magnetic field is set up, causing the armature to rotate. The wow and flutter of this particular machine is 0.035 total rms.

For automatic pitch control, three control amplifiers are necessary, and are mounted in the lower portion of the cabinet. A preview head is mounted on the magnetic-tape playback transfer machine to provide the control amplifiers with advance knowledge of the modulation to be fed to the cutting head. The output of the control amplifiers associated with the preview head is fed to the control amplifiers. For monophonic recording, the depth of cut is held *constant*, while the pitch is varied as a function of the preview information. In stereophonic recording, the pitch control is actuated by the *sum* of the left and right channel signal, while the depth of cut is varied according to the difference signal obtained from a stereophonic preview head. It is the function of the pitch-control amplifier to translate the preview signal through an equalizer into variations of braking current, which in turn are applied to the pitch-control motor to vary its speed and, with it, the lines per inch of recording.

The depth-control amplifier is identical to the pitch-control amplifier; however, its output to the solenoid in the cutting-head suspension produces a varying relief of cutting-head pressure, acting against a counterbalancing spring on the cutting-head mounting mechanism. A microphotograph of a group of recorded grooves, showing the action of the variable pitch and depth control appears in Fig. 13-2B. In the recording of both lateral and vertical modulation (stereo), increased depth requires increased pitch, so any deepening of the groove caused by the depth-control amplifier must be translated into increased pitch. This is accomplished by an integrating amplifier, which adds to the pitch-control current whenever increased depth is required. It is claimed that such a system, when properly adjusted, can add up to 6 minutes of recording time on a 12-inch record.

The microscope is 156 power with concentric illumination, brightly lighting the groove and leaving the land between the grooves dark, and is moved across the turntable by means of a rack and pinion gear. The microscope support arm also acts as the vacuum conductor for the vacuum-chuck turntable. The microscope graticule is calibrated to read in 0.001-inch graduations. The chip collector is contained in the lower portion of the cabinet. A pickup arm is generally monnted at the left for playback purposes, and may be used for simultaneous monitoring of the playback signal, while also monitoring the signal from the negative-feedback loop to the cutting head. A half-speed converter permits the turntable to be rotated at 16⅔ rpm, and half-speed for 45 or 78 rpm for experimental work or for cutting frequency discs.

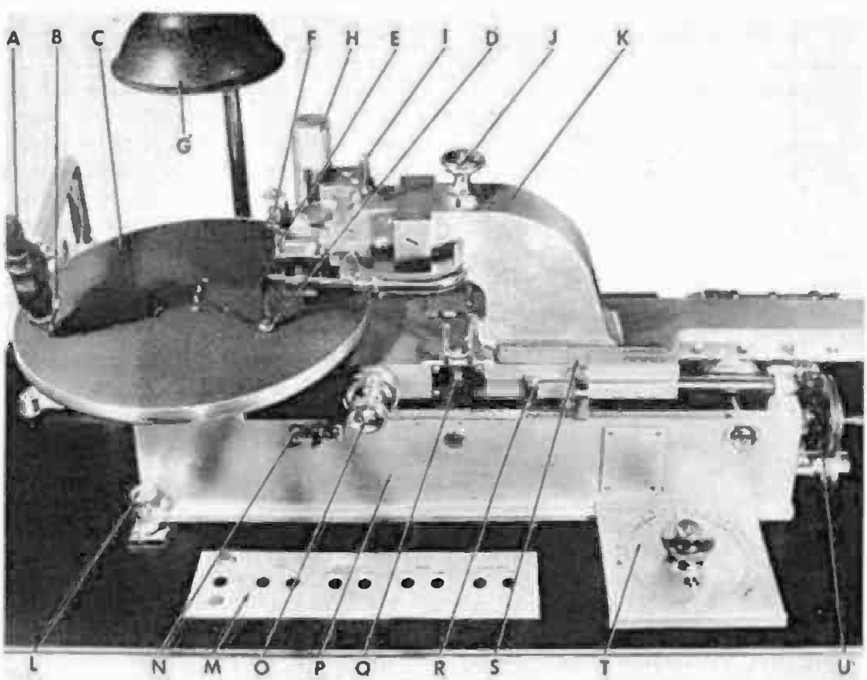

Fig. 13-2D. Scully Machine Co. recording lathe.

A second recording lathe, manufactured by the Scully Recording Instrument Corp., appears in Fig. 13-2C. Like the Neumann lathe, it also has variable pitch and depth control and many of the features previously described. At A and B is the microscope and its light, C the turntable, D a vacuum-suction pipe for removing the chip from the disc, E the cutting head, F depth-control adjustment, H cutting-head dash pot, I plug connection for the cutting head, K sled, L leveling screws, M push-button control panel, O carriage hand knob, P recorder base, Q feed-nut adjustment, R carriage-limit stop, and S line-per-inch indicator scale. The motor with its gear box and mechanical filter are mounted below the table.

In Fig. 13-2D is shown an overall view of a similar recorder with a monophonic cutting head. The letter symbols correspond to the previous view. By means of the control T, the lines per inch may be varied over a range from 70 to 400 lines per inch. At U is a lead-screw hand wheel. Automatic control of pitch and depth are accomplished in a manner somewhat similar to the Neumann lathe. Anticipation amplification is approximately 20-dB greater in the 50 to 60-hertz range, returning to normal frequency response around 750 Hz. A gain control adjusts the amplitude of the original signal from the control head on the magnetic-tape reproducer. An excursion control determines the amount of decrease in the number of lines per inch for a particular recording. A return control adjusts a time-delay network in the output of a signal-control amplifier. Delay in returning the feed from coarse to fine permits the continuance of sufficiently coarse lines to prevent post-groove over-cuts.

13.3 Define the term lateral recording.—Lateral disc recording was invented in 1888 by Berliner and Johnson for engraving a sound track on a disc record. A stylns mounted in a cutting head (recording head) is actuated by the sound modulatious and moves at right angles to the direction of travel of the recording blank. In lateral recording, the dept of cut and groove width are nearly constant. Both monophonic and stereophonic sound may be recorded by this method.

13.4 What is vertical recording?—Vertical recording is the principle used by Thomas A. Edison in his original cylinder recorder pictured in Fig. 13-4. The sound waves are picked up by a small metal horn and directed to a metal diaphragm to which is attached a stylus. Pressure changes in the horn, caused by the sound waves, moved the diaphragm causing the sylus to indent a sound track in a vertical direction on the surface of a revolving tin-foil cylinder. The sound track recorded on the tin-foil cylinder was reproduced by the same stylus riding in the indented sound track. The movement of the sty-

Fig. 13-4. Thomas A. Edison with his original tin-foil phonograph. Taken in Washington, D.C., April 18th, 1887, where he demonstrated the machine before the National Academy of Science. (Courtesy, Smithsonian Institute.)

lus caused the diaphragm to which it was attached to vibrate, disturbing the air column in the horn. Thus, sounds were generated which were similar to the waveforms inscribed on the tin-foil cylinder.

In a modern vertical-recording head, the actuating mechanism is designed to eliminate any lateral motion. Thus, distortion caused by the combination of a lateral and a vertical motion is eliminated. The sound track made by a vertical recording head varies in both depth and width. Because the variation in width of the groove is small, a greater number of lines per inch may be recorded in a given space.

At one time, vertical recording was considered to be superior to lateral recording; however, with the development of microgroove lateral recording, vertical recording is now considered to be obsolete.

In the original Edison cylinder recorder shown, the record revolved at a constant speed; therefore, the machine recorded with a constant-groove velocity. In the present day recorders, the angular velocity of the turntable is constant and the groove velocity decreases as the smaller diameters are approached. (See Question 13.22.)

13.5 What is hill and dale recording?—It is another name for vertical recording.

13.6 What is a long-playing record?—A disc record having a playing time longer than 5 minutes, 10 to 12 inches in diameter and turning at 33⅓ rpm, recorded with approximately 150 to 300 lines per inch.

13.7 Define a microgroove recording.—A microgroove recording has from 200 to 300 or more lines per inch, with a groove width in the pressing suitable for reproduction, using a stylus having an included angle of 40 to 55 degrees and a tip radius of 0.001 inch.

For stereophonic recording the lines are the same, but the groove width in the pressing must be such that it may be reproduced using a stylus of 45 to 55-degrees with a tip radius of 0.5 to 0.7 mil. Styli dimensions are discussed in Section 15.

13.8 What are the advantages of microgroove recording?—Longer playing time with low surface noise, wider frequency range, lower distortion and greater dynamic range. The weight of the pickup on the record has been reduced from 27 grams for older type recordings to 0.5 to 3 grams. This lower playback weight results in longer life of the record, lower distortion, and better tracking, and removes the pressure from the side walls of the groove. Because of the light pressure, it is important that the playback turntable be level; otherwise, the pickup will skate across the record if jarred.

The reproducing stylus for microgroove recordings has a tip radius of 1 mil (or less) and the included angle is 45 degrees. (See Question 15.5.)

13.9 What are standard turntable speeds?—Standard speeds are 33⅓ and 45 rpm. It is recognized that both 78.26 rpm and 16-inch coarse-pitch transcriptions running at 33⅓ rpm are still in limited use; however, these two latter speeds are no longer considered standard. A speed of 16⅔ rpm is also used for special recording purposes, but it also is not considered standard.

13.10 What medium is used for recording disc records?—Originally soft wax was employed, but in the early 1930's this was replaced with the modern acetate disc, which has also undergone several changes in its material composition since its introduction.

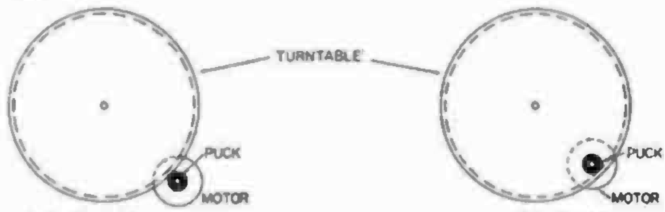
13.11 What materials other than acetate are used for recording on disc records?—For purposes where quality of recording is not of prime importance, materials other than acetate are aluminum, paper, and many different types of plastics.

13.12 What is a pregrooved recording blank?—A disc with a prepared groove in which the recording stylus rides. This type of blank was nsed in early-day home recording equipment to eliminate the costly lead screw and half-nut.

13.13 What is a recording lathe?—It is another name for a disc recording machine. (See Question 13.2.)

13.14 What is a direct-drive disc recorder?—One in which the power is transmitted to the turntable from the motor by means of gears. (See Question 3.71.)

13.15 What is a rim-driven turntable?—One in which the motive power is transmitted to the turntable by a puck on the motor shaft in contact with either the inside or outside edge of the turntable. When driven on the outside



(a) *Outside.* (b) *Inside.*

Fig. 13-15. Rim-driven turntables.

edge, a rubber tire is placed on the outer edge of the turntable which makes contact with a metal puck on the motor shaft. These two methods are used more than any other type of drive system. Typical rim drives are shown in Fig. 13-15.

13.16 What is an idler?—A wheel placed in the mechanical transmission system between the driving member and the turntable in a recorder or reproducing machine.

13.17 Does an idler between the motor and the driving puck have any effect on the speed?—No. It only serves as a means of transmitting the power from the driving source to the turntable. The turntable size and the diameter of the driving puck on the motor determine the speed. (See Question 3.71.)

13.18 What is a puck?—A circular piece of metal or fiber used to transmit power from the driving source to the driven member.

13.19 What is linear speed?—A constant velocity in a given direction.

13.20 What is a constant angular velocity device?—A device driven at a constant speed in rpm.

13.21 What is a weight-driven recorder?—Because of the lack of constant speed drives, early recorders were driven by means of a weight mechanism similar to that of a clock. The recorder was set on a tripod about six feet above the floor. Heavy weights, wound up by means of a windlass, supplied the motive power which was controlled by a centrifugal governer.

13.22 What is a constant-groove velocity recorder?—A disc recording machine so designed that as the recording progresses across the surface of the record toward the smaller diameters, the turntable speed is increased. In this manner, the groove velocity is held constant throughout the whole recording and is the same for any given diameter. The steady increase of speed is accomplished by a planetary drive system contacting the underside of the turntable. The design of this machine permits a greater number of lines per inch to be recorded, thereby increasing the playiug time. Twenty-seven minutes may be recorded at 300 lines per inch on an 8-inch disc.

The principal drawback to this type recording is that the playback machine must be of the same design as the recorder in order to obtain exactly the same increase of speed as when recorded. Generally, such machines are used with embossing-type recording heads using a constant-amplitude recording characteristic as described in Question 14.5. It has often been stated that the combination of constant-groove velocity recording and constant-amplitude recording is the classical system of recording.

Constant-groove velocity recorders use an embossing-type stylus with a 1-mil tip radius. The groove velocity is generally around 2 inches per second, at 300 lines per inch. This slow velocity is used only for dialogue recording and will give 93 minutes of recording time on an 8-inch disc. For music recording the groove velocity is increased to 10 ips. The frequency range is approximately 80 to 5500-Hz. (See Questions 13.204 to 13.206).

13.23 Describe a monogroove recording.—In an early attempt to record stereophonic sound in a single record groove, the groove carried both lateral and vertical modulation and employed a cutting head based on the design shown in Fig. 13-23. With the development of the 45/45-degree cutting head and pickup by Charles C. Davis of Westrex Corp., almost all stereo recordng system have adopted this latter system. Stereophonic cutting heads are discussed in Questons 13.217 and 14.2.

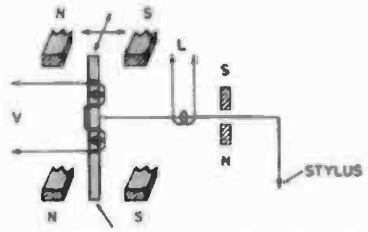


Fig. 13-23. Magnetic structure for a monogroove pickup or recording head. Sound waves are recorded in both the lateral and vertical directions simultaneously.

13.24 What is a variable-pitch recorder?—A disc recorder designed in such a manner that the lines per inch may be varied as the recording progresses. When the program material is of low amplitude, the speed of the cutting-head carriage is slowed down, thereby increasing the number of lines cut per inch. For high amplitudes, the carriage is speeded up to reduce the number of lines per inch. In this manner, greater amplitudes may be recorded and a longer recording time secured.

In the early days of motion picture recording when disc records were used, a 10-minute, 16-inch disc was reduced to a 12-inch disc in this manner. This type recording is also called *margin recording* and many present day high-quality, long-playing records are made using margin recording with a hot stylus, resulting in superior recordings.

13.25 What is a lead screw?—A threaded shaft used to move the cuttiug-head carriage across the face of the recording blank on a disc or cylindrical recorder. (See Question 13.2.)

13.26 What is cutting rate?—The number of lines per inch the lead screw moves the cutting head carriage across the face of the recording blank. Before the advent of microgroove recording, the lines per inch for coarse-pitch recording were 96, 104, 112, 128, 136 or greater, increasing in multiples of eight lines per inch. For microgroove recording, 200 to 400 lines per inch are used. 265 lines being average.

13.27 How are the lines per inch changed in a recorder?—In nonprofessional recorders, the lines per inch are fixed. In professional equipment, the lead screw is changed or the gears that drive it. In a variable-pitch machine as described in Question 13.24, the lead screw is rotated by a separate motor and the lines per inch are increased or decreased by controlling the speed of the driving motor.

13.28 In what direction are disc recordings recorded?—From the outside in and rotated in a clockwise direction as viewed from the side being reproduced. In the early days of making broadcast transcriptions (before diameter equalization), if the program material consisted of several records, they were recorded to start outside-in on the first record, with the next record recorded inside-out to compensate for the loss of high frequencies at the smaller diameters. This procedure was followed to the last record, and the listener was often unaware of the loss of high frequencies as the program changed to the next record; however, the *increase* in high-frequency response was quite noticeable as the larger diameters of the second record were approached.

13.29 What does the term coarse-pitch recording mean?—To distinguish recordings using less lines than that used for microgroove recording, they are referred to as coarse-pitch recordings. The lines for coarse-pitch recording vary between 96 and 150 lines, while those of a microgroove recording range from 200 to 300 lines per inch or more, the average being about 265 lines. Variable-pitch techniques may be applied to either type recording.

13.30 What is the angle of the recording stylus relative to the surface of the recording disc?—This subject has been uuder discussion for considerable time and to date no standard has been set for the angle of the recording stylus. The Westrex 3C and 3D cutting heads are operated at an angle of 23 degrees; however, different recording activities may set them to a different angle. Experimental work by Bauer indicates that increasing the angle of the cutting head beyond 23 degrees will reduce the discrepancy between the recorded groove and that of the pressing, and result in a recorded groove of 15 degrees. The principal cause of the discrepancy in the groove is the spring-back of the lacquer, and the recording stylus.

In the normal recording of records the groove walls form an augle of 90 degrees, which is particularly important in recording stereophonic records

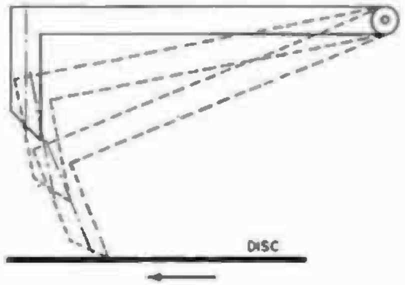

Fig. 13-30A. Because of the stylus suspension in a 45/45-degree stereophonic cutting head, the stylus inscribes an arc in the vertical mode because of the tilt from vertical.

using the 45/45-degree system. For records cut before the advent of stereo, lateral records were cut using an 87-degree *included angle stylus*, on the assumption that after processing the groove grew to 90 degrees. This was controlled in the finished product by the recording engineers, experienced with lacquer-disc recording.

Because of the nature of the stylus suspension in a stereophonic cutting head, the stylus describes an arc in the vertical mode, and because of this motion the cutting face is tilted back from the vertical (Fig. 13-30A). This results in an increase of the included angle of the groove (Fig. 13-30B). In view of this fact, and that the reproducing *stylus rides on the wall of the groove and not the bottom*, the waveform is distorted and increases with an increase in the recorded level. For the Westrex stereo system, the recording angle is specified to be 23 degrees; however, several activities have studied the angle problem and recommended that the angle of the recording stylus be changed. It is hard to predict the final angle, since factors other than stylus angle inject themselves into the study. Among these factors are: fit of the recording stylus in the recording head, stylus shank material, and the bonding of the

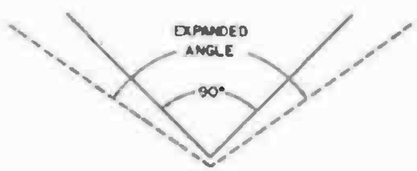

Fig. 13-30B. Increase in the groove included angle because of the tilting action of the recording stylus.

jewel in the stylus shank. Any shifting of the jewel tip because of the bonding will cause resonance and also affect the vertical angle. The jewel and stylus shank must act as an integral part.

When reproducing a record cut at a 23-degree angle (or greater), the reproducer stylus angle is set to an angle of 15 degrees to reduce the distortion caused by the difference in the angle of the recorded groove. It has been agreed by the RIAA, NAB, and the manufacturers of sound-reproducing equipment in both the United States and most of Europe that the angle for the reproducing stylus is to be 15 degrees. At the present time, this leaves the record manufacturer with the problem of establishing the correct angle for the recording stylus to produce a 15-degree groove in the finished product. Certain recording activities using coarse-pitch and microgroove techniques still use the 3-degree to 5-degree drag angle, discussed in Question 13-32. (See Questions 16.58 and 16.59.)

13.31 How is a recording stylus aligned laterally? — By observing the reflection of the recording stylus on the surface of the recording blank as shown in Fig. 13-31. When the reflected image is in perfect alignment with the actual stylus shank, the alignment is correct. (See Question 23.78.)

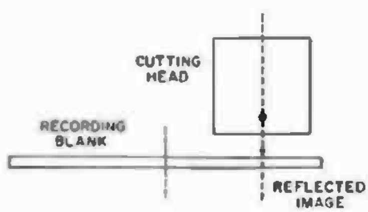

Fig. 13-31. Vertical alignment of stylus by observing its reflection on the surface of the disc.

13.32 What is the drag angle of a recording stylus?—In coarse-pitch recording used before the advent of microgrove recordiug and hot-stylus techniques, the recording stylus was given a slight angle relative to the surface of the recording disc (Fig. 13-32). The recording head was tilted backward about 3 degrees to 5 degrees against the motion of the disc. This was to prevent the stylus from digging into the recording blank aluminum base, as might occur

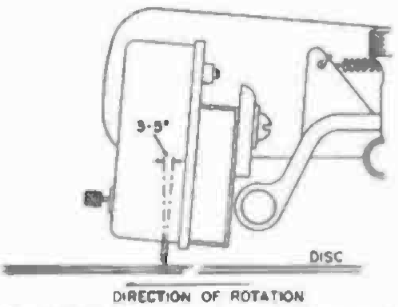

Fig. 13-32. Drag angle of early recorder cutting heads. The stylus angle is determined by observing the image of the stylus on the surface of the disc.

if the stylus had been set vertical. For stereophonic microgroove recording using a hot stylus, the stylus is set to about 23 degrees perpendicular to the surface of the disc surface. The stylus in the reproducing pickup is set with a drag-angle of 15 degrees. (See Question 13.30.)

13.33 What is flutter?—A waver in the reproduction of a tone or group of tones, caused by the irregularities in the speed of a turntable which results in frequency modulation of the tones. (See Fig. 13-33.) High rates of flutter are on the order of 10 Hz. Low rates of flutter occur one per revolution and are often referred to as once-arounds, or wow, because of the frequency characteristic. Typical resulting flutter waveforms are shown in Fig. 23-149.

13.34 How is flutter measured?—With a flutter bridge as described in Question 22.41.

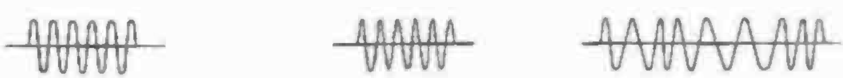
13.35 What is the standard for wow and flutter in a recorder turntable?—The average deviation measured over a range of 0.5 to 200 Hz, from the mean speed of the turntable while recording, shall not exceed 0.04 percent of the mean speed. The average deviation is measured, using a meter having the same dynamic characteristics of a standard VU meter. The term "average" is defined to mean the average of the measuring device rather than the period of time over which the measurement is made.

The measurement is conducted using a stroboscope disc illuminated by either a 50- or 60-Hz lamp operating from the normal power source. For 33⅓ rpm, the stroboscope is to have 216 bars or spots in 360 degrees; for 45 rpm, 160 bars or spots are required. For a recorder, not more than 7 bars or spots may pass a given reference point (either direction) in one minute.

13.36 What is the standard for wow and flutter in a reproducer turntable?—The average deviation from the mean speed of the reproducing turntable when reproducing shall not exceed 0.1 percent of the mean speed. The term "average" is defined to mean the average of the measuring device rather than the period of time over which the measurement is made.

The measurement is conducted using a stroboscope disc illuminated by a lamp operated form the normal 50- or 60-Hz power source. For 33⅓ rpm, the stroboscope disc is to have 216 bars or spots in 360 degrees; and for 45 rpm, 160 bars or spots. For a reproducing turntable, not more than 21 bars are to pass a given reference point in one minute, for either direction.

13.37 Describe a magnetically supported turntable.—The turntable about to be described is manufactured by Stanton Magnetics Inc., and is unusual in its design because the turntable is supported entirely by *magnetic repulsion* at the main bearing (Fig. 13-37A). The repulsion or suspension system consists of two flat circular magnets which are charged so that their force-fields are in the *vertical* plane. One magnet is placed around the bearing well and the other on the under side of the turntable, surrounding the shaft. The magnetic force-field provides an *air suspension;* in other words, the turntable rides on air. Therefore, the turntable has no mechanical contact with the rest of the structure, the turntable shaft is only used for rotational guidance. The turntable is driven through a soft idler wheel, which in turn is driven by a capstan on the



(a) *Undistorted sine wave.* (b) *High - frequency flutter.* (c) *Wow (once around)*

Fig. 13-33. The effects of irregular speed on a waveform.

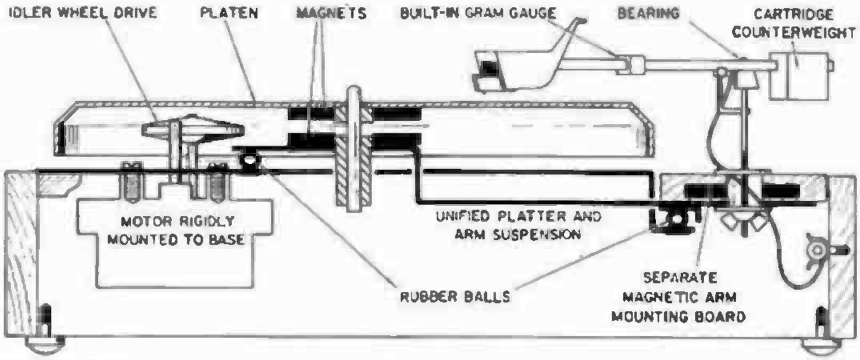


Fig. 13-37A. Cross-sectional view of Stanton Magnetics Inc. Model 800B magnetically suspended turntable.

motor shaft. This structure aids materially in the reduction of transmission of mechanical vibration to the turntable. The motor is a four-pole synchronous type, with sufficient power to quickly bring the platen up to speed.

The pickup arm is mounted on a separate structure, isolated by rubber balls, which affords acoustic isolation between the turntable and the pickup arm. The pickup arm is supported on a single pivot bearing for both vertical and lateral motion. The motor board section supporting the pickup arm is held in place magnetically and aligned with guide pins. This permits easy removal of the arm for experimental work. The arm resonance is below 10 Hz; flutter is less than 0.15 percent; rumble is minus 43 dB below the standard reference of 7 centimeters per second. A view of the complete turntable is shown in Fig. 13-37B.

13.38 What is the effect of flutter on recorded program material?—The music and voices will waver, becoming more noticeable at the higher frequencies. A piano will take on the quality of a harp. Flutter is, in reality, frequency modulation of the program material because of the irregular turntable speed.

13.39 What causes flutter in a disc recorder?—Some of the causes of flutter in a disc recorder are: slippery driving pucks, binding in the drive system, off-center hole in the disc, cutting-head carriage bind on the guide bars, chip brush dragging, and high spots in the drive gears.

13.40 Define the term "once-around."—It is a variation in the sound that occurs once per revolution of the turntable. (See Question 13.33.)

13.41 What causes a pattern or spokes in a disc record?—Vibration in the recorder or excessive alternating-current hum in the amplifier. The pattern resembles wheel spokes when observed under a light. During reproduction, patterns cause a low-frequency rumble and high background noise.

13.42 What is a moiré pattern?—A shadow pattern on a disc record caused

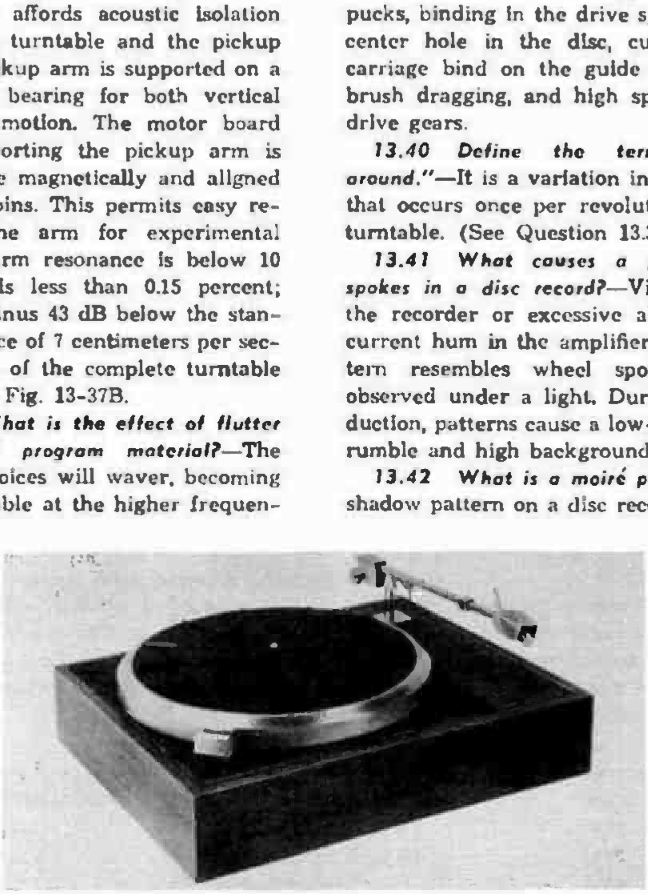

Fig. 13-37B. Stanton Magnetics, Inc. Model 800B turntable using magnetic repulsion to support the platen.

by vibration. It is so named because of its resemblance to moiré cloth.

13.43 What is the cause of rumble in a recording?—Rumble is generally a low-frequency sound caused either by the reproducing turntable drive mechanism, or it was recorded in the original master recording. Low-frequency noise and rumble is sometimes induced in the recording lathe by earth noises, drive gears, and the cutting-head carriage rails. (See Question 23.76.)

13.44 How does turntable rumble affect the reproduction of stereophonic records?—Turntable rumble has a pronounced effect since most of the rumble is in the vertical plane. Turntables employed for the reproduction of stereophonic recordings must have a low rumble factor, at least 10, and preferably 20 dB below that of a turntable used to reproduce laterally-cut records.

13.45 What is a drive hole?—An offset hole in a recording blank for setting over a pin in the recorder turntable to prevent slippage.

13.46 What is a recording medium?—Any material used for the purpose of recording a sound track. Common materials are: photographic film, acetate discs, magnetic tape, and plastics.

13.47 What does the term groove velocity mean?—The amount of disc surface passing under the stylus tip in one second. For constant-angular recording, the groove velocity is continually changing with the diameter of the record groove, decreasing as the center or smaller diameters are approached. For constant-groove velocity recording, the groove velocity is the same at any point on the disc, regardless of the diameter. (See Question 13.22.)

13.48 What are the average groove velocities for different recording speeds?—See Fig. 13-48.

13.49 Describe the effect of a hot and cold stylus on the frequency response of a microgroove recording.—The results from a study by Jackson of this effect are tabulated below. With a reference level of 5 centimeters per second, unfiltered output measurements were taken of the signal frequencies from 30 Hz to 15,000 Hz, using both a hot and cold stylus. The tests were conducted by turning the stylus heater current on and off, and each frequency recorded from an 8-inch diameter to 7.5 inches on the same disc. There was no noticeable difference from 30 Hz to 1000 Hz. The first noticeable change occured at 2000 Hz, with larger differences occuring as the frequency was increased up to 15,000 Hz. The hot-stylus recording measured an increased output over the cold stylus as tabulated below.

2000 Hz + 0.2 dB	10,000 Hz + 1.3 dB
4000 Hz + 0.2 dB	12,000 Hz + 1.6 dB
6000 Hz + 0.5 dB	15,000 Hz + 2.0 dB
8000 Hz + 0.6 dB	

Signals of 50,000, 100,000, 10,000 and 15,000 Hz were recorded, each on a separate disc at various diameters, using both a hot and a cold stylus. The results of these tests are given in the chart in Fig. 13-49. It will be noted, even at 50,000 Hz and at diameters of 4 inches, that there is a slight increase in the output. As in the preceding measurements, the output level was either the same or slightly higher. However, an exception to this last statement occurred only at 4-inch diameter, where 50,000 Hz, 100,000 Hz and 15,000 Hz read plus with a cold stylus, while 10,000 Hz read plus with a hot stylus. All these measurements were repeatable.

The tests tabulated were made using a Westrex Corp. 3C stereophonic recording head, a Cappscoop 90-degree prewired stylus, and a Scully recording lathe. The discs were manufactured by the Audiotape Corp.

13.50 What effect does changing the diameter and groove velocity have on a 78.26 rpm record?—Very little, the losses at the smaller diameters are negligible compared to the same frequency at a diameter of 11.5 inches. (See Question 13.49.)

Recording-speed rpm	*Recording-blank diameter*	*Groove velocity inches per second*
33⅓	16-inch coarse pitch	10 to 25
33⅓	12-inch microgroove	8.5 to 20
45	7-inch microgroove	9 to 19
78.26	12-inch coarse pitch	16 to 48

Fig. 13-48. Average groove velocities for recording speeds.

Diameter	50,000 Hz	100,000 Hz
11.5 inch	Same hot and cold	Same hot and cold
8 inch	Same hot and cold	Same hot and cold
6 inch	Same hot and cold	Same hot and cold
4 inch	+ 0.2 dB cold	+ 0.1 dB cold
	10,000 Hz	15,000 Hz
11.5 inch	+ 0.2 dB cold	+ 0.9 dB hot
8 inch	+ 1.0 dB hot	+ 1.8 dB hot
6 inch	+ 2.5 dB hot	+ 2.0 dB hot
4 inch	+ 4.7 dB hot	+ 2.3 dB cold

Fig. 13-49. Effects of hot and cold stylus on frequency response.

13.51 What are the diameter losses for 45-rpm recordings?—See Question 13.49.

13.52 What is the formula for calculating linear velocity?

$$\text{Velocity} = \lambda \times f$$

where,

λ (lambda) is the wavelength in inches,
f is the frequency in hertz.

13.53 How are lacquer discs manufactured?—Basically, the disc consists of an aluminum base, which after visual inspection for defects and flatness, is cleansed and washed in a detergent solution. The disc is then passed through the coating machine, using a modified curtain-coating method. A carefully controlled film of lacquer is laid on the disc surface as it passes through the curtain. The disc is then dried by passing through a heated tunnel, followed by a cure for a specified period of time. The process is then repeated on the second face, followed by a controlled temperature cure. Finally, quality grading is done through 100-percent visual inspection of both sides. They are then packaged for shipment. Throughout the manufacturing process, white-room conditions must prevail.

The final quality of the disc is dependent on the extreme flatness of the aluminum substrate. The manufacturer must be concerned with minute pits or pimples on the aluminum surface, which result in defects of equal degree in the lacquer coating regardless of the thickness. In addition, during the coating process, the temperature and humidity must be closely controlled and the air supply filtered to remove 99 percent of particles of 0.30 microns or larger. The viscosity of the lacquer must be kept within 5 percent of the coating viscosity, and the temperature to within 2 degrees Fahrenheit, with the pressure of the lacquer entering the coating head absolutely constant.

13.54 What is an instantaneous recording?—A recording made on an acetate disc. See Question 13.53.

13.55 Define the term, "coarse-pitch recording."—Recordings made using 96 to 120 lines per inch are termed *coarse-pitch*, contrasted to *microgroove* recordings made using 250 to 400 lines per inch. To differentiate between these two recording techniques, dimension and equipment used in the first category are termed coarse-pitch and will be referred to as such throughout this work.

13.56 What is the cosmetic effect in a lacquer disc?—The aluminum used for making recording discs is stretched to obtain as near as flat a surface as possible, which causes a *cosmetic effect*. Since the lacquer is not completely opaque, certain cosmetic effects on the surface of the aluminum disc manifest themselves by two flashes per second as the disc revolves. To the recordist unaware of this effect, the disc may be rejected as unsuitable for recording. Discs of this nature are quite satisfactory for recording if they meet the other requirements for a good recording disc.

13.57 What are the recommended disc sizes for recording masters?—See Fig. 13-57. At least one *unmodulated groove* is to be recorded at both the start and end of the recorded area. The diameter of the innermost modulated groove is to be not less than 4¾ inches for 33⅓-rpm discs and not less than 4½ for 45-rpm discs. The center hole must be concentric with the recorded groove spiral within 0.005 inch and has been standardized as follows:

Nominal	Finished Disc (pressing or instantaneous)	Outer Modulated Groove Diameter (outside start)
12 inches	11⅞ ± 1/32 inches	11 7/16 inches maximum
10 inches	9⅞ ± 1/32 inches	9 7/16 inches maximum
7 inches	6⅞ ± 1/32 inches	6 11/16 inches maximum

Fig. 13-57. Recommended disc sizes for master recordings.

33⅓ rpm	0.286 inch + 0.001, − 0.002 inch diameter
45 rpm	1.504 inches ± 0.002-inches diameter

The warp of the disc, when measured using a surface indicator, is to be not greater than 1/16 inch and within any 45-degree segment not greater than 1/32 inch. Following the innermost recording groove, a leadout spiral and a concentric locking groove are provided.

13.58 What is the cause of surface noise using cold-stylus recording techniques?—The causes of surface noise in cold-stylus recording are many and varied. Among them are dull recording stylus, improper alignment, hard recording blank, and many of the effects noted in Questions 13.65 to 13.68. Surface noise may also be induced in the reproduction because of vertical pressure of the pickup, improper tracking angle, pickup stylus at an improper angle with respect to the disc surface, and pinch effect.

13.59 What causes noisy pressings?—Generally speaking, a pressing can be no quieter than the original recording; however, finger prints on the master and poor compounds used for pressing can cause a considerable amount of surface noise.

13.60 How does the signal to noise vary for hot- and cold-stylus recording?—Studies made by Jackson show the signal-to-noise ratios for a master disc in Fig. 13-60A. Older type discs will measure between 2 and 4 dB less signal-to-noise ratio.

A disc with a once-around, warp, bump, or unevenness produces a swinging-type noise, and the signal-to-noise ratio under these conditions may measure as given in Fig. 3-60B.

The measurements were made using a constant velocity of 5.5 cm/sec at 1000 Hz, using a Westrex 3C recording head, a Cappscoop prewired stylus, Scully recording lathe, and Audiotape Corp. recording disc. The signal-to-noise measurements as given in Figs. 13-60A and B apply to both 45 and 78.26-rpm recording, assuming a hot stylus is used. (See Question 13.49.)

13.61 Is it permissible to play back a master to be processed?—No. Masters are never played back for fear of damaging the sound track. As a rnle, two discs are cut simultaneously, a master and a playback for checking quality and cues. The master is checked by visual inspection only.

13.62 How does the hardness of an acetate disc affect the frequency response?—For cold-stylus techniques, the high-frequency response is increased at the expense of background noise. Generally speaking, all discs regardless of manufacture have the same frequency characteristics at the larger diameters. However, this is not true for smaller diameters, as high frequencies fall off at different rates, depending on the degree of hardness.

In addition, the situation is further complicated by the diminishing groove velocity at the smaller diameters. This may be partially compensated for by the use of a diameter equalizer or a hot stylus. (See Questions 13.111 and 13.153.)

Diameter	12-inch	10-inch	8-inch	6-inch	5-inch	4-inch
Hot stylus	−68.5 dB	−69 dB	−69.5 dB	−69.5 dB	−70 dB	−70 dB
Cold stylus	−67.0 dB	−66 dB	−63 dB	−60 dB	−57 dB	−53 dB

Fig. 13-60A. Signal-to-noise ratios for a master disc.

Diameter	12-inches	10-inches	8-inches	6-inches	4-inches
Hot stylus	−66/58 dB	−66/58 dB	−66/60 dB	−67 dB	−67 dB

Fig. 13-60B. Signal-to-noise ratios for a deformed master disc.

13.63 Is there an appreciable difference between recording discs of different manufacture?—There is very little difference among those of good manufacture. Experience indicates the frequency response of a particular disc is the combination of cutting-head frequency response, length of the recording stylus, diameter of the recording area, the electronics of the recording system, and if the recording is made using a cold or hot stylus. Using hot-stylus recording techniques, the resistance of the disc to the stylus is practically nonexistent with regard to frequency response. (See Question 13.49.)

13.64 What is white noise?—When the noise spectrum is uniform over a wide frequency band, it is referred to as white noise because it is analogous to white light. (See Question 1.140.)

13.65 What is orange peel?—A term applied to the surface of a recording blank which looks similar to orange peel. Such surfaces have high background noise.

13.66 What is a buzz?—A rasping noise heard in the background of a record and is generally caused by hum or noise in the system.

13.67 What is chatter?—A rattle in the reproduction caused by improper seating of the reproducing stylus in the sound track.

13.68 What is a chip?—The material removed from a record during the recording process.

13.69 What is an unmodulated groove?—A groove cut in a record without modulation. Such grooves are used at the start and ending of a recording and also to measure the signal-to-noise ratio.

13.70 What is an undulation?—A rising or falling appearance of the groove.

13.71 What is a dry cut?—A bad groove in a disc record. The chip is kinky and brittle because of a dull or improperly aligned recording stylus. It may also be caused by recording blanks which have become hardened with age. This effect is noticed when using cold-stylus recording techniques.

13.72 What is a cutover?—A breaking through the wall of one groove into the wall of the next groove. It is caused by overmodulation.

13.73 What causes a stylus to whistle when recording?—The stylus may be dull or out of alignment. Also, the disc may be old and dry. This effect is related to cold-stylus recording.

13.74 What causes a gray cut?—A cold stylus that is dull or a disc that is dry and hard.

13.75 What is the depth of cut?—The distance from the surface of the recording blank to the bottom of the groove. (See Question 13.150.)

13.76 What is a spiral out?—A groove at the inside end of a recording for the purpose of tripping an automatic record changer.

13.77 What is a locked groove?—A spiral groove at the inside end of a recording, closed by a concentric groove, for the purpose of tripping an automatic record reproducing machine. The locked groove provides a groove for the pickup stylus to ride in until the mechanism trips.

13.78 What is twinning?—When two grooves overlap or touch as a result of overmodulation. Twinning is also caused by improper groove-to-land ratios or a defective lead screw. (See Question 13.25.)

13.79 What is land?—The space between adjacent recording grooves.

13.80 What causes an echo effect in a blank groove?—A sound from an adjacent groove caused by overmodulation. Although the groove wall is not damaged, it is deformed by the excessive modulation in the adjacent groove. If the relationship is just right, with respect to the original modulation, what appears to be an echo is heard.

13.81 What is skating?—A condition existing when a reproducing stylus is pinched out of the groove and moves rapidly across the face of the record. Skating is also caused by the reproducing turntable not being level. It is particularly important, for microgroove reproduction, that the turntable be level in all directions.

13.82 What are horns in a sound track?—Raised edges on the sides of the groove (Fig. 13-82), caused by the

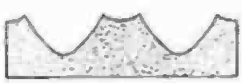

Fig. 13-82. Cross-sectional view of a sound track in a disc record showing the small horns raised at the upper edges by the recording stylus, caused by cold flow in the recording medium.

cutting stylus. The horns are small in size and very delicate; therefore, they are easily damaged by rubbing the surface of the record. The use of the hot stylus technique (see Question 13.153) eliminates this difficulty.

13.83 What is an advance ball?— A rounded sapphire support mounted on the cutting head, either beside or ahead of the stylus, and bearing on the surface of the record. Its purpose is to maintain a constant depth of cut regardless of irregularities in the surface of the record.

Advance balls were originated for soft-wax recording, before the advent of the acetate disc, and are still used in some instances for acetate-disc recording. However, with the use of automatic depth control and hot-stylus recording, advance balls are not used to the extent they were once used. If the recording disc has been stored for several hours at a temperature of 130-degrees Fahrenheit, it can be scored by the advance ball. In this instance, a hard deposit adheres to the advance ball, and if not removed, will score all succeeding discs. Lacquer discs should not be stored in a temperature exceeding 100-degrees Fahrenheit. (See Question 13.49.)

The placement of the advance ball in relation to the cutting-head stylus is shown in Fig. 14-21.

13.84 What is the formula for calculating the wave length of a recorded sound wave?

$$\text{Wavelength} = \frac{V}{F}$$

where,

V is the velocity of the record groove in inches per second at a given diameter,

F is the frequency of the recorded wavelength.

13.85 What is the standard signal-to-noise ratio for monophonic record reproduction? — For monophonic record reproduction the low-frequency noise voltage generated by the turntable, pickup, and equalizer, when playing an essentially rumble-free silent groove, shall be at *least* 40 dB below a reference level of 1.4 centimeters per second peak velocity at 100 Hz. (See Question 23.130.)

The frequency response of the pickup and its equalizers shall conform to the NAB standard reproducing curve, as shown in Fig. 13-95. The amplifier and indicating meter shall have uniform frequency response, within plus-minus 1 dB between 10 and 250 Hz, with the 500-Hz response 3 dB below the 100-Hz response, and an attenuation rate of at least 12 dB per octave at frequencies above 500 Hz (this may be obtained by means of a low-pass filter). The amplifier and indicating meter shall decrease at a rate of at least 6 dB per octave below 10 Hz.

The meter is to have the same dynamic characteristics as a standard VU meter USASI (ASA) C16-1961. (See Question 10.3.) If the meter fluctuates, the maximum values are used. In making these measurements, the pickup-arm resonance must fall outside the prescribed passband or be sufficiently damped to remove any possibility of affecting the measurement. The results are the electrical measurement, and not the aural annoyance value of low-frequency noise, such as rumble at frequencies below audibility. A strong low-frequency noise such as rumble, can cause severe intermodulation distortion with the low-frequency response of modern sound reproducing systems. The inaudible noise can be more serious than the indicated noise.

High-frequency noise is measured with the same meter characteristics when reproducing on a flat velocity basis, over a frequency range of 500 to 15,000 Hz, and shall be at least 55 dB below the level obtained under the same conditions of reproduction, using 1000 Hz recorded at a peak velocity of 7 centimeters per second. The frequency response at 500 Hz shall be 3 dB below the response at 1000 Hz, and shall fall off at a rate of at least 12 dB per octave below 500 Hz (using a high-pass filter). The response of the system at 15,000 Hz shall be 3 dB below the response at 1000 Hz and shall fall off at a rate of 12 dB per octave above 15,000 Hz.

13.86 What is the standard signal-to-noise ratio for stereophonic record reproduction? — For stereophonic record reproduction, the low-frequency noise voltage in each channel generated by the turntable, pickup, and equalizer—when playing an essentially rumble-free silent groove—shall be at least 35 dB below a reference level of 1 centimeter per second peak velocity at 100 Hz in the plane of modulation (vertical or lateral). The frequency response of the pickup and preamplifier shall conform to the NAB standard reproducing curve (Fig. 13-95), and the test equipment as stated in Question 13.85. The reference level of 1 centimeter per second peak velocity at 100 Hz corresponds in amplitude to 5 centimeters per second peak velocity at 500 Hz as it is in the constant-amplitude portion of the recording characteristic.

The high-frequency noise is measured with the same meter characteristics when reproducing on a flat velocity basis, over a frequency range of 500 to 15,000 Hz, and shall be at least 50 dB below the level obtained under the same conditions of reproduction, using 1000 Hz and fall-off rate of at least 12 dB per octave below 500 Hz. The response of the system at 15,000 Hz shall be 3 dB below the response at 1000 Hz and fall off at a rate of at least 12 dB per octave above 15,000 Hz.

13.87 What are the standard recording reference levels used for monophonic and stereophonic recording?—The NAB standard specifies that for monophonic microgroove recording, the recorded program level is to produce a reference level (using a standard VU meter) equivalent to a 1000-Hz tone, recorded at a peak velocity of 7 cm per second.

For stereophonic program material, the reference level is to be equivalent to a 1000-Hz tone, recorded at a peak velocity of 5 cm per second, as indicated on a standard VU meter. This is approximately 3 dB below the level for monophonic recording.

13.88 What percentage distortion is permissible for microgroove recording at 33⅓ rpm?—The distortion at 400 Hz should not exceed 1 percent total rms harmonic distortion. The intermodulation distortion should not exceed 3 percent using 100 and 7000 Hz mixed in a ratio of 4:1. Intermodulation measurements are discussed in Question 23.113.

13.89 What percentage distortion is permissible for microgroove recording at 45 rpm?—The distortion at 400 Hz should not exceed 1 percent total rms harmonic distortion. The intermodulation distortion using 100 and 7000 Hz should not exceed 4 percent mixed in a ratio of 4 to 1.

13.90 What are the recommended land-to-groove ratios?—For other than microgroove recording the ratio is set by the width of the groove, which is generally less than 4 mils and not greater than 5 mils, with a land-to-groove ratio of 60:40.

For 33⅓-rpm microgroove recording, the groove width is approximately 2.75 to 3.0 mils, with a groove-to-land width ratio of 70:30. For 45-rpm microgroove recording, it is the same. If variable-pitch recording is used, the groove-to-land ratio is constantly changing.

13.91 What is the appearance of a vertical-recorded groove? — Its appearance is as shown in Fig. 13-91. In vertical recording the depth of the cut and its width are constantly changing with the percentage of modulation. The sound track is engraved in the bottom of the groove. The unmodulated groove width is maintained at 0.003 inch for 125 to 150 lines per inch.

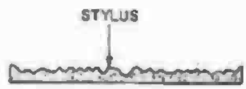

Fig. 13-91. Cross-sectional view of a vertical-cut sound track.

13.92 What is the appearance of a lateral-recorded groove?—It is as shown in Fig. 13-92. The groove depth and width remain almost constant with the grooves moving in a lateral direction or from side to side. The amount of lateral movement is dependent on the percentage of modulation of the audio signal.

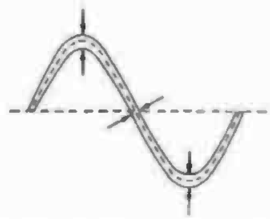

Fig. 13-92. Modulated lateral groove showing how the reproducing stylus is pinched by the narrowing of the groove. The dotted line indicates the center line of the groove.

13.93 Why was the NAB standard changed from a recording characteristic to a reproducing standard?—In the original Standard (1949 and 1953) only the recording characteristic was specified. However, it was found from experience that it was more practical to supply the manufacturer of record-reproducing

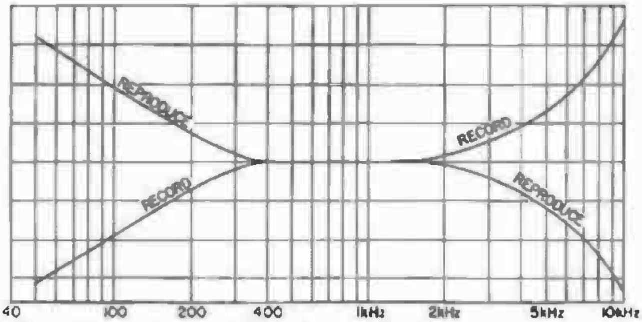

Fig. 13-94. Recording and reproducing characteristics for vertical records. This is the standard characteristic used in 1953, when such records were still in use. Each major vertical division is 5 dB.

equipment a test record with a standard reproducing characteristic than to specify the recording characteristic for the record manufacturer. Therefore, in the NAB Standard, March, 1964, only the reproducing characteristic is specified, with the understanding that the record manufacturer will adjust his recording characteristic to an inverse characteristic of the reproducing standard. On this basis, a reproducing standard was specified.

13.94 What is the recording and reproducing characteristic for vertical recording?—Although it is recognized that vertical recording is no longer used, the characteristics for both recording and reproducing are given in Fig. 13-94 for reference. It will be noted that the turnover frequency is 400 Hz.

13.95 What is the standard reproducing characteristic for disc recordings?—It is shown graphically in Fig. 13-95. This characteristic is known as the RIAA standard and was originally adopted by the disc recording industry in June, 1953, and was reaffirmed in March, 1964, by both the RIAA and NAB. It is used for the reproduction of 33⅓-, 45-, and 78.26-rpm recordings. The recording characteristic is an inverse of the reproducing characteristic, and it is used for both monophonic and stereophonic reproduction. This characteristic may be obtained by the use of three networks, consisting of an L/R parallel network having a time constant of 3180 microseconds, a series R/C network having a time constant of 318 microseconds, and an R/C parallel network of 75 microseconds.

13.96 What is the standard reference level for monophonic recording?—For monophonic recording the recorded program level shall produce the same deflection on a standard VU meter as that reproduced by a 1000-Hz tone recorded at a peak velocity of 7 centimeters per second. A margin of 10 dB is required between the sine-wave load handling capabilities of a system and the level of the program material mea-

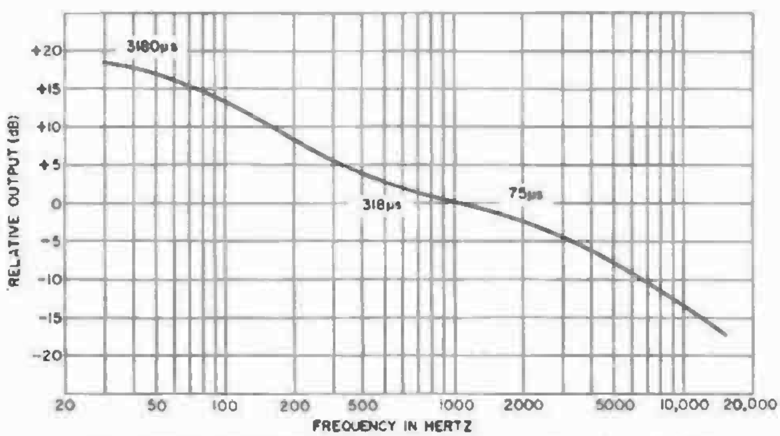

Fig. 13-95. NAB (RIAA) standard reproducing characteristic.

sured on a standard VU meter. (See Question 10.3.)

13.97 What is the standard reference level for stereophonic recording?—For stereophonic recording, the reference program level shall, for each channel in its plane of modulation, produce the same reference deflection on a standard VU meter as that produced by a 1000-Hz tone recorded at a peak velocity of 5 centimeters per second. This is approximately 3 dB below the level of the monophonic reference level.

Experience indicates that at least a 10-dB margin is required between the sine-wave load handling capabilities of a system and the level of the program material, measured on a standard VU meter. This would then contemplate program material running as high as a velocity of 21 centimeters per second and is believed to be the maximum velocity that can be traced without excessive distortion at the smaller diameters of a disc turning at 33⅓ rpm.

13.98 What is a minigroove recording?—A 78.26-rpm recording made using microgroove techniques, including hot-stylus and variable-pitch recording. Although the number of lines per inch is greater than is normally used for 78-rpm recording, it is not enough so that the record may be called long playing, or extended play. The frequency characteristic used is that of Fig. 13-95, known as the RIAA recording characteristic.

13.99 What is an orthocoustic recording?—It is a recording characteristic introduced by RCA Victor several years ago for recording 16-inch transcriptions at a speed of 33⅓ rpm. This characteristic, shown in Fig. 13-99, had been used by the broadcasting and recording industries for many years until the advent of the RIAA recording characteristic.

The orthocoustic characteristic makes use of pre-equalization in the recording circuits and post-equalization in the reproducing circuits as described in Question 6.11. The principal advantage gained by the use of such equalizers is the increased signal-to-noise ratio above 2000 Hz.

13.100 What is an orthophonic recording characteristic?—A reproducing characteristic introduced by RCA Victor some years ago; it is similar to the RIAA characteristic. The orthophonic recording and reproducing characteristic employs both pre- and post-equalization, discussed in Question 6.11.

13.101 Define constant-amplitude recording.—Constant-amplitude recording indicates a mechanical recording characteristic for a fixed amplitude of a sine-wave signal; the resulting recorded amplitude is independent of frequency. This subject is discussed in Question 14.5. As a rule, this method of recording is used with nonprofessional recording equipment employing a crystal cutting head, as it requires no equalization in either the recording or reproducing system.

13.102 Show the original Audio Engineering Society reproducing characteristic.—This characteristic is shown in Fig. 13-102. The original charactreistic has now been modified and corresponds to the RIAA curve shown in Fig. 13-95.

13.103 What is the RIAA reproducing characteristic? — A reproducing characteristic adopted by the Record Industry Association of America as a standard for reproduction of disc records. It is a modification of the original

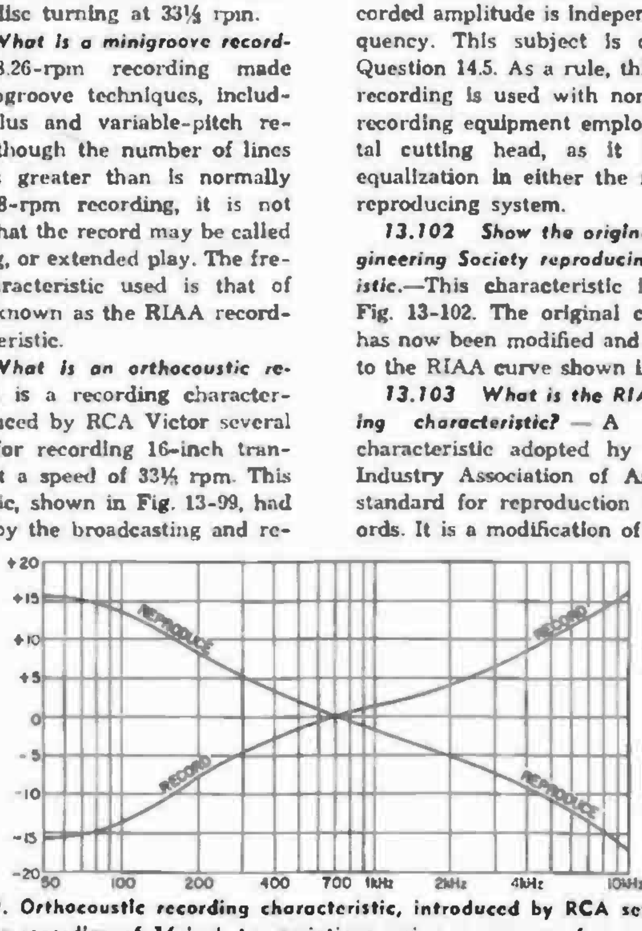

Fig. 13-99. Orthocoustic recording characteristic, introduced by RCA several years ago for the recording of 16-inch transcriptions, using a crossover frequency of 700 Hz; now superseded by the RIAA-NAB standard.

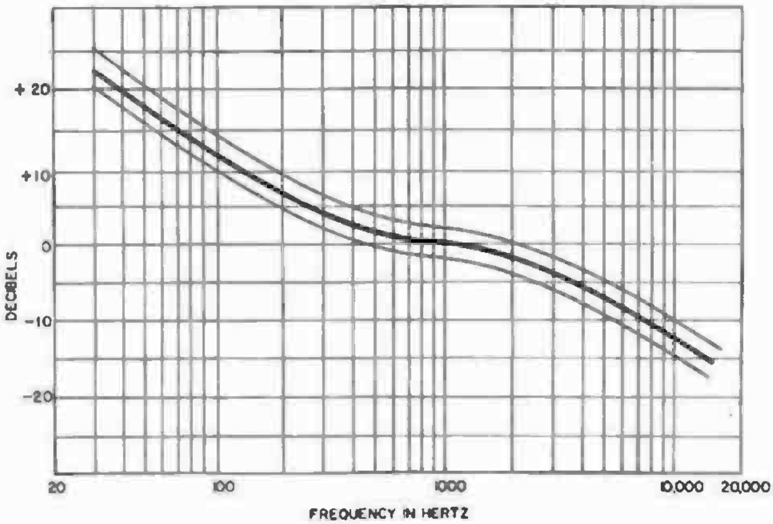

Fig. 13-102. The original AES reproducing characteristic, now superseded by the RIAA characteristic.

reproducing characteristic recommended by the Audio Engineering Society (Fig. 13-102). The present standard is shown in Fig. 13-95.

13.104 What is the standard groove shape for a monophonic pressing?—The groove shape shall have an included angle of 90 degrees, plus-minus 5 degrees, with a top width of not less than 0.0022 inch. For these groove dimensions, it is recommended that the reproducing stylus have a tip radius of 0.001 inch, plus 0.0001 inch, minus 0.0002 inch, with an included angle of 40 to 50 degrees. (See Question 13.180.)

13.105 What is a flat recording characteristic?—One which uses no pre-equalization in the recording circuits. Equalization is used in the reproducing equipment to compensate for the constant-amplitude constant-velocity characteristics of the recording head. This method of recording is seldom used, except in home-recording systems, because of the low signal-to-noise ratio above 2000 Hz.

13.106 What is the purpose of a low-frequency equalizer in a reproducer circuit?—To compensate for the constant-amplitude characteristic of the recording head below the turnover frequency. The equalizer has an inverse-frequency characteristic to the recording characteristic.

13.107 What is the turnover frequency?—The frequency at which a cutting head changes from a constant-velocity characteristic to a constant-amplitude characteristic. This is illustrated in Fig. 14-9.

13.108 What is the purpose of recording disc masters at half-speed?—Because of the high levels recorded on present-day disc records, certain recording activities in both the United States and Europe are recording their masters at half the normal recording lathe speeds. Reduced speeds decrease

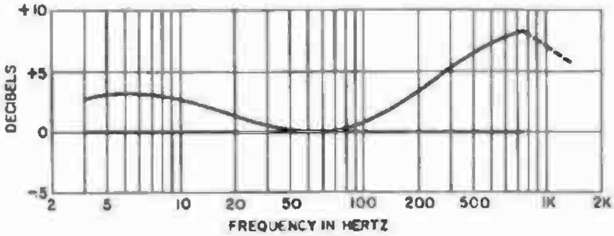

Fig. 13-108. Equalization characteristic for transferring tapes recorded at 15 ips and reproduced at 7.5 ips for recording disc masters at half-speed.

the load on the cutting-head stylus and reduce the elastic spring-back characteristics of the acetate recording blank, thus reducing the distortion. The result of recording at half-speed (or one octave lower) is the cutting-head system response extends to only one-half the normal frequency range, or about 7500 Hz. The additional octave is retrieved by adjusting the equalization in the negative-feedback circuit of the cutting-head amplifier circuit.

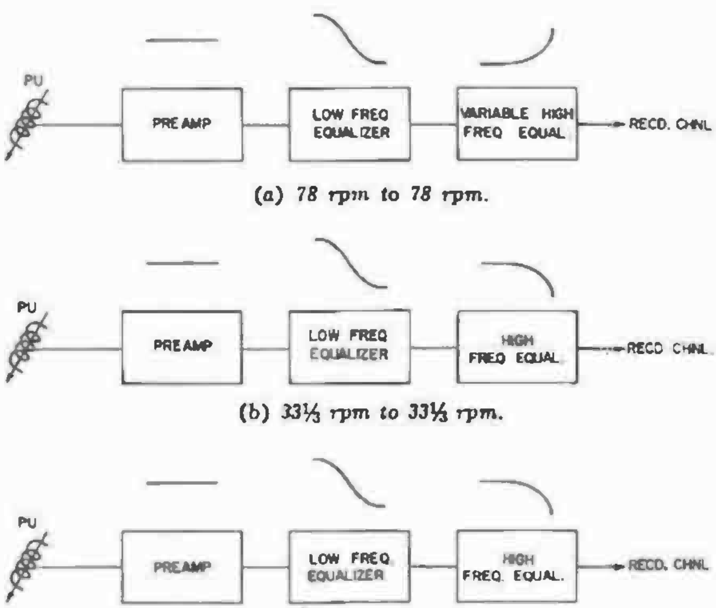
Reducing the recording lathe speed by one-half shifts the pre-equalization characteristics by one octave. To restore the final recording to the RIAA standard special equalization is required between the master tape and the disc-recording amplifier, so that when the disc is played back at its normal speed, it has the RIAA standard characteristics. To accomplish this, the following conditions must prevail:

> Tape recorder equalized for NAB standard characteristic at both 7.5 and 15 ips.
>
> Disc-recording system equalized for RIAA recording characteristic.
>
> Tape originally recorded at 15 ips, using standard NAB characteristic, played back at 7.5 ips.
>
> The recording lathe is rotated at 16⅔ rpm for recording 33⅓-rpm masters, or 22½ for 45-rpm masters, and 39.13 for 78.26 rpm.

Although this method of recording is generally confined to 45-rpm recordings, it may be used successfully with any system if due consideration is given to the intervening equalization.

Pressings made from half-speed recordings are played back at their normal speed of 33⅓ rpm or 45 rpm. A typical equalization curve suitable for connection between the master tape machine and the disc-recording channel is given in Fig. 13-108. (See Question 17.228.)

13.109 What are the methods used for recording from one characteristic to another?—They are as shown in Fig. 13-109. At (a) the pickup is shown feeding a preamplifier with a fixed low-frequency equalizer and variable high-frequency equalizer at its output. This circuit may be used to rerecord one 78-rpm recording to another 78-rpm recording. The low-frequency equalizer is set for the proper low-frequency compensation and the high-frequency equalization is used to boost or attenuate the high frequencies as required. If possible, the high frequencies should



(a) 78 rpm to 78 rpm.

(b) 33⅓ rpm to 33⅓ rpm.

(c) 33⅓ rpm to 78 rpm.

Fig. 13-109. Various methods used for transferring disc records of one characteristic to another.

be increased from 4 to 6 dB, surface noise permitting.

A 33⅓-rpm recording being transferred to a similar type recording is shown at (b). The regular equalization used for reproducing such records is used. The recording equalization is that which is regularly used for such type recordings.

A 33⅓-rpm recording being transferred to a 78-rpm disc is shown at (c). Again, the regular reproducing equalizers are used; however, the equalization in the recording circuits is that required for normally recording 78-rpm records.

An important point to remember is that the original recording is reproduced in a normal manner, except for a slight increase of high frequencies to compensate for transfer losses. The recording circuits are normal for the type recording being made.

13.110 What are the actual values in decibels of equalization used for the RIAA standard reproducing characteristic?—The actual values in decibels are tabulated below and are values from which the curve of Fig. 13-95 is plotted. The recording characteristic is the *inverse* of this curve. The original standard specified the frequency response of the recording system, but later it was found to be more practical to specify the reproducing characteristic. (See Question 13.93.) The characteristics of this curve may be obtained by the use of three networks having 3180, 318, and 75 microseconds each.

Hz	*dB*
30	−18.61
50	−16.96
70	−15.31

13,000	+15.95
14,000	+16.64
15,000	+17.17

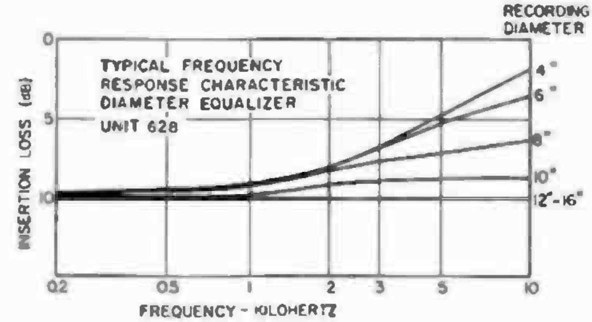
*Reference frequency.

13.111 What is diameter equalization?—The use of a variable equalizer in the recording circuit to compensate for the loss of high frequencies at the smaller groove diameters caused by the decreasing groove velocity. The equalizer consists of a bridged-T network of constant insertion loss as described in Question 6.15. The shaft of the equalizer attenuator is mechanically connected to the cutting-head carriage on the recorder as shown at R in Fig. 13-2. The loss of the attenuator is controlled by the position of the cutting-head carriage relative to the diameter of the recording surface. Thus, the correct amount of equalization is inserted for a particular diameter.

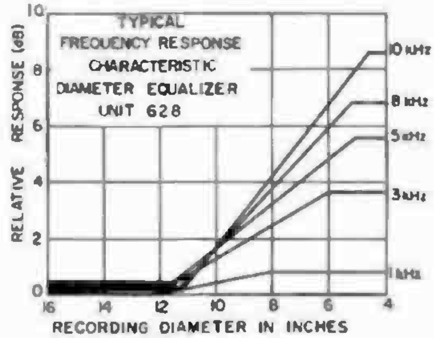
Generally, for 16-inch transcriptions, the equalization begins to take effect at a diameter of 12 inches and continues in steps of 0.5 dB for a total of 6 to 8 dB to a diameter of 5 inches. The resonant frequency of the equalizer depends on the bandwidth of the recording. Diameter equalization is not practical at diameters less than 6.5 inches, as the intermodulation and tracking problems in the finished record increase quite rapidly below 7 inches.

A typical diameter equalizer-attenuator, with its mounting bracket and control pulley, is shown in Fig. 13-111A. A spiral spring under the pulley returns the attenuator to its normal posi-

Fig. 13-111A. A diameter equalizer-attenuator control manufactured by Cinema Engineering Co. The cord is attached to the cutting-head carriage.



(a) *Insertion loss versus frequency.*



(b) *Recording diameter versus the relative response at various frequencies.*

Fig. 13-111B. Diameter equalizer characteristics.

tion when the recording-head carriage is returned to the outside diameters. The network elements are mounted in a nested shielded case separate from the attenuator pot. Diameter equalization should not be confused with pre- and post-equalization as they are two separate networks. Typical frequency characteristics for diameter equalization are shown in Fig. 13-111B.

With the advent of hot-stylus recording techniques, diameter equalization is not always used. However, with cold-stylus recording it is essential. In using diameter equalization, one important factor must be borne in mind. As the high-frequency equalization is increased, so are the high-frequency distortion products. Therefore, the distortion in the amplifier system must be kept to a low value.

13.112 Where is a diameter equalizer connected in a recording channel?—A typical monophonic recording channel is shown in Fig. 13-112, with both pre- and diameter equalization, and the

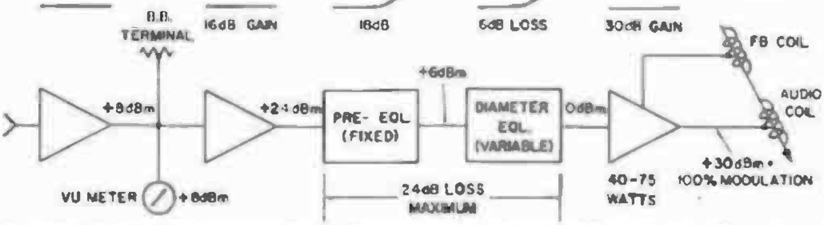


Fig. 13-112. Block diagram for a disc-recording channel showing the placement of pre- and diameter equalization with the losses and gain for an average recording system. The levels shown are in reference to 400-Hz or a lower frequency, depending on the design of the equalizers.

approximate operating levels. The signal from the mixer console or tape machine is applied to a line amplifier which, in turn, drives a bridging bus. From the bus, the signal goes through a bridging amplifier to a pre-equalizer having such characteristics that the playback characteristic conforms to the industry standard (Fig. 13-95).

From this equalizer, the signal passes to the diameter equalizer, which is variable, and automatically operated from a mechanical connection on the recording lathe. (See Question 13.111.) This is followed by a power amplifier of 40- to 75-watts output for driving the cutting head. Although the circuit diagram indicates a negative-feedback cutting head, the same circuitry is used with a nonfeedback head.

The approximate gain and frequency characteristic is shown above the various components. In lining up such a channel for recording, either 400 Hz or some other frequency may be used, depending on the frequency characteristics of the equalizers. Because of the characteristics of the equalizers, the exact same frequency must be used each time the channel is lined up. This is accomplished by applying, for example, 400-Hz signal to the line amplifier and setting the bus level to plus 8 dBm, and making a test cut which should measure 100-percent modulation of the cutting head.

The components shown in the diagram are not of any given manufacture or design but are only representative of typical characteristics and placement in the circuit. A complete magnetic tape transfer channel to disc is discussed in Question 17.228.

13.113 What power is recommended for the bridging amplifier shown in Fig. 13-112?—It should be capable of producing one watt or more of power to prevent the distortion from becoming excessive when the full equalization is being used.

13.114 What output power is recommended for driving a cutting head?—The minimum for satisfactory results is 40 watts; 75 is desirable, and 100 to 150 watts is not uncommon. The amplifier output should have a damping factor of at least 20, and higher if possible. The harmonic and intermodulation distortion should not exceed 1 percent at full power output.

13.115 What is the formula for calculating the playing time of a disc record?

$$T = \frac{NS}{rpm}$$

where,

T is the playing time in minutes,
S is the recorded width in inches,
N is the number of lines per inch,
rpm is the turntable speed in revolutions per minute.

13.116 What is a stroboscopic disc?—A circular disc containing a number of black and white bars, which is used for checking the speed of turntables and other rotating machines. (See Fig. 13-116.) The disc is placed on the turntable and the bars observed under a light source fed from the normal ac lighting circuits. When the speed of the turntable is correct, the black bars will appear to stand still. If the table is turning too fast, the bars speed up and drift in the direction of rotation. When running slow, the reverse takes place. Stroboscopic bars may be painted around the rim of a turntable and a 115-volt neon light mounted close by for constant observation.

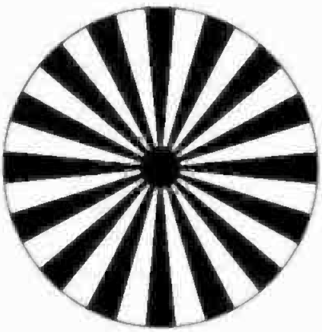

Fig. 13-116. *A stroboscope disc used for checking the rotational speed of a turntable.*

13.117 What is the formula for calculating the bars on a stroboscopic disc?

$$\text{Bars} = \frac{F \times 2 \times 60}{rpm}$$

where,

F is the frequency of the light used to observe the bars,
rpm is the speed of the turntable in revolutions per minute.

The number of bars required in a stroboscopic disc using 60-Hz lighting current is:

rpm	*bars*
16	450
33⅓	216
45	159
78.26	92

The design of stroboscopic discs for use on projectors and cameras is discussed in Question 3.87.

13.118 What is a light pattern?—A test record recorded to measure the frequency response of a disc-recording channel. Frequencies of constant amplitude are sent into the channel and recorded, using the normally employed equalizers. The finished record is then viewed under a light held parallel to the surface of the record. The pattern seen is the frequency response of the recording channel including all components and the cutting-head characteristics. The subject is further discussed in Question 23.75.

13.119 What is a Christmas tree pattern?—A light pattern similar to that described in Question 13.118.

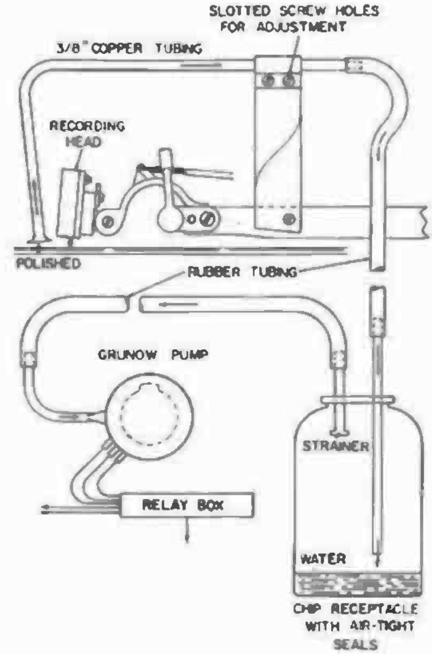

Fig. 13-120. A typical vacuum system for removing the chip from a disc record while recording. (Courtesy, Audio Devices Inc.)

13.120 What is a vacuum system and its purpose?—A suction system used for removing the chip from a disc record as the recording head moves across the face of the disc. A typical vacuum system is shown in Fig. 13-120.

13.121 How is a recording blank held by vacuum to a recording turntable?—The vacuum system used for removing the chip from the record while recording is connected to a group of holes in the periphery of the turntable, thus holding the blank in place. (See Question 13.2.)

13.122 What does the term "cut" mean?—To stop or cut off. It is also used to designate a sound track in a disc record.

13.123 What is a copper master?—A thin sheet of copper which is electroplated onto the surface of an acetate or soft wax master disc. When removed from the master, it is a negative of the original.

13.124 What is a nickel master?—A nickel-plated copper master; also a negative.

13.125 What is silver spraying?—It is a method of metallizing the lacquer master with silver, using a dual spray nozzle, wherein ammoniated silver nitrate and a reducer are combined in an atomized spray to precipitate the metallic silver.

13.126 What is gold sputtering?—A method of gold plating a master disc record by the use of a water-cooled vacuum chamber. A metal plug is inserted in the center hole of the record and connected to a source of positive dc high voltage. A gold button connected to the negative high voltage is placed near the center of the record. The high voltage causes the molecules of the gold button to pass to the surface of the disc, depositing a layer of gold approximately one molecule in thickness on the disc. This method is used in place of electroplating. This method is now obsolete.

13.127 What is a stamper?—The metal negative of the original master used in a hydraulic press for stamping the finished record. A typical record press is shown in Fig. 13-127. Hydraulic pressure combined with heat supplied by live steam passing through the record press molds the plastic biscuit into a record. Cold water is circulated through the blocks in the press for a few moments before releasing the pressure and removing the record.

13.128 What is a matrix?—A stamper. The image is negative.

Fig. 13-127. Disc record press as used in the RCA Victor record pressing plant at Camden, N.J.

13.129 What is a mother?—A nickel-plated positive of the original record used for making stampers.

13.130 What is a pressing?—A commercial phonograph record. It may be formed with or without heat.

13.131 What is a metal master?—A copper master. (See Question 13.123.)

13.132 What is a back plate?—A metal or wood backing to which a copper or negative master is attached to facilitate handling.

13.133 What is a master recording?—The original recording which may be a disc, film, or a magnetic tape.

13.134 What is a platen?—A flat circular plate used in the hydraulic press to hold the stamper.

13.135 What is a reverse copy?—A metal copy of the nickel master made by means of electroplating. It is an exact duplicate of the original recording. After mounting on a back plate it is called a master.

13.136 What is a shellac pressing?—A commercial record made some years ago, and so called because the compound contained shellac, which provided a hard surface; now obsolete.

13.137 What is a binder?—A substance used to bind the basic materials in a processed record together.

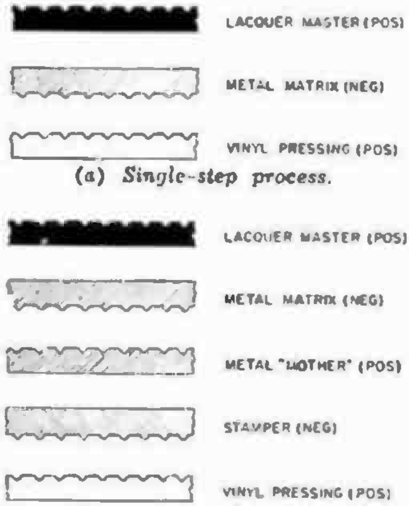
13.138 What is a filler?—A substance added to the basic material used in processed records to provide color and weight.

13.139 What is a biscuit?—A dough-like material used in the manufacture of phonograph records. (See Fig. 13-127.)

13.140 What is a wax record?—A recording blank made of soft wax and composed of soap, styric acid, and other ingredients. It is used for recording the original master and is processed in a manner similar to any other master. Soft wax was the original method used for making disc records; however, it is now obsolete, having been replaced by the acetate disc master.

13.141 What is vinylite?—A plastic material used in the manufacture of phonograph records because of its low surface noise and its resistance to breakage.

13.142 Describe the procedures for processing disc records.—Two methods may be used—the single-step and the three-step process—as illustrated in Fig. 13-142. The single-step method is used when less than 200 pressings are to be made and consists of a lacquer master, metal matrix, and a vinylite pressing. The three-step method is used



(a) *Single-step process.*

(b) *Three-step process.*

Fig. 13-142. Record-processing procedures. (Courtesy, Audio Devices Inc.)

when more than 200 pressings are required and the master must be reused.

13.143 What method is recommended for storing disc records?—They should be stored edgewise.

13.144 How should masters be packed for shipment?—They should be packed as shown in Fig. 13-144.

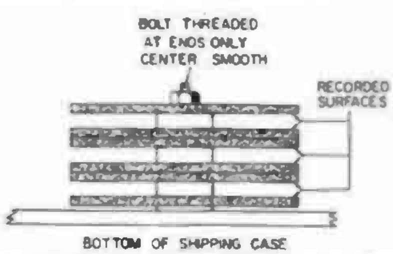


Fig. 13-144. The suggested method for shipping masters. (Courtesy, Audio Devices Inc.)

13.145 What is an air check?—A recording made from a radio broadcast by means of a radio receiver.

13.146 How should recording blanks be handled?—They should be handled by the edges only. Never permit the hands to come in contact with the recording surfaces as the oil from the fingers causes noisy spots in the processed disc.

13.147 What precautions should be taken when recording a master to be processed?—It should be visually inspected for defects in the surface before recording. After recording, it should again be inspected with a magnifying glass for breakthroughs in the walls of the sound track. A playback record cut at the same time the master was recorded is used for checking for quality and cues. Discs to be processed are never played back, as damage to the sound track may result.

13.148 Describe a compatible recording.—In the reproduction of disc records, if a stereophonic recording is played on a reproducer employing a lateral or monophonic pickup, the sound track modulations will be damaged because of the nonvertical compliance of the pickup motor mechanism. It has long been the aim of recording engineers to produce a sound track that would play equally well usiug either a monophonic or stereophonic pickup. Experiments seemed to indicate that it was the low-frequency vertical signal that caused most of the wear. If the low-frequency signal was removed from the vertical portion of the sound track, the low frequencies would appear in the lateral component which represents the sum of the two channels, because the vertical information represents the stereo information equal to the difference between the two channels. Recordings made in this manner show considerably less wear when reproduced using a lateral pickup. However, further study indicates that stereo information is carried by the low frequencies and leads to the degradation of the quality of reproduction.

Experience indicates that at the present time *stereophonic* recordings should not be played back using a *monophonic* pickup. However, *monophonic* recording can be reproduced quite satisfactorily using a *stereophonic pickup.*

13.149 How may acetate discs be cleaned?—With a weak solution of soap in cool water.

13.150 How may the sound-track groove depth be calculated?

For an included angle of 87 degrees:

$$\text{Groove depth} = 0.5269 \times A - 0.4527 \times R$$

For an included angle of 70 degrees:

$$\text{Groove depth} = 0.7141 \times A - 0.7434 \times R$$

where,

A is the groove width,
R is the stylus tip radius.

The groove width is measured with a calibrated microscope.

13.151 How much does the RIAA high-frequency pre-equalization improve the signal-to-noise ratio?—It will improve the signal-to-noise ratio by 8 dB, resulting in an effective signal-to-noise ratio of 58 dB under minimum conditions. (See Question 13.95.)

13.152 What is a negative-feedback cutting head?—This device is discussed in Section 14.

13.153 What is hot-stylus recording?—The use of a heated stylus during the recording process. This method reduces the pressure on the recording stylus and improves the high-frequency response as well as the signal-to-noise ratio. This subject is discussed in length in Questions 15.60 to 15.71.

13.154 How does turntable rumble affect low-frequency reproduction?—Turntable rumble has a high energy content and causes the cone of the loudspeaker to operate in the nonlinear portion of the speaker characteristic, distorting the low frequencies. If the rumble is great enough, the reproduction sounds as though the cone were breaking up.

13.155 Show how a given waveform is affected by a change in the groove velocity.—A given waveform recorded at a diameter of 12.5 inches and at 5.5 inches is shown in Fig. 13-155. It will be noted the waveform at 5.5 inches is cramped into a space less than half that at 12.5 inches. This complicates tracking and increases the noise and distortion.

13.156 What is the minimum separation specified for stereophonic reproduction?—The separation between recorded and unrecorded channels measured at the output of the reproducer with its equalizer and preamplifier must be at least 26 dB over the range of 100 to 7500 Hz, and the separation shall not fall off at a greater rate than 6 dB per octave. As the values specified may be subject to noise and erratic measurement, it is suggested, if possible, that a tuned voltmeter be used for such measurements.

13.157 What is the standard for balance between stereophonic channels?—Playing back a record, with the output of each channel adjusted to within 0.25 dB at 1000 Hz, the frequency response of each channel shall agree with the standard reproducing curve of Fig. 13-95, within plus-minus 1 dB between 100 Hz and 7500 Hz, and within plus-minus 2 dB above and below these frequencies. Equal modulation for the two sides may be obtained by using a monophonic lateral test record.

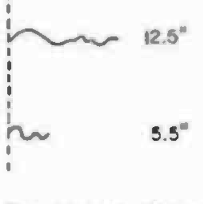
13.158 What is the standard for phasing a stereophonic recording channel?—For recording, the standard states that equal in-phase signals applied to the left and right channel inputs of a stereo disc recorder shall result in lateral modulation of the stereo groove. Conversely, equal antiphase signals produce vertical modulation. For reproducing, the lateral modulation of the groove will produce equal in-phase voltages at the output of the pickup, and, conversely, that vertical modulation will produce equal antiphase voltages. (See Question 13.202.)

13.159 How does the distortion vary for lateral recording?—It varies as the square of the signal amplitude, as the square of the stylus radius, as the square of the frequency, and, inversely as the groove velocity.

13.160 How does the distortion vary for a vertical recording?—It varies directly as the signal amplitude, directly as the frequency, directly as the stylus radius, and directly as the groove velocity.

13.161 Define groove angle.—It is the angle between the two side walls of a groove, measured in a radial plane perpendicular to the disc surface.

13.162 Show the schematic diagram for a cutting-head filter or preequalizer.—A recording filter or equalizer for recording, using the RIAA recording



(a) Waveform recorded at a high groove velocity.

(b) Same waveform recorded at a low groove velocity.

Fig. 13-155. The effect of groove velocity on recorded waveforms.

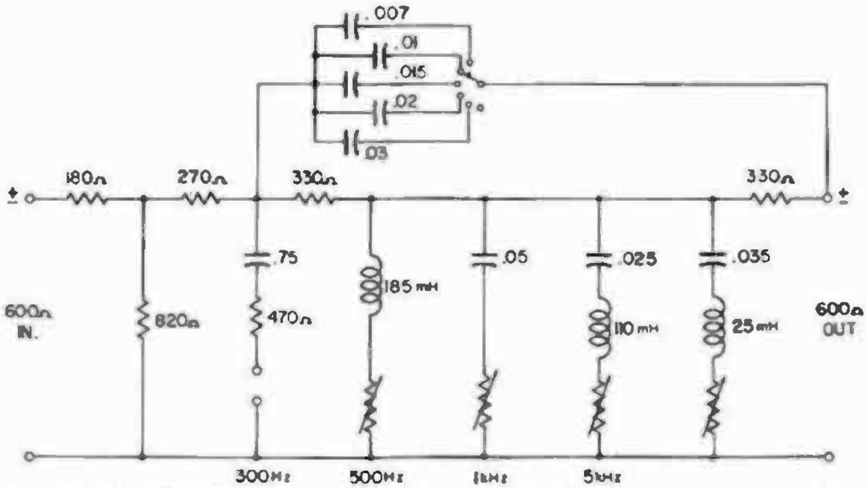


Fig. 13-162A. Recording pre-equalizer for adjusting the frequency response of a cutting head.

characteristic, developed by H. E. Roys of RCA is shown in Fig. 13-162A.

The circuit consists of an input pad, and five adjustable circuits for smoothing out the frequency response of the cutting head. An ideal cutting-head recording characteristic and a practical response curve are shown in Fig. 13-162B, with the RIAA recording characteristic. The practical response is attained by the use of the recording filter shown in Fig. 13-162A. The small peaks and valleys in the final cutting-head response are quite small and may be considered to be flat for all practical purposes. The high-frequency tilt-up of the RIAA characteristic is obtained by the adjustment of the capacitors in parallel with the upper portion of the filter network. The frequency response of the cutting head is adjusted by means of the adjustable circuits in the filter network for the smoothest frequency response by recording a series of light

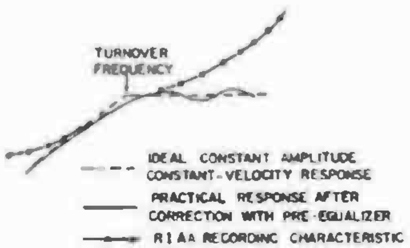

Fig. 13-162B. The ideal cutting head recording characteristic and a practical response curve. Also shown is the RIAA recording characteristic.

patterns or by the use of a cutting-head calibrator, discussed in Question 14.49. (See Question 23.75.)

13.163 How is the recording filter of Fig. 13-162 connected in the recording circuit?—The recording filter or equalizer may be connected in the recording channel in several different ways. The network is connected ahead of the recording amplifier at part (a) in Fig. 13-163A. At part (b) it is connected in tandem with a variable diameter equalizer.

Three disc recorders driven from a bridging bus are shown in Fig. 13-163B. In this instance, the recording filters are designed with a 10,000-ohm bridging input transformer connected across a 600-ohm bus. Separate recording amplifiers are used for each recorder. In this type arrangement a diameter equalizer cannot be used.

13.164 How is 100-percent modulation of a cutting head determined?—It may be acheved by two methods: by having a VU meter connected across the head circuit or by recording an unmodulated groove and measuring its width, using a calibrated microscope. The latter method is preferred, as it takes into consideration the characteristics of the disc material, stylus heat (if used), and any other factors associated with the actual displacement of the cutting-head stylus. The gain control in the recording amplifier should have ½-dB steps to permit accurate adjustment of the 100-percent modulation. The frequency used for lining-up the

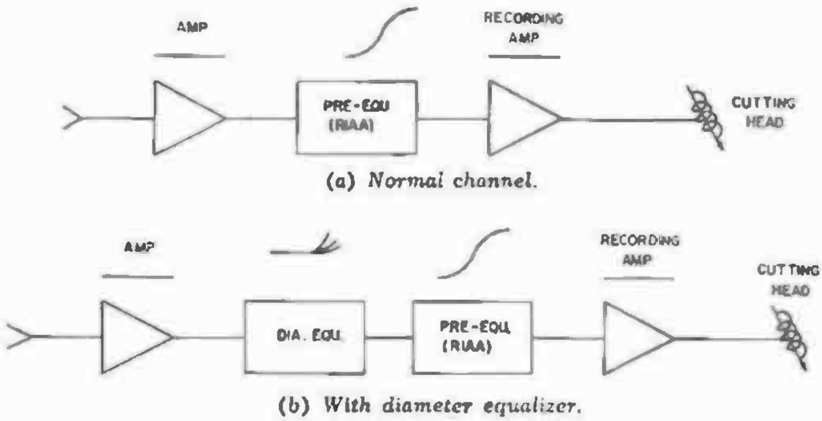

Fig. 13-163A. Position of the recording pre-equalizer in the recording channel.

channel before recording should be at a predetermined frequency, taking into consideration the equalizer characteristics. (See Question 13.112.)

13.165 Define translation loss (playback).—It is the loss suffered in the reproduction of a pressing, whereby the amplitude of the reproducer stylus differs from the recorded amplitudes on the record.

13.166 What is the recommended reproducing characteristic for 16-inch 33⅓-rpm recording?—The same frequency response as for 33⅓-rpm microgroove recording (Fig. 13-95). As this type recording uses coarse pitch, the recording stylus uses an included angle of 88 degrees, plus-minus 5 degrees, with a tip radius of 1.5 mils.

13.167 What is the recommended reproducer characteristic for 78.26-rpm recording?—The same frequency response as for 33⅓-rpm microgroove recording (Fig. 13-95). Because this type recording uses a coarse pitch, the recording stylus uses an included angle of 87 degrees, with a tip radius of 1.5 mils.

13.168 What is the recommended reproducing characteristic for 16⅔-rpm recording? — The frequency response follows the same general characteristic as for the microgroove. However, it may require some correction to obtain a satisfactory finished product. Such records are recorded using microgroove techniques. Recordings such as these are used for books for the blind and other extremely long playing records. (See Question 13.22.)

13.169 What does the abbreviation "RIAA" mean?—It is the initials of the Record Industry Association of America. It is also used to designate the reproducing characteristic adopted by all

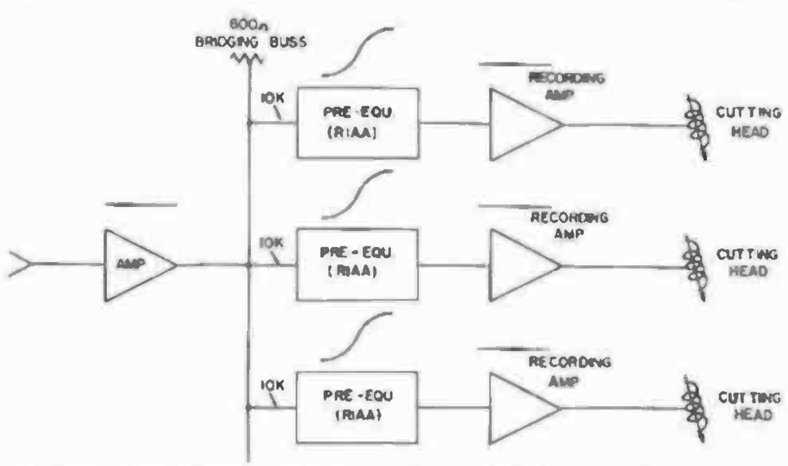

Fig. 13-163B. Three disc recorders driven from a bridging bus. The pre-equalizers have 10,000-ohm bridging input impedance.

the leading recording companies as a standard for record reproduction. It has also been adopted by many of the record manufacturers of Europe. The standard was adopted in June, 1953, and reaffirmed in March, 1964. This characteristic is discussed in Question 13.95, and the actual values of equalization in Question 13.110.

13.170 What is pinch effect?—See Question 16.27.

13.171 Define tracking error—It is the *inability* of the reproducing pickup stylus to properly follow the recorded groove, thus inducing distortion and noise with possible damage to the groove modulations. *Trackability* is now the generally accepted term, rather than tracking error. (See Questions 13.172 to 13.174, and 16.42.)

13.172 What are the most common causes of poor tracking in a reproducer?—Some of the most common causes are pinch effect, groove too shallow or too light, turntable not level, bent recording blank, overmodulation of the sound track, and side walls of the groove broken through.

13.173 What is tracing distortion?—Nonlinear distortion in reproduction of a disc record. Distortion is created because the curve traced by the playback stylus is not an exact replica of the modulated groove. Tracing distortion is caused by the stylus tip which is round and of finite radius. If the wavelengths of the modulations are of the same dimensions as the stylus tip, difficulty will be experienced when attempting to reproduce the sound track.

The effects of tracing distortion become greater as the smaller diameters are approached because of the lower groove velocities. Tracing distortion is created because the playback stylus and the cutting head stylus contact do not occur at exactly the same point. In tracing a groove, the playback stylus contacts the groove wall at a point different from that made by the recording stylus. This difference of position causes distortion in the reproduction. With the advent of the biradial or elliptical reproducing stylus, the effect of tracing distortion has been considerably reduced. (See Questions 13.30 and 13.32.)

13.174 What is tangent error?—When a laterally recorded disc record is recorded, the cutting head is carried across the face of the recording disc at right angles to the direction of the disc motion. However, when reproduced, the pickup is never at right angles to the direction of motion, except at one point, because the pickup arm is pivoted in such a manner that it swings across the face of the disc in an arc as shown in Fig. 13-174. Point A is the only place where the stylus point is at right angles to the direction of motion.

The constant change of angle by the playback stylus causes a strain on the sidewalls of the record groove, which eventually tears out the high frequency modulations, leading to increased noise and distortion. (See Question 16.52.)

13.175 Define constant-velocity recording.—Constant-velocity recording indicates a mechanical recording characteristic wherein, for a fixed amplitude sine wave, the resulting recorded amplitnde is inversely proportional to frequency.

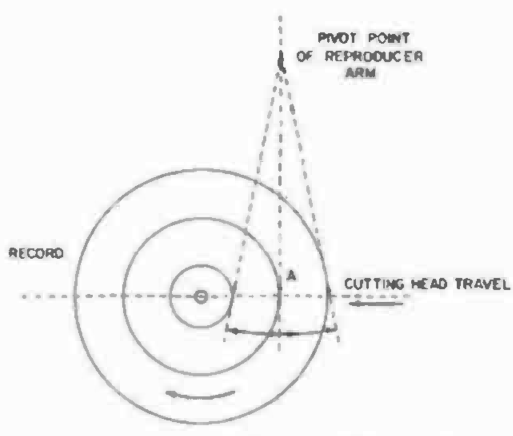

Fig. 13-174. Tangent error in a reproducing arm. The error is zero at point A only.

13.176 What is a sweep-frequency record?—A test record on which have been recorded a series of constant-amplitude frequencies. Each frequency is repeated 20 times per second starting at 50 Hz and continuing up to 10,000 Hz or higher.

The record is played back and its output observed by means of an oscilloscope connected at the output of the playback unit. Marker frequencies appear at intervals to identify the frequencies. The use of these records is discussed in Question 23.141.

13.177 What is the nomenclature for recording and reproducer styli?—This subject is discussed in Section 15.

13.178 What are the included angles used with recording and reproducing styli?—This information is given in Section 15.

13.179 What are the characteristics of a magnetic cutting head?—This subject is discussed in Section 14.

13.180 What are the standard groove characteristics for stereophonic recordings?—The plane of modulation in a 45/45-degree stereophonic disc groove shall have orthogonal modulation planes inclined at 45 degrees to a radial line on the surface of the disc and at the intersection of the modulation planes and be normal to the radial lines. The outer wall of the groove shall contain the *right-hand channel* information and the inner wall the *left-hand information*. The phase relationship between channels shall be such as to result in *lateral* groove displacement when the stereo-recording system is driven with equal amplitude and in-phase signals, and the groove displacement shall be *vertical* when the recording system is driven by equal amplitude signals in antiphase or 180 degrees. (See Figs. 13-180A and B, and Question 13.104.)

13.181 What is the standard groove shape for stereophonic pressings?—The groove shape shall have an included angle of 90 degrees, plus-minus 2 degrees, with a top width of not less than 0.001 inch, and a bottom radius not greater than 0.0002 inch. For these groove dimensions it is recommended the reproducing stylus have a tip radius of 0.0005 to 0.0007 inch, with an included angle of 40 to 45 degrees.

It will be noted that the groove dimensions mentioned above apply to the *finished product* rather than to the recording stylus. In some instances, the groove dimensions may depart slightly from those of the recording stylus; however, these variations can generally be controlled in the processing plant. In the event that it is necessary to play back both monophonic and stereophonic discs with the same reproducer, the use of a 0.007-inch stylus is desirable.

13.182 What is the lines-per-inch rate for starting spirals?—Eight grooves per inch, plus or minus 2.

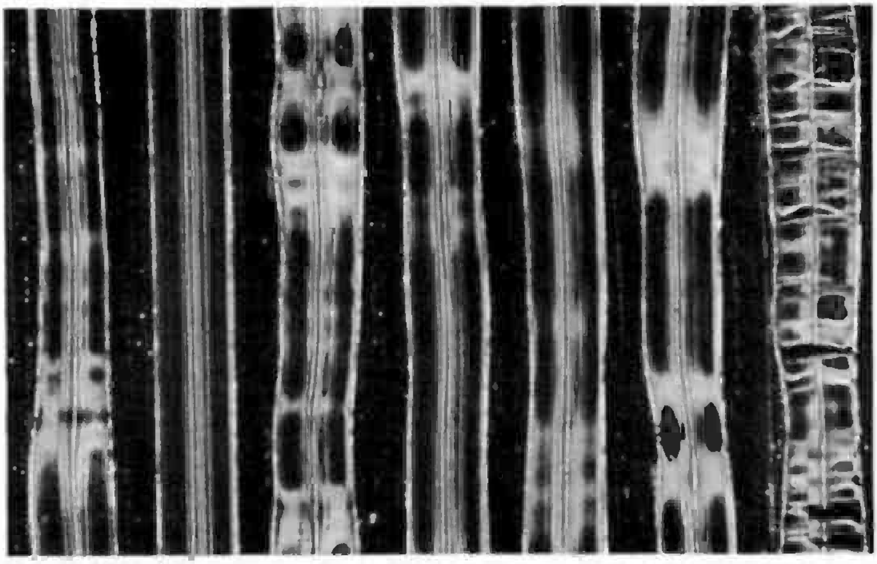

Fig. 13-180A. Photomicrograph of 45/45 grooves recorded with stereophonic program material.

13.183 How many grooves are recommended before the first modulation occurs?—Not less than two nor more than four complete revolutions.

13.184 What are the smallest recommended diameters to be recorded?—

For 16-inch transcriptions at 33⅓ rpm using a reproducing stylus of 2.3 mils, 7.5 inches.

For 78.26-rpm recordings, 3¾ inches.

For 45-rpm recordings, 4¼ inches.

For 33⅓-rpm microgroove recordings, 4¾ inches.

13.185 What is the standard for run-in grooves and the smallest groove on the inside?—There shall be at least one unmodulated groove at the recording pitch before the recording, and one at the end of the recording. The last modulated groove shall not be less than 4¾ inches in diameter for 33⅓-rpm discs, and 4¼ inches for 45-rpm discs.

13.186 What is the standard for concentricity of the center hole?—It shall be concentric with the recorded groove spiral within 0.005 inch, with a diameter of 0.286 inch plus 0.001 inch, minus 0.002 inch for 33⅓-rpm recording. For 45-rpm discs, the hole is 1.504 inches, plus-minus 0.002 inch. Warping of the disc shall not exceed a total indicator reading of the surface in excess of 1/16 inch, within any 45-degree segment, with a total reading of the indicator not to exceed 1/32 inch.

13.187 What is the recommended groove width for coarse-pitch recording?—For lateral recording, the finished groove should have an included angle of 88 degrees, plus or minus 5 degrees, for a top width of not less than 4.0 mils for records to be reproduced with a stylus having a tip radius of 2.3 mils.

13.188 What is the average dynamic range of a disc recording?—For high quality recordings, the dynamic range is:

Shellac pressings, lateral cut	32 to 40 dB
Microgroove vinylite	40 to 55 dB
Vertical cut	40 to 45 dB
Special systems, microgroove	45 to 60 dB
16-inch coarse-pitch, lateral cut	45 to 60 dB

13.189 What is the recommended groove width for vertical recordings?—For an included angle of 88 degrees, plus or minus 5 degrees, the bottom radius should be 2.0 to 2.3 mils, with a top width of not less than 4.0 mils.

13.190 What is grouping?—Uneven spacing of the grooves. The grooves should be so spaced that at no one point does the pitch deviate from the mean by more than 5 percent for constant-groove space recording.

13.191 What is flash?—It is the excess compound generated at the edge of a pressing, during the compression moulding of a disc record. The edge is later buffed smooth.

13.192 What is the procedure for recording standard test records?—Standard procedures for this type recording have been set forth in the National As-

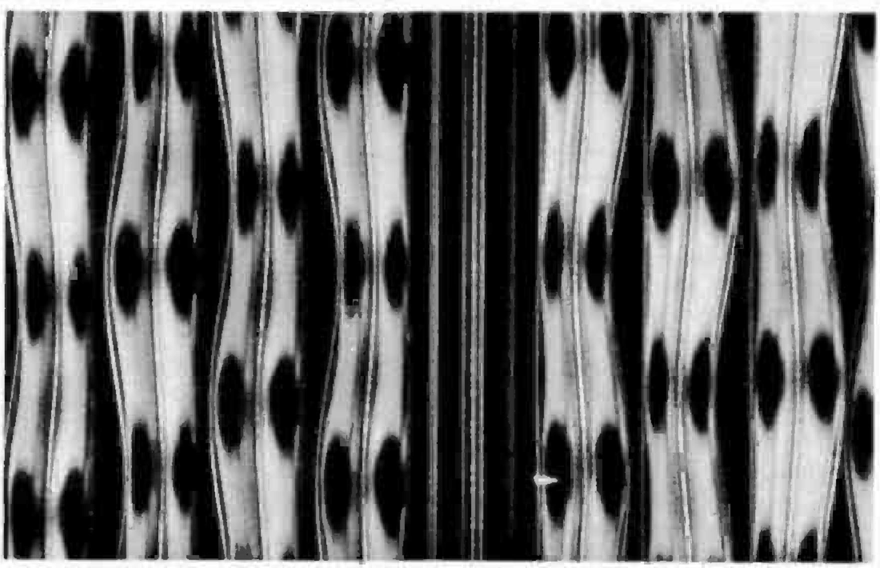

Fig. 13-180B. Photomicrograph of single-channel 45/45 stereophonic record groove.

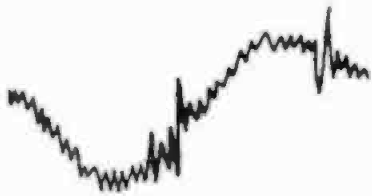

Fig. 13-193. Modulation noise superimposed on a fundamental frequency.

sociation of Broadcasters (NAB) Standard, "Disc Recording and Reproduction," March, 1964.

13.193 What is modulation noise? —Noise created by the signal. The signal is not included as a part of the noise. A typical modulation noise pattern is shown in Fig. 13-193. With the use of hot-stylus techniques, modulation noise has ceased to be a problem.

13.194 What is a poid?—The curve traced by the center of a sphere when it rolls or slides over a surface having a sinusoidal profile. It is the path traced by the reproducer stylus of a vertical pickup.

13.195 What is shaving a record?— In the days when soft wax was used for recording masters, the recording blank was rotated at a high speed and a thin shaving was removed from the surface to obtain a high polish.

13.196 How does tracing distortion differ in a vertical recording?—When a sine wave is reproduced from a vertical recording, the curve traced by the stylus tip is a poid. (See Questions 13.173 and 13.194.)

13.197 What is the transition frequency?—It is the frequency where the recording characteristic departs from constant velocity to one of constant amplitude. It is also called the crossover or turnover frequency. (See Question 14.8.)

13.198 Define the term "off-set angle."—In lateral-disc reproduction, the off-set angle is the smaller of the two angles between the projections into the plane of the disc of the vibration axis of the pickup stylus and the line connecting the vertical pivot (assuming a horizontal disc) of the pickup arm, with the stylus point. (See Questions 13.30, 13.32, and 16.60.)

13.199 Describe a typical pickup and reproducing system test record.— Several different test records are available for making individual tests on pickup and for testing complete reproducing systems. Records for the testing of pickup characteristics include frequency response measurements with frequency announcements from 20 to 20,000 Hz, separation tests (crosstalk), pickup-arm resonance, stylus wear, wavelength loss, and compliance and phasing. A standard reference level is also included (7 cm per second). Other records for the measurement of harmonic and intermodulation distortion are also available.

Records designed for complete system testing generally include identification of left and right channels, stereo balance, loudspeaker phasing, rumble test, stylus wear, pickup-arm resonance, flutter, RIAA frequency-response section, and a standard reference level. (See Question 13.192.)

13.200 What is side thrust?—The radial component of force on a pickup arm caused by stylus drag.

13.201 Show an RC equalizer circuit suitable for reproducing the RIAA reproducing characteristic. — Two such circuits are shown in Fig. 13-291. Solid-state circuits are given in Section 12.

13.202 Show the relationship between the coils of a stereophonic cutting head and those of a pickup.—Referring to Fig. 13-202, the connections for the cutting head coils are shown at part (a) and those of the pickup are shown at part (b). Because of the mechanical design of the cutting head, the left- and right-hand sides of the program mate-

Fig. 13-202. Cross-sectional view of stereophonic record groove showing how the program material is recorded and reproduced. Because of the mechanical design of the pickup, the right- and left-hand sides of the grooves are reproduced by the coils on the opposite sides of the record groove.

rial are reproduced by the coils on the *opposite* sides of the record groove.

When the program material is recorded, as shown at part (a), the left-hand side is recorded on the *left*, or on the *inside wall of the groove*. The right-hand side of the program material is recorded on the *right, or outside of the groove*.

When the record is reproduced, the *right-hand pickup coil is connected to the left-hand amplifier and loudspeaker*. The *left-hand pickup coil is connected to the right-hand amplifier and loudspeaker*. This procedure is necessary because of the mechanical design of the pickup.

The RIAA standard for stereophonic reproduction is that when two identical signals are fed to the cutting head actuating the coils in-phase, only a lateral sound track is recorded. Conversely, equal antiphase signals will produce only vertical modulations. It is assumed that the reproducing system after leaving the pickup is properly phased. (See Question 13.158.)

13.203 What are the general characteristics of an embossed sound track? —In an embossed sound track the material is not removed from the disc but is pushed aside, creating tiny horns at the upper edges of the sound track. The frequency response of an embossed sound track is rather limited and generally falls between 70 and 5500 Hz. The signal-to-noise ratio will vary with different types of recording materials.

The harmonic and intermodulation distortion is affected by the material of the record, the amplitude of the signal, and an effect known as cusping in the sound track. A fairly good average of distortion is 6 to 10 percent at 400 Hz when recording and reproducing on the same machine. Crystal or magnetic cutting heads may be used; however, the crystal is preferred as it may be coupled to the recording amplifier to produce a constant-amplitude recording characteristic. The output stage should have at least 12 dB of negative feedback. (See Question 13.32.)

13.204 What is the frequency characteristic for an embossing recorder amplifier?—It is as shown in Fig. 13-204. It will be noted the upper midrange frequencies have been pre-equalized to obtain a greater signal-to-noise ratio and to add presence to the reproduction. The amount of pre-equalization will vary with the recording media, stylus, and cutting head.

13.205 Can embossed records be played back from the recorder using the same head and stylus?—Yes, but with a loss of signal-to-noise ratio. Using the same stylus has the disadvantage that the same included angle is used to reproduce as that used to record. This permits the stylus to ride in the bottom of the groove increasing the noise in the reproduction. The signal-to-noise ratio for this type operation is about 20

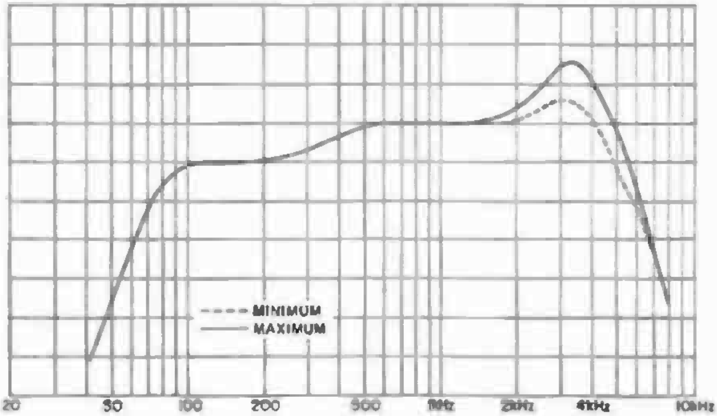

Fig. 13-204. Recording characteristic for embossing recorder.

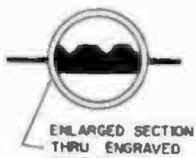
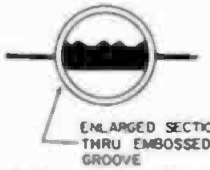
dB. Playing the same record back using a greater tip radius will increase the signal-to-noise ratio 10 dB.

13.206 What is the relationship of a constant-groove velocity to recording time?—The recording time is proportional to the area of the recording. Since the area of a circle is proportional to the square of its radius, it becomes possible to record long periods of playing time using 300 lines per inch.

13.207 Show a cross-sectional view of an engraved and an embossed sound track.—A cross-sectional view of an engraved sound track is shown at part (a), and an embossed sound track is shown at part (b) in Fig. 13-207. In the engraved sound track the material is removed from the disc as the recording progresses. In the embossed sound track the material of the disc is displaced and shoved upward, appearing as two small ridges at the edges of the sound track.



(a) *Engraved sound track.*



(b) *Embossed sound track.*

Fig. 13-207. Enlarged sections of record grooves.

13.208 What is the average pressure developed in an embossing system of recording?—About 20,000 pounds per square inch. To reduce the friction, the recording blank is impregnated with a lubricant and the surface treated with wax.

13.209 What type medium is recommended for embossed sound tracks?—As a rule, cellulose acetate about 0.15 inch in thickness is used; however, in some instances vinylite is used.

13.210 What is acoustic recording?—The original method of recording by causing the sound waves to actuate a diaphragm to which is attached a stylus. The stylus bears on the recording medium and mechanically engraves a sound track corresponding to the impressed sound waves. This is the method used before the advent of electrical recording. Acoustic recording is also called mechanical recording.

Because the output of most of the instruments used for recording is low and a considerable amount of energy is required to obtain a satisfactory level on the record, horns were attached to the string instruments to reinforce their acoustic output. A typical recording session in the early 1920s is pictured in Fig. 13-210.

The sound mixer consisted of a ball of yarn in a tube attached to the large horn at the left. The position of the ball of yarn in the tube was varied to regulate the volume of sound fed to the recording diaphragm and stylus.

13.211 Describe the geometry of a 45/45-degree stereophonic record groove cut with a 90-degree included angle stylus.—A cross-sectional view of a 45/45-

Fig. 13-210. A recording session in the early twenties at the RCA Victor plant in Camden, N.J.

degree record groove for four limiting conditions is shown in Fig. 13-211. A recording stylus with an included angle of 90 degrees is used.

The plot at the upper left illustrates the type of groove that will be recorded when the signal is fed to the left-hand channel only. The right-hand wall of the groove will be a slant line varying in depth. The right-hand edge will be smooth and without modulation. The left edge of the groove will be varied in accordance with the signal.

The plot at the upper right of the diagram depicts the reverse condition when the signal is fed to the right-hand channel only. The plot at the lower left of the diagram shows the type of groove recorded when two identical signals in phase are fed to the two cutting-head driving coils. For this condition, a vertical recording results.

The plot at the lower right shows the groove recorded when the two signals are out of phase at the driving coils. For such a condition, a lateral recording will result. During an actual stereophonic recording session, all four of the

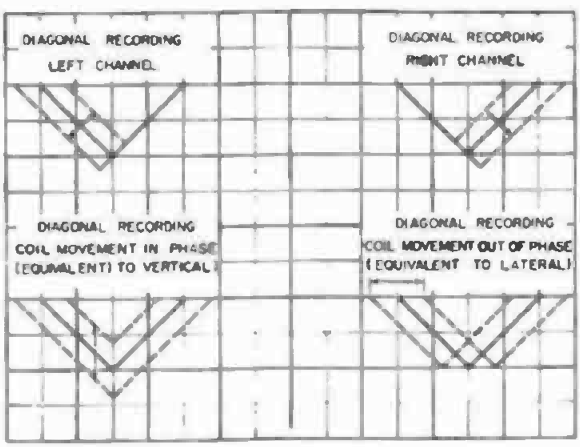


Fig. 13-211. Cross section of 45/45 grooves for four limiting conditions.

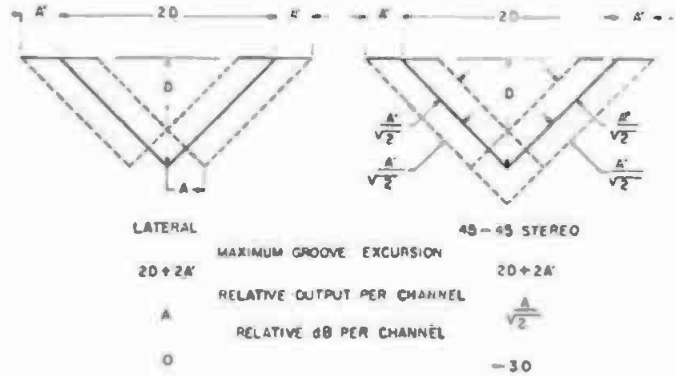

Fig. 13-212. Comparison of 45/45 stereophonic groove with standard lateral groove.

described conditions are taking place under very complex conditions of the stylus motion.

13.212 Compare a monophonic groove to that of a 45/45-degree stereophonic groove, showing the maximum permissible groove excursion. — This comparison is shown in Fig. 13-212 for the conventional lateral recorded disc and for the lateral motion in a stereophonically recorded disc. The maximum excursion for either type of groove is:

$$2\,D + 2\,A'$$

The maximum modulation for the conventional lateral groove is:

$$A = A'$$

In the 45/45 groove, the maximum modulation for either channel is:

$$\frac{A'}{\sqrt{2}}$$

Thus, each channel for a stereophonically recorder disc will have a 3-dB lower output level with respect to a conventional lateral recording.

The maximum amount of lines recommended for stereophonic recording by the 45/45-degree method is 225 lines per inch, with a minimum groove width of 1 mil and a maximum bottom radius of 0.2 mil.

13.213 What are the limiting factors relative to the maximum modulation that can be applied to a 45/45-degree groove?—Refer to the cross-sectional view of a 45/45-degree stereophonically recorded groove in Fig. 13-213. The specified minimum depth is shown at D, and the maximum modulation for either cutting-head coil is indicated at A. For these conditions, the maximum horizontal excursion will be:

$$2\,D + 4\,\sqrt{2\,A}$$

The maximum depth of the groove is:

$$D + 2\,\sqrt{2\,A}$$

13.214 What is the average harmonic and intermodulation distortion for stereophonic recording and reproducing systems?—It has become the policy of most manufacturers not to quote figures for harmonic or intermodulation distortion, as the value of distortion depends on many factors. However, intermodulation distortion at 3.5-cm velocity for

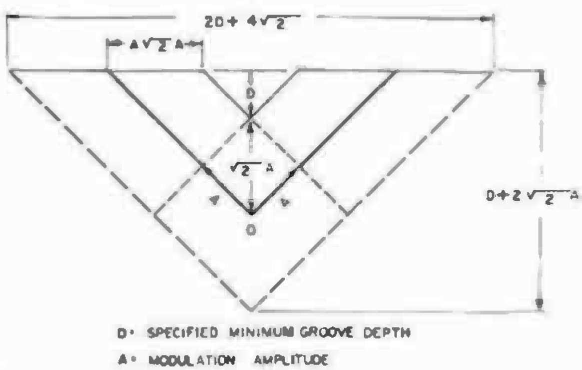

Fig. 13-213. Cross section of 45/45 groove for maximum groove excursion.

each channel will not be more than 3.5 to 4 percent for a diameter of 11 inches. As the diameter is decreased. the distortion will rise to about 5 to 6 percent. This is based on the use of 60 and 6000 Hz in a ratio of 4:1. For monophonic recording, using 7-cm velocity and 400 Hz, the distortion generally does not exceed 2.5 percent at a diameter of 6 inches.

It should be taken into consideration that these measurements include the distortion contributed by the test oscillator, recording amplifiers, cutting head and cutting-head stylus angle, and the disc record. On the reproducing side, measurements include the distortion of the disc record, pickup, preamplifiers, and any distortion induced by equalization in either the recording or reproduction circuitry. Considering the many factors involved in disc recording and reproduction, this is not a high figure of distortion. No doubt the greatest distortion factor is the angle of the stylus to the surface of the disc. (See Question 13.30.)

13.215 Describe the RCA dynagroove stereophonic disc record.—The dynagroove system developed by RCA-Victor is a combination of many factors. It is a correlation between the artist and engineer to achieve a record that will more nearly approach concert-hall reproduction in the average home by the use of several devices in the recording system. It has been found by extensive measurements that 90 percent of the consumers listen to record reproduction in their homes at a peak level of 70 to 90 dB, with the average about 80 dB. The peak level of a full symphony orchestra is about 100 dB. Thus, it may be seen that the peak level in the home is considerably lower than the concert hall. The principal reason for this lower level is that the tolerable peak level in a small room is lower than that of a concert hall, due to the shorter path of travel and the faster growth in the smaller enclosure; hence, a lower peak level of listening. Six factors enter into the realistic reproduction of sound in the home; the peak sound level, loudness versus the loudness level, frequency response of the human ear, and the reverberation characteristics of the enclosure.

When recording the original master tape in the studio, several factors are taken into consideration. such as the studio acoustics, microphone placement and directivity, frequency response, distortion of the amplifier system, and the record speed and signal-to-noise ratio. It has been found that operating the recorder at 30 inches per second, the random signal-to-noise ratio is increased 3 dB, with a reduction in flutter and wow of 50 percent, as compared to a speed of 15 ips.

After the original magnetic tape is recorded, it is transferred to a submaster tape using a Dynamic Spectrum Equalizer to correct for differences in the listening conditions and to that of an average dwelling. The design of this equalizer is such that its frequency response is altered continuously as the program is recorded, and is a function of the program amplitude and differences in the types of musical combinations and selections. Typical frequency-response curves for this equalizer are shown in Fig. 13-215.

When the level is low, the low frequencies are accentuated. At medium levels, only a slight amount of accentuation is used in the low frequencies and in the presence range (2000 to 6000 Hz), with a reduction in the response in the region between 400 and 1000 Hz. At high sound levels, the presence region is accentuated and the range below 1000 Hz is reduced. The whole object is to increase or decrease the sound level in the appropriate frequency bands so the program material may be appreciated under the existing ambient noise level and acoustic environment. Properly handled, the dynamic range is not disturbed and reproduction in a small room enhanced.

In the recording of both the master tape and the submaster, they are carefully monitored using peak-indicating volume-indicator meters. After the submaster tape has been recorded, it is transferred to a master disc, using devices termed, "Dynamic Styli Correlators," in the left and right channels. This device corrects for the discrepancies between the angle of the recorder and reproducer stylus used by the consumer and reduces the tracking distortion at the smaller diameters by a factor of 6:1.

In addition to the factors mentioned, certain changes have been made in the record-processing procedure to improve

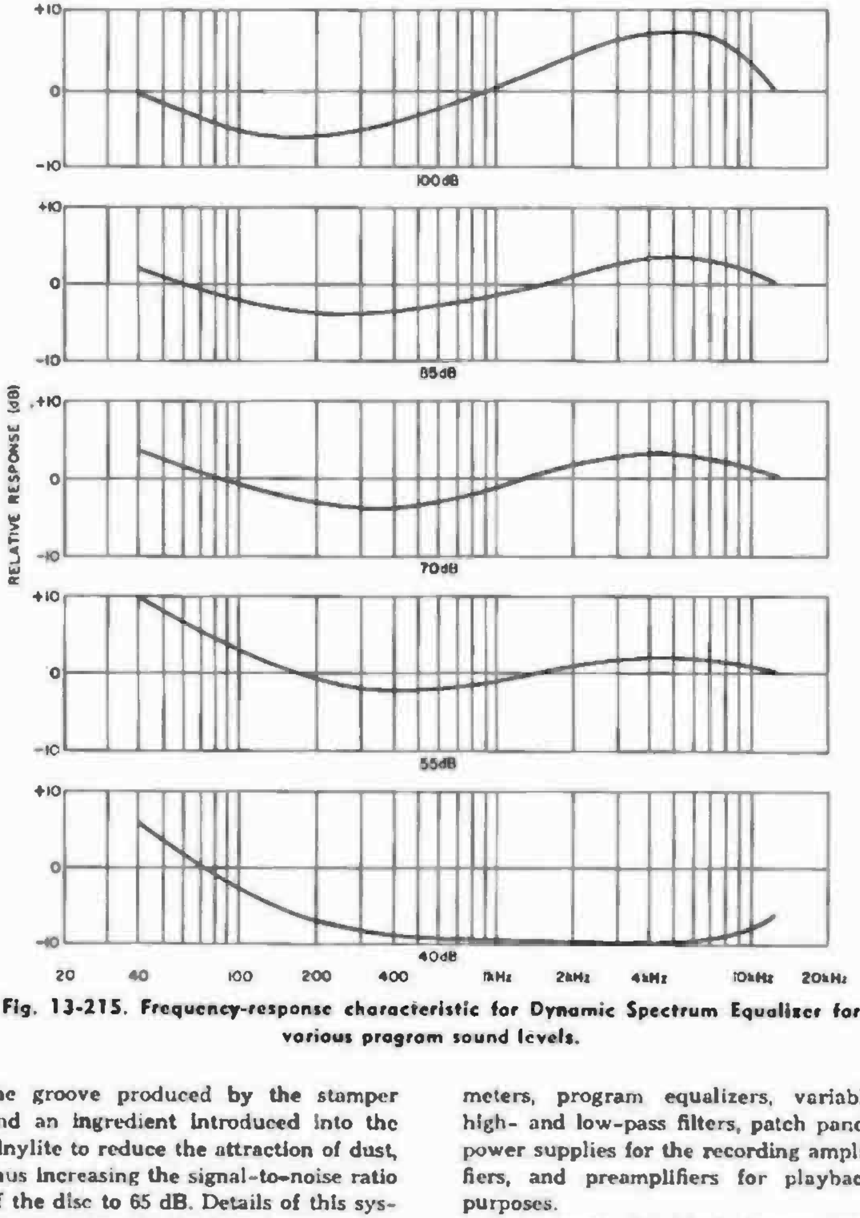

Fig. 13-215. Frequency-response characteristic for Dynamic Spectrum Equalizer for various program sound levels.

the groove produced by the stamper and an ingredient introduced into the vinylite to reduce the attraction of dust, thus increasing the signal-to-noise ratio of the disc to 65 dB. Details of this system are given in the literature.

13.216 Describe a monophonic and stereophonic magnetic tape or film to disc transfer channel.—Pictured in Fig. 13-216A is a Westrex magnetic tape- or film-transfer channel for monophonic or stereophonic disc mastering. The channel shown is complete except for the monitor speakers, disc recording lathe, magnetic tape or film reproducer, playback turntable, and pickup.

Two cabinet-type racks house two RA-670 amplifiers, two RA-1574D 75-watt recording amplifiers, gain controls, two 40-watt monitor amplifiers, VU meters, program equalizers, variable high- and low-pass filters, patch panel, power supplies for the recording amplifiers, and preamplifiers for playback purposes.

Referring to the block diagram Fig. 13-216B, at the upper left the input signals from the left and right channels are applied to the input of two RA-670 limiter amplifiers. These amplifiers have extremely fast attack time (50-microseconds) and a variable release time. Leaving the limiter, the signals pass through high- and low-pass filters, then to the variable program equalizers. At the output of the equalizers is a gain control for balancing the gain of each channel and a two-gang attenuator for adjusting the gain of the two sides simultaneously.

The signals are now applied to a monitor switching panel where the monitoring may be taken from one of several different points in the system—the left or right cutting-head circuits, the recording channel immediately preceding the recording amplifier, the tape reproducer, or the phono jack. Two line amplifiers feed through a record on-off panel and then to two RA-1574D power amplifiers, which drive a Westrex 3-D cutting head on the recording lathe.

At the lower portion of the diagram are shown the 40-watt monitor amplifiers, preceded by a two-gang gain control and two repeat coils. At the lower left is a stereo preamplifier for playback purposes, and pickup.

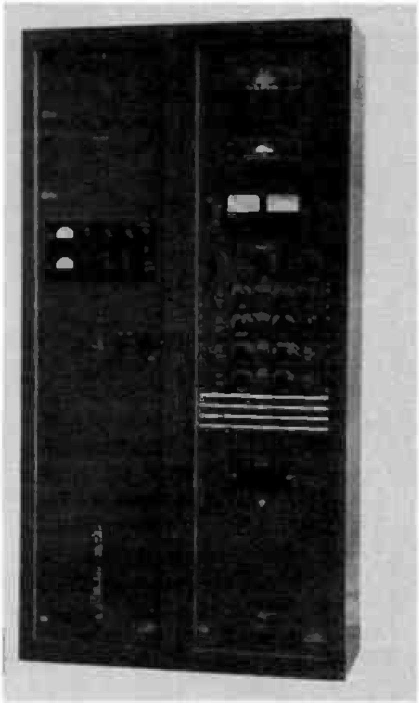

Fig. 13-216A. Westrex Corp. Model 2300 StereoDisc magnetic tape to disc record transfer channel.

Referring to the schematic diagram in Fig. 13-216C, the RA-1574D StereoDisc recording amplifier, the incoming signal is fed to a 600-ohm impedance input transformer T1 which drives a cathode follower V1A that functions as a constant-voltage generator for the plug-in equalizer. The output from this unit is amplified by V2A and B and has a low-frequency boost for the RIAA recording characteristic. (See Question 17.162.) The signal from V2B drives V3B, then phase-inverter V3A which in turn drives power stages V4A, V4B, V5, and V6. The output transformer T2 secondary is designed for a load of 5 to 10 ohms.

A negative-feedback circuit is returned from the feedback coil in the cutting head to potentiometer P1 in the control grid of tube V7B at the lower left. The feedback signal is amplified by tubes V7B, V7A, and V1B. The output signal from V1B injects feedback voltage into the cathode of V3B and provides a high-level signal to pin A of the monitor-amplifier equalizer C-98461 at the lower center of the diagram. The signal at the output of the equalizer drives tubes V8B and V8A feeding output transformer T3, which provides a 600-ohm output at a level of plus 4 dBm, for feeding the monitor power amplifier and speaker. The plus 4 dBm develops for a peak velocity of 3.54 cm/sec recording level at the cutting head stylus tip. Tubes V9 and V10 are employed for voltage regulation for the screens of V5 and V6.

The circuitry for the equalizers is given in Figs. 13-216G and H. The Westrex 3-D cutting head is discussed in detail in Question 14.2.

Two power supplies are required, one for each amplifier. The power supply is unregulated, regulation being supplied by the circuitry in the RA-1574D amplifiers. Referring to the schematic diagram in Fig. 13-216D, the power transformer T1 has three primary taps for line voltages of 105 to 120 volts. Full-wave high voltage is obtained through rectifiers CR4 and CR5, consisting of two units in parallel, feeding a choke input filter L1. Negative-bias voltage is generated by rectifier CR1 and is adjusted by control P1. The normal voltage is around 38 volts. The dc heater voltage is obtained from rectifiers CR2A and CR2B operating as voltage doublers. The output voltage is adjusted by control R1. Pilot-light voltage is supplied from the same winding. Transformer T2 provides isolation and heater voltage for regulator tube V9. A delay of 50 seconds in applying the 600 volts dc to the amplifier is obtained by the use of a delay unit VS3. Interconnections between the RA-1574D amplifier and power supply are shown at the lower left of the diagram.

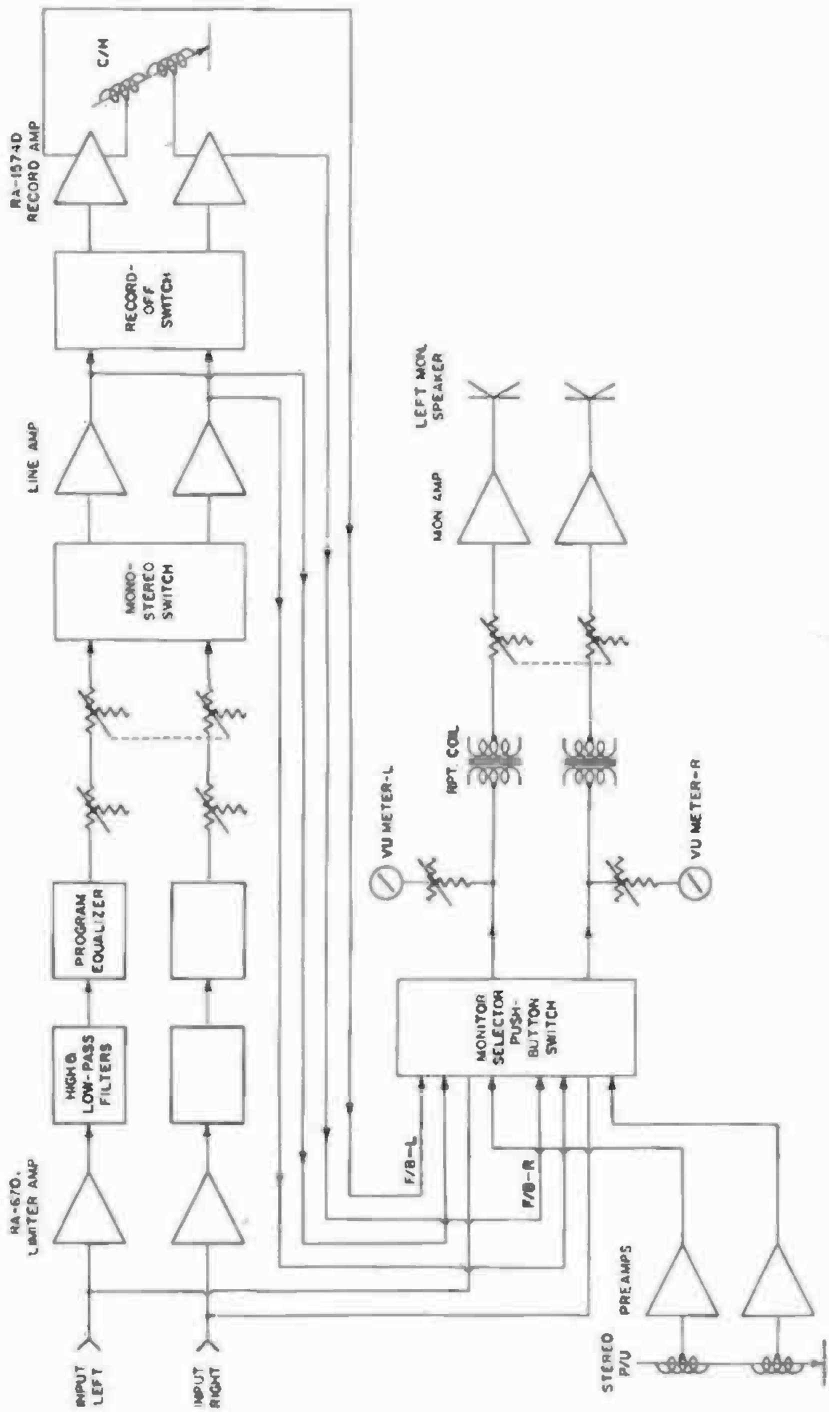

Fig. 13-216B. Block diagram of the Westrex Corp. Model 2300 StereoDisc magnetic tape to disc record transfer channel.

Since the monitoring signal is taken from the negative-feedback circuits in the cutting head, a network (C-98461) is required having an *inverse frequency characteristic* to the RIAA characteristic (Fig. 13-216H). This creates the proper listening response. Equalizer C-98451 is connected between tubes V1A and V2A to supplant the negative-feedback loop characteristics and pro-

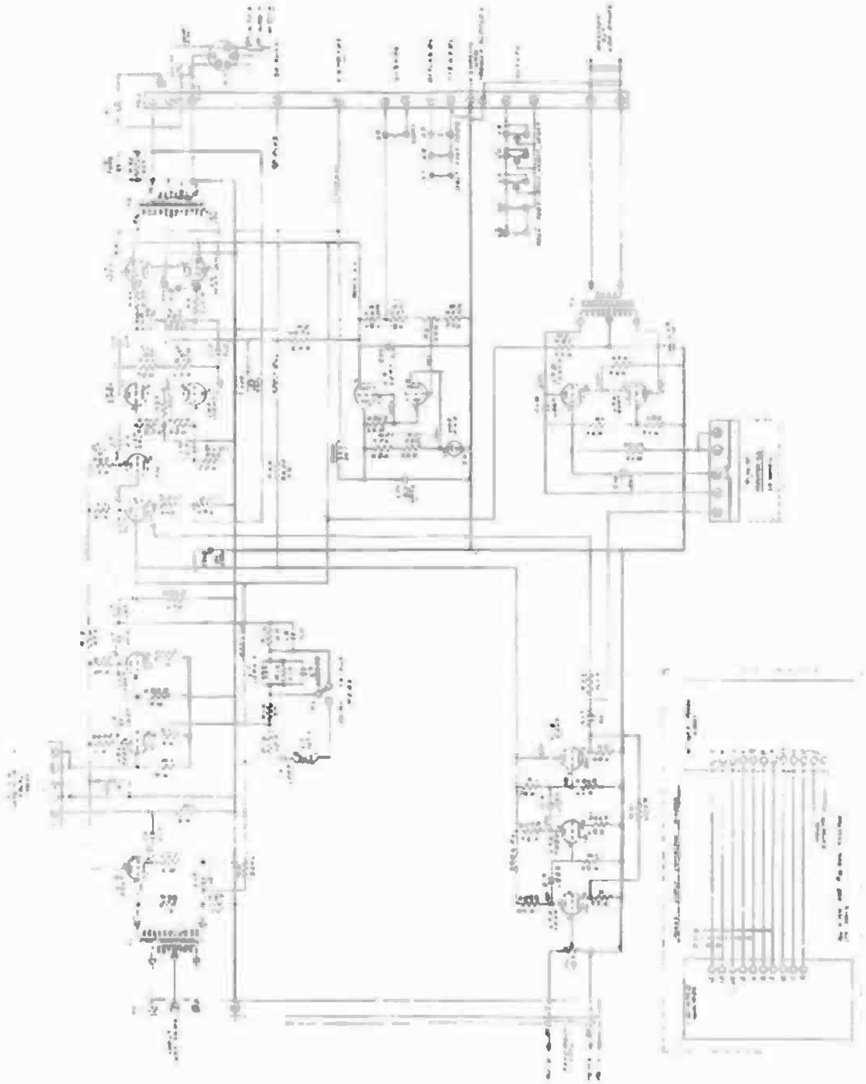

Fig. 13-216C. Schematic diagram for Westrex Model RA-1574D stereophonic recording amplifier.

vide an RIAA recording characteristic from 30 to 1000 Hz, and then constant-velocity from 1000 to 15,000 Hz (Fig. 13-216G). The insertion loss for this network is approximately 18 dB.

The statistics for the RA-1574D amplifiers are: Input impedance 600-ohms. Cutting head output 10 ohms for driving coils, and 11 ohms for negative-feedback coils. Sensitivity 14 dBm for 3.54 cm/sec peak recording velocity at 1000 Hz for both channels. Adjnstable feedback up to 29 dB. Power output 75 watts continuous for 1 percent THD. Output noise 3 millivolts across 10 ohms. Monitor output level for a peak velocity of 3.54 cm/sec is plus 4 dBm.

13.217 Describe the difference between a lateral-vertical and 45/45-degree stereophonic recording system.—The basic principles of 45/45-degree recording heads have been discussed in Questions 13.211 to 13.213 and will not be repeated here. Both of the above methods of recording stereophonic sound cut *identical* grooves. In the 45/45-degree system, the driving coils of the cutting head exert their forces at an angle of 45 degrees with respect to the recording disc surface. In the lateral-vertical method, a *matrixing network* composed of two transformers employing double secondaries convert the left and right channel information into *sum of vectors* for each channel lateral and vertical. The resulting signal then becomes identical with the 45/45-degree system of recording.

The principal difference, in the two systems is the *initial* alignment of the left and right sides. Separation in the 45/45-degree system is fixed and depends on the mechanical construction of the cutting head. In the lateral-vertical system, this parameter is a function of balance of *gain* between the two

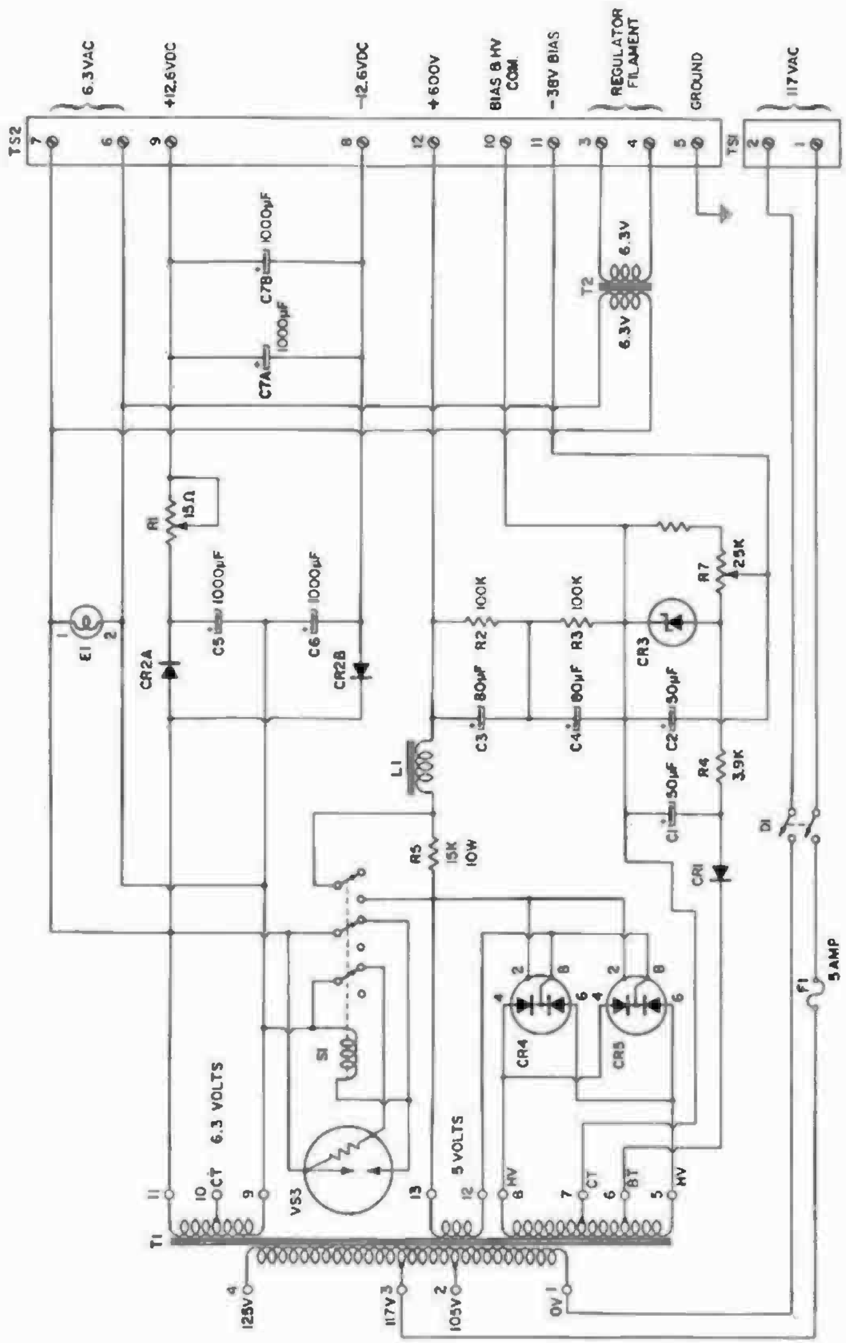

Fig. 13-216D. Westrex Corp. RA-1567 power-supply unit for RA-1574D power amplifier.

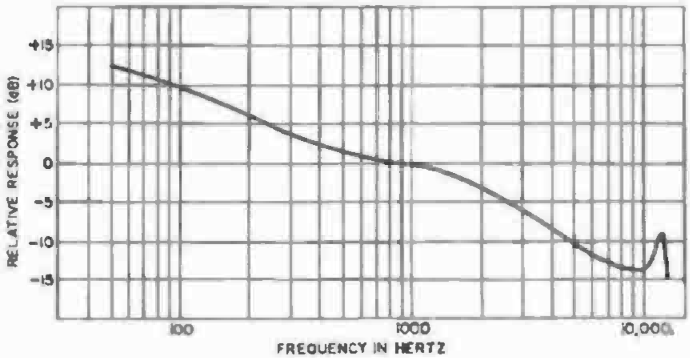

Fig. 13-216H. Typical frequency-response characteristic of Westrex Corp. C-98461 equalizer.

sides of the system. Because the gain is fixed by the matrixing network, an absolute balance is not possible.

Since a lateral-vertical recording depends on two vector forces produced simultaneously by the lateral and vertical sides, varying the gain of one channel results in a changing of the resulting driving forces, thus reducing cross-talk ratio between the two sides. Also, if the two sides are not of identical frequency response, the effect is that of a change in gain in one side. Because of the above disadvantages, the 45/45-degree method of recording has been adopted by most recording organizations.

Recording heads manufactured by Holtzer, Westrex, Neumann, and Ortofon are the 45/45-degree variety, while those of Fairchild employ the lateral-vertical design.

The lateral-vertical system is aligned initially by adjusting the amplifier gain of each side at 1000 Hz for maximum channel separation, then again adjusted for a uniform frequency response and separation simultaneously.

Section 14

Cutting Heads

Because angles, mechanical mounting and alignment, and electronics are critical, an understanding of physics, mechanics, and electronics is useful in the understanding of disc cutting heads (recording heads).

This section discusses both monophonic- and stereophonic-type recording heads, and their associated equipment and recording techniques. Crystal, ceramic, and various types of magnetic cutting heads are discussed, as well as cutting head calibration. Hot- and cold-stylus recording techniques are also discussed.

14.1 What is an electromechanical transducer?—A device which transforms electrical energy into mechanical energy, or vice versa. A recording or cutting head is a typical example of this principle.

14.2 Describe the basic principles of a cutting head and the details of construction.—Recording or cutting heads, as they are commonly called, are electromechanical transducer devices that translate electrical waveforms into mechanical motion and are used to engrave a sound track on a plastic or nitrocellulose disc record. Cutting heads may be designed to record in the lateral or vertical direction or a combination of both for stereophonic recording. The essential parts for a lateral-type head are shown in Fig. 14-2A. A permanent magnetic field is supplied by a magnet, indicated by north and south poles N and S. A soft-iron armature A is supported and centered in the magnetic field on a knife-edge bearing B and connected to a damping spring at the rear (not shown). Two coils C surround the ends of the armature and carry the audio-frequency currents to be recorded. These currents induce a magnetic field in the armature that is continuously changing polarity. This causes the armature to be attracted or repelled by the permanent magnet in accord-

ance with the strength of the induced audio current; thus, the stylus D mounted in chuck E enscribes the electrical waveform applied to the coils C in a disc record. Although cutting heads can be obtained similar to the basic construction, present-day commercial recording heads generally make use of negative-feedback coils within the heads, as such design reduces distortion, increases the signal-to-noise ratio, and has a more uniform frequency response.

A commercial cutting head, manufactured by Neumann of West Germany is shown in Fig. 14-2B. This head is designed for monophonic lateral groove recording and employs a negative-feedback moving-coil structure, having a resonant frequency of 55,000 Hz, thus permitting a large value of negative feedback to be used. Its frequency characteristic is linear over a range of 30 to 24,000 Hz, without equalization. The armature is made in the shape of a hollow cone, the apex forming the stylus holder. Near the tip of the cone are two feedback coils, with the driving coil mounted at the opposite end or open end of the armature. The feedback voltage is a true representation of the stylus motion. The audio signal, negative feedback, and the stylus heating-coil connections are brought to the back of the head on a 10-pin subminiature connector. A sapphire recording stylus mounted in an aluminum shaft is inserted by means of a stylus wrench in

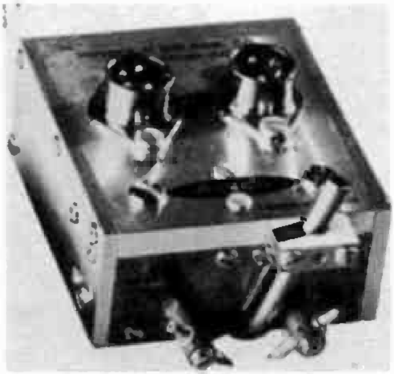

Fig. 14-2F. Holzer Audio Engineering Co. Model SC-1 stereophonic cutting head. It is of moving-iron feedback design requiring no linkage or suspensions.

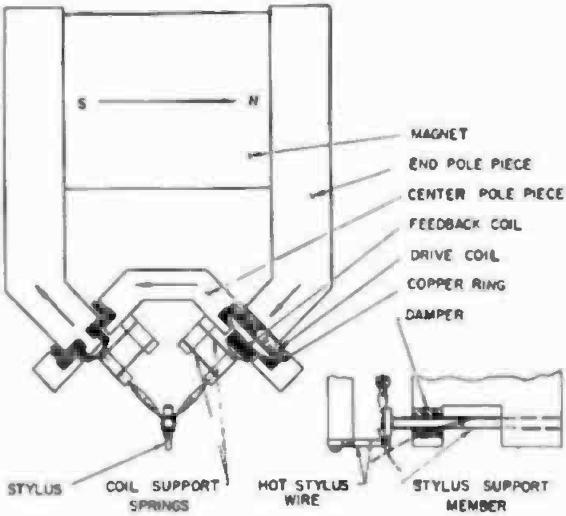

Fig. 14-2G. Simplified cross-sectional view of Westrex Corp. stereophonic cutting head.

the stylus chuck. The stylus heater wires are connected by means of spring-loaded binding posts. A special amplifier having a continuous output power of 75 watts is required. The impedance of the feedback coils is 150 ohms, and of the drive coils, 6 ohms.

In Fig. 14-2C is an exterior view of a stereophonic recording head, showing connections to the stylus heating coil. The interior construction is shown in Fig. 14-2D. The moving-coil structure A is somewhat similar to its monophonic counterpart in Fig. 14-2B, using an aluminum oxide armature, on which are wound two drive coils B for the left and right channels. The feedback coils are mounted at right angles to drive-coils directly at the stylus shank C. This type of construction permits both drive and feedback coils to be wound on a common armature and has the advantage of assuring that the feedback voltage is an actual reproduction of the cutting stylus excursions. The driving-coils are so wound (onto the armature) as to result in a direct 45/45-degree motion *sum and difference formation or matrixing*. The diaphragm structure suspension has the property of infinite stiffness in the lateral plane and complete elasticity to vertical and rotational movements. The stylus and heating coil are shown at D, and the permanent magnet structure is at E. Two special power amplifiers are required for operation. The frequency range is 30 to 16,000 Hz. Channel separation at 100 Hz is greater than 20 dB, at 1000 Hz, 30 dB, and at 10,000 Hz, 20 dB. Motional feedback is approximately 47 dB. Maximum current capability is 500 milliamperes.

A moving-vane balanced armature stereophonic-type cutting head is one of the simplest in construction, as it employs no springs or balancing mechanism. An interior view of its constructional features appears in Fig. 14-2E. The ends of the armature A, both in the assembly and below, are clamped between two U-shaped steel yokes B, within which lie two magnets C and

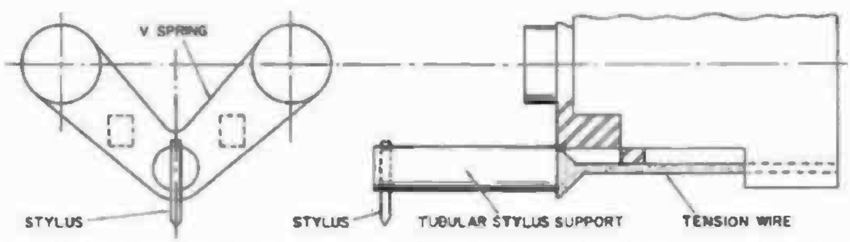

Fig. 14-2H. Stylus support member for Westrex Corp. Model 3D stereophonic recording head.

laminated pole pieces D, with brass clamping blocks E. The metal at the bottom of the slots is shaped to form torsion bars which support the active center position of the armature on the gap between the pole pieces. To prevent nonaxial deflections, these torsion bars are made as short as possible, consistent with reasonable stress at maximum excursion. Through the center of one torsion bar passes the long shank of the cutting stylus clamping screw F; the thread is carried in an external block G. The shank has high torsional compliance so that the presence of the clamping screw does not add appreciably to the mechanical impedance of the armature.

The coil H lies in slots in the faces of the pole pieces, within the main winding is a second coil connected to the cathode of the second stage of the driving amplifier to provide the negative-feedback voltage. The mechanical resonance of the armature, which is around 10,000 Hz, is damped out by the use of silicon damping fluid in the air gaps between armature A and pole pieces D. Silicone oil has the property of maintaining a constant viscosity over a wide temperature range.

A stereophonic cutting head developed by R. T. Speiden and manufactured by Holzer Audio Engineering Co., (HAECO) is shown in Fig. 14-2F and has similar constructional features. The impedance is 16 ohms, with a constant-velocity frequency response plus-minus 1.5 dB from 1000 Hz to 15,000 Hz. It is recommended that 10 dB of negative feedback be introduced at 1000 Hz. For a flat frequency response down to 30 Hz, the feedback is increased to 16 dB. The sensitivity is such that 1 watt of power (plus 30 dBm) will produce a 7-centimeter cut from 1000 to 15,000 Hz. Adding the RIAA pre-equalization characteristic of 13.75 dB at 10,000 Hz requires approximately 20 watts for full modulation. The design is such that at no time does the feedback voltage of the cutter drop to less than 90 degrees,

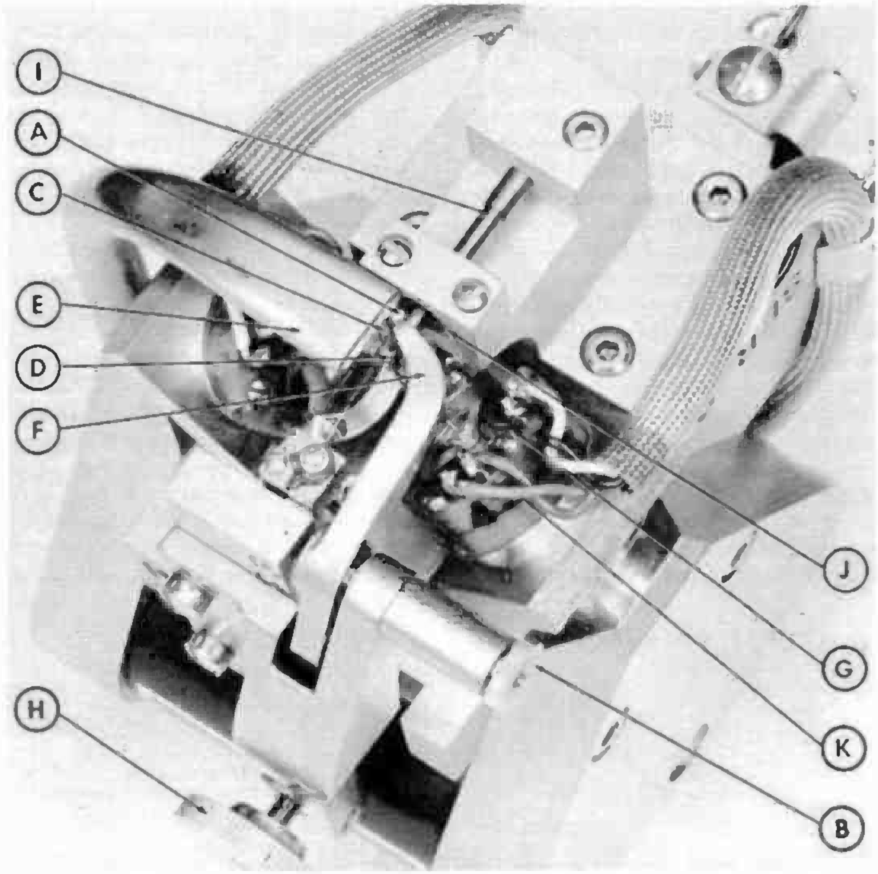

Fig. 14-2I. Underside view of Westrex Corp. StereoDisc recording head.

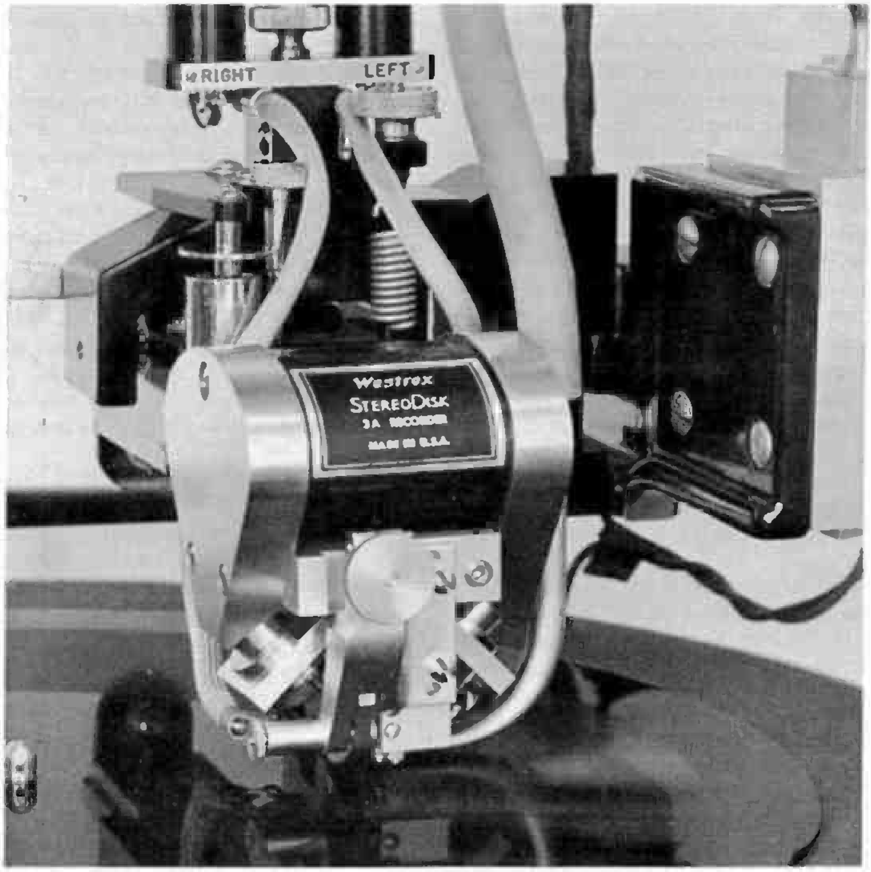

Fig. 14-2J. Westrex StereoDisc cutting head mounted on recording lathe.

or increase to more than 270 degrees from the signal input to the driver system.

A simplified constructional diagram of the Westrex Corp. Model 3C and 3D StereoDisc recording heads (Westrex refers to cutting heads as recording heads) is given in Fig. 14-2G. The following discussion holds true, generally, for both the 3C and 3D heads, except for certain modifications mentioned in the discussion. The cutting-head assembly contains two magnesium coil form assemblies, each associated with a given recording channel. Each coil assembly contains a driving coil and a negative-feedback coil located in separate pole pieces with annular gaps. The pole pieces are attached to a single Alnico V dc magnet. The magnetic gaps of the driving and feedback coils are arranged in a series-parallel fashion to insure equal flux densities in the corresponding gaps.

Copper slugs or shields are used to reduce cross talk between the driving and negative-feedback coils. These shields or slugs can be seen in the shaded areas near the coils. The springs supporting the coils are made of beryllium copper and are V-shaped to maintain the alignment of the coils.

The coil assemblies are attached to the stylus holder through links which are stiff longitudinally, but flexible laterally. These links are braced in the center to prevent excessive lateral compliance. This structure results in a stiff forward driving system with a high compliance in the lateral direction.

The supporting member for the Model 3C stylus consists of a tubular cantilever spring (Fig. 14-2G), with the support used in the Model 3D shown in Fig. 14-2H. This type of support was selected because the compliance of a cantilever spring will be the same for all directions of motion. This compliance permits the stylus to present a uniform impedance to complex motions in any direction in the vertical plane. This uniform impedance is particularly true for those frequencies in the recording spectrum where the negative-feedback voltage exercises little control over the stylus motion. The use of a cantilever spring also reduces the tendency of cross talk between the two channels because of the rotational compliance of the stylus. The damping material at the front of the stylus support has little or no effect on the recording at frequencies below 10,000 Hz and little effect above 10,000 Hz. Its purpose is to smooth out the peaks and valleys in the monitor output.

The system damping is not affected by temperature because damping is supplied by the negative-feedback coil in the driving amplifier system. The driving coil impedance is 10 ohms, and the negative-feedback coil impedance is 11 ohms.

The stylus for the 3D head is somewhat different from that of the 3C head, in that it can be replaced without removing the head assembly from the recording lathe. The stylus diameter is 1.5 times that of the 3C stylus and has a flattened face 5-mils deep and a ground flat of 39 mils, ground the full length of the stylus shank. These details are discussed in Question 15.73. The stylus heating coil for both the 3C and 3D heads consists of 7½ turns of 0.005-inch resistance wire having a resistance of 32 ohms to the foot. The coil is wound on a mandrel 0.038 inches in diameter or on the shank of a No. 62 drill. The completed coil is slipped over the stylus shank and held in place by the natural spring tension of the wire.

The heating current for the coil can be taken from a 6.3-volt transformer with a resistance in series with the coil or from a Variac in the primary winding.

Fig. 14-2I is an underside view of the 3B head, with its principal components called out. They are: (A) advance ball, (B) advance ball lateral adjustment, (C) stylus tip, (D) heater coil, (E) chip suction pipe, (F) stylus linkage, (G) coil assembly, (H) groove depth, (I) stylus support, (J) damping member, (K) driving and negative-feedback coil leads.

In Fig. 14-2J is pictured a Westrex Model 3A recording head mounted on a recording lathe. This method of mounting the head assembly is quite similar for all Westrex heads. Vertical adjustment screw A and lateral screw B are for adjusting the angle of the recording stylus. Because of the wide difference of opinion relative to the recording angle, Westrex recommends a cutting angle of 23 degrees, established with the Model 3C recording head. Distortion versus the effective vertical-cutting angle is an extremely complex problem involving such factors as frequency, peak stylus velocity, groove spacing, groove diameter, depth of cut, and the properties of the recording blank. (See Question 13.30.)

The negative-feedback circuit in both the 3C and 3D heads displays a

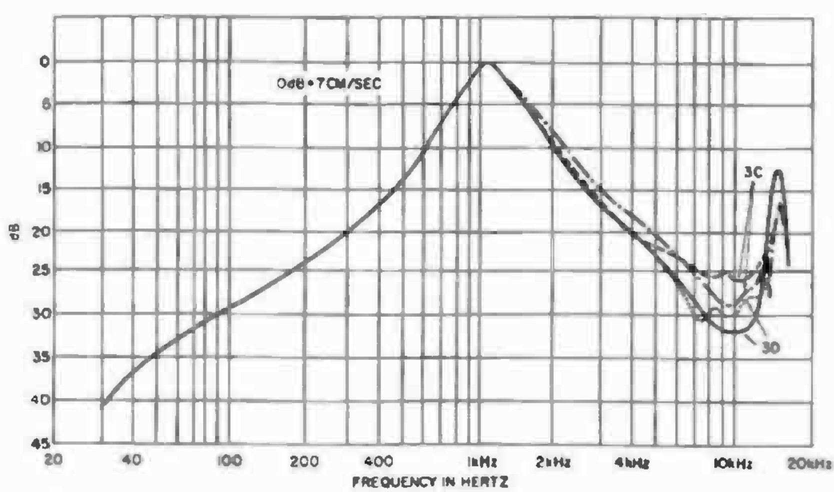

Fig. 14-2K. Resonant-frequency characteristic, without feedback, of Westrex Corp. Model 3C and 3D negative-feedback recording heads.

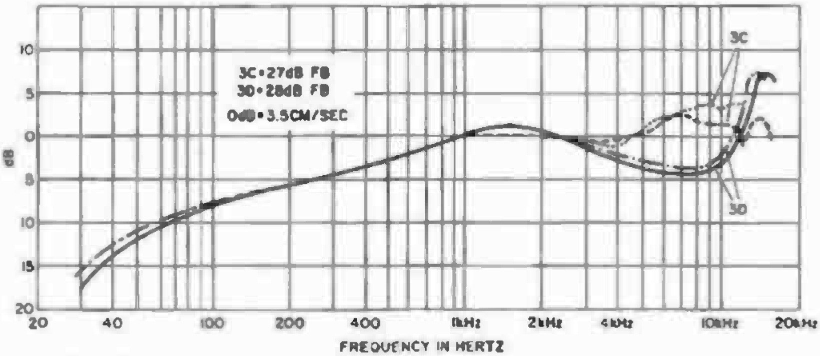

Fig. 14-2L. Frequency characteristics, with feedback, of Westrex Corp. Model 3C and 3D negative-feedback recording heads.

resonant peak around 1300 Hz (Fig. 14-2K). Applying 27 dB negative feedback to the 3C head or 28 dB to the 3D head, the frequency response appears as given in Fig. 14-2L. After connecting the head to a special amplifier (RA-1574D described in Question 17.228) with its equalizers, the frequency response at both the low and high ends is flattened out to within plus-minus 1 dB, 50 to 12,000 Hz, and plus-minus 2 dB, 12,000 to 15,000 Hz. RIAA equalization is provided from 30 to 1000 Hz. The 3D head has an overall increase in sensitivity of about 25 percent, as compared to that of model 3C.

14.3 What are the normal frequency characteristics of a magnetic cutting head?—Constant velocity as shown in Fig. 14-3. It will be noted that, using 500 Hz as a reference frequency, each time the frequency is doubled the amplitude is halved. If the frequency is halved, the amplitude is doubled. This is a true constant-velocity characteristic. However, this characteristic is not suitable for commercial recording, as frequencies below 250 Hz would be overmodulated or overcut and the high frequencies would be too low in amplitude. To prevent overcutting at the low frequencies, cutting heads are designed to record a modified, constant-amplitude constant-velocity characteristic as shown in Fig. 14-6A.

14.4 What does the term "constant velocity" mean?—It means that the stylus will travel the same distance in a given time, regardless of the frequency. To better illustrate the term, refer to Fig. 14-3 and assume the amplitude at 1000 Hz is one inch. At 2000 Hz the frequency has been doubled but the amplitude is half that at 1000 Hz; therefore, the distance traveled by the stylus in one second is still one inch. At 100 Hz, the amplitude is 10 times that at 1000 Hz; however, the frequency is 1/10

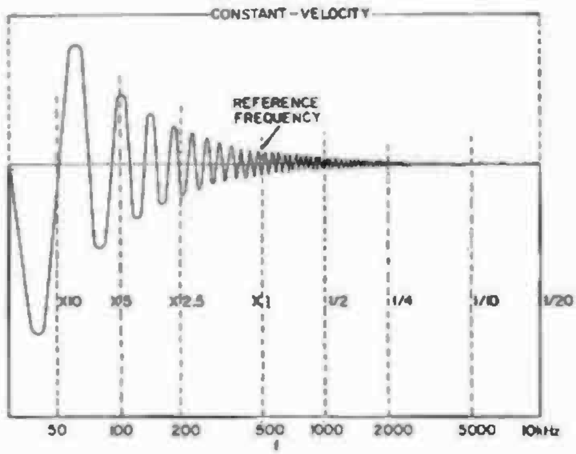

Fig. 14-3. Frequency characteristic of a magnetic cutting head operating as a constant-velocity device.

that at 1000 Hz. Therefore, the same distance is traveled by the stylus. The same reasoning holds true for any frequency within the operating range of the head.

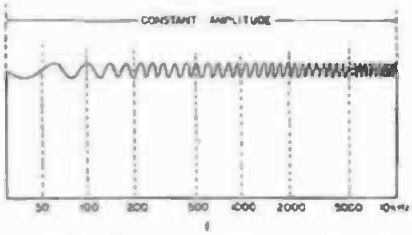

Fig. 14-5. Frequency characteristic of a crystal cutting head operating as a constant-amplitude device.

14.5 What does the term "constant amplitude" mean? — That for a constant signal amplitude to the head, the recording characteristic will be of a constant amplitude as shown in Fig. 14-5. A crystal cutting head is a good example for describing constant-amplitude recording. Because the impedance of a crystal cutting head decreases as the frequency increases, the crystal impedance will be high with respect to the coupling circuit over the entire operating range. Therefore, it may be operated as a constant-amplitude device. It will be noted that, regardless of frequency, the amplitude swing of the stylus is constant. This is the normal recording characteristic of a crystal cutting head. Crystal cutting heads are not used professionally, but have been used on home recording equipment quite extensively.

14.6 What is the recording characteristic used with magnetic cutting heads?—A modified constant-amplitude constant-velocity characteristic as is shown in Fig. 14-6A. It will be noted that a frequency, called the turnover frequency, separates the characteristic into two parts. The portion to the left of the turnover frequency is called the constant-amplitude portion and that to the right the constant-velocity portion. The constant velocity portion behaves as described in Question 14.3.

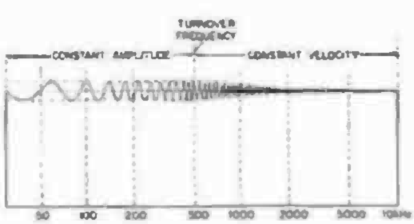

Fig. 14-6A. Frequency characteristic of a magnetic cutting head adjusted for a constant-amplitude, constant-velocity recording characteristic.

To achieve the constant-amplitude portion of the characteristic, the cutting head is so designed that regardless of frequency, the amplitude swing below the turnover frequency is constant.

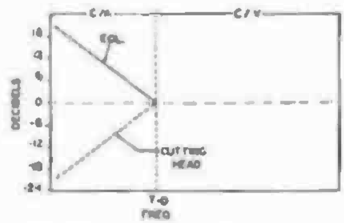

Fig. 14-6B. Equalizer frequency characteristics required to compensate for the constant-amplitude characteristics of the cutting head when reproducing.

To secure a constant amplitude below the turnover frequency, each time the frequency is halved the amplitude is reduced by half, or 6 dB. This will result in a constant-amplitnde characteristic for a constant-amplitude signal across the bead from the turnover frequency to the lowest frequency.

Because this type characteristic reduces the amplitude of the frequencies below the turnover frequency approximately 6 dB per octave, it is necessary to employ an equalizer in the reproducer circuit which has an inverse characteristic to the constant amplitude portion of the recording characteristic. (See Fig. 14-6B.)

14.7 What are the advantages of a constant-amplitude constant-velocity recording characteristic? — It permits a higher recording level at the higher frequencies because of the constant-amplitude characteristic below the turnover frequency; thus, the signal-to-noise ratio of the frequencies in the constant-velocity portion are increased.

If reproduced with a magnetic pickup, the frequency response above the turnover frequency is almost uniform. The use of a low-frequency equalizer below the turnover frequency having a rise of 6 dB per octave returns lower frequencies to a flat response. (See Fig. 14-6B.)

14.8 What is the turnover frequency of a magnetic cutting head?—A frequency where the characteristic of the cutting head departs from a constant-amplitude characteristic to one of constant velocity. In the past, the turnover frequency has varied with different manufacturers of cutting heads and with different recording activities. However, in June, 1953, the RIAA placed the turnover frequency at 1000 Hz. Records made before this date used turnover frequencies anywhere between 250 and 1200 Hz. As a rule, the frequency characteristic is specified on the record envelope.

14.9 What effect does the turnover frequency have on reproduction?—If the correct turnover frequency is not used during the reproduction, an improper balance is obtained between the frequencies lying in the constant-amplitude constant-velocity sections of the recording characteristic. It is highly important, when reproducing a record, that the reproducing circuits shall be capable of being adjusted to the correct turnover frequency.

The effect of using a turnover frequency that is too low and one that is too high is shown in Fig. 14-9. It will be noted that if the turnover frequency is too low (A), there is a step downwards in the frequency response. If the turnover frequency is too high (B), the low end starts rising too soon upsetting the balance between the high and low frequencies.

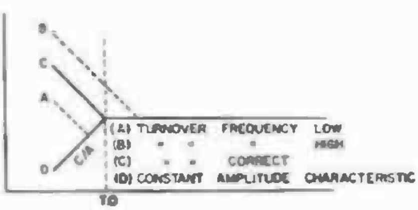

Fig. 14-9. The effect of correct and incorrect turnover frequency in a reproducing circuit. The effect when the turnover frequency is too low is shown at A. The effect when the turnover frequency is too high is shown at B. The correct turnover frequency is illustrated at C, and the constant-amplitude characteristic is given at D.

14.10 What are turnover frequencies used with early cutting heads?—Since the adoption of the RIAA characteristics, the turnover frequency has been standardized at 1000 Hz. (See Fig. 14.10.)

14.11 How are the damping springs and material applied to the mechanical construction of a magnetic cutting head?—Magnetic cutting heads designed for disc recording may be considered to be multisection mechanical bandpass filters terminated in an artificial line. The primary function of a cutting head is to engrave on the disc a faithful reproduction of the applied electrical waveforms.

The cutting head converts electrical energy into mechanical energy; therefore, it is similar to an electric motor or a loudspeaker. For present day requirements, a cutting head must be capable of recording with uniform characteristics up to at least 10,000 Hz. Many recording activities record to 15,000 Hz.

The interior construction for a typical monophonic balanced-armature cutting head is shown in Fig. 14-11. Refer to the front view shown at (a) in Fig. 14-11 for the following explanation. A balanced armature A is placed in a permanent magnetic field supplied by a permanent magnet B. At the upper and lower ends of the armature are placed actuating coils C connected in series. The use of two coils in series cancels the even harmonics and reduces the distortion. The armature A is constructed of laminated steel with a V-shaped saddle D at the center. The saddle rests on a ground knife-edge support E. Steel rod F balances the armature in the exact center of the gap

between the pole pieces. Two steel rods G with offset loops are used to supply pressure to the outer ends of the saddle mount D, to balance the armature in the center of the magnetic structure.

The rear view of the cutting head is shown at (b) in Fig. 14-11. In this view the rear end of the armature is shown connected to a thermoplastic damper H which removes resonant peaks and helps to smooth out the frequency response. This damping material is sometimes referred to as an artificial line. A metal washer I secures the damping member to the aruuature. A side view showing how the damping material is secured to the magnetic structure ap-appears at C in Fig. 14-11. The cutting-head just discussed is of the *nonnegative feedback* type.

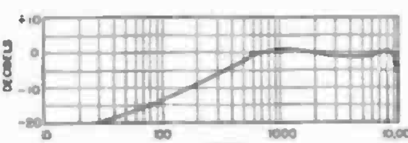

Fig. 14-12. Frequency response of a magnetic cutting head plotted from a light pattern.

14.12 How are the damping material and springs adjusted to secure the desired frequency response?—The adjustment of a cutting head to secnre a desired recording characteristic is both tedious and difficult and is somewhat of a cut-and-try job. The adjustment is started by centering the armature between the pole pieces by means of the balance springs G (shown in Fig. 14-11) while observing the contact between the knife-edge and the saddle on the armature under a microscope. When the contact is uniform, the springs are locked in place.

The next procedure is to adjust the various areas of the damping material which control the frequency response of the cutting head. This is done by removing sections of the damping material shown at (b) in Fig. 14-11. Areas J of the damping material affect the frequency response between 800 and 2000 Hz, while areas K affect the region between 3000 and 5000 Hz. Areas L may be used to control frequencies between 5000 and 6500 Hz. Areas M, N, and O control the frequencies above 6500 Hz.

The calibration should be carried out at normal room temperature, as temperature has a pronounced effect on the final response. The calibration is made by recording light patterns and measuring the response visually by playing back and measuring it electrically, or by means of an fm calibrator described in Question 14.49. A typical frequency response plotted from a light pattern is shown in Fig. 14-12. (See Question 23.75.)

14.13 Will a cutting head calibrated for 33⅓ rpm be satisfactory for 45 rpm?—It is possible to obtain satisfactory calibration for both speeds; however, if the cutting head is of the negative-feedback type, generally the amplifier system is equalized for 33⅓, 45, and 78.26 rpm and will be adjustable within the specified tolerances for the RIAA Standard reproducing response.

14.14 How does temperature affect the calibration of a magnetic cutting head?—If the cutting head is calibrated at normal room temperature and then operated at a low room temperature, the frequency characteristic will change. Certain manufacturers incorporate a small heating unit in the cutting head to maintain it at an even temperature regardless of the room temperature.

When making calibrations of a cutting head, single frequencies should not be applied to the head for long periods of time as the damping material becomes overheated and softens, permitting the calibration to change. If the head has been subjected to overheating, it should be permitted to cool slowly and then should be rechecked for calibration.

14.15 What is the material used for the damping member of a magnetic cutting head?—A thermoplastic called Viscoloid. In some instances tungsten-loaded rubber is used.

14.16 How is a monophonic signal (lateral cut) obtained with a stereophonic cutting head?—Identical signals having the same phase and level produce a lateral (monophonic) signal. Identical signals out-of-phase produce a vertical cut. (See Question 13.202.)

14.17 What is a mechanical transmission line used with magnetic cutting heads?—In the early Western Electric cutting heads, a rubber damping line, composed of three rubber tubes, one within the other, was used to damp out mechanical resonance of the moving parts. The rubber line was attached to the armature by means of a metal fin running the entire length of the rubber line. The mechanical transmission line reduced distortion besides smoothing out the frequency response. This system was used with the lateral coarse-pitch cutting heads, before the use of negative-feedback cutting heads.

14.18 Is the impedance of a magnetic cutting head constant?—No, it varies with frequency. As a rule, the magnetic cutting head will show its stated impedance only between 400 and 1000 Hz, then rise to several thousand ohms at the higher frequencies. Below 1000 Hz the impedance may drop to one-tenth that at 1000 Hz. A typical impedance curve for a 500-ohm head of the nonnegative feedback type is shown in Fig. 14-21A.

14.19 What are the standard values for cutting impedance?—There are *no standards* relative to cutting impedance; the values are optimal with the manufacturer. Typical impedances run from 5.6 ohms for the Westrex 3B stereo-cutting head, up to 600 ohms for others, but generally they are below 200 ohms.

14.20 What is the purpose of connecting an RC network in series with a cutting head?—To prevent the cutting head from loading down the driving amplifier at the lower frequencies because of the decreasing impedance as explained in Question 14.18. It also helps to maintain the 6 dB per octave dropoff in the constant-amplitude portion of the recording characteristic. (See Fig. 14-12.)

14.21 Explain the action of an RC network connected in series with a nonfeedback cutting head.—Fig. 14-21A shows the impedance characteristics for a typical nonfeedback magnetic cutting head, rated 500 ohms at 1000 Hz. As may be seen, this head has an impedance of 90 ohms at 40 Hz, 500 ohms at 1700 Hz, and then rises to over 3000 ohms at 10,000 Hz.

With the cutting head described in the foregoing connected across the output of a driving amplifier, the amplifier output sees 500 ohms at only one frequency (1700 Hz). This means the amplifier will be overloaded at the lower frequencies because of the lowered impedance of the cutting head decreasing

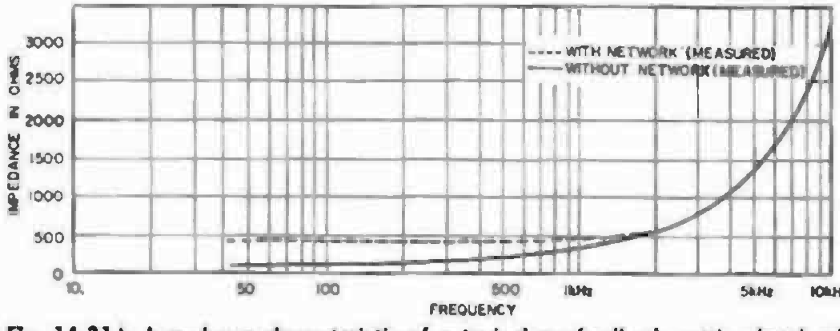

Fig. 14-21A. Impedance characteristic of a typical nonfeedback cutting head, with and without RC network.

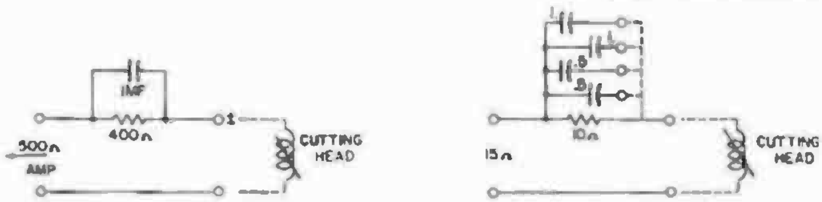

(*a*) *500 ohms.* (*b*) *15 ohms.*

Fig. 14-21B. RC networks used with nonfeedback cutting heads to maintain a constant-amplitude, constant-velocity frequency characteristic.

the power output and increasing the harmonic distortion. The impedance rise above 1700 Hz will have little effect on the amplifier as it acts as a bridging load across the output. This statement only holds true if the output stage consists of triodes or pentodes using a considerable amount of negative feedback. To prevent the low impedance of the cutting head from disturbing tbe output stage of the driving amplifier, an RC network is connected in series with the output circuit, as shown in Fig. 14-21B.

An RC network for a cutting head rated 500 ohms impedance consists of a 400-ohm noninductive resistor and a 1-μF capacitor connected in parallel. The parallel impedance of this network is 148.4 ohms at 1000 Hz. When connected in series with the cutting head, the load impedance seen by the amplifier output is the network impedance plus the impedance of the cutting head as shown by the dotted line in Fig. 14-21A. The curves shown are actual impedance curves measured on a commercial cutting head. The variation in impedance between 100 and 1700 Hz is due to the head characteristics and is of little consequence to the over-all recording characteristic. With the RC network described in the circuit, the impedance, as may be seen, cannot fall below 400 ohms which appears in the region of 1000 Hz. The action of the network when connected in the circuit may be explained as follows:

At a frequency of 1700 Hz, the network in series with the impedance of the cutting head presents a load impedance to the output of the amplifier of 500 ohms. As the frequency decreases, the cutting-head impedance decreases. However, the reactance of the capacitor in the network is rising and, at a frequency of 40 Hz, the reactance of the capacitor has reached about 4000 ohms, which leaves practically pure resistance in the circuit.

It will be noted the load impedance below 1000 Hz never rises above 400 ohms. Above 1700 Hz, the reactance of the capacitor in the network drops very rapidly and effectively shorts out the resistor, leaving only the impedance of the cutting head in the circuit.

If such a network as is described in the foregoing is not used, high distortion may be expected at frequencies below 1000 Hz and the frequencies below the turnover frequency will not drop off at the rate of 6 dB per octave. The constants of the RC network will vary with cutting heads of different manufacture and impedance. The cor-

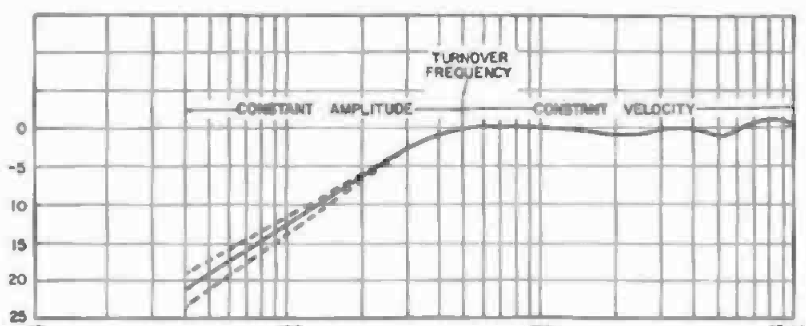

Fig. 14-21C. A typical response for a nonfeedback monophonic cutting head plotted from a light-pattern measurement.

rect value may be obtained experimentally by measuring the impedance of the cutting head and then designing the RC network. Measurements are then made with the cutting head and the network connected in series and plotted as shown in Fig. 14-21A.

Light patterns are also helpful in arriving at the final characteristic. A typical frequency characteristic plotted from a light pattern is shown in Fig. 14-12C. The recording of light patterns is discussed in Question 23.75.

14.22 What is the standard reference level and frequency used for cutting head calibration?—It is 7 centimeters per second for both coarse pitch and microgroove at speeds of 33⅓, 45, and 78.26 rpm. It is also the same for vertical recording. (See Fig. 14-22.)

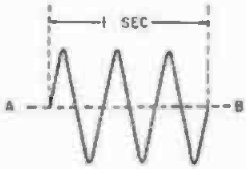

Fig. 14-22. Illustration of a standard reference level. The amplitude is such the stylus travels 7 centimeters from A to B in one second at a frequency of 1000 Hz.

14.23 How is the sensitivity of a cutting head stated?—Cutting heads are rated in watts input for a given velocity in centimeters per second, at a frequency of 1000 Hz. The average power required for driving a modern cutting head is approximately 1 watt (plus 30 dBm). This holds true for both monophonic or stereophonic heads.

14.24 How is the turnover frequency of a nonfeedback cutting head controlled?—By the resonant frequency of the mechanical system, the effective mass of the moving parts, and the stiffness of the centering springs.

Below the resonant frequency of the mechanical system, the cutter mechanism acts as a spring, resulting in a constant armature deflection for a constant input across the head. Thus, a constant-amplitude characteristic is obtained below the turnover frequency.

Above the resonant frequency of the mechanism the system is mass controlled and for a constant input, results in a constant-velocity characteristic. In this manner an overall constant-amplitude constant-velocity characteristic is obtained.

14.25 What limits the maximum amplitude swing of the armature of a cutting head?—The swing of the armature is limited by the mechanical structure and the damping mechanism. The maximum amplitude is also limited by the amount of power that may be safely applied to the actuating coils. If the power is too great, the coils will overheat the damping material and necessitate the recalibration of the head for both sensitivity and frequency response. Overmodulation also increases the noise and distortion.

14.26 What is a vertical cutting head?—A cutting head which engraves the sound track on a disc record in a vertical plane. The sound track varies in depth and width. A cross-sectional view of a negative-feedback cutter with the principal components indicated is shown in Fig. 14-26.

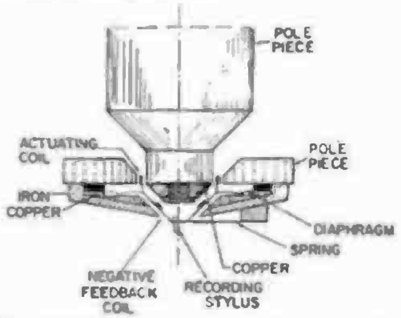

Fig. 14-26. Cross-sectional view of a vertical, negative-feedback, cutting head. (Courtesy, Bell Telephone Labs.)

14.27 What is the turnover frequency of a vertical cutting head?—Approximately 250 Hz for those not using negative feedback. For those employing feedback, the turnover frequency is 400 Hz.

14.28 What is the purpose of using negative feedback with a vertical cutting head?—To obtain a more uniform frequency response and reduce distortion, as the head mechanism has a rather sharp peak around 1000 Hz. Approximately 43 dB of negative feedback is required to obtain a uniform frequency response between 40 to 12,000 Hz. A special power amplifier is required.

14.29 What are the advantages of using negative feedback with a cutting

head?—The use of negative feedback with a cutting head adds approximately 16 dB to the signal-to-noise ratio at 10,000 Hz, at a diameter of 6 inches. Tests made on heads using negative feedback indicate a 69 dB signal-to-noise ratio, using a hot-stylus recording technique. A vibrating coil may be controlled over a wide range of frequencies by the application of negative feedback. The feedback eliminates the need for heavy mechanical damping materials, and reduces the effects of the disc material on the tip of the recording stylus. Negative feedback governs the power rather than absorbing it in the control process. Furthermore, the use of viscous damping offers difficulties as its effectiveness deteriorates over a period of time and its characteristics are affected by temperature and changes resulting from the use of a hot stylus.

Intermodulation distortion measurements made at a velocity of 8 centimeters per second show:

Distortion	*Frequency Range*
0.61%	40-2000 Hz
0.62%	60-2000 Hz
0.61%	100-2000 Hz

The test frequencies were set in a ratio of 4:1, the high frequency being 12 dB lower in amplitude than the lower frequency.

14.30 What is a crystal cutting head?—A cutting head which employs a piezoelectric crystal for the stylus actuating mechanism. The crystal is similar (except heavier) to that used in a crystal pickup. A typical crystal cutting head is shown in Fig. 14-30.

The audio currents cause the crystal to twist in a lateral direction. A recording stylus mounted in a chuck is attached to the crystal slabs for the purpose of engraving the sound track on the recording disc.

Ceramic crystals have to some extent replaced the Rochelle salt crystal; however, because of the greater sensitivity, Rochelle salt crystals find their greatest usage in pickups, microphones, and headphones. Generally, ceramic crystals are treated both electrically and mechanically much the same manner as Rochelle crystals. (See Question 25.103.)

14.31 What are the recording characteristics of a crystal cutting head?—Constant amplitude as shown in Fig. 14-5. If a constant voltage is applied to the crystal slabs, the amplitude motion of the recording stylus will be constant regardless of the applied frequencies. Recordings made with a crystal cutting head require no equalization in either the recording or reproduction circuits if played back with a crystal pickup.

14.32 What is the impedance of an average crystal cutting head at 1000 Hz?—Approximately 20,000 to 40,000 ohms.

14.33 How are crystal cutting heads coupled to the output of an amplifier stage?—Crystal cutting heads may be coupled to an amplifier output stage in a number of ways. The output stage may be single or double ended. The recording characteristic is controlled by

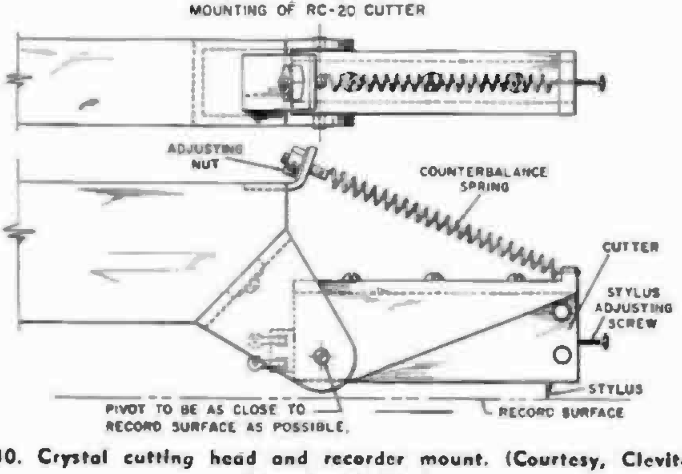

Fig. 14-30. Crystal cutting head and recorder mount. (Courtesy, Clevite Corp., Piezoelectric Div.)

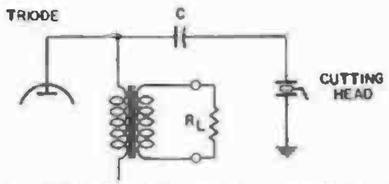

Fig. 14-33A. A coupling circuit for operating a crystal cutting head constant-amplitude. Plate load must not exceed 4000 ohms.

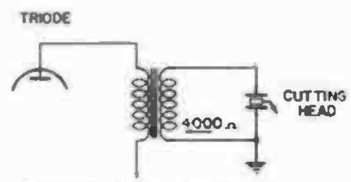

Fig. 14-33B. Method of driving a crystal cutting head as a constant-amplitude recording device.

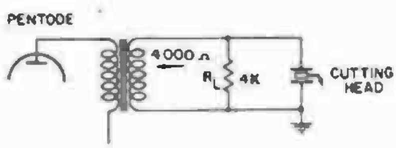

Fig. 14-33C. Crystal cutting head coupled to a pentode or beam-power tube for constant-amplitude recording. The terminating resistor R_L supplies the correct load to the cutting head.

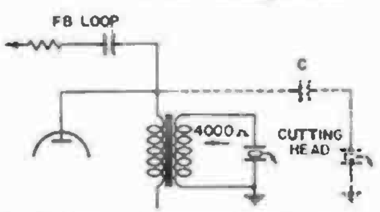

Fig. 14-33D. A crystal cutting head using constant-amplitude recording characteristics coupled to a pentode or beam-power tube using negative feedback.

the output impedance presented to the cutting head.

For constant-amplitude recording the head may be coupled as shown in Fig. 14-33A. Here the crystal is coupled to the output tube, a triode, through coupling capacitor C. In Fig. 14-33B, the cutting head is driven from an output winding, the terminating impedance being the plate resistance of the tube. The impedance presented to the crystal should fall between 3000 and 4000 ohms.

To operate a crystal cutting head from a pentode or beam-power tube without negative feedback, the coupling circuit shown in Fig. 14-33C is used. Beam-power tubes use a load impedance approximately one-fifth the plate resistance, and the distortion without feedback will rise quite sharply. The output transformer is terminated by a resistor R_L to reflect the correct load impedance to both the plate of the tube and the cutting head. For an output stage using negative feedback, the desired output impedance is supplied by the output transformer winding (Fig. 14-33D). It is important that the output impedance seen by the cutting head does not exceed 4000 ohms, including the output impedance as modified by the negative feedback. Coupling circuits for driving crystal cutting heads employing a constant-amplitude constant-velocity recording characteristic are discussed in Question 14.37.

14.34 What is the signal voltage required to drive a crystal cutting head? —For constant-amplitude recording, about 50 volts. For constant-amplitude constant-velocity, approximately 150 volts. This is the rms voltage as measured across the crystal with a vacuum-tube voltmeter.

14.35 What type load characteristic does a crystal cutting head present to the output circuit of an amplifier?—A crystal cutting head presents a capacity load in which the impedance decreases as the frequency increases. For this reason, it is recommended that only class-A triode amplifiers or beam-power amplifiers using at least 12 dB of negative feedback be used for driving crystal cutting heads.

Since a crystal cutter is of the actuated type, the stylus displacement (amplitude) is proportioual to the impressed voltage over practically its entire operating range. Because of this characteristic, constant-amplitude records may be cut without equalization in the recording circuits.

Commercial constant-amplitude constant-velocity recordings may be cut by the use of special coupling circuits which are explained in Questions 14.37 and 14.38.

14.36 What is the internal capacitance of a crystal cutting head?—Approximately 0.007 to 0.10 μF.

14.37 How are crystal cutting heads coupled to an amplifier for a constant-

amplitude constant-velocity recording characteristic? — As shown in Fig. 14-37A. When the crystal impedance is equal to the impedance of the coupling circuit, the freqnency response will be down 3 dB at the frequency where the two impedances are equal. Above this frequency (the turnover frequency) the frequency response will fall off at a rate of 6 dB per octave. In other words, the cutting head will operate on a constant-velocity basis above the turnover frequency and on a constant-amplitude basis below the turnover frequency.

By the selection of the proper component values for the coupling circuit, the turnover frequency can be placed anywhere in the normal frequency range. If the turnover frequency is established between 800 to 1000 Hz, the cutting head will record a commercial constant - amplitude constant - velocity characteristic (also called a modified constant-velocity characteristic). If the turnover frequency is placed at the upper extreme of the frequency spectrum, the cutting head will record a constant-amplitude characteristic as shown by the line at zero amplitude in Fig. 14-37B.

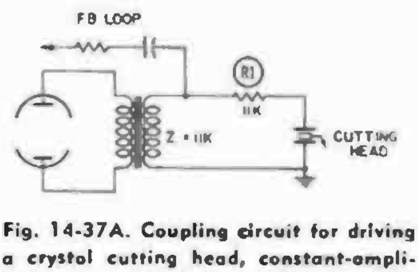

Fig. 14-37A. Coupling circuit for driving a crystal cutting head, constant-amplitude, constant-velocity with a turnover frequency of 1000 Hz.

14.38 How are the coupling circuit values selected for a constant-amplitude constant-velocity recording characteristic?—By the impedance of the coupling circuit and the desired turnover frequency. The frequency response of a crystal cutting head coupled for three different turnover frequencies (250, 500, and 800 Hz) is shown in Fig. 14-37B. The flat portion of the curve is the constant-amplitude section and the right-hand portion the constant-velocity section.

A graph that may be used for selecting the circuit constants for a particular turnover frequency is given in Fig. 14-38. Assume a turnover frequency of 1000 Hz is desired. Following the 1000 Hz line upward to where it intersects the diagonal line then reading at the left, it will be noted a source impedance (output) of 22,000 ohms is required. This impedance is divided equally between the output winding and the series resistor R1, or 11,000 ohms each. As this is rather an odd value of output

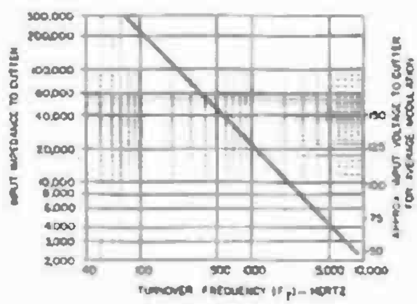

Fig. 14-38. Graph for selecting circuit constants to operate a crystal cutting head constant velocity, or modified constant velocity. (Courtesy, Clevite Corp., Piezoelectric Div.)

impedance to obtain from an output transformer, a matching transformer may be connected between the regular output transformer and the cutting head with the proper impedance ratio. A 10-percent variation in impedance match is acceptable. The series resistor R1 should never be smaller in value than the output impedance of the coupling transformer.

It will also be noted in Fig. 14-37B that frequencies below the turnover frequency are recorded approximately 10 dB higher in amplitude than for the constant-amplitude characteristic. Also, frequencies above turnover frequency fall off at a rate of 6 dB per octave.

14.39 Why is a lower recording level used for constant-amplitude recording?—To provide easier tracking for the pickup stylus when reproducing. Constant-amplitude recordings can be cut at a higher level, if the high frequency response is restricted to a frequency below 9000 Hz. If a constant-amplitude recording is cut at the same level used for constant-amplitude constant-velocity recording, difficulty may be experienced in obtaining satisfactory tracking at the high frequencies during reproduction.

14.40 Can hot-stylus techniques be used with a crystal cutting head?—No, the heat would damage the crystal. (See Question 14.14.) The techniques of hot-stylus operation are discussed in Questions 15.58 to 15.71.

14.41 What precautions should be taken to prevent damage to a crystal cutting head?—Direct current should never be permitted to come in contact with the crystals. Sudden high-level signals of sine-wave character should not be applied to the head when testing, as the crystal may be shattered. Bring the level up gradually.

14.42 Why are magnetic cutting heads preferred to crystals for commercial recording?—Because magnetic recording heads are more rugged in their construction and will hold their frequency characteristics over long periods of time. Crystal cutting heads are affected by both temperature and humidity. Also, they may be damaged quite easily if the stylus is struck against the side of the turntable.

Because the impedance of a magnetic cutting head is generally on the order of 500 to 600 ohms, it may be operated at a considerable distance from its driving amplifier. Crystal cutting heads, being high-impedance devices, require that they be operated fairly close to the driving amplifier.

14.43 What is the composition of a ceramic crystal? — Ceramic elements used in transducer manufacture are usually ammonium dihydrogen phosphate, lithium sulphate, barium titanate, or several variations of lead zirconate and lead titanate ceramics. The ceramics are polycrystalline in nature and do not have piezoelectric properties in their original state. The magnitude and character of the piezoelectric effect is greatly dependent on the orientation of the applied force or the electric field, with respect to the axes of the material. Slabs are cut from the crystal, rather than from the whole crystal itself. They are cut in a similar manner to quartz crystals for radio use, as described in Questions 25.103 and 25.191.

14.44 What Is an embossing head?—A magnetic or crystal cutting head similar in construction to the cutting head used for standard recording. They may be operated at constant amplitude, or constant amplitude, constant velocity. The stylus is dull-pointed and does not remove any material from the record as it records. The sound track is indented in the recording media and record material displaced rather than removed.

Embossed records are used in dictating machines and similar devices. A typical embossing recorder is shown in Fig. 13-22.

14.45 What is the relationship between the pressure wave at a microphone and the stylus motion?—For a constant-amplitude recording, a constant pressure at the microphone produces a constant-amplitude motion at the recording stylus, if the frequency characteristics of the recording system are uniform. For constant-amplitude constant-velocity recording, the amplitude of the undulations in the record are inversely proportional to the frequency in the constant-velocity range. Below the turnover frequency, they are constant amplitude or follow the frequency characteristic of the cutting head.

14.46 Describe the different methods used for calibrating a cutting head.—The frequency response can be measured by several different methods, by applying a constant voltage to the head and recording a series of frequencies prodncing a light pattern. This pattern is then measured electrically by playing it back or photographing the image and calculating the variations in response. Another method used rarely is the deflection of the stylus tip in a special fixture having a calibrated eye piece or by use of a frequency-modulation calibrator, described in Question 14.49. The preferred method is the light pattern electrically measured. The recording of light patterns is discussed in Question 23.75.

14.47 What is the formula for calculating the frequency response of a light pattern?—The measurements are referred to a reference frequency, generally 1000 Hz. The ratio of the other frequencies to the reference frequency is:

$$20 \operatorname{Log}_{10} \frac{F_1}{F_2}$$

where,

F_1 is the reference frequency,
F_2 is any other frequency.

It should be mentioned the electrical response from a light pattern is not quite the same as for an optical measurement of the same pattern. Generally the light pattern is used to measure the high-frequency response, and the electrical response of the pattern for the low frequencies.

14.48 How is the sensitivity of several cutting heads adjusted for uniform sensitivity?—Assnme the several cutting heads are similar in design and have approximately the same frequency characteristics. An unmodulated groove is cut and the width of the cut is measured and adjusted to normal. A 1000-Hz test signal is applied to the head under test and the gain of the driving amplifier adjusted to produce a 7-centimeter per second cut. The exact power to the cutting head is then noted for future reference.

Each cutting head is measured in a similar manner. The gain of each cutting-head driving amplifier is adjusted to produce the same percentage of modulation within plus or minus 0.5 dB. Thus, compensation is made for the difference in sensitivity for each individual cutting head. After the power level has been established for each head the recording of a test signal may be dispensed with, and only the output power level of the driving amplifier need be measured.

If the cutting heads employ internal heaters, sufficient time must be permitted for the head to come up to its normal operating temperature. Such procedures should be a part of the daily operating routine.

Section 15

Recording and Reproducing Styli

It has been said that the entire evolution of sound reproduction can be divided into two parts, (1) learning how to make a sound, and (2) the reduction of distortion. This is a thumbnail sketch of the history of recording and reproducing styli. Imperfections induced by either the recording or reproducing stylus will be manifest as distortion. In the 1920s, a cactus or bamboo phonograph reproducing needle was very popular, as it failed to reproduce the distortion of the higher frequencies, as heard when a steel or tungsten needle was used. Work done by Frank and Isabel Capps, Charles Davis, and C. J. LeBel greatly improved the status case of the stylus.

This section covers the materials in general use in the manufacture of styli, geometry involved, stylus pressures, stylus heating-coil design and use, characteristics, and measurements.

15.1 What is a recording stylus?—A sharp-pointed, gouge-shaped instrument for engraving a sound track on a cylindrical or disc record. The tip may be of precious or semiprecious stone, or metal. Commercial recording styli use sapphire tips. (See Fig. 15-1.)

15.2 Describe a reproducer stylus?—A stylus somewhat similar to that used for recording, except the tip is not sharp, but conical. The tip is designed to fit the side walls of the groove but clear the bottom of the groove. The tip may be a sapphire, a ruby, or a diamond. (See Fig. 15-2.)

15.3 What are the essential parts of a recording stylus and the basic principles of manufacture?—The recording stylus is one, if not the most important, component in a recording system, and as far as is known was first used by Edison in 1877. With the advent of present-day high-quality sound, wide frequency range, low distortion, increased signal-to-noise ratio, long play and stereophonic recordings, and improved recording media, a great responsibility is placed on both the recording and reproducing styli. Since its first use, many different materials have been use for their manufacture—steel alloys, sapphire, and diamond. However, over the

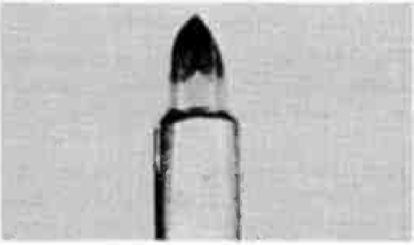

Fig. 15-1. A coarse-pitch recording stylus with 87-degree included angle, 1.5-mil tip radius.

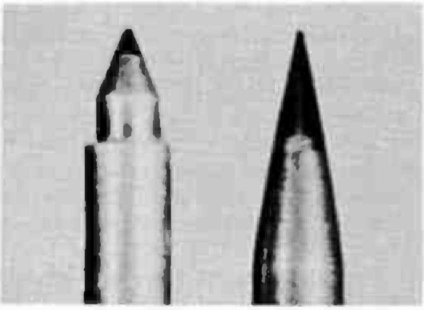
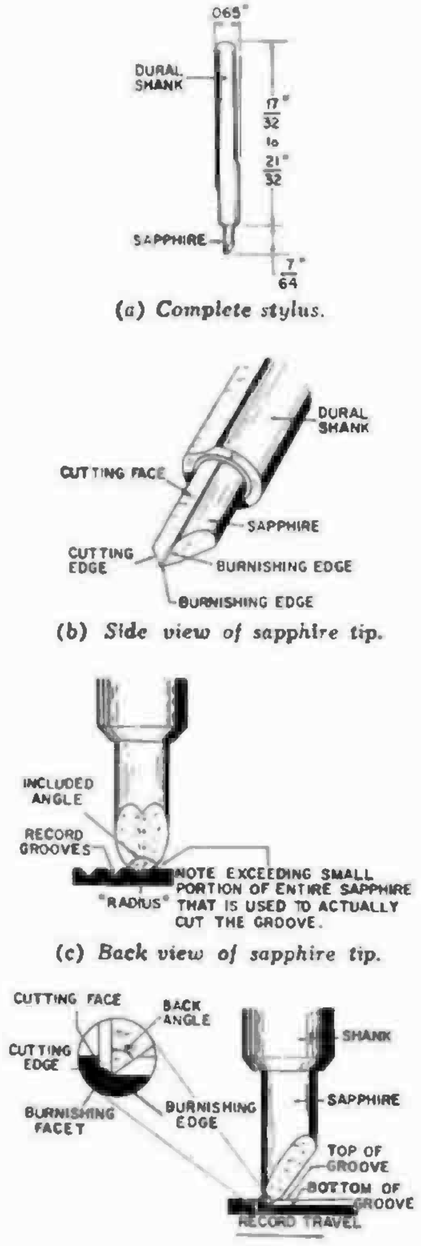


(a) 56-degree ruby, dural shank. (b) 26-degree sapphire, brass shank.

Fig. 15-2. Coarse-pitch reproducing styli for acetate disc.

years it has been found that *corundum* is the most practical of all material for recording styli. Corundum can be obtained in several different colors, among them are: red, blue, green, violet, yellow, and colorless, which is many times used for identification. Both the natural and synthetic sapphire (blue, ruby red, etc.) are corundum (AL_2O_3) of a hexagonal crystalline structure with a hardness of 9 on the Moh scale and 1525 to 2000 on a Knoop scale. Because of its lack of grain, crystalline structure, and cleavage, sapphire may be ground to very accurate dimensions and angles, while still retaining a very fine cutting edge. This latter property is of prime importance in the manufacture of recording styli. Although the diamond is much harder than corundum for use in recording styli, it is impractical because of its grain and internal stresses, as well as its cost. However, as a reproducing stylus, it is ideal because of its long life and ruggedness. As a recording stylus, the sapphire will outlast a diamond and produce superior recordings.

Several views of a recording stylus are shown in Fig. 15-3. At part (a) is shown a complete stylus. The stylus consists of a sapphire held in a dural shank, shown at part (b). The sapphire tip has a flat face ground on one side. The end of the sapphire is ground to a point with a rounded tip. Extending from the tip upward and along its edges are burnishing facets, and it is a most difficult and exacting part of the stylus grinding, as the dimensions are only a few ten-thousandths of an inch. The *burnishing facets* polish the groove as it is cut. The length of the burnishing facet not only affects the signal-to-noise ratio, but also the frequency response. A cold-stylus coarse-pitch recording with a burnishing facet of 0.4 to 0.6 mil will effect a loss at 10,000 Hz, compared to 1000 Hz of 3 to 6 dB. It will be noted at part (c) only a very small portion of the stylus tip is used to engrave the sound track on the record. An enlarged view of the burnishing facet is shown at part (d).



(a) Complete stylus.

(c) Back view of sapphire tip.

(d) Enlarged view of tip, showing the burnishing facet.

Fig. 15-3. Essential parts of a recording stylus. (Courtesy, Electronic Industries and Frank L. Capps Co.)

For high-quality recording of any type, the noise level of the stylus itself must be at least 55 dB, and as a rule if not abused, will run 57 to 60 dB below the reference level of 7 centimeters at a frequency of 1000 Hz. The noise level is measured while playing back an unmodulated groove. It is important that the unmodulated groove used for measurement is normal in every respect, that the chip has cleared the groove properly, that the stylus heat current is optimum, and that the disc is of good quality. (See Question 13.30.)

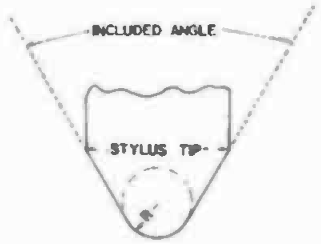

Fig. 15-4. Tip radius of a recording stylus.

15.4 What is the tip radius of a stylus?—The radius formed by the tip of the recording jewel as shown in Fig. 15-4.

15.5 What is the recommended tip radius for recording styli?

For microgroove recording at 16⅔, 33⅓, and 45 rpm, 0.00025 inch or less.

For coarse-pitch 33⅓-rpm recording, 0.0015 inch (16-inch transcriptions).

For coarse-pitch 78-rpm recording, 0.0015 inch.

15.6 What is the included angle of a stylus?—The angle formed by the two sides of the stylus tip. (See Fig. 15-4.)

15.7 Which way does the flat side of a recording stylus face?—Against the direction of motion of the recording blank as shown at part (d) in Fig. 15-3.

15.8 What is a burnishing facet on a recording stylus?—A small flat surface ground on the sides of the stylus tip and used for polishing the groove as it cuts. (See Fig. 15-3.)

15.9 What effect do the burnishing facets have on the frequency response?—If the dimension of the facet is kept to 0.15 mil, it has little effect on the frequency response. However, a facet of 0.5 mil will attenuate 8000 Hz 3 dB and 10,0000 Hz from 3 to 6 dB. Increasing the facet dimensions to 0.60 mil will attenuate 10,000 Hz 6 dB (cold stylus).

15.10 What does the term "mechanical bias" mean when applied to a recording stylus?—For coarse-pitch recording, the stylus is given a slight mechanical twist, relative to the shank, generally about 1 degree. The purpose of the mechanical bias is to throw the chip toward the center of the record as the groove is cut, and thus prevent fouling of the stylus tip. Mechanical bias is not used in stereophonic recording.

15.11 What are the included angles used with coarse-pitch recording?—The finished groove must have an included angle of 88 degrees plus or minus 5 degrees. The top of the groove shall not be less than 4 mils in width for reproducing with a 2.3-mil stylus and not less than 2.0 mils for records to be reproduced with a 1-mil stylus. The bottom radius is 1.5 mils.

15.12 What is the included angle for vertical-recording styli?—The finished groove shall have an included angle of 88 degrees plus or minus 5 degrees, with a top width of not less than 4.0 mils. The bottom radius is 2.0 to 2.3 mils.

15.13 What is the bottom radius of a coarse-pitch lateral groove?—For less than 136 lines per inch, 1.5 mils. For more than 136 lines per inch, 0.25 mil.

15.14 What is the bottom radius for a vertical-cut groove?—From 2.0 to 2.3 mils.

15.15 What is a master contour?—A magnified shadow of a stylus of known size and shape for comparing finished styli. Used in the manufacture of recording and reproducing styli.

15.16 Are diamonds used for recording styli tips?—No. They are used only in reproducer styli.

15.17 What is an "ANM" recording stylus?—A special antinoise modulation stylus (ANM) developed by Capps and Co. to reduce modulation noise while recording. The stylus is ground with two or more burnishing facets compared to the single facet of the conventional recording stylus. A cross-sectional view of a conventional recording stylus with a single burnishing facet in an unmodulated groove is shown at (a) Fig. 15-17.

At (b) in Fig. 15-17, the stylus is shown in a groove with a 20-degree slope and at (c) with a 30-degree slope. As will be observed, the burnishing angle made by the facet is increased depending on the stylus motion. When the modulation is high, the burnishing facets cannot function properly and leave rough places in the groove, (d) of Fig. 15-17, resulting in increased noise. This type noise is particularly noticeable because the rough spots are on the side of the groove which has the greatest effect on the stylus.

An "ANM" stylus has three burnishing facets on each side of the tip as

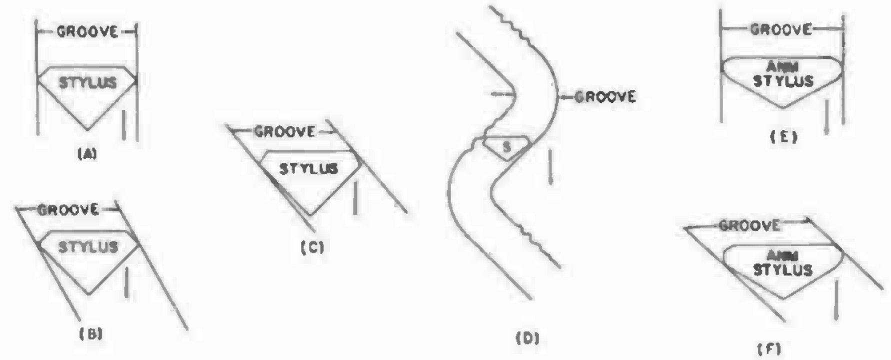

Fig. 15-17. Single and multiburnishing facet recording styli. (a) Single facet—250 degree angle to groove. (b) Single facet—45 degree angle to groove. (c) Single facet—55 degree angle to groove. (d) Facets causing noise patches. (e) ANM stylus with three burnishing facets. (f) ANM stylus with groove slope of 45 degrees. (Courtesy, Audio)

shown at part (e) in Fig. 15-17. It will be observed at part (f) in Fig. 15-17 the additional facets permit the groove to be polished even at high percentages of modulation. The angles of the facets are: leading facet 60 degrees, center facet 25 degrees, and last facet 10 degrees.

ANM styli are used for both standard and microgroove recording. Frequencies up to 20,000 Hz have been successfully recorded at speeds of 78.26 rpm. This stylus cuts a V-shaped groove rather than the rounded-bottom groove. ANM styli are used particularly for microgroove recording using hot-stylus techniques. (See Questions 15.60 to 15.71.)

15.18 What is the standard for reproducer styli included angles?—

For coarse-pitch, direct-acetate playback 33⅓ rpm, 26 degrees.

For coarse-pitch pressings, 33⅓ and 78.26 rpm, 40 to 55 degrees.

For microgroove monophonic 45 rpm, 40 to 55 degrees.

For microgroove stereophonic 33⅓ rpm, 40 to 55 degrees.

15.19 What is the standard tip radius for reproducing styli?—

For coarse-pitch 33⅓ and 78.26 rpm, 2.5 mils plus-minus 0.1 mil.

For coarse-pitch vertical 33⅓ rpm, 2.3 mils plus-minus 0.2 mil.

For microgroove 33⅓ rpm, 0.5 to 0.7 mil. (monophonic and stereo).

For microgroove 16⅔ rpm, 0.3 to 1.0 mil.

15.20 What are the recommended vertical pressures for reproducing styli?—Each manufacturer has a given pressure that is best for their particular type pickup. In the absence of such data, the user may be guided by the following pressures.

For a tip radius of 2.5 to 3.5 mils, 10 to 14 grams.

For a tip radius of 1.0 mil, 1 to 6 grams.

For a tip radius of 0.5 to 0.7 mil, 0.75 to 1.5 grams.

15.21 What is the relationship of a reproducer stylus tip radius to the modulation radius?—For the lowest distortion, the radius of the reproducer stylus at the point of contact with the groove must be less than the radius of the modulation.

15.22 What is the relationship between the included angles of recording and reproducing styli?—The relationship is as shown in Fig. 15-22. It will be noted that, although the included angle of the reproducing stylus

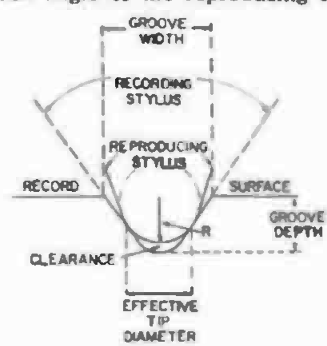

Fig. 15-22. Cross-sectional view of record groove, showing the included angle of recording and reproducing styli, and how they fit the groove.

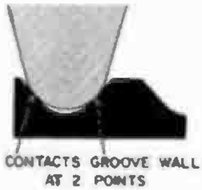
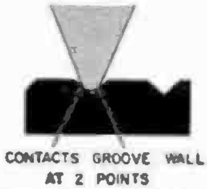


(a) *Coarse-pitch, 2.5-mil radius.*



(b) *Microgroove, 1-mil radius.*

Fig. 15-23. Cross-sectional view of reproducer stylus in a record groove.

is less than the recording stylus, it contacts the groove side walls at a point where the tip clears the bottom of the groove. This is made possible because the tip radius of the reproducer stylus is greater than the tip radius of the recording stylus. (See Question 13.104 and 13.180.)

15.23 How does a reproducer stylus contact the side walls of a record groove?—Fig. 15-23 shows how a coarse-pitch stylus and a microgroove stylus fit the walls of the record groove. It will be noted the stylus sides contact the groove walls at only one point and that a considerable clearance exists between the stylus tip and the bottom of the groove. This is an ideal fit and results in a minimum of distortion.

15.24 What is the pressure developed at the point of contact between the stylus tip and the record groove side wall during reproduction?—It has been stated that the pressure of the reproducer stylus tip on the side walls of the record groove will run to as high as 50,000 pounds per square inch using the conventional methods of calculating stylus pressure. This would tend to create the impression that the reproduction of a fine groove record (microgroove, long playing) would be impossible. However, this is not the case as evidenced by the present-day use of such records.

To properly evaluate the pressure the stylus applies to the groove wall is quite involved and must take into consideration many factors often overlooked. Among these factors are: the area of the stylus tip contact, tip radius,

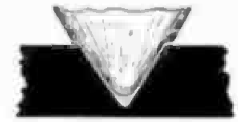


Fig. 15-25. How a worn reproducer stylus fits in a record groove.

included angle of the tip, deformation of the record wall, stylus pressure (vertical), recovery time of the record plastic after deformation by the stylus, the time of contact for a given area, and the heat generated by the friction of the stylus against the groove wall. From the foregoing it may be seen that the calculation is not a simple one. Calculations encompassing the foregoing factors indicate for a stylus of 1-mil tip radius, the pressure may run from 6000 pounds per square inch to 16,000 pounds per square inch.

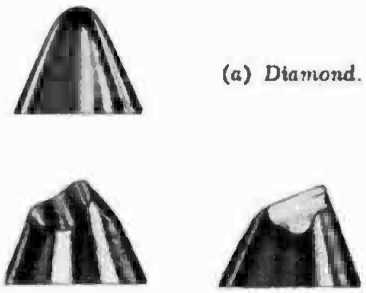
15.25 How does a worn stylus fit a record groove?—Fig. 15-25 shows a worn stylus in a normal record groove. As will be seen, the flat sides of the stylus lay against the groove walls and ride on top of the groove. This condition results in distortion, noisy reproduction, and rapid deterioration of the groove.

15.26 What effect does a worn stylus have on the record groove?—Small portions of the modulations in the groove are removed each time the record is played. The material thus removed acts as an abrasive and adds to the wear of both the stylus and the groove.

15.27 What does the reproduction from a worn stylus sound like?—The reproduction is fuzzy with rather high distortion of the higher frequencies. This is particularly true at the smaller diameters where the groove velocity is the lowest.

15.28 What is the average life of a sapphire reproducing stylus?—Wear tests made by Weiler indicate about 30 hours, depending on the quality of the disc and the sapphire. The wear is chiefly caused by the abrasive action of the dust from the stylus itself. Typical wear patterns of sapphire styli are shown in Figs. 15-28A and B. Vertical pressure was increased purposely to spread the wear.

15.29 How does the wear of a sapphire stylus compare to a diamond stylus?—It has been noted by Weiler that it takes 3½ hours to wear a 0.00075-



(a) *Diamond.*

(b) *Sapphire.* (c) *Sapphire (side view).*

Fig. 15-28A. Coarse-pitch 2.5-mil styli after 1000 hours of play using 1.5-ounce pressure to speed up the wear. (Courtesy, Audio Engineering Society)

inch flat in a sapphire stylus. To wear the same flat in a diamond stylus takes approximately 143 hours of playing.

15.30 What is the difference in pressure and friction for a new and a used stylus?—When a reproducer stylus is new and its shape unaltered, the pressure and friction are the greatest. As a flat is worn in the sides of the stylus tip, the pressure is reduced per unit area. The frictional heat is reduced for the same reason. Thus, the greatest wear to the record groove occurs when the record is played the first few times with a new stylus.

(a) *Diamond.* (b) *Sapphire.*

Fig. 15-28B. 0.7-mil styli after 15 plays, 8-grams pressure to speed up wear. (Courtesy, Audio Engineering Society)

15.31 What is the temperature rise created by the friction between the stylus tip and the record groove?—Temperatures of 2000 degrees Fahrenheit are possible when the stylus is new. As the stylus point wears, the temperature drops and when at its lowest is still in the vicinity of 1000 degrees Fahrenheit.

15.32 What is an osmium alloy stylus?—A stylus made of a hard dense metal alloy with a high degree of resistance to wear. This alloy was used for reproducer styli only. Now obsolete.

15.33 What type reproducing stylus is recommended for the lowest distortion and longest life?—A diamond-tipped stylus. As the diamond has a life many times greater than a sapphire or ruby, less damage is done to the record because of less wear to the stylus tip. Most high-quality reproducers are equipped with a diamond-tipped stylus. Contrary to general belief, a diamond-tipped stylus does not decrease the life of the record groove.

15.34 Define the term "compliance."—It is the ratio of displacement of the stylus to the applied force, expressed in centimeters per dyne. For a high quality pickup, this will range from 9×10^{-6} to about 35×10^{-6}. The term compliance refers to the lateral or vertical motion of the stylus or its compliance with the modulations in the record groove and is the *opposite* of stiffness. For stereophonic pickups the compliance in the vertical direction is made *slightly less* than in the lateral direction. However, if made too light in the vertical direction, the stylus may not be able to support the pickup at the desired stylus pressure. For a stylus pressure of 1 gram, the pressure is equal to 1000 dynes.

15.35 What is the effective mass of a stylus?—The lumped mass at the stylus tip that would result in the same mechanical impedance as caused by the moving elements of the pickup structure.

15.36 What is stylus force?—It is the vertical or downward force the pickup applies to the record groove, expressed in grams. Present-day pickups employ a stylus force or vertical pressure of 0.75 to 6 grams. Older type pickups measured their vertical pressure in ounces, some types taking up to four ounces to properly track a groove.

15.37 How is stylus force measured?—By playing back a constant-frequency record of at least 15 centimeters per second velocity, and measuring the distortion, or observing the waveform on an oscilloscope. The stylus force is adjusted for the lowest distortion consistent with the pressure as measured at the recorded surface.

15.38 What effect does the friction of the stylus have on the side walls of the record groove?—A small amount of side thrust is acceptable and unavoidable. If the thrust is too great, it tends to pull the stylus out of the groove, particularly at the smaller diameters.

15.39 ***How are styli coded for identification?***—By a color code similar to that used for identifying resistors.

15.40 ***Of what is the dirt in a record groove chiefly composed?***—Silica particles, stylus material, soot, grit, and particles of the record groove mixed with lint and flocculated fibres.

15.41 ***What is a truncated reproducer stylus and its purpose?***—A reproducer stylus shaped as shown in Fig. 15-41 and designed to be used with either coarse-pitch or microgroove recording. It will be noted at part (a) that when used in a standard groove the flat tip rides on the curvature of the groove leaving a small clearance between the bottom of the groove and the stylus tip. At part (b) in Fig. 15-41 the stylus is shown riding in a microgroove record. Here it will be noted the sides of the tip ride near the upper limits of the modulations at the top of the groove. Referring back to part (a), if the groove is coarse pitch and not worn, the stylus tip will ride as shown; however, if the groove is worn the stylus will ride in the bottom of the groove and the signal-to-noise ratio will be considerably reduced. At best, such a stylus is a compromise. The pressure of the stylus is increased to 9 grams to prevent it from skating in the bottom of the groove (now obsolete).

15.42 ***What is a compromise stylus?***—When microgroove recording first made its appearance, a stylus was designed to provide the user with a means of playing back both coarse-pitch and microgroove recordings, and was known as a compromise stylus. *It is now obsolete.* A cross-sectional view of a compromise stylus for a coarse-pitch and microgroove recording is shown in Fig. 15-42.

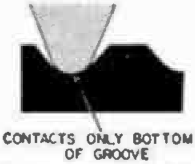
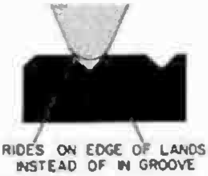
(b) *Stylus in a microgroove.*

Fig. 15-41. Compromise or truncated reproducing stylus (now obsolete).



(a) *In coarse-pitch groove.*



(b) *In microgroove.*

Fig. 15-42. Compromise styli.

15.43 ***How are recording styli tested for noise?***—By recording a series of unmodulated grooves and measuring the noise at a normal playback level. This subject is discussed further in Question 23.78.

15.44 ***What is a shadowgraph?***—A device for projecting the shadow images of styli. The image of the stylus is magnified 25 to 100 times its normal size. Variations in manufacture may be noted by rotating the image against a master contour.

15.45 ***Describe the difference between a long and a short-shank recording stylus.***—Recording and reproducing styli are manufactnred with either long or short shanks. The reason for the difference is the design of the recording head. Some recording heads require a longer shank because of the distance the stylus is projected into the armature tip. It is extremely important that the proper length stylus be used in a cutting head; if not used, the frequency response may be seriously affected. (See Question 15.46.)

15.46 ***Describe the effect of shank shape on the frequency response of a recording stylus.***—Unless the stylus has been specifically designed for a given type cutting head, the frequency response can be seriously altered by the shape and length of the material of the stylus shank. The long shank has a

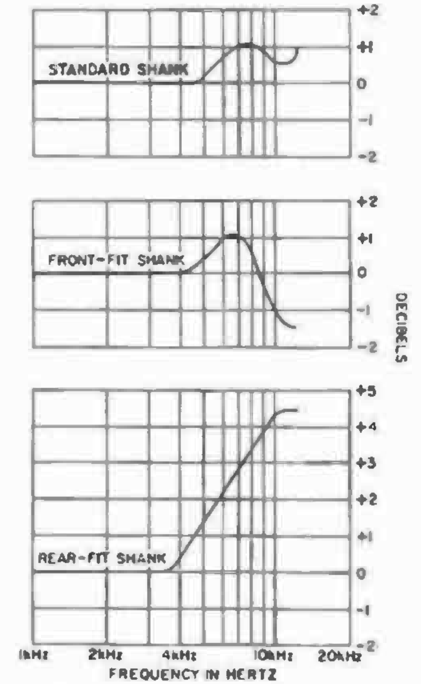


Fig. 15-46A. Frequency response of recording styli using different shank tapers. (Courtesy, Capps & Co., Inc.)

greater amplitude swing but *less* high-frequency response, as compared to the shorter shank. The material of which the shank is made also affects the response. Frequency response curves for three styli of the same manufacture and length, but of different shape are given in Fig. 14-46A. The shapes are shown in Fig. 15-46B. (See Question 15.3.)

15.47 Do recording styli of the same type and manufacture have the same frequency characteristic?—No, there can be considerable variation as may be seen by the plot of eight different styli of the same manufacture and type (Fig. 15-47). This is also true for coarse-pitch

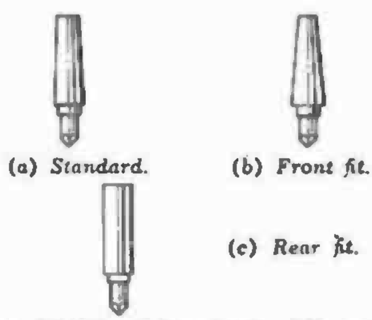

Fig. 15-46B. Stylus shanks. (Courtesy, Capps & Co., Inc.)

reproducing styli. For stereophonic, both the shape and length of the shank have considerable effect, as shown in the plots in Fig. 15-46A. The frequency response of each recording styli should be measured before using and graded.

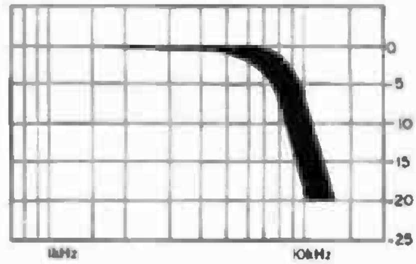

Fig. 15-47. Frequency response for a group of coarse-pitch recording styli of the same manufacture and type.

15.48 Can recording sapphires be resharpened?—Yes. There are several companies which make a specialty of such work.

15.49 Can reproducer styli be resharpened?—Yes, but the cost compared to that of new styli does not warrant it.

15.50 What is a boule?—A carrot-shaped lump of material used in the manufacture of commercial sapphires. (See Fig. 15-50.)

15.51 What is a jewel?—A sapphire or ruby used in recording and reproducer styli.

15.52 What is Stellite?—A commercial trade name for a metallic alloy used for recording styli.

15.53 What type sapphire is used for recording styli?—Commercial sapphire is manufactured from synthetic corundum. For all practical purposes, synthetic sapphires are identical in physical and chemical composition to the natural mineral. The name sapphire is used to identify clear synthetic corundum and differentiate it from the more familiar blue variety of this mineral. Synthetic white sapphire is a single, homogeneous crystal which can be given an exceptionally smooth surface polish by either flame or mechanical processes. There are no interruptions on their mirrorlike surfaces and no potential weak spots such as might develop in multicrystalline structures to offer locations for wear. Typical sapphire and ruby rods used in the manufacture of styli are shown in Fig. 15-53.

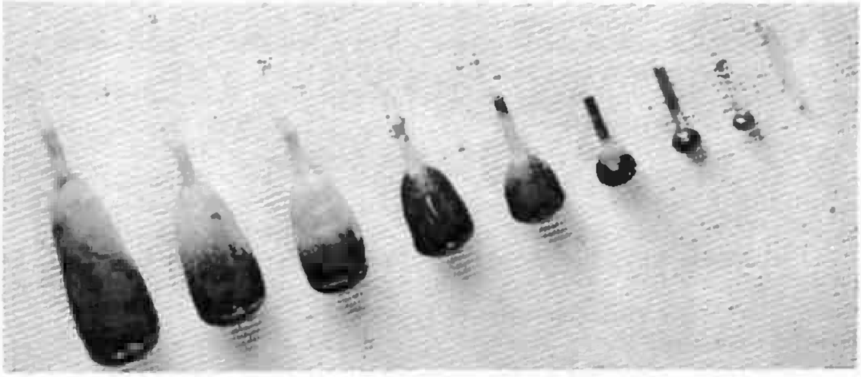

Fig. 15-50. Steps in boule growth in the manufacture of commercial sapphire used for recording and reproducing styli. (Courtesy, Linde Co.)

15.54 Where does sapphire fall on the hardness scale?—Synthetic corundum has a hardness rating on Moh's scale of 9 as compared to 10 for diamond and 5.5 to 7 for hardened steel. Laboratory tests show synthetic white sapphire has a tensile strength of the same order of magnitude as steel. When heat treated between 1700 and 2000C (3090 and 3632F), this material exhibits a plasticity which will permit it to be worked by flame-forming techniques.

15.55 How is commercial sapphire manufactured?—The greater part of synthetic corundum is obtained by feeding finely divided particles of aluminum into a small oxyhydrogen burner. There the material is gradually fused in the flame and a carrot-shaped crystal known as a boule is grown. The finished boule is allowed to cool very slowly in the furnace and then split along a crystallographic plane to relieve stresses built up during the growing process. The average boule weight is 200 carats. Boules in their growing stages are shown in Fig. 15-50.

15.56 What is the life of a recording sapphire stylus?—If treated with care, about six to eight hours. The tip of the stylus should be wiped off with lacquer solvent after each use. This will prevent small microscopic particles from sticking to the tip and fouling the groove while recording.

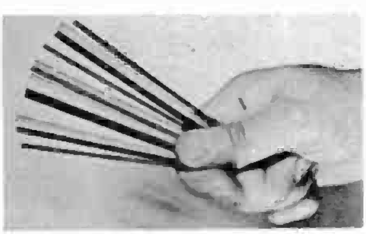

Fig. 15-53. Sapphire and ruby rods used in the manufacture of recording and reproducing styli. (Courtesy, Linde Co.)

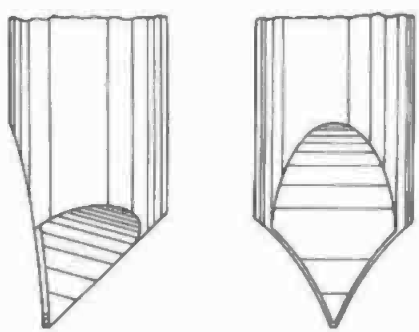
15.57 What is the purpose of a scoop-shaped stylus?—It is used to reduce the error of the vertical groove motion es discussed in Question 13.30. The scooped stylus is manufactured by Capps & Co., Inc., and is marketed under the name of Cappscoop. Its construction is shown in Fig. 15-57.

By making the cutting face of the stylus a circular arc, it is possible to reduce considerably the deviation of the cutting head face from the perpendicular to the record surface. In addition, the curved surface of the stylus facilitates the removal of the chip, while improving the signal-to-noise ratio for an average of 3 dB, compared to the conventional flat-faced stylus. Based on considerable research and study, the conclusions reached were that groove walls recorded using a flat-faced stylus



(a) Side view. *(b) Front view.*

Fig. 15-57. Cappscoop recording stylus for stereophonic microgroove recording.

are not actually straight, but are concave, due to the nature of the lacquer disc and the motion of the stylus. This may be verified by a study of the chip, which is not a true triangle.

15.58 What is hot-stylus recording?—A technique of recording using a stylus which is heated to a rather high temperature by a small heating coil wound around the tip of the recording stylus.

15.59 What are the advantages of hot-stylus recording?—The horns caused by cold flow at the upper edges of the record groove are eliminated, permitting a higher level to be recorded. A lower noise level results when cutting at low groove velocities; thus, the signal-to-noise ratio is increased. With hot-stylus techniques, diameter equalization is not always used because of the improved high-frequency response.

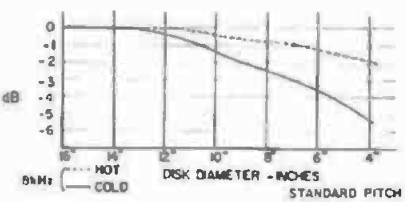


Fig. 15-59. Comparison of the frequency response obtained with a hot and cold stylus.

15.60 To what temperature is a hot stylus heated?—Operating temperatures vary from 350 degrees Fahrenheit upward. In a series of tests conducted by Jackson, under controlled conditions, it was learned that the particular coil in use produced the highest output level at a current of 500 milliamperes. As an example, let the output level for the current of 500 mA at 5 inches equal the reference level. Changing the current through the stylus heater-coil over a range of 50 mA to 650 mA and recording from a diameter of 5 inches to 4 inches revealed the information shown in Fig. 15-60.

These tests were made using a Westrex 3C recording head, Capps & Co. Cappscoop prewired stylus, Scully Instrument Corp. recording lathe, and Audiotape Corp. recording blanks.

15.61 How is modulation noise affected using a hot stylus?—Experience indicates that modulation noise is practically nonexistent.

15.62 What type current is used to heat a hot stylus?—Either alternating or direct current.

15.63 Will alternating current induce hum modulation in the stylus?—No.

15.64 Describe the construction of a typical stylus heating coil.—The average coil will consist of about 7.5 turns of resistance wire, 0.005 inch in diameter, having a resistance of 32 ohms per foot. The coil is closely wound on a drill shank slightly larger than the stylus diameter, to permit the coil to be slipped over the stylus and held in place by the natural spring tension of the coil. As the current through the coil is increased, the signal-to-noise ratio will be increased, up to a point of about 1 ampere. Beyond this point, the chip may be caused to burn and adhere to the stylus, so that its removal will damage the tip. Under no circumstances should the recording be made without the suction pump being on. It is of interest that the use of a hot stylus was experimented with, in 1891, using a flame.

15.65 Can radio-frequency current be used to heat the stylus tip?—Yes, if the stylus is insulated from the cutting head mechanism to prevent heat conduction to the damping materials.

15.66 Is diameter equalization required with hot-stylus recording?—As a rule, diameter equalization is not required with bot-stylus recording since

Current through the coil	*Output level*
650 mA (wire red-hot)	—1.0 dB (5-inch diameter)
500 mA	0.0 dB Zero reference
400 mA	—0.5 dB
300 mA	—1.0 dB
200 mA	—2.0 dB
100 mA	—2.0 dB
50 mA	—0.5 dB (4-inch diameter)

Fig. 15-60. Changing current through stylus heater affects output level.

the high-frequency losses are less than 2 dB at the smaller diameters. However, some recording activities do use a small amount of diameter equalization, even though they are using a hot stylus.

15.67 ***Is less power required to modulate the recording head when using a hot stylus?***—Yes. Slightly less power is required at the higher frequencies; however, at the middle and low frequencies, the power is the same as for a cold stylus.

15.68 ***Does a suction system have a cooling effect on a hot stylus?***—Not to any extent. A normal suction system may be used.

15.69 ***Will a hot stylus permit hard discs to be recorded?***—Yes; discs considered too hard for cold stylus recording may be used if the hot-stylus technique is utilized.

15.70 ***What is the procedure for starting a hot-stylus recording?***—The suction pump is started first. The stylus heater is turned on after the stylus has been lowered onto the disc. If this precaution is not taken, difficulties may be encountered, because the chip becomes quite limp and may foul before the suction system can act.

15.71 ***What is the average increase in the signal-to-noise ratio when using a hot stylus?***—About 18 dB over a cold stylus, resulting in a noise level of approximately 70 dB below the standard NAB signal level. (See Questions 13.85 and 13.86.)

15.72 ***What is a stylus disc?***—A special test record for testing the wear of reproducing styli. The disc is made with cam action grooves which will cause a worn stylus to scrape the side walls changing the color and thus making the wear visible.

15.73 ***Describe the method of mounting styli in a stereophonic recording head.***—One such method is shown in Fig. 15-73A, used in both the Westrex 3C and 3D cutting head. In the 3D head, design of the stylus and the torque tube are such that to replace the stylus, the cutting head does not have to be removed from the recording lathe. The stylus is 1.5 times the diameter of the one used in the 3 C head and has a flattened face 6-mils deep and 39-mils wide, ground the full length of the sapphire. The ground surface serves as the stylus cutting face and as a flat for mating to the precision mount, designed

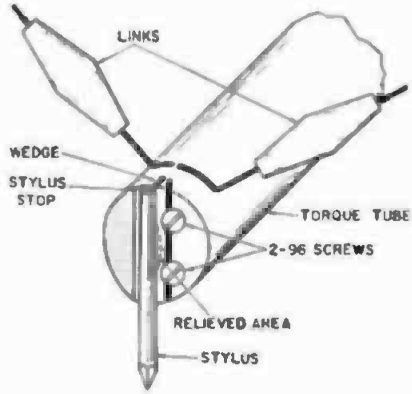

Fig. 15-73A. Torque tube and stylus as used in the Westrex 3C and 3D stereophonic recording head.

to result in a precision alignment of the burnishing facets and cutting face. The sapphire is 0.43 inch in length and inserts in a V way at the end of the torque tube. The V mount is an integral part of the torque tube. Two 2-96 screws located adjacent to a V bind on a wedge and apply pressure to the stylus wall, thereby securing the sapphire in a rigid mount. In Fig. 15-73B, is shown the alignment of the cutting face, which must be within plus-minus 4 degrees of the perpendicular to the central axis of the torque tube. This latter adjustmeut applies to any stereophonic recording stylus. (See Fig. 14-2G.)

15.74 ***Describe the construction of an elliptical reproducer stylus.***—The design of the reproducer stylus has undergone many changes since the invention of the acoustical and electrical phonograph. Problems in the manufacture of styli for monophonic reproduction seem small compared to that now required for the production of styli for stereophonic reproduction. One of the major problems facing the styli design engineer is to obtain a faithful tracking of the sound-track modulations as they

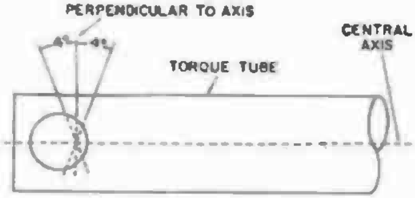

Fig. 15-73B. Torque tube of Westrex stereophonic cutting head showing the alignment of the recording stylus.

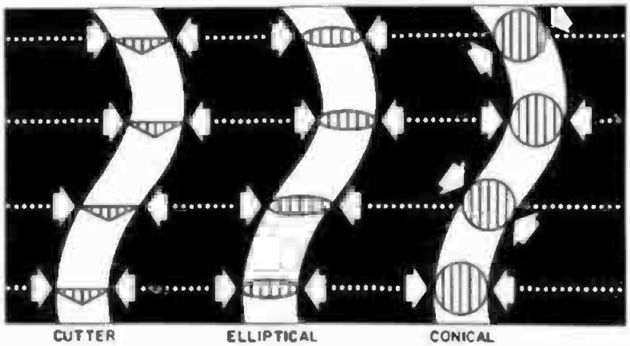

Fig. 15-74A. Tracking angles for an elliptical and a conical reproducing stylus compared to a recording stylus.

were made by the recording stylus. Discussed to some length in Question 13.30 were the problems arising from the shape of the recorded groove in the master, and the difficulty of getting the reproducer stylus to properly track the groove of the pressing, without adding distortion and undue wear. Several types of distortion are possible, namely tracking distortion, tracing distortion, dynamic distortion, and that caused by the loss of contact between the stylus and groove.

Lateral-tracking distortion can be minimized by proper design of the pickup arm. Vertical-tracking distortion is minimized by matching the playback stylus to the vertical-tracking angle of the recorder-stylus angle. Tracking distortion is caused chiefly by the fact that the reproducer stylus is different in shape from that of the recording stylus. Dynamic distortion occurs under reproducing conditions when the stylus deforms the record material and follows a contour that is not quite the same as when the record is static. Distortion caused by the loss of stylus contact and the groove occurs when the reproducer stylus starts jumping off the sound track surface or rattling in the groove.

Referring to Fig. 15-74A, at the left is a drawing, showing the wedge-

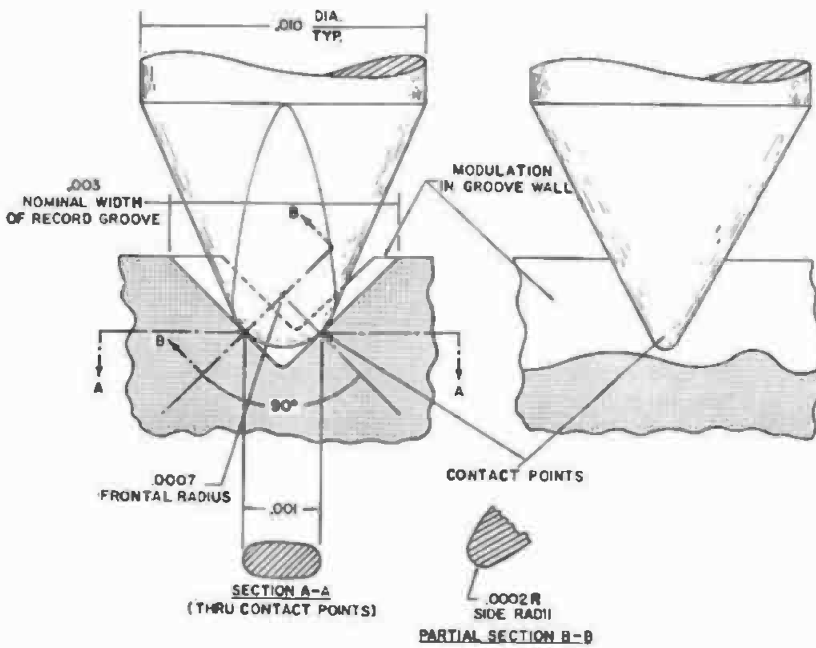

Fig. 15-74B. Bilateral-elliptical pickup stylus dimensions and radii. (Courtesy, Shure Brothers, Inc.)

shaped recording stylus. For perfect reproduction, the reproducing stylus must move in a manner the same as the recording stylus. This cannot be accomplished using a round-end stylus, because the point of tangency between the round end of the stylus and the record changes as a function of modulation. This difference in motion in termed *tracing distortion*, and is directly proportional to frequency and cutting velocity, and inversely proportional to the groove velocity squared. Therefore, tracing distortion is most noticeable as the center of the record is approached for heavily modulated high frequencies. The difference in design between the recording and playback stylus also causes a pinch effect, which is most noticeable when playing back a monophonic record with a stereophonic cartridge.

Fig. 15-74C. Elliptical pickup stylus in a stereo groove.

Referring to the recording stylus groove again, it will be noted that the groove, as cut by the wedge-shaped recording stylus, imparts a vertical motion to the reproducer stylus having a round tip. The perpendicular distance between points of tangency for the round tip is smaller where the sine wave crosses the zero axis at the peaks of the waveform.

Because a stereo cartridge will respond to both vertical and lateral modulation, an electrical output is produced which is primarily second harmonic in nature. Although tracing distortion may be minimized by reducing the stylus point to an extremely small dimension, this can cause noise and distortion because the stylus rides in the bottom of the groove. A minimum acceptable dimension is 0.4 to 0.5 mil. Tracing distortion could also be reduced by making the reproducer stylus an exact copy of the recording stylus. However, because of the cutting edges, this would cause undue wear on the modulations. Therefore, a compromise is necessary between the shape of the recording and reproducing stylus; hence came the *elliptical or biradial* reproducer stylus. The term "biradial-elliptical stylus" is one introduced by Kogen and Samson, to indicate the existence of two different radii, one at the *point of contact* with the sound track modulation, and a second at the *end of the stylus tip*. However, this design is referred to as an elliptical stylus.

The minute dimeusions of a biradial-elliptical reproducer stylus manufactured by Shure Brothers, Inc., appear in Fig. 15-74B. The groove radii portion of the tip are to a scale of 1000:1. A simulated view of a biradial-elliptical stylus in a record groove is pictured in Fig. 15-74C. To achieve the full benefits from a biradial-elliptical stylus, about 1.5 grams vertical pressure should be employed, with the stylus angle set to 15 degrees from the perpendicular.

Section 16

Pickups

Men like Pierce and Hunt, Pickering, Olson, Stanton, LeBel, Badmaieff, Bauer and many others have all made valuable contributions to the design of the modern day pickup. It has been developed from a device with a vertical force of about one-half pound with an upper response of 3500 Hz, to a unit with vertical pressure as low as ½ gram and a frequency response from 10 Hz to 20,000 Hz and greater. The pickup arm has also received considerable attenuation, with much thought given to tangent error and resonance. In the early days of mechanical reproduction, the arm was designed to serve as a throat which connected the sound box (pickup) to the horn; hence, the name tone arm. Since the arm no longer serves in that capacity, the term "tone arm" is a misnomer, although it is still frequently referred to as such.

This section deals with such aspects as driving force, acceleration, compliance, and tracking, for both monophonic and stereophonic recordings. It supplies information as to types, such as ceramic and crystal, magnetic, variable-reluctance, dynamic, fm, and others. It discusses the design of arms, resonance and mounting, and gives other pertinent data relative to the use of snch devices.

16.1 What is an electric pickup?—An electromechanical device for tracing the vibrations in a sound track of a record in such a manner that the instantaneous vibratory velocity of its moving system is in proportion to the undulations of the record groove. The mechanical vibration of the pickup system causes an electrical current to be generated, which is then amplified and reproduced over a loudspeaker.

The output voltage of an electric pickup, depending on the design, may be proportional to the velocity or the amplitude of the moving system.

16.2 Describe the basic construction of a magnetic pickup.—The basic principle of an early magnetic pickup, used for record reproduction and known as a balanced armature, is shown in Fig. 16-2. Although present-day designs are quite different, the same principles of operation, electrically, still apply. The essential parts are: a permanent magnet A, with its pole pieces B, a soft-iron armature C, pivoted at D and mounted between the pole pieces of the magnet in rubber bearings E. Movement of the armature by the stylus H disturbs the magnetic lines of force (shown by the dotted lines) causing a voltage to be generated in coil F. Two tungsten-loaded rubber damping blocks G are used to center the armature in the center of the magnetic field.

In these early model pickups, the stylus pressure was several ounces (at least 3 to 4), while the modern pickup uses 1 to 2 grams. The stylus was generally a steel needle, similar to those used in an acoustic sound box, as described in Question 16.24. The greatest drawback to this design was the frequent replacement of rubber bearings E, damping blocks G, and the centering of the armature C in the magnetic field. The output voltage was proportional to the stylus velocity, and, as there were no standards for recording and reproduction, little or no equalization was used. If the armature was not accurately centered in the magnetic field, the distortion was quite high and was compensated for by attenuating the high frequencies with a "fuzz filter" (a simple low-pass filter) consisting of a coil and capacitor. This filter also helped somewhat in reducing the surface noise of the shellac pressings used at the time.

16.3 *Explain the basic design of variable-reluctance pickups.*—Since the introduction of the original variable-reluctance pickup, many different versions of its design have appeared. One of the earliest was that by Clark in 1947 and is given in Fig. 16-3A, and in principle, is still used for both monophonic and stereophonic design. The magnetic structure consists of two pole pieces A, with a small permanent magnet B between them. At one end, coil C is mounted with a soft rubber insert D.

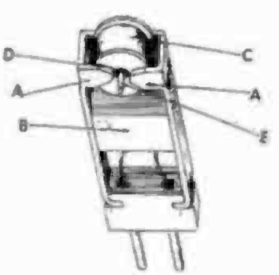

Fig. 16-3A. Variable-reluctance magnetic pickup (after Clark).

The stylus E, which is also the armature, is held in the exact center of the magnetic structure by the rubber insert. When the stylus is actuated, its movement causes a voltage to be generated in the coil. Because of its construction, the frequency response was above the normal audio-frequency band. Output voltage was on the order of 100 millivolts at 1000 Hz, with an output impedance of 500 ohms. The recommended stylus pressure was 15 to 20 grams. The stylus weighed 31 milligrams and was removable. Although the recommended pressure was 15 to 20 grams, the pressure could be as low as 7 milligrams.

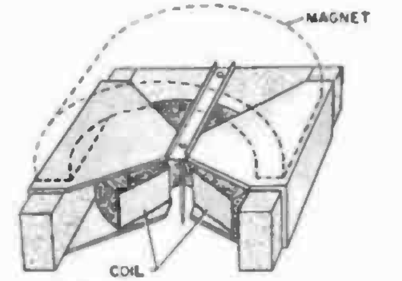

Fig. 16-3B. Internal construction of early model Pickering variable-reluctance pickup.

The frequency response was plus-minus 2 dB, 20 to 20,000 Hz.

A second variable-reluctance pickup to make its appearance was that by Pickering (Fig. 16-3B) and was of similar construction and design. This early model used a stylus pressure of 15 grams and developed an output voltage of 17 millivolts for an impedance of 500 ohms. The magnet was placed as shown by the dotted lines. The frequency range was about the same as for the first structure by Clark. The compliance was 1×10^{-6} cm/dynes. The stylus was not replaceable.

A third design, shown in Fig. 16-3C was that used by General Electric in their variable-reluctance pickup, which made its appearance about 1952. In this design, the magnetic circuit consists of two coils A, yoke B, and pole pieces C. Armature D, which also acts as a stylus bar, is mounted in such a manner that one end is held in the exact center of the pole pieces. The armature rests on a rubber damping block G, which also reduced the vertical compliance. The sty-

lus is mounted on the forward end of the armature at F. The magnetic circuit extends from the south pole of the magnet E, through the armature, up through the pole pieces, and back through the air to the north pole of the magnet to complete the circuit. If the armature is properly centered, the magnetic flux is divided equally between the pole pieces. Lateral motion of the armature between the pole pieces conducts the magnetic flux alternately through the cores of the two coils which are connected to operate push-pull. When the armature is moved in a lateral direction by the stylus action, the magnetic flux is increased or decreased through the coils. Thus, the output voltage varies directly with the change of flux, or in direct proportion to the velocity of the armature. Mechanical design limits the motion to the lateral direction only, thus reducing noise and distortion. The impedance of such a design is rather high and is on the order of 3000 ohms at 1000 Hz. The output voltage is about 10 millivolts. The frequency response was within plus-minus 2 dB, from 30 to 15,000 Hz. Stylus pressure was 6 to 8 grams. It also could be obtained in a dual model, in which the stylus bar carried a 1.0-mil and a 3.0-mil stylus. Either stylus could be selected by rotating the stylus bar.

In about 1956, a decided improvement was made in the design of variable-reluctance pickups, with the appearance of the Pickering Fluxvalve, designed by Stanton. The pickup was manufactured in two models, a single

pickup mechanism, and a dual type in which two replaceable styli inserts were used and could be removed at the front of the pickup body by sliding the inserts forward. One side of the pickup carried a 3-mil stylus for reproducing coarse-pitch recordings, and the other side a 1.0-mil stylus for reproduction of microgroove recordings. A phantom drawing of its construction appears in Fig. 16-3D, with the stylus insert shown in Fig. 16-3E. The insert consists of a plastic mounting A, containing an inverted cup B, surrounding the stylus shank C, containing the stylus tip D. The stylus shank C is held in place by a wire support E, embedded in the plastic insert A. At the upper portion of cup B, a small metal button F surrounds the upper end of the stylus shank, but leaves it quite free to move by the action of the stylus in the record groove. With the stylus insert in place (Fig. 16-3D), the upper end of the stylus G projects parallel over the center pole
